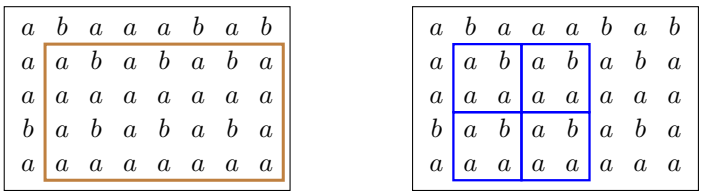
Pattern matching and combinatorics on 2D strings have been studied for more than 40 years, see e.g. [1, 4, 9, 14, 18, 25]. In this paper we consider 2-dimensional versions of runs, introduced by Amir et al. [5, 6], and of repetitions in 2D-strings, introduced by Apostolico and Brimkov [7]. As discussed in [6, 8], one could potentially exploit such repetitions in a 2D-string, which could for instance be an image, in order to compress it.

A *2D-run* in a 2D-string A is a subarray of A that is both horizontally periodic and vertically periodic and that cannot be extended by a row or column without changing the horizontal or vertical periodicity (a formal definition follows in Section 2); see Figure 1(a). Amir et al. [5, 6] have shown that the maximum number of 2D-runs in an $n \times n$ array is $\mathcal{O}(n^3)$ and presented an example with $\Theta(n^2)$ 2D-runs. In [6] they presented an $\mathcal{O}(n^2 \log n + \mathsf{output})$-time algorithm for computing 2D-runs.

A *quartic* is a configuration that is composed of 2×2 occurrences of an array W (see Figure 1(b)) and a *tandem* is a configuration consisting of two occurrences of an array W that share one side (Apostolico and Brimkov [7] also considered another type of tandems, which

share one corner; see also [3]). An array W is called *primitive* if it cannot be partitioned into non-overlapping replicas of some array W'. Apostolico and Brimkov [7] considered only quartics and tandems with primitive W (we call them *primitively rooted*) and showed tight asymptotic bounds $\Theta(n^2 \log^2 n)$ and $\Theta(n^3 \log n)$ for the maximum number of occurrences of such quartics and tandems in an $n \times n$ array, respectively. In [8] they presented an optimal $\mathcal{O}(n^3 \log n)$-time algorithm for computing all *occurrences* of tandems with primitive W. This extends a result that a 1D-string of length n contains $\mathcal{O}(n \log n)$ occurrences of primitively rooted squares and they can all be computed in $\mathcal{O}(n \log n)$ time; see [17, 46]. In this paper we consider the numbers of *all distinct* quartics, which is a more complicated problem.



(a) a 2D-run **(b)** a quartic

Figure 1 Examples of a 2D-run and a quartic.

When computing 2D-runs we consider positioned runs: two 2D-runs with same content but starting in different points are considered distinct. However in case of quartics, similarly as in case of 1D-squares, we consider unpositioned quartics; if two quartics have the same content but start in different positions, we consider them equal.

Our Results.

- We show that the number of 2D-runs in an $n \times n$ array is $\mathcal{O}(n^2 \log^2 n)$. This improves upon the $\mathcal{O}(n^3)$ upper bound of Amir et al. [5, 6] and proves that their algorithm computes all 2D-runs in an $n \times n$ 2D-string in $\mathcal{O}(n^2 \log^2 n)$ time **(Section 3)**.
- We show that the number of distinct quartics in an $n \times n$ array is $\mathcal{O}(n^2 \log^2 n)$. This can be viewed as an extension of the bounds on the maximum number of distinct square factors in a 1D-string [26, 29] **(Section 4)**.
- We present algorithmic implications of the new upper bound for 2D-runs. We show that all occurrences of primitively rooted quartics can be computed in quasi-linear, $\mathcal{O}(n^2 \log^2 n)$ time, which is optimal by the bound of Apostolico and Brimkov [7]. Thus our algorithm complements the result of Apostolico and Brimkov [8] who gave an optimal algorithm for computing all occurrences of primitively rooted tandems. We also show that all distinct quartics can be computed in quasi-linear, $\mathcal{O}(n^2 \log^2 n)$ time, which extends efficient computation of distinct squares in 1D-strings [11, 22, 33] to 2D **(Section 5)**.
- As an easy side result, we show tight $\Theta(n^3)$ bounds for the maximum number of distinct tandems in an $n \times n$ array and how to report them in $\mathcal{O}(n^3)$ time **(Section 2)**.

2 Preliminaries

1D-Strings. We denote by $[a, b]$ the set $\{i \in \mathbb{Z} : a \leq i \leq b\}$. Let $S = S[1]S[2] \cdots S[|S|]$ be a *string* of length $|S|$ over an alphabet Σ. The elements of Σ are called *letters*. For two positions i and j on S, we denote by $S[i\,..\,j] = S[i] \cdots S[j]$ the *fragment* of S that starts at position i and ends at position j (it equals ε if $j < i$). A positive integer p is called a *period* of S if $S[i] = S[i + p]$ for all $i = 1, \ldots, |S| - p$. We refer to the smallest period as *the period* of the string, and denote it by $\mathsf{per}(S)$.

▶ **Lemma 1** (Periodicity Lemma (weak version), Fine and Wilf [27]). *If p and q are periods of a string S and satisfy $p+q \leq |S|$, then $\gcd(p,q)$ is also a period of S.*

A string S is called *periodic* if $\mathsf{per}(S) \leq |S|/2$. By ST and S^k we denote the concatenation of strings S and T and k copies of the string S, respectively. A string S is called *primitive* if it cannot be expressed as U^k for a string U and an integer $k > 1$.

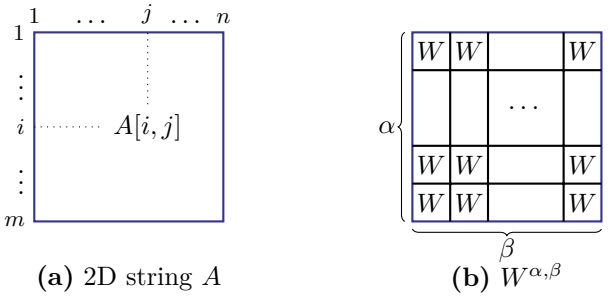
A string of the form U^2 for string U is called a *square*. A square U^2 is called *primitively rooted* if U is primitive. We will make use of the following important property of squares.

▶ **Lemma 2** (Three Squares Lemma, [24]). *Let U, V and W be three strings such that U^2 is a proper prefix of V^2, V^2 is a proper prefix of W^2 and U is primitive. Then $|U|+|V| \leq |W|$.*

A *run* (also known as *maximal repetition*) in S is a periodic fragment $R = S[i\,..\,j]$ which cannot be extended either to the left or to the right without increasing the period $p = \mathsf{per}(R)$, i.e. if $i > 1$ then $S[i-1] \neq S[i+p-1]$ and if $j < |S|$ then $S[j+1] \neq S[j-p+1]$. Let $\mathcal{R}(S)$ denote the set of all runs of string S. For periodic fragment $U = S[a\,..\,b]$, the run that extends U is the unique run $R = S[i\,..\,j]$ such that $i \leq a \leq b \leq j$ and $\mathsf{per}(R) = \mathsf{per}(U)$. An occurrence of a square U^2 is said to be *induced* by a run R if R extends U^2. Every square is induced by exactly one run [22].

2D-Strings. Let A be an $m \times n$ array (2D-string). We denote the height and width of A by $\mathsf{height}(A) = m$ and $\mathsf{width}(A) = n$, respectively. By $A[i,j]$ we denote the cell in the ith row and jth column of A; see Figure 2(a). By $A[i_1\,..\,i_2, j_1\,..\,j_2]$ we denote the subarray formed of rows $i_1,\ldots,i_2$ and columns $j_1,\ldots,j_2$.

A positive integer p is a *horizontal period* of A if the i-th column of A equals the $(i+p)$-th column of A for all $i = 1,\ldots,n-p$. We denote the smallest horizontal period of A by $\mathsf{hper}(A)$. Similarly, a positive integer q is a *vertical period* of A if the i-th row of A equals the $(i+q)$-th row of A for all $i = 1,\ldots,m-q$; the smallest vertical period of A is denoted by $\mathsf{vper}(A)$.



(a) 2D string A **(b)** $W^{\alpha,\beta}$

Figure 2 A 2D-string and the structure of $W^{\alpha,\beta}$.

An $r \times c$ subarray $B = A[i_1\,..\,i_2, j_1\,..\,j_2]$ of A is a *2D-run* if $\mathsf{hper}(B) \leq c/2$, $\mathsf{vper}(B) \leq r/2$ and extending B by a row or column, i.e. either of $A[i_1-1, j_1\,..\,j_2]$, $A[i_2+1, j_1\,..\,j_2]$, $A[i_1\,..\,i_2, j_1-1]$, or $A[i_1\,..\,i_2, j_2+1]$, would result in a change of the smallest vertical or the horizontal period.

If W is a 2D array, then by $W^{\alpha,\beta}$ we denote an array that is composed of $\alpha \times \beta$ copies of W; see Figure 2(b). A *tandem* of W is an array of the form $W^{1,2}$ and a *quartic* of W is the array $W^{2,2}$. A 2D array A is called *primitive* if $A = B^{\alpha,\beta}$ for positive integers α, β implies that $\alpha = \beta = 1$. The *primitive root* of an array A is the unique primitive array B for which $A = B^{\alpha,\beta}$ for $\alpha, \beta \geq 1$.

Apostolico and Brimkov [7] proved the following upper bound, and showed that it is tight by giving a corresponding lower bound.

▶ **Fact 3** (Lemma 5 in [7]). *A 2D array of size $n \times n$ has $\mathcal{O}(n^2 \log^2 n)$ occurrences of primitively rooted quartics.*

We say that a quartic $Q = W^{2,2}$ is *induced* by a 2D-run R if Q is a subarray of R and $\mathsf{hper}(R)$ and $\mathsf{vper}(R)$ divide the width and height of W, respectively.

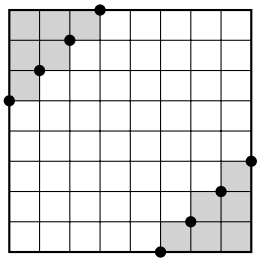


Figure 3 Shaded positions contain letters b, all the other the letters a. Each rectangle with top-left and bottom-right corners marked is a 2D-run; altogether there are 18 distinct 2D-runs, including two of the form $b^{2,2}$. There are also 10 distinct quartics $a^{\alpha,\beta}$, where $0 < \alpha, \beta \leq 8$ are even and $\alpha + \beta \leq 10$. There is also the quartic $b^{2,2}$ (altogether 11 distinct quartics). The centrally placed quartic $a^{2,2}$ is contained in 16 2D-runs. There are only two distinct primitively rooted quartics.

▶ **Observation 4.** *Every quartic is induced by a 2D-run. However; the same quartic can be induced even by $\Theta(n^2)$ 2D-runs; say the middle quartic $a^{2,2}$ in Figure 3.*

▶ Remark 5. The fact that a string of length n has $\mathcal{O}(n \log n)$ occurrences of primitively rooted squares immediately shows (by the fact that a square is induced by exactly one run) that it has $\mathcal{O}(n \log n)$ runs. However, an analogous argument applied for quartics and 2D-runs does not give a non-trivial upper bound for the number of the latter because of Observation 4.

In our algorithms, we use a variant of the Dictionary of Basic Factors in 2D (2D-DBF in short) that is similar to the one presented in [25]. Namely, to each subarray of A whose width and height is an integer power of 2 we assign an integer identifier from $[0, n^2]$ so that two arrays with the same dimensions are equal if and only if their identifiers are equal. The total number of such subarrays is $\mathcal{O}(n^2 \log^2 n)$ and the identifiers can be assigned in $\mathcal{O}(n^2 \log^2 n)$ time; see [25]. Using 2D-DBF, we can assign an identifier to a subarray of A of arbitrary dimensions $r \times c$ being a quadruple of 2D-DBF identifiers of its four $2^i \times 2^j$ subarrays that share one of its corners, where $2^i \leq r < 2^{i+1}$ and $2^j \leq c < 2^{j+1}$. Such quadruples preserve the property that two subarrays of the same dimensions are equal if and only if the 2D-DBF quadruples are the same.

As an illustration, we show a tight bound for the number of distinct tandems and an optimal algorithm for computing them.

▶ **Theorem 6.** *The maximum number of distinct tandems in an $n \times n$ array A is $\Theta(n^3)$. All distinct tandems in an $n \times n$ array can be reported in the optimal $\Theta(n^3)$ time.*

Proof. Let us fix two row numbers $i < i'$ in A. Then, the number of distinct tandems with top row i and bottom row i' is $\mathcal{O}(n)$ by the fact that a string of length n contains $\mathcal{O}(n)$ squares [26, 29]. Thus, in total there are $\mathcal{O}(n^3)$ distinct tandems. For the lower bound, let

the ith row of A be filled with occurrences of the letter i. Every subarray of A of even width is a tandem. For each distinct triplet of top and bottom rows and even width, we obtain a distinct tandem.

Let us proceed to the algorithm. For a height $h \in [1, n]$, we assign integer identifiers from $[1, n^2]$ that preserve lexicographical comparison to all height-h substrings of columns of A. They can be assigned using the generalized suffix tree [18, 47] of the columns of A in $\mathcal{O}(n^2 \log n)$ time. Let B_h be an array such that $B_h[i, j]$ stores the identifier of $A[i\,..\,i+h-1, j]$. To a subarray $W = A[i\,..\,i+h-1, j\,..\,j+w-1]$ we assign an *identifier* $\mathsf{id}(W) = B_h[i, j\,..\,j+w-1]$. Then for any two subarrays W and W' of height h, $W = W'$ if and only if $\mathsf{id}(W) = \mathsf{id}(W')$. For every height $h = 1, \ldots, n$ and row i, we find all distinct squares in $B_h[i, 1], \ldots, B_h[i, n]$ in $\mathcal{O}(n)$ time [11, 22, 33]. This corresponds to the set of distinct tandems with top row i and bottom row $i + h - 1$. Finally, we assign identifiers from 2D-DBF of A to each of the tandems and use radix sort to sort them and enumerate distinct tandems. ◀

3 Improved Upper Bound for 2D-Runs

We introduce the framework that Amir et al. used for efficiently computing 2D-runs [5, 6].

We say that a subarray $B = A[i_1\,..\,i_2, j_1\,..\,j_2]$ of A is a *horizontal run* if it is horizontally periodic (that is, $\mathsf{hper}(B) \le \mathsf{width}(B)/2$) and extending B by either of the columns $A[i_1\,..\,i_2, j_1 - 1]$ or $A[i_1\,..\,i_2, j_2 + 1]$ would result in a change of the smallest horizontal period. (Note that B does not have to be vertically periodic.)

For $k \in [1, \lfloor \log n \rfloor]$ and $i \in [1, n - 2^k + 1]$, let H_i^k be the string obtained by replacing the columns of array $A[i\,..\,i + 2^k - 1, 1\,..\,n]$ with metasymbols such that $H_i^k[j] = H_i^k[j']$ if and only if $A[i\,..\,i + 2^k - 1, j] = A[i\,..\,i + 2^k - 1, j']$. Notice that each such horizontal run of height 2^k corresponds to a run in some H_i^k.

The following lemma will enable us to "anchor" each 2D-run R in the top-left or bottom-left corner of a horizontal run of "similar" height as R. It was proved in [6], but we provide a proof for completeness.

▶ **Lemma 7** (Lemma 7 in [6]). *Let R be a 2D-run whose height is in the range $[2^k, 2^{k+1})$. Then there is a horizontal run R' of height 2^k with $\mathsf{hper}(R') = \mathsf{hper}(R)$ and $\mathsf{width}(R') \ge \mathsf{width}(R)$ such that top-left or bottom-left corners of R and R' coincide (see Figure 4).*

Proof. Let $R = A[i_1\,..\,i_2, j_1\,..\,j_2]$ be the 2D-run in scope and let $k = \lfloor \log(i_2 - i_1 + 1) \rfloor$. We have to show that at least one of the two following statements holds.

- There is a run $R_1 = S[j_1\,..\,b]$ in $S = H_{i_1}^k$ with smallest period p and $b \ge j_2$.
- There is a run $R_2 = T[j_1\,..\,d]$ in $T = H_{i_2 - 2^k + 1}^k$ with smallest period p and $d \ge j_2$.

Since $\mathsf{vper}(R) \le \mathsf{height}(R)/2$, all distinct rows of R are represented in each of $U = S[j_1\,..\,j_2]$ and $V = T[j_1\,..\,j_2]$ and hence $p = \mathsf{per}(U) = \mathsf{per}(V)$. Let $R_1 = S[a\,..\,b]$ be the run that extends U and $R_2 = T[c\,..\,d]$ be the run that extends V. Let us suppose towards a contradiction that $\max(a, c) < j_1$. Then, $A[i_1\,..\,i_2, j_1 - 1] = A[i_1\,..\,i_2, j_1 - 1 + p]$, which contradicts R being a run, since R and $B = A[i_1\,..\,i_2, j_1 - 1\,..\,j_2]$ have the same horizontal and vertical periods. ◀

The sum of the lengths of the runs in a string of length n can be $\Omega(n^2)$ as shown in [32]. However, we prove the following lemma, which is crucial for our approach. We will use it to obtain an overall bound on the possible widths of 2D-runs for our anchors.

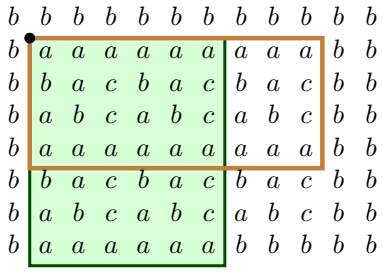

Figure 4 The shaded 7×6 subarray is a 2D-run R, with vertical period 3 and horizontal period $p = 3$. The other marked 4×9 rectangle encloses a horizontal run R' with the same top-left corner and the same horizontal period as R. We have $2 \cdot p \leq width(R) \leq width(R')$.

▶ **Lemma 8.** *For any string S of length n we have that*

$$\rho(S) := \sum_{R \in \mathcal{R}(S)} (|R| - 2 \cdot per(R) + 1) = \mathcal{O}(n \log n).$$

Proof. We consider for each run $R = S[i..j]$ of S the interval $I_R = [i, j - 2 \cdot \mathsf{per}(R) + 1]$. Note that $\rho(S) = \sum_{R \in \mathcal{R}(S)} |I_R|$.

Observe that for every $a \in I_R$ the string $S[a..a + \mathsf{per}(R) - 1]$ is primitive, since if it was of the form U^k for a string U and an integer $k > 1$, then $|U| < \mathsf{per}(R)$ would be a period of R, a contradiction. Hence, at each position $a \in I_R$ there is an occurrence of a primitively rooted square of length $2 \cdot \mathsf{per}(R)$.

A direct application of the Three Squares Lemma (Lemma 2) implies that at most $\mathcal{O}(\log n)$ primitively rooted squares can start at each position a. Each such square extends to a unique run. Thus, each position i belongs to $\mathcal{O}(\log n)$ intervals I_R for $R \in \mathcal{R}(S)$. This completes the proof. ◀

We are now ready to prove the main result of this section.

▶ **Theorem 9.** *There are $\mathcal{O}(n^2 \log^2 n)$ 2D-runs in an $n \times n$ array A.*

Proof. We will iterate over all horizontal runs $R' = A[i..i', j..j']$ whose height is a power of 2, i.e. $i' = i + 2^k - 1$ for some k. For each such horizontal run R', we consider the 2D-runs R with:

(a) top-left corner $A[i, j]$ or bottom-left corner $A[i', j]$,
(b) $\mathsf{hper}(R) = \mathsf{hper}(R')$, and
(c) $\mathsf{height}(R) \in [2^k, 2^{k+1})$.

For each such 2D-run R, we have $\mathsf{width}(R) \in [2 \cdot \mathsf{hper}(R'), \mathsf{width}(R')]$, else the horizontal period would break, i.e. property (b) would be violated. Let us notice that R' corresponds to a run $U = H_i^k[j..j'] \in \mathcal{R}(H_i^k)$. In particular, $\mathsf{width}(R) \in [2 \cdot \mathsf{per}(U), |U|]$.

Lemma 7 implies that each 2D-run is accounted for at least once in this manner. It is thus enough to bound the number of considered runs. We have n choices for i and $\log n$ choices for k. Further, due to Lemma 8, for each corresponding meta-string H_i^k we have $\mathcal{O}(n \log n)$ choices for a pair (j, c) such that $U = H_i^k[j..j'] \in \mathcal{R}(H_i^k)$ and $c \in [2 \cdot \mathsf{per}(U), |U|]$. In total, we thus have $\mathcal{O}(n^2 \log^2 n)$ choices for (i, k, j, c). We will complete the proof by showing that there is only a constant number of 2D-runs with top-left corner $A[i, j]$, width w and whose height is in the range $[2^k, 2^{k+1})$. (2D-runs with bottom-left corner $A[i', j]$ can be bounded symmetrically.)

▷ Claim 10 (cf. Lemma 10 in [6]). Let B be an $r \times c$ array with $r \in [2^k, 2^{k+1})$. Then, there are at most two integers $p > 2^{k-1}$ such that $p = \mathsf{vper}(B') \leq \mathsf{height}(B')/2$ for B' consisting of the top $\mathsf{height}(B') \geq 2^k$ rows of B.

Proof. Consider S to be the meta-string obtained by replacing the rows of B by single letters. Then, a direct application of the Three Squares Lemma (Lemma 2) to S yields the claimed bound. ◁

We apply Claim 10 to $B = A[i\,..\,\min(i + 2^{k+1} - 2, n), j\,..\,j + c - 1]$. If $\mathsf{vper}(R) \leq 2^{k-1}$, then $\mathsf{vper}(R) = \mathsf{vper}(R')$ by the Periodicity Lemma (Lemma 1) applied to the meta-string obtained by replacing the rows of the intersection of R' and B by single letters. Now Claim 10 implies that there are at most three choices to make for the vertical period: $\mathsf{vper}(R')$ and the two integers from the claim. Finally, for fixed top-left corner, width and vertical period we can have a single 2D-run. This concludes the proof. ◀

Amir et al. [6] presented the following algorithmic result.

▶ **Theorem 11** ([6]). *All 2D-runs in an $n \times n$ array can be computed in $\mathcal{O}(n^2 \log n + \mathsf{output})$ time, where output is the number of 2D-runs reported.*

By combining Theorems 9 and 11 we get the following corollary.

▶ **Corollary 12.** *All 2D-runs in an $n \times n$ array can be computed in $\mathcal{O}(n^2 \log^2 n)$ time.*

4 Upper Bound on the Number of Distinct Quartics

Fact 3 that originates from [7] shows that an $n \times n$ array A has $\mathcal{O}(n^2 \log^2 n)$ occurrences of primitively rooted quartics. This obviously implies that the number of distinct primitively rooted quartics is upper bounded by $\mathcal{O}(n^2 \log^2 n)$. Unfortunately, an array can contain $\Theta(n^4)$ occurrences of general quartics; this takes place e.g. for a unary array. In this section we show that $\mathcal{O}(n^2 \log^2 n)$ is also an upper bound for the number of *distinct* general quartics, i.e. subarrays of A of the form $W^{\alpha,\beta}$ for even $\alpha, \beta \geq 2$ and primitive W.

The following lemma and its corollary are the combinatorial foundation of our proofs. An array W with $\mathsf{height}(W) \in [2^a, 2^{a+1})$ and $\mathsf{width}(W) \in [2^b, 2^{b+1})$ will be called an (a, b)-*array*.

▶ **Lemma 13.** *Let a, b be non-negative integers and W, W' be different primitive (a, b)-arrays. If occurrences of $W^{2,3}$ and $(W')^{2,3}$ (of $W^{3,2}$ and $(W')^{3,2}$, respectively) in A share the same corner (i.e., top-left, top-right, bottom-left or bottom-right), then $\mathsf{width}(W) = \mathsf{width}(W')$ ($\mathsf{height}(W) = \mathsf{height}(W')$, respectively).*

Proof. Clearly it is sufficient to prove the lemma for $W^{2,3}$ and $(W')^{2,3}$. Assume w.l.o.g. that occurrences of $W^{2,3}$ and $(W')^{2,3}$ in A share the top-left corner and consider their overlap X.

Each of the rows of X has periods $\mathsf{width}(W)$ and $\mathsf{width}(W')$. Assume w.l.o.g. that $\mathsf{width}(W) \leq \mathsf{width}(W')$. Then

$$\mathsf{width}(X) = 3 \cdot \mathsf{width}(W) \geq \mathsf{width}(W) + 2^{a+1} \geq \mathsf{width}(W) + \mathsf{width}(W').$$

By the Periodicity Lemma (Lemma 1), $p = \gcd(\mathsf{width}(W), \mathsf{width}(W'))$ is a horizontal period of X.

The array X contains at least one occurrence of W and W' in its top-left corner. Hence, W and W' have a horizontal period p. If $\mathsf{width}(W) < \mathsf{width}(W')$, then $\mathsf{width}(W')$ cannot be a multiple of $\mathsf{width}(W)$, because then we would have $\mathsf{width}(W') > 2^{a+1}$. Hence, if $\mathsf{width}(W) < \mathsf{width}(W')$, we would have $p < \mathsf{width}(W)$ which by $p \mid \mathsf{width}(W)$ would mean that W is not primitive. This indeed shows that $\mathsf{width}(W) = \mathsf{width}(W')$. ◀

▶ **Corollary 14.** *Let a, b be non-negative integers and W, W' be different (a, b)-arrays. If occurrences of $W^{3,3}$ and $(W')^{3,3}$ in A share the same corner (i.e., top-left, top-right, bottom-left or bottom-right), then at least one of W, W' is not primitive.*

If $V^{2,2}$ is a non-primitively rooted quartic, then there exists a primitive array W such that $V = W^{\alpha,\beta}$ and at least one of α, β is greater than one. We will call the quartic $W^{2\alpha,2\beta}$ *thin* if $\alpha = 1$ or $\beta = 1$ for this decomposition, and *thick* otherwise. We refer to *points* in A as the $(n+1)^2$ positions where row and column delimiters intersect. Let us first bound the number of distinct thin quartics. For $\beta > 1$, we consider any rightmost occurrence of every such quartic, that is, any occurrence $A[i_1 \,..\, i_2, j_1 \,..\, j_2]$ that maximizes j_1.

▶ **Lemma 15.** *The total number of distinct thin quartics in A is $\mathcal{O}(n^2 \log^2 n)$.*

Proof. We give a proof for quartics of the form $W^{2,2\beta}$ for primitive W and $\beta > 1$; the proof for quartics of the form $W^{2\alpha,2}$ for $\alpha > 1$ is symmetric. We consider each pair of positive integers a, b and show that each point holds the top-left corner of at most two rightmost occurrences of $W^{2,2\beta}$ for primitive (a, b)-arrays W and $\beta > 1$.

Assume to the contrary that the rightmost occurrences of $W^{2,2\beta}$, $(W')^{2,2\beta'}$ and $(W'')^{2,2\beta''}$ share their top-left corner for primitive (a, b)-arrays W, W', W''. The arrays W, W', W'' are pairwise different, since otherwise one of the occurrences would not be the rightmost. By Lemma 13, we have $\mathsf{width}(W) = \mathsf{width}(W') = \mathsf{width}(W'')$. Assume w.l.o.g. that $\mathsf{height}(W) < \mathsf{height}(W') < \mathsf{height}(W'')$.

Let (i, j) denote the top-left corner of the three quartics. Let us consider three length-2ℓ strings formed of metacharacters that correspond to row fragments:

$$(A[i, j \,..\, j + w - 1]), \ldots, (A[i + 2\ell - 1, j \,..\, j + w - 1])$$

for $w = \mathsf{width}(W)$ and $\ell \in \{\mathsf{height}(W), \mathsf{height}(W'), \mathsf{height}(W'')\}$. All the three strings need to be primitively rooted squares. We apply the Three Squares Lemma (Lemma 2) to conclude that $\mathsf{height}(W'') > \mathsf{height}(W) + \mathsf{height}(W') > 2^{a+1}$, a contradiction. ◀

Now let us proceed to thick quartics. Unfortunately, in this case a single point can be the top-left corner of a linear number of rightmost occurrences of thick quartics; see the example in Figure 3. Let us consider an occurrence of $W^{\alpha,\beta}$ for even $\alpha, \beta > 2$ and primitive W, called a *positioned quartic*. It implies $\alpha \cdot \beta$ occurrences of W. Let us call all corners of all these occurrences of W *special points* of this positioned quartic. Each special point stores a direction in $\{\text{top-left}, \text{top-right}, \text{bottom-left}, \text{bottom-right}\}$. A special point has one of the directions if it is the respective corner of an occurrence of $W^{3,3}$ in this positioned quartic. Clearly, since $\alpha, \beta \geq 4$, for every special point in $W^{\alpha,\beta}$ except for the middle row if $\alpha = 4$ or middle column if $\beta = 4$, one can assign such a direction (if many directions are possible, we choose an arbitrary one); see Figure 5.

The quartics with primitive root W are called *W-quartics*. The set of all special points (with directions) of *all* positioned thick W-quartics for a given W is denoted by *SpecialPoints*(W). Among W-quartics of the same height we distinguish the ones with maximal width, which we call *h-maximal* (horizontally maximal). Let us observe that each W-quartic is contained in an occurrence of some h-maximal W-quartic.

▶ **Theorem 16.** *The number of distinct quartics in an $n \times n$ array is $\mathcal{O}(n^2 \log^2 n)$.*

Proof. By Fact 3 and Lemma 15 it suffices to show that the total number of distinct thick quartics in A is $\mathcal{O}(n^2 \log^2 n)$. Let us fix non-negative integers a, b. It is enough to show that the number of distinct subarrays of A of the form $W^{\alpha,\beta}$ for even $\alpha, \beta > 2$ and any primitive (a, b)-array W is $\mathcal{O}(n^2)$.

The sets of special points have the following properties. Claim 17 follows from Corollary 14.

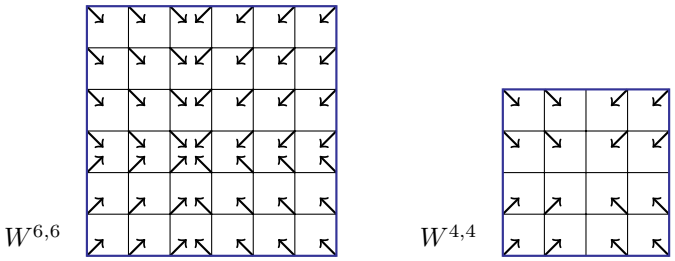

Figure 5 Special points of a positioned quartic with primitive root W with associated directions of four types. The arrow indicates the corner (four possibilities) of $W^{3,3}$ which is contained in the quartic. If several assignments of directions are possible, only one of them is chosen (it does not matter which one). In case of $W^{4,4}$ the middle row and column are not special.

▷ Claim 17. For primitive (a, b)-arrays $W \neq W'$, $\mathit{SpecialPoints}(W) \cap \mathit{SpecialPoints}(W') = \emptyset$.

For an array W, let us denote by $\mathit{ThickQuartics}(W)$ the total number of thick quartics in A with primitive root W.

▷ Claim 18. For a primitive (a, b)-array W, $\mathit{ThickQuartics}(W) < |\mathit{SpecialPoints}(W)|$.

Proof. For each $\alpha = 4, 6, \ldots$ in this order, we select one positioned h-maximal W-quartic U_α of height $\alpha \cdot \mathsf{height}(W)$. The number of distinct W-quartics in A of height $\alpha \cdot \mathsf{height}(W)$ is at most the number of special points in U_α in any of its rows. Note that this statement also holds if $U_\alpha = W^{\alpha,4}$; then there are still four special points in each (non-middle if $\alpha = 4$) row.

We describe a process of assigning distinct W-quartics to distinct special points in $\mathit{SpecialPoints}(W)$. Assume all points in this set are initially not marked. We choose any single row from U_α with all special points in this row still not marked. Then we mark all these special points. We can always choose a suitable row because the heights are increasing.

This way each W-quartic is assigned to only one special point from $\mathit{SpecialPoints}(W)$. ◁

By the claims, the total number of thick W-quartics for primitive (a, b)-arrays W is bounded by:

$$\sum_W \mathit{ThickQuartics}(W) < \sum_W |\mathit{SpecialPoints}(W)| \leq 4(n+1)^2,$$

where the sum is over all primitive (a, b)-arrays W. The conclusion follows. ◀

5 Algorithms for Computing Quartics

In this section we show algorithmic applications of 2D-runs related to quartics.

▶ **Theorem 19.** *All occurrences of primitively rooted quartics in an $n \times n$ array A can be computed in the optimal $\mathcal{O}(n^2 \log^2 n)$ time.*

Proof. Let us consider a 2D-run $R = A[i_1 \,..\, i_2, j_1 \,..\, j_2]$ with periods $\mathsf{hper}(R) = p$ and $\mathsf{vper}(R) = q$. It induces primitively rooted quartics of width $2p$ and height $2q$. The set of top-left corners of these quartics forms a rectangle $\hat{R} = [i_1, i_2 - 2p + 1] \times [j_1, j_2 - 2q + 1]$. We denote by $\mathcal{F}_{p,q}$ the family of such rectangles $\hat{R}$ over 2D-runs R with the same periods p, q.

Such rectangles for different 2D-runs may overlap, even when the dimensions of the quartic are fixed (see Observation 4). In order not to report the same occurrence multiple times, we need to compute, for every dimensions of a quartic, all points in the union of

the corresponding rectangles. This could be done with an additional $\log n$-factor in the complexity using a standard line sweep algorithm [12]. However, we can achieve $\mathcal{O}(n^2 \log^2 n)$ total time using the fact that the total number of occurrences reported is $\mathcal{O}(n^2 \log^2 n)$.

▷ Claim 20. Let $\mathcal{F}_1, \ldots, \mathcal{F}_k$ be families of 2D rectangles in $[1, n]^2$ and let $r = \sum_{i=1}^{k} |\mathcal{F}_i|$. We can compute k (not necessarily disjoint) sets of grid points $Out_i = \bigcup \mathcal{F}_i$ in $\mathcal{O}(n + r + \mathsf{output})$ total time, where $\mathsf{output} = \sum_i |Out_i|$ is the total number of reported points.

Proof. We design an efficient line sweep algorithm. We will perform a separate line sweep, left to right, for each family $\mathcal{F}_i$.

The sweep goes over horizontal (x) coordinates in a left-to-right manner. The broom stores vertical (y) coordinates of horizontal sides of rectangles that it currently intersects. They are stored in a sorted list L of pairs (y, c), where y is the coordinate, and c is the count of rectangles with bottom side at coordinate y minus the count of the rectangles with top side at coordinate y. Only pairs with non-zero second component are stored. Clearly, the second components of the list elements always sum up to 0.

A coordinate x is processed if L is non-empty before accessing it or there exist any vertical sides of rectangles at x. All vertical sides with the same y-coordinate are processed in a batch. For every such batch we want to guarantee that endpoints of all sides are stored in a list B in a top-down order.

A top (bottom) endpoint at vertical coordinate y is stored as $(y, +1)$ ($(y, -1)$, respectively).

Let us now describe how to process a horizontal coordinate x. Let us merge the list L that is currently in the broom with the list B of the batch by the first components. If there is more than one pair with the same first component, we merge all of them together, summing up the second components.

Let us denote by L' the resulting list. We iterate over all elements of L', keeping track of the partial sum of second components, denoted as s. For every element (y, c) of L', the point (x, y) is reported for $\bigcup \mathcal{F}_i$. Moreover, if the partial sum s before considering c was positive and the previous element of L' is (y', c'), all points $(x, y' + 1), \ldots, (x, y - 1)$ are reported to Out_i.

Finally, all pairs with second component equal to zero are removed from L' which becomes the new list L.

Let us now analyze the complexity of the algorithm. The line sweep makes n steps. The total size of lists B across all families $\mathcal{F}_i$ is $\mathcal{O}(r)$ and they can be constructed simultaneously in $\mathcal{O}(n + r)$ time via bucket sort.

Processing a batch with list B takes $\mathcal{O}(|L| + |B|)$ time plus the time to report points in Out_i. As we have already noticed, the sum of $\mathcal{O}(|B|)$ components is $\mathcal{O}(r)$. For every element (y, c) of the initial list L, a point with the vertical coordinate y is reported upon merging; hence, the sum of $\mathcal{O}(|L|)$ components is dominated by $\mathcal{O}(\mathsf{output})$. Overall we achieve time complexity $\mathcal{O}(n + r + \mathsf{output})$. ◁

We apply the claim to the families $\mathcal{F}_{p,q}$. Then r and output are upper bounded by $\mathcal{O}(n^2 \log^2 n)$ by Theorem 9 and Fact 3, respectively. The optimality of our algorithm's complexity is due to the $\Omega(n^2 \log^2 n)$ lower bound on the maximum number of occurrences of primitively rooted quartics from [7]. ◀

We proceed to an efficient algorithm for enumerating distinct, not necessarily primitively rooted, quartics using 2D-runs. The solution for an analogous problem for 1-dimensional strings (computing distinct squares from runs) uses Lyndon roots of runs [22]. However, in 2 dimensions it is not clear if a similar approach could be applied efficiently, say, with the aid

of 2D Lyndon words [40] as Lyndon roots of 2D-runs. We develop a different approach in which the workhorse is the following auxiliary problem related to the folklore nearest smaller value problem.

Let us consider a grid of height m in which every cell can be black or white. We say that the grid forms a *staircase* if the set of white cells in each row is nonempty and is a prefix of this row (see Figure 6). A staircase can be uniquely determined by an array $Whites[1\,..\,m]$ such that $Whites[i]$ is the number of white cells in the ith row. We consider *shapes* of white rectangles. Each shape is a pair (p, q) that represents the dimensions of the rectangle. These shapes (and corresponding rectangles) are partially ordered by: $(p, q) < (p', q') \;\Leftrightarrow\; (p, q) \neq (p', q') \;\wedge\; p \leq p' \;\wedge\; q \leq q'$.

MAX WHITE RECTANGLES
Input: An array $Whites[1\,..\,m]$ that represents a staircase.
Output: Shapes of all maximal white rectangles in this staircase.

▶ **Lemma 21.** *MAX WHITE RECTANGLES problem can be solved in $\mathcal{O}(m)$ time.*

Proof. Assume that $Whites[0] = Whites[m + 1] = -1$. Let us define two tables of size m:

$$NSVUp[i] = \max\{j \,:\, j < i,\ Whites[j] < Whites[i]\},$$
$$NSVDown[i] = \min\{j \,:\, j > i,\ Whites[j] < Whites[i]\}.$$

They can be computed in $\mathcal{O}(m)$ time by a folklore algorithm for the nearest smaller value table; see e.g. [13]. Then the problem can be solved as in Algorithm 1 presented below. After the first for-loop, for each maximal white rectangle R we have $MaxWidth[\mathsf{height}(R)] = \mathsf{width}(R)$, but we could have redundant values for non-maximal rectangles. In order to filter out non-maximal rectangles, we process the candidates by decreasing height and remove the ones that are dominated by the previous maximal rectangle in the partial order of shapes. ◀

Algorithm 1 The first phase computes a set of shapes of type $(h, MaxWidth[h])$, at most one for each height h; see also Figure 6. In the second phase only inclusion-maximal shapes from this set are reported.

ComputeCandidates:
$MaxWidth[1\,..\,m] := (0, \ldots, 0)$
for $i := 1$ **to** m **do**
  $h := NSVDown[i] - NSVUp[i] - 1$
  $MaxWidth[h] := \max(MaxWidth[h], Whites[i])$

ReportMaximal:
$mw := 0$
for $h := m$ **down to** 1 **do**
  if $MaxWidth[h] > mw$ **then**
    Report the shape $(h, MaxWidth[h])$
    $mw := MaxWidth[h]$

▶ Remark 22. Note that the total area (and width) of a staircase can be large but the complexity of our algorithm is linear with respect to the number of rows, thanks to the small representation (array $Whites$).

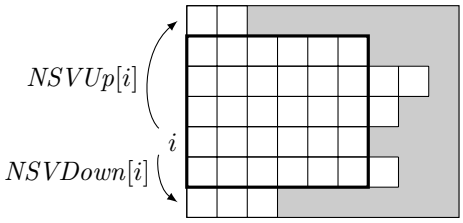

Figure 6 A maximal white rectangle containing row i is computed using the NSV tables for i.

Now our approach is graph-theoretic. The graph nodes correspond to occurrences of primitively rooted quartics. For a fixed primitively rooted quartic $W^{2,2}$ we consider the graph $G_W = (V, E)$, where V is the set of top-left corners of occurrences of $W^{2,2}$. Let $r = \mathsf{height}(W)$ and $c = \mathsf{width}(W)$. The edges in G connect vertex (i, j) with vertices $(i \pm r, j)$ and $(i, j \pm c)$, if they exist. See also Figure 7. This graph can be efficiently computed since we know its nodes due to Theorem 19.

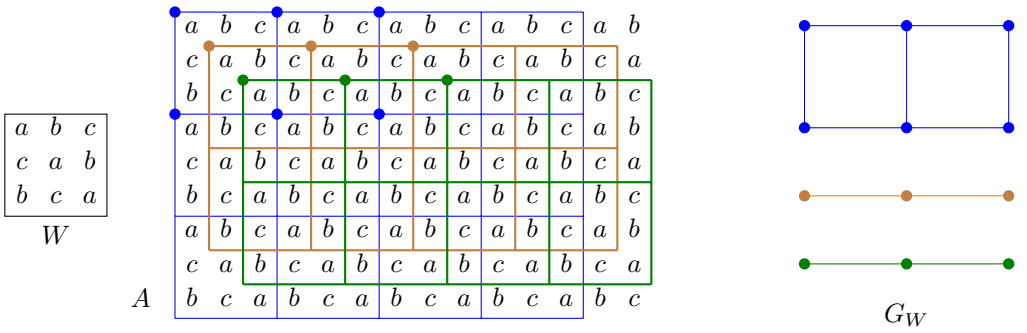

Figure 7 Graph G_W has 12 vertices that form two components with 3 vertices each (green and brown) and one component with 6 vertices (blue). Note the non-trivial occurrences of W in $W^{3,4}$.

▶ **Lemma 23.** *All graphs G_W, and their connected components, for all W which are primitive roots of quartics in A can be constructed in $\mathcal{O}(n^2 \log^2 n)$ time.*

Proof. We first compute all occurrences of primitively rooted quartics in A using Theorem 19. By Fact 3, there are $\mathcal{O}(n^2 \log^2 n)$ of them in total.

We can assign 2D-DBF identifiers (quadruples) to each of the occurrences and group the occurrences by distinct primitively rooted quartics via radix sort in $\mathcal{O}(n^2 \log^2 n)$ time. This gives us the vertices of G_W.

To compute the edges, we use an auxiliary $n \times n$ Boolean array D that will store top-left corners of occurrences of each subsequent primitively rooted quartic $W^{2,2}$.

Initially D is set to zeroes and after each W, all cells with ones are zeroed in $\mathcal{O}(|G_W|)$ time. Using this array and the positions of occurrences of $W^{2,2}$, the edges of G_W can be computed in $\mathcal{O}(|G_W|)$ time. It also allows to divide G_W into connected components via graph search in $\mathcal{O}(|G_W|)$ time. ◀

▶ **Theorem 24.** *All distinct quartics in an $n \times n$ array A can be computed in $\mathcal{O}(n^2 \log^2 n)$ time.*

Proof. We first apply Lemma 23. Now consider a fixed primitive W of height c and width r. Let us note that if $(i,j),(i',j')$ belong to the same connected component H of G_W, then $i \equiv i' \pmod r$ and $j \equiv j' \pmod c$. We say that a connected component H of G_W *generates* an occurrence of a power $W^{\alpha,\beta}$ if the $\alpha\beta$ occurrences of W that are implied by it belong to H. If $W^{\alpha,\beta}$ has an occurrence in A, then it is generated by some connected component H of G_W, unless $\min(\alpha,\beta)=1$.

We say that $W^{\alpha,\beta}$ is a *maximal* power if there is no other power $W^{\alpha',\beta'}$ in A such that $\alpha' \geq \alpha$, $\beta' \geq \beta$, and $(\alpha',\beta') \neq (\alpha,\beta)$. Similarly, we consider powers that are maximal among ones that are generated by a connected component H. Let $\mathit{MaxPowers}_W(H)$ be the set of maximal powers generated by a connected component H. It can be computed in linear time using Lemma 21 as shown in Algorithm 2, which we now explain.

For each vertex (i,j) in H, we insert four points to a set S, which correspond to the four occurrences of W underlying the occurrence of quartic $W^{2,2}$ at position (i,j). If S is treated as a set of white cells in a grid, then $W^{\alpha,\beta}$ for $\alpha > 1$ is a power generated by H if and only if the grid contains a white rectangle of shape (α,β). For a cell $(i,j) \in S$, we denote $R[i,j] = \min\{p \geq 0 : (i,j+p) \notin S\}$. Assuming that the cells of S are sorted by non-increasing second component, each value $R[i,j]$ can be computed from $R[i,j+1]$ in constant time, for a total of $\mathcal{O}(|S|)$ time. The sorting for all S can be done globally, using radix sort. Also, the array R can be stored globally and used for all S, cleared after each use. Finally, we process each maximal set of consecutive cells $(i,j),\ldots,(i+m-1,j) \in S$ that are located in the same column and apply Lemma 21 to solve the resulting instance of the Max White Rectangles problem. The total time required by this step is $\mathcal{O}(|S|)$.

Algorithm 2 Computing $\mathit{MaxPowers}_W(H)$ for a component H of G_W.

$S := \emptyset$
foreach (i,j) **in** $V(H)$ **do**
  $a := \lfloor i/r \rfloor$; $b = \lfloor j/c \rfloor$
  $S := S \cup \{(a,b),(a+1,b),(a,b+1),(a+1,b+1)\}$
$R[0\,..\,n, 0\,..\,n] := (0,\ldots,0)$
foreach (i,j) **in** S *in non-increasing order of* j **do**
  $R[i,j] := R[i,j+1]+1$
Result $:= \emptyset$
foreach *maximal set* $\{(i,j),(i+1,j)\ldots,(i+m-1,j)\} \subseteq S$ **do**
  Whites$[1\,..\,m] := R[i\,..\,i+m-1,j]$
  Result $:=$ *Result* $\cup$ MaxWhiteRectangles(*Whites*)
remove redundant rectangles from *Result*
return *Result*

In the end we filter out the powers $W^{\alpha,\beta}$ that are not maximal in A similarly as in the proof of Lemma 21, using a global array *MaxWidth*. Let $W^{\alpha_1,\beta_1},\ldots,W^{\alpha_k,\beta_k}$ be the resulting sequence of maximal powers, sorted by increasing first component, and let $\alpha_0 = \beta_0 = 0$. Then the set of all quartics in A with primitive root W contains all $W^{2\alpha,2\beta}$ over $\alpha_{p-1} < 2\alpha \leq \alpha_p$, $1 \leq 2\beta \leq \beta_p$, for $p \in [2,k]$. They can be reported in $\mathcal{O}(n^2 \log^2 n)$ total time over all W due to the upper bound of Theorem 16. ◀

6 Final Remarks

We showed that the numbers of distinct runs and quartics in an $n \times n$ array are $\mathcal{O}(n^2 \log^2 n)$. This improves upon previously known estimations. We also proposed $\mathcal{O}(n^2 \log^2 n)$-time algorithms for computing all occurrences of primitively rooted quartics and all distinct quartics. A straightforward adaptation shows that for an $m \times n$ array these bounds and complexities all become $\mathcal{O}(mn \log m \log n)$.

We pose two conjectures for $n \times n$ 2D-strings:

- The number of 2D-runs is $\mathcal{O}(n^2)$.
- The number of distinct quartics is $\mathcal{O}(n^2)$.

A Alternative Algorithm for the Proof of Lemma 21

An alternative, space efficient and more direct algorithm that does not use additional tables *NSVDown* and *NSVUp*, is shown below. The algorithm computes only the table *MaxWidth*. Then, we can use the second phase from Algorithm 1. We assume that the table *MaxWidth* is initially filled with zeros.

Algorithm 3 Alternative implementation of the first phase in Algorithm 1.

```
Whites[0] := Whites[m + 1] := 0
S := empty stack; push(S, 0)
for i := m down to 0 do
    while Whites[i] < Whites[top(S)] do
        k := top(S); h := top(S) − i − 1
        MaxWidth[h] := max(MaxWidth[h], Whites[k])
        pop(S)
    if Whites[top(S)] = Whites[i] then pop(S)
    push(S, i)
```

The algorithm is a version of a folklore algorithm for the Nearest Smaller Values problem and correctness can be shown using the same arguments. If $Whites[i] < Whites[i+1]$, then the algorithm produces shapes of all Max White Rectangles anchored at $i+1$, otherwise $i+1$ is "nonproductive". Observe that $i+1 = top(S)$ when we start processing $i \geq 1$.

Let us analyze the time complexity of the algorithm. In total $m+2$ elements are pushed to the stack. Each iteration of the while-loop pops an element, so the total number of iterations of this loop is $\mathcal{O}(m)$. Consequently, the algorithm works in $\mathcal{O}(m)$ time. In the end one needs to filter out non-maximal rectangles as in the previous proof of Lemma 21.

New Bounds on Augmenting Steps of Block-Structured Integer Programs

Abstract

Iterative augmentation has recently emerged as an overarching method for solving Integer Programs (IP) in variable dimension, in stark contrast with the volume and flatness techniques of IP in fixed dimension. Here we consider *4-block n-fold integer programs*, which are the most general class considered so far. A 4-block n-fold IP has a constraint matrix which consists of n copies of small matrices A, B, and D, and one copy of C, in a specific block structure. Iterative augmentation methods rely on the so-called *Graver basis* of the constraint matrix, which constitutes a set of fundamental augmenting steps. All existing algorithms rely on bounding the ℓ_1- or ℓ_∞-norm of elements of the Graver basis. Hemmecke et al. [Math. Prog. 2014] showed that 4-block n-fold IP has Graver elements of ℓ_∞-norm at most $\mathcal{O}_{FPT}(n^{2^{s_D}})$, leading to an algorithm with a similar runtime; here, s_D is the number of rows of matrix D and $\mathcal{O}_{FPT}$ hides a multiplicative factor that is only dependent on the small matrices A, B, C, D, However, it remained open whether their bounds are tight, in particular, whether they could be improved to $\mathcal{O}_{FPT}(1)$, perhaps at least in some restricted cases.

We prove that the ℓ_∞-norm of the Graver elements of 4-block n-fold IP is upper bounded by $\mathcal{O}_{FPT}(n^{s_D})$, improving significantly over the previous bound $\mathcal{O}_{FPT}(n^{2^{s_D}})$. We also provide a matching lower bound of $\Omega(n^{s_D})$ which even holds for arbitrary non-zero lattice elements, ruling out augmenting algorithm relying on even more restricted notions of augmentation than the Graver basis. We then consider a special case of 4-block n-fold in which C is a zero matrix, called 3-block n-fold IP. We show that while the ℓ_∞-norm of its Graver elements is $\Omega(n^{s_D})$, there exists a different decomposition into lattice elements whose ℓ_∞-norm is bounded by $\mathcal{O}_{FPT}(1)$, which allows us to provide improved upper bounds on the ℓ_∞-norm of Graver elements for 3-block n-fold IP. The key difference between the respective decompositions is that a Graver basis guarantees a *sign-compatible* decomposition; this property is critical in applications because it guarantees each step of the decomposition to be feasible. Consequently, our improved upper bounds let us establish faster algorithms for 3-block n-fold IP and 4-block IP, and our lower bounds strongly hint at parameterized hardness of 4-block and even 3-block n-fold IP. Furthermore, we show that 3-block n-fold IP is without loss of generality in the sense that 4-block n-fold IP can be solved in FPT oracle time by taking an algorithm for 3-block n-fold IP as an oracle.

1 Introduction

A powerful mathematical tool for modeling of various optimization problems is Integer Programming:

$$\min\{\mathbf{w}\cdot\mathbf{x} \,:\, \mathcal{A}\mathbf{x}=\mathbf{b},\, \mathbf{l}\leq\mathbf{x}\leq\mathbf{u},\, \mathbf{x}\in\mathbb{Z}^N\}, \tag{IP}$$

where $\mathbf{w},\mathbf{b},\mathbf{l},\mathbf{u}$ are integer vectors of the *objective function*, *right hand side*, and *lower and upper bounds*, respectively, $\mathcal{A}$ is an integer *constraint matrix*, and $\mathbf{x}$ is a vector of *variables*. It plays a key role in theory as a component in the design of approximation and parameterized algorithms, as well as in practice, with current solvers being routinely utilized in industry and capable of handling models with thousands of variables.

In general, Integer Programming is NP-hard, as was shown already by Karp [23], which motivates the search for tractable special cases. Famous polynomially solvable cases are IPs with few rows and small coefficients as shown by Papadimitriou in 1981 [30], and IPs with few variables as shown by Lenstra in 1983. Arguably the most significant development in the last 20 years has been the introduction of *iterative augmentation* methods which led to the development of fast algorithms for wide classes of IPs whose constraint matrix has a special block structure, and to subsequent breakthrough applications in parameterized and approximation algorithms [5, 21, 27]. In fact, essentially *all* known tractable classes of IP in variable dimension are of this kind, except total unimodular IPs from the '60s.

An iterative augmentation algorithm starts with an initial feasible solution $\mathbf{x}$ and iteratively finds *augmenting steps* $\mathbf{g}\in\mathbb{Z}^N$, i.e., $\mathbf{x}+\mathbf{g}$ is feasible and $\mathbf{w}(\mathbf{x}+\mathbf{g})<\mathbf{w}\mathbf{x}$. A major question is *where* to obtain "good" augmenting steps. The *Graver basis of* $\mathcal{A}$, $\mathcal{G}(\mathcal{A})$, has emerged as an excellent choice, with good guarantees on convergence to optimal solutions while still being algorithmically "tame". Specifically, at the heart of iterative augmentation techniques are bounds on the ℓ_1- and ℓ_∞-norm of elements of the Graver basis, which enable dynamic programming to be used to find Graver elements.

We stress the role of bounds on the elements of $\mathcal{G}(\mathcal{A})$. Historically, all tractable classes of IP were discovered by proving new norm bounds and subsequently designing a dynamic program around them, with the former typically being much harder than the latter. Moreover, recent runtime improvements have followed from improving existing bounds [8, 28], and the most challenging questions in the field are tightly connected to norm bounds. Our focus here is the currently least understood class of IPs, *4-block n-fold IP*:

$$(\mathrm{IP})_{n,\mathbf{b},\mathbf{l},\mathbf{u},\mathbf{w}}: \quad \min\{\mathbf{w}\cdot\mathbf{x} : H\mathbf{x}=\mathbf{b},\, \mathbf{l}\leq\mathbf{x}\leq\mathbf{u},\, \mathbf{x}\in\mathbb{Z}^{t_B+nt_A}\}, \tag{1}$$

where H (called a 4-*block n-fold matrix*) is build from smaller blocks A, B, C and D:

$$H=\begin{pmatrix} C & D \\ B & A \end{pmatrix}^{(n)} := \begin{pmatrix} C & D & D & \cdots & D \\ B & A & 0 & & 0 \\ B & 0 & A & & 0 \\ \vdots & & & \ddots & \\ B & 0 & 0 & & A \end{pmatrix}.$$

Here, A, B, C, D are $s_i \times t_i$ matrices, $i = A, B, C, D$, respectively, and H consists of n copies of A, B, D and one copy of C. Notice that by plugging A, B, C, D into the above block structure we require that $s_C = s_D$, $s_A = s_B$, $t_B = t_C$ and $t_A = t_D$. Let Δ be the largest absolute value among all the entries of A, B, C, D. Let H_0 be a matrix obtained from H by setting $C = \mathbf{0}$. We also study *3-block n-fold IP*, obtained by replacing H with H_0.

For ease of presentation, we introduce the submatrices E and F such that

$$E := \begin{pmatrix} D & D & \cdots & D \\ A & 0 & & 0 \\ 0 & A & & 0 \\ \vdots & & \ddots & \\ 0 & 0 & & A \end{pmatrix} \qquad F := \begin{pmatrix} B & A & 0 & & 0 \\ B & 0 & A & & 0 \\ \vdots & & & \ddots & \\ B & 0 & 0 & & A \end{pmatrix}, \tag{2}$$

4-block n-fold IP remains the simplest case of block-structured IPs for which an algorithm of runtime $f(s_A, t_A, \ldots, s_D, t_D, \Delta)n^{O(1)}$ (i.e., an FPT algorithm; see below) remains unknown. From another perspective, Koutecký et al. [28] has recently resolved the complexity of IP with respect to the structural parameters *primal* and *dual treedepth* td_P and td_D, respectively, by showing that IPs with small td_P and td_D are efficiently solvable. IPs with small *incidence treedepth* td_I subsume both of the aforementioned classes as well as 4-block n-fold IP, and 4-block n-fold IP remains the simplest open case with respect to td_I.

Our Contribution. Because we are interested in efficient algorithms, we wish to confine the exponential dependence on the input into the small numbers s_i, t_i, $i = A, B, C, D$, and Δ. Thus we take the perspective of *parameterized complexity*: for a problem instance I with a *parameter* k, we call an algorithm with runtime $f(k)|I|^{O(1)}$ a *fixed-parameter tractable (FPT)* algorithm, and an algorithm with runtime $|I|^{f(k)}$ an *XP algorithm* (for *slice-wise polynomial*). If such algorithms exist, we say that the problem is *FPT* or *XP parameterized by* k, respectively.

In this paper, we provide new and improved upper bounds and resulting algorithms for 4-block and 3-block n-fold IP, as well as the very first lower bounds for these classes which we believe to hint at the parameterized hardness of these problems. We denote by $\ker_{\mathbb{Z}}(H) = \{\mathbf{x} \in \mathbb{Z}^{t_B + nt_A} \mid H\mathbf{x} = \mathbf{0}\}$ the *integer kernel of* H, also called the *lattice of* H, and by $g_\infty(H) = \max_{\mathbf{g} \in \mathcal{G}(H)} \|\mathbf{g}\|_\infty$ the largest ℓ_∞-norm of an element of the Graver basis $\mathcal{G}(H)$ (a precise definition is given below in Section 2); analogously for H_0. First, we show an upper bound on $g_\infty(H)$.

▶ **Theorem 1.** *For any 4-block n-fold matrix* H, $g_\infty(H) \leq \mathcal{O}_{FPT}(n^{s_D})$.

This improves on the previous bound of $\mathcal{O}_{FPT}(n^{2^{s_D}})$ [16]. We also establish the first explicit lower bound matching our upper bound, making it tight up to an FPT factor. Importantly, our lower bound even applies to the first t_B coordinates (denoted $\mathbf{x}^0$ for a vector $\mathbf{x} \in \mathbb{Z}^{t_B + nt_A}$) which play a special role in algorithms for 4-block n-fold IP. What is more, our lower bound even applies to *any* non-zero element of $\ker_{\mathbb{Z}}(H)$:

▶ **Theorem 2.** *For arbitrary integer* $t \in \mathbb{N}$, *there exists a 4-block n-fold matrix* H *such that* $s_i, t_i \in O(t)$ *for* $i = A, B, C, D$, *and for* any $\mathbf{g} \in \ker_{\mathbb{Z}}(H)$ *we have* $\|\mathbf{g}^0\|_\infty = \Omega(n^t)$.

Therefore, even augmenting via a different set of steps may have to deal with steps that are unbounded by $\mathcal{O}_{FPT}(1)$. Combining Theorem 1 with the original idea of Hemmecke et al. [16] and a strongly polynomial framework of Koutecký et al. [28], we obtain the currently fastest algorithm for 4-block n-fold IP:

▶ **Theorem 3.** *4-block n-fold IP can be solved in time* $\mathcal{O}_{FPT}(n^{O(s_D t_B)})$.

Second, we restrict our attention to 3-block n-fold IP. The motivation is that 3-block n-fold IP is essentially no less general than 4-block n-fold IP. Indeed, for any 4-block n-fold IP, there exists an equivalent 3-block n-fold IP where the largest coefficient, number of rows and columns of the submatrices only increase by $\mathcal{O}(1)$ times (see Theorem 19 and Definition 17 in Appendix 5 for a formal statement).

Interestingly, the lattice elements (i.e., augmenting step candidates) of 3-block n-fold IP admit a decomposition with ℓ_∞-norm bounded by $\mathcal{O}_{FPT}(1)$:

▶ **Theorem 4.** *Any* $\mathbf{g} \in \ker_{\mathbb{Z}}(H_0)$ *decomposes to* $\sum_{i=1}^{N} \mathbf{e}_i$ *for some* $N \in \mathbb{Z}_{\geq 0}$ *with* $\mathbf{e}_i \in \ker_{\mathbb{Z}}(H_0)$ *and* $\|\mathbf{e}_i\|_\infty \leq \mathcal{O}_{FPT}(1)$ *for each* i.

However, this decomposition is not "sign-compatible", meaning possibly none of its elements is a feasible step on its own, which makes its immediate algorithmic use complicated. Nevertheless, we are able to use it to establish an upper bound of $\min\{\mathcal{O}_{FPT}(n^{s_D}), \mathcal{O}_{FPT}(n^{t_A^2+1})\}$ (below, and Theorem 1):

▶ **Theorem 5.** *For any 3-block n-fold matrix* H_0, $g_\infty(H_0) \leq \mathcal{O}_{FPT}(n^{t_A^2+1})$.

This upper bound of $\mathcal{O}_{FPT}(n^{t_A^2+1})$, which is singly exponential in t_A, is much more involved compared with the upper bound of Theorem 1. This coincides with the existing results for 4-block n-fold IP [16], where an upper bound depending on A, B (instead of C, D) is much more complicated. Our proof relies on a completely new approach, which first establishes the decomposition of Theorem 4 and then modifies it into a sign-compatible decomposition through merging summands. This may be of separate interest for deriving upper bounds on $g_\infty(\mathcal{A})$ for other classes of matrices $\mathcal{A}$, particularly for deriving an upper bound on $g_\infty(H)$ which has an explicit dependency on s_A, s_B, t_A, t_B in the exponent of n. Moreover, we show that any 4-block n-fold IP can be embedded in a 3-block n-fold IP (Theorem 19) in a particular way, which allows us to transfer the 4-block n-fold lower bound (now restricted to *feasible* lattice elements):

▶ **Theorem 6.** *For arbitrary integer* $t \in \mathbb{N}$, *there exists a 3-block n-fold IP with a matrix* H *such that* $s_i, t_i \in O(t)$ *for* $i = A, B, C, D$, *and for any* feasible *nonzero* $\mathbf{g} \in \ker_{\mathbb{Z}}(H_0)$ *we have* $\|\mathbf{g}^0\|_\infty = \Omega(n^t)$.

Finally, using our new upper bound of Theorem 5, we get that:

▶ **Theorem 7.** *3-block n-fold IP can be solved in time* $\min\{\mathcal{O}_{FPT}(n^{O(s_D t_B)}, \mathcal{O}_{FPT}(n^{O(t_A^2 t_B)})\}$.

Related Work

4-block n-fold IP originated as a generalization of two previously studied classes of IP, the *n-fold* and *2-stage stochastic* IP, which are obtained by substituting the constraint matrix H with E and F we defined before. We also call E the n-fold matrix and F the 2-stage stochastic matrix, respectively. The origins of iterative augmentation methods for 2-stage stochastic IP reach the work of Hemmecke and Schultz in 2001 [19]. De Loera et al. [7] first studied n-fold IP in 2008. Later, Hemmecke et al. [17] showed an FPT algorithm for n-fold IP based on dynamic programming, which led to a breakthrough in computational social choice [26] and was also applied in the context of scheduling by Knop and Koutecký [25]. Later, this FPT algorithm inspired a better algorithm for a special case of *combinatorial*

n-fold IP developed by Knop et al. [27], who also apply it to problems in stringology and graph algorithms. Finally, this algorithm was lifted to the general n-fold IP by Koutecký et al. [28] and Eisenbrand et al. [8].

An extension of n-fold IP to tree-structured matrices called *tree-fold IP* was developed by Chen and Marx [5] and applied to scheduling problems. Jansen et al. [21] have used n-fold IP to obtain efficient PTASes for scheduling problems. An extension of 2-stage stochastic IP analogous to tree-folds is called multi-stage stochastic and was studied by Aschenbrenner and Hemmecke [4]. Ganian and Ordyniak [12] studied the structural parameters primal treedepth and treewidth, and later Ganian et al. [13] studied dual and incidence treedepth and treewidth. Koutecký et al. [28] discovered that tree-fold and multi-stage stochastic IPs are essentially equivalent to IPs with small dual and primal treedepth, settling the parameterized complexity with respect to these parameters. The work of Koutecký et al. [28] subsumes essentially all current knowledge about the solvability of IP in variable dimension with the exception of totally unimodular constraint matrices and two related classes [2, 3], with the main remaining open problem being the complexity of 4-block n-fold IP and, more generally, IP with respect to incidence treedepth.

Bounds on $g_\infty(\mathcal{A})$ and $g_1(\mathcal{A}) = \max_{\mathbf{g}\in\mathcal{G}(\mathcal{A})} \|\mathbf{g}\|_1$ play a central role in the recent developments. For example, Chen and Marx [5] showed that tree-fold IP is FPT, but a naïve analysis yields a tower-of-exponentials dependence on the parameters. Eisenbrand et al. [8] lower this to double-exponential by improving the bounds on $g_1(\mathcal{A})$, and, at least with the current approach, the only way to obtain a single-exponential algorithm is by obtaining single-exponential bounds on $g_1(\mathcal{A})$. It has been known for a long time that 2-stage stochastic IP is FPT [19], however, there are no known bounds at all for this algorithm except for the computability of the parameter dependence f due to no bounds being available for $g_\infty(F)$. Very recently, Klein [24] is able to obtain such a bound for $g_\infty(F)$, which yields an FPT algorithm with a concrete running time. Lower bounds on $g_\infty(\mathcal{A})$ have been rare so far. Finhold and Hemmecke [11] study them in the context of n-fold IP. Koutecký et al. [28] show lower bounds (only using elementary techniques) for IPs in terms of their primal and dual treewidth.

We use the Steinitz Lemma, which has recently gained renewed attention [10, 8, 22].

2 Preliminaries

Notations

We write vectors in boldface, e.g. $\mathbf{x}, \mathbf{y}$, and their entries in normal font, e.g. x_i, y_i. Any (t_B+nt_A)-dimensional vector $\mathbf{x}$ can be divided into $n+1$ *bricks*, such that $\mathbf{x} = (\mathbf{x}^0, \mathbf{x}^1, \cdots, \mathbf{x}^n)$ where $\mathbf{x}^0 \in \mathbb{Z}^{t_B}$ and each $\mathbf{x}^i \in \mathbb{Z}^{t_A}$, $1 \leq i \leq n$. We call $\mathbf{x}^i$ the *i-th brick* for $0 \leq i \leq n$. We write $0_{s\times t}$ for an $s \times t$ matrix consisting of 0, and I_t for an $t \times t$ identity matrix. For a vector or a matrix, we write $\|\cdot\|_\infty$ to denote the maximal absolute value of its elements. For two vectors $\mathbf{x}, \mathbf{y}$ of the same dimension, $\mathbf{x} \cdot \mathbf{y}$ denotes their inner product.

Throughout this paper, we write $\mathcal{O}_{FPT}(1)$ to represent a parameter that is only dependent on $\Delta, s_A, s_B, s_C, s_D, t_A, t_B, t_C, t_D$ where Δ is the maximal absolute value among all the entries of A, B, C, D, that is, $\mathcal{O}_{FPT}(1)$ is only dependent on the small matrices A, B, C, D and is independent of n. For any computable function $f(x)$, we write $\mathcal{O}_{FPT}(f)$ to represent a computable function $f'(x)$ such that $|f'(x)| \leq \mathcal{O}_{FPT}(1) \cdot |f(x)|$, and $\Omega_{FPT}(f)$ to represent a function f'' such that $|f''(x)| \geq \Omega(1) \cdot |f(x)|$. If no FPT-term is hidden, we will use $\mathcal{O}$ in its standard meaning (e.g., in Theorem 6).

Two vectors $\mathbf{x}$ and $\mathbf{y}$ are called *sign-compatible* if $x_i \cdot y_i \geq 0$ holds for every pair of coordinates (x_i, y_i). Furthermore, we call a summation $\sum_i \mathbf{x}_i$ *sign-compatible* if the summands are pair-wise sign-compatible.

Graver basis

Consider the general integer linear programming in the standard form (IP). Let $\sqsubseteq$ be the *conformal order* in $\mathbb{R}^m$ defined such that $\mathbf{x} \sqsubseteq \mathbf{y}$ if $\mathbf{x}$ and $\mathbf{y}$ lie in the same orthant, i.e., $x_i \cdot y_i \geq 0$ for each $i = 1, \ldots, m$, and $|x_i| \leq |y_i|$ for each $i = 1, \ldots, m$. Given any subset $X \subseteq \mathbb{R}^n$, we say $\mathbf{x}$ is an $\sqsubseteq$-*minimal* element of X if $\mathbf{x} \in X$ and there does not exist $\mathbf{y} \in X$, $\mathbf{y} \neq \mathbf{x}$ such that $\mathbf{y} \sqsubseteq \mathbf{x}$. It is known that every subset of $\mathbb{Z}^m$ has finitely many $\sqsubseteq$-minimal elements. We study the Graver basis:

▶ **Definition 8** (Graver basis [14])**.** *The* Graver basis *of an integer matrix E is the finite set $\mathcal{G}(E) \subseteq \ker_{\mathbb{Z}}(E)$ of all $\sqsubseteq$-minimal elements of $\ker_{\mathbb{Z}}(E) \setminus \{\mathbf{0}\}$.*

For clarity, we sometimes emphasize that $\mathbf{g}$ comes from $\mathcal{G}(H)$ by writing it as $\mathbf{g}(H)$, and similarly for other vectors. We use the fact that any $\mathbf{x} \in \ker_{\mathbb{Z}}(H)$, $\mathbf{x} \neq 0$ can be written as $\mathbf{x} = \sum_i \alpha_i \mathbf{g}_i(H)$, where $\alpha_i \in \mathbb{Z}_+$, $\mathbf{g}_i(H) \in \mathcal{G}(H)$ and $\mathbf{g}_i(H) \sqsubseteq \mathbf{x}$ [29, Lemma 3.4].

The Graver basis $\mathcal{G}(H)$ is only dependent on H. Let $\|B\|_\infty$ be the largest absolute value over all entries. For any $\mathbf{g} \in \mathcal{G}(A)$, we have the following rough estimation for some constant c_1, c_2 [29]:

$$|\mathcal{G}(H)| \leq (c_1 \|H\|_\infty)^{mn} \quad \text{and } \|g\|_\infty \leq (c_2 \|A\|_\infty)^{mn}.$$

Augmentation algorithms for IP and Graver-best oracle

There is a general framework for solving (IP) by utilizing $\mathcal{G}(\mathcal{A})$, which was developed in a series of papers [5, 17, 21, 27]. A recent paper by Koutecký et al. [28] formalizes this framework and extends it to also obtaining *strongly polynomial* algorithms (algorithms whose number of arithmetic operations does not depend on the length of the numbers on input).

We say that $\mathbf{x}$ is *feasible* for (IP) if $\mathcal{A}\mathbf{x} = \mathbf{b}$ and $\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}$. Let $\mathbf{x}$ be a feasible solution for (IP). We call $\mathbf{g}$ a *feasible step* if $\mathbf{x} + \mathbf{g}$ is feasible for (IP). Further, call a feasible step $\mathbf{g}$ *augmenting* if $\mathbf{w}(\mathbf{x} + \mathbf{g}) < \mathbf{w}(\mathbf{x})$. An augmenting step $\mathbf{g}$ and a *step length* $\rho \in \mathbb{Z}$ form an $\mathbf{x}$-*feasible step pair* with respect to a feasible solution $\mathbf{x}$ if $\mathbf{l} \leq \mathbf{x} + \rho\mathbf{g} \leq \mathbf{u}$. An augmenting step $\mathbf{h}$ is a *Graver-best step* for $\mathbf{x}$ if $\mathbf{w}(\mathbf{x} + \mathbf{h}) \leq \mathbf{w}(\mathbf{x} + \rho\mathbf{g})$ for all $\mathbf{x}$-feasible step pairs $(\mathbf{g}, \rho) \in \mathcal{G}(\mathcal{A}) \times \mathbb{Z}$. The next definition and theorem show that it is sufficient to focus all our attention on finding Graver-best steps. This takes care of matters such as finding an initial feasible solution, using a proximity theorem to shrink $\mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}$ and so on.

▶ **Definition 9** (Graver-best oracle)**.** *A* Graver-best oracle *for an integer matrix $\mathcal{A}$ is one that, queried on $\mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}$ and $\mathbf{x}$ feasible to* (IP)*, returns a Graver-best step $\mathbf{h}$ for $\mathbf{x}$.*

▶ **Theorem 10** ([28])**.** *Given a Graver-best oracle for E, (IP) can be solved in strongly polynomial oracle time.*

We remark that the polynomial dependence on the dimension N and in particular the number of bricks n when it comes to 4-block n-fold IP, can be reduced using an *approximate Graver-best oracle* introduced by Altmanová et al. [1] and implicitly by Eisenbrand et al. [8].

Finiteness theorems for n-fold and 2-stage stochastic matrices

Consider an n-fold matrix E that consists of A and D (i.e., $B = C = 0$ in a 4-block n-fold matrix). It is shown that $g_\infty(E)$ is $\mathcal{O}_{FPT}(1)$. More precisely, we have the following lemma.

▶ **Lemma 11** ([9, Lemma 28]). *Let E be an n-fold matrix. Then $g_1(E) \leq (\|E\|_\infty s_D s_A)^{O(s_D s_A)}$.*

▶ **Lemma 12** ([9, Lemma 26]). *Let F be a two-stage stochastic matrix. Then $g_\infty(F) \leq f(t_B, t_A, \|A, B\|_\infty)$ for a double-exponential function f.*

Both lemmas hold for more general classes of tree-fold and multi-stage stochastic matrices.

The Steinitz lemma

The Steinitz lemma has been utilized in several recent papers [8, 10, 22] to establish better algorithms for IP. We use it as well.

▶ **Lemma 13** ([15]). *Let an arbitrary norm be given in $\mathbb{R}^\kappa$ and assume that $\|\mathbf{x}_i\| \leq \zeta$ for $1 \leq i \leq m$ and $\sum_{i=1}^m \mathbf{x}_i = \mathbf{x}$. Then there exists a permutation π such that for all positive integers $\ell \leq m$, $\|\sum_{i=1}^{\ell} \mathbf{x}_{\pi(i)} - \frac{\ell-\kappa}{m}\mathbf{x}\| \leq \kappa\zeta$.*

3 4-block n-fold IP

In this section we consider IP (1) for arbitrary H and derive matching upper and lower bounds on the ℓ_∞-norm of its Graver basis depending on the parameter $s_{\mathrm{C}} = s_{\mathrm{D}}$.

We first establish the following upper bound that improves significantly the current result.

▶ **Theorem 1.** *For any 4-block n-fold matrix H, $g_\infty(H) \leq \mathcal{O}_{FPT}(n^{s_D})$.*

Proof. Let $\mathbf{g} \in \mathcal{G}(H)$. Recall the definition of F in Eq (2). As $F \cdot \mathbf{g} = 0$, there exist $\alpha_j \in \mathbb{Z}_+$, $\mathbf{g}_j(F) \in \mathcal{G}(F)$ and $\mathbf{g}_j(F) \sqsubseteq \mathbf{g}$ such that $\mathbf{g} = \sum_{j=1}^m \alpha_j \mathbf{g}_j(F)$. Furthermore, $\|\mathbf{g}_j(F)\|_\infty = \mathcal{O}_{FPT}(1)$ according to Lemma 12. Let $\mathbf{h}_j = C \cdot \mathbf{g}_j^0(F) + \sum_{i=1}^n D\mathbf{g}_j^i(F)$, which is an s_{D}-dimensional vector such that $\|\mathbf{h}_j\|_\infty = \mathcal{O}_{FPT}(n)$. As $H\mathbf{g} = 0$, it follows that

$$\sum_{j=1}^m \alpha_j \mathbf{h}_j = \underbrace{\mathbf{h}_1 + \mathbf{h}_1 + \cdots + \mathbf{h}_1}_{\alpha_1} + \underbrace{\mathbf{h}_2 + \mathbf{h}_2 + \cdots + \mathbf{h}_2}_{\alpha_2} + \cdots + \underbrace{\mathbf{h}_m + \mathbf{h}_m + \cdots + \mathbf{h}_m}_{\alpha_m} = 0,$$

i.e., the sequence of $\mathbf{h}_i$'s sum up to 0. According to Lemma 13, there exists a permutation of the sequence such that $\|\sum_{i=1}^{\ell} \mathbf{z}_i\|_\infty \leq s_{\mathrm{D}} \cdot \mathcal{O}_{FPT}(n) = \mathcal{O}_{FPT}(n)$ for all $\ell \leq m'$, where $m' = \sum_{i=1}^m \alpha_i$ and $\mathbf{z}_1, \mathbf{z}_2, \cdots, \mathbf{z}_{m'}$ is a permutation of the sequence $\underbrace{\mathbf{h}_1, \mathbf{h}_1, \cdots, \mathbf{h}_1}_{\alpha_1}, \underbrace{\mathbf{h}_2, \mathbf{h}_2, \cdots, \mathbf{h}_2}_{\alpha_2}$, $\cdots, \underbrace{\mathbf{h}_m, \mathbf{h}_m, \cdots, \mathbf{h}_m}_{\alpha_m}$. Let $\tau = \mathcal{O}_{FPT}(n)$ be the upper bound on $\|\sum_{i=1}^{\ell} \mathbf{z}_i\|_\infty$, then we know that $\sum_{i=1}^{\ell} \mathbf{z}_i \in \{-\tau, -\tau+1, \cdots, \tau\}^{s_{\mathrm{D}}}$. Consequently, if $m' > (2\tau+1)^{s_{\mathrm{D}}} + 1$, there exists $\ell_1 < \ell_2$ such that $\sum_{i=1}^{\ell_1} \mathbf{z}_i = \sum_{i=1}^{\ell_2} \mathbf{z}_i$, i.e., $\sum_{i=1}^{\ell_2-\ell_1} \mathbf{z}_i = 0$. Recall that every $\mathbf{z}_i$ corresponds to some $\mathbf{h}_{i'}$. Suppose $\sum_{i=1}^{\ell_2-\ell_1} \mathbf{z}_i = \sum_{j=1}^m \alpha'_j \mathbf{h}_j$ for $\alpha'_j \leq \alpha_j$, then by the definition of $\mathbf{h}_j$ it follows that

$$C\left(\sum_{j=1}^m \alpha'_j \mathbf{g}_j^0(F)\right) + \sum_{i=1}^n D\left(\sum_{j=1}^m \alpha'_j \mathbf{g}_j^i(F)\right) = 0.$$

Hence, $H\sum_{j=1}^m \alpha'_j \mathbf{g}_j(F) = 0$. That is, if $m' = \sum_{j=1}^m \alpha_j > (2\tau+1)^{s_{\mathrm{D}}} + 1$, then there exists some $\mathbf{g}' = \alpha'_j \mathbf{g}_j(F)$ such that $H\mathbf{g}' = 0$, $\mathbf{g}' \sqsubset \mathbf{g}$ and $\mathbf{g}' \neq \mathbf{g}$, contradicting the fact that $\mathbf{g} \in \mathcal{G}(H)$. Thus, $\sum_{j=1}^m \alpha_j \leq (2\tau+1)^{s_{\mathrm{D}}} + 1$, implying that $\|\mathbf{g}\|_\infty = \mathcal{O}_{FPT}(n^{s_{\mathrm{D}}})$. ◀

We complement our upper bound by establishing a matching lower bound. We remark that lower bound from Theorem 2 not only holds for the ℓ_∞-norm of Graver basis elements, but even holds for any non-zero lattice element. This gives a sharp contrast to 3-block n-fold IP. As we will show later in Theorem 6 and Theorem 4, a similar lower bound also exists for the ℓ_∞-norm of Graver basis elements of $\ker_{\mathbb{Z}}(H_0)$, however, $\ker_{\mathbb{Z}}(H_0)$ does admit a decomposition into lattice elements whose ℓ_∞-norm is bounded by $\mathcal{O}_{FPT}(1)$.

▶ **Theorem 2.** *For arbitrary integer $t \in \mathbb{N}$, there exists a 4-block n-fold matrix H such that $s_i, t_i \in O(t)$ for $i = A, B, C, D$, and for* any *$\mathbf{g} \in \ker_{\mathbb{Z}}(H)$ we have $\|\mathbf{g}^0\|_\infty = \Omega(n^t)$.*

Proof. We let $A = I_{t\times t}$, $B = -I_{t\times t}$. We define $(t-1)\times t$ matrices D and C such that

$$D = \begin{pmatrix} 1 & -1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & -1 & \cdots & 0 & 0 \\ \vdots & & & \ddots & & \\ 0 & 0 & 0 & \cdots & 1 & -1 \end{pmatrix} \qquad C = \begin{pmatrix} -1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & -1 & 0 & \cdots & 0 & 0 \\ \vdots & & & \ddots & & \\ 0 & 0 & 0 & \cdots & -1 & 0 \end{pmatrix}$$

Consider any nonzero $\mathbf{y} \in \ker_{\mathbb{Z}}(H)$. According to $A\mathbf{y}^0 - B\mathbf{y}^i = 0$, we know that $\mathbf{y}^0 = \mathbf{y}^i$ for every $1 \le i \le n$. According to $C\mathbf{y}^0 + \sum_{i=1}^{n} D\mathbf{y}^i = 0$, we have $(C + nD)\mathbf{y}^0 = 0$, i.e.,

$$\begin{pmatrix} n-1 & -n & 0 & \cdots & 0 & 0 \\ 0 & n-1 & -n & \cdots & 0 & 0 \\ \vdots & & & \ddots & & \\ 0 & 0 & 0 & \cdots & n-1 & -n \end{pmatrix} \cdot \mathbf{y} = 0$$

Let $\mathbf{y}^0 = (y_1, y_2, \cdots, y_t)$, the following is true:

$$(n-1)y_i = ny_{i+1}, \quad 1 \le i \le t-1 \tag{3}$$

It is easy to see that as long as $\mathbf{y} \neq 0$, we have $\mathbf{y}^0 \neq 0$ and consequently $y_i \neq 0$ for every $1 \le i \le t$. According to $(n-1)y_{t-1} = ny_t$, y_{t-1} is dividable by n. Let $y_{t-1} = nz_{t-1}$ for some $z_{t-1} \in \mathbb{Z}_{\neq 0}$. According to $(n-1)y_{t-2} = ny_{t-1} = n^2 z_{t-1}$, we know that y_{t-2} is dividable by n^2. Let $y_{t-2} = n^2 z_{t-2}$ and we plug it into $(n-1)y_{t-3} = ny_{t-2}$. In general, suppose we have shown that $y_{t-k} = n^k z_{t-k}$ for all $k \le k_0$. Now for $k = k_0 + 1$, we have $(n-1)y_{t-k_0-1} = ny_{t-k_0} = n^{k_0+1} z_{n-k_0}$, then y_{t-k_0-1} is dividable by n^{k_0+1}. Hence, we conclude that y_1 is dividable by n^{t-1}, i.e., $\|\mathbf{y}\|_\infty = \Omega(n^{t-1})$ and Theorem 2 is proved. ◀

4 3-block n-fold IP

In this section we focus on 3-block n-fold IP where $H = H_0$, i.e., $C = \mathbf{0}$. As we will show in this section, 3-block n-fold IP admits several properties that make it a particularly interesting and important special case. First, 3-block n-fold IP is without loss of generality – any 4-block n-fold IP reduces to 3-block n-fold IP with a constant increase in the parameters. Second, any element of $\ker_{\mathbb{Z}}(H_0)$ admits a decomposition into lattice elements with bounded ℓ_∞-norm, which is in certain contrast to Theorem 2. Unfortunately, a strong lower bound of $\Omega(n^t)$ for *feasible* lattice elements still exists for $s_i = t_i = \mathcal{O}(t)$. Nevertheless, we establish an alternative upper bound of $\mathcal{O}_{FPT}(n^{t_A^2+1})$ on the ℓ_∞-norm of the Graver basis elements for 3-block n-fold IP which only depends on parameters of A.

4.1 Decomposition into lattice elements with bounded ℓ_∞-norm

The goal of this subsection is to prove the following theorem.

▶ **Theorem 4.** *Any* $\mathbf{g} \in \ker_{\mathbb{Z}}(H_0)$ *decomposes to* $\sum_{i=1}^{N} \mathbf{e}_i$ *for some* $N \in \mathbb{Z}_{\geq 0}$ *with* $\mathbf{e}_i \in \ker_{\mathbb{Z}}(H_0)$ *and* $\|\mathbf{e}_i\|_\infty \leq \mathcal{O}_{FPT}(1)$ *for each* i.

Proof. Since $H_0\mathbf{g} = 0$, we know that $F \cdot \mathbf{g} = 0$. Therefore, there exist $\alpha_j \in \mathbb{Z}_+$ and $\mathbf{g}_j(F) \sqsubseteq \mathbf{g}$ such that $\mathbf{g} = \sum_j \alpha_j \mathbf{g}_j(F)$, where $\mathbf{g}_j(F) \in \mathcal{G}(F)$. Consider each $\mathbf{g}_j(F)$. As F is a two-stage stochastic matrix (recall its definition in Eq (2)), by Lemma 12 it holds for every j that $\|\mathbf{g}_j(F)\|_\infty = \mathcal{O}_{FPT}(1)$. Note that each $\mathbf{g}_j(F)$ can be written into $n+1$ bricks such that $\mathbf{g}_j(F) = \left(\mathbf{g}_j^0(F), \mathbf{g}_j^1(F), \cdots, \mathbf{g}_j^n(F)\right)$ where $\mathbf{g}_j^0(F)$ is a t_B-dimensional vector, and $\mathbf{g}_j^i(F)$ is a t_A-dimensional vector for every $1 \leq i \leq n$. It is obvious that $\|\mathbf{g}_j^i(F)\|_\infty = \mathcal{O}_{FPT}(1)$ for every $0 \leq i \leq n$, and it holds that

$$B\mathbf{g}_j^0(F) + A\mathbf{g}_j^i(F) = 0, \quad \forall 1 \leq i \leq n.$$

The claim below follows from picking a suitable $\mathbf{v}_j^*$ such that $\mathbf{g}_j^i(F) - \mathbf{v}_j^*$ has "balanced" coefficients.

▷ Claim 14. For every $\mathbf{g}_j(F)$ and $1 \leq \ell \leq |\mathcal{G}(A)|$, there exist some $\mathbf{v}_j^*$ and $\alpha_{j,\ell}^i \in \mathbb{Z}_{\geq 0}$ with

- $\mathbf{g}_j^i(F) - \mathbf{v}_j^* = \sum_{\ell=1}^{|\mathcal{G}(A)|} \alpha_{j,\ell}^i \mathbf{g}_\ell(A), \quad \forall 1 \leq i \leq n.$
- For every $1 \leq \ell \leq |\mathcal{G}(A)|$, either $|\{i : \alpha_{j,\ell}^i > 0\}| = 0$, or $|\{i : \alpha_{j,\ell}^i > 0\}| \geq n/2$.
- $\max_{i,j,\ell} |\alpha_{j,\ell}^i| \leq \alpha_{\max}$, where $\alpha_{\max} = 2g_\infty(F) = \mathcal{O}_{FPT}(1)$
- $\|\mathbf{v}_j^*\|_\infty = \mathcal{O}_{FPT}(1)$.

Proof. Consider an arbitrary $\mathbf{v}_j$ such that $\begin{pmatrix} \mathbf{g}_j^0(F) \\ \mathbf{v}_j \end{pmatrix} \in \ker_{\mathbb{Z}}([B, A])$ and $\| \begin{pmatrix} \mathbf{g}_j^0(F) \\ \mathbf{v}_j \end{pmatrix} \|_\infty \leq g_\infty(F) = \alpha_{\max}/2$. Such $\mathbf{v}_j$ exists since $\mathbf{g}_j(F)$ satisfies that $B\mathbf{g}_j^0(F) + A\mathbf{g}_j^i(F) = 0$ for any $1 \leq i \leq n$. We have $A(\mathbf{g}_j^i(F) - \mathbf{v}_j) = 0$ for every $1 \leq i \leq n$, hence there exist $\bar{\alpha}_{j,\ell}^i \in \mathbb{Z}_+$, $\mathbf{g}_\ell(A) \in \mathcal{G}(A)$ and $\mathbf{g}_\ell(A) \sqsubseteq \mathbf{g}_j^i(F) - \mathbf{v}_j$ such that for some integer m,

$$\mathbf{g}_j^i(F) - \mathbf{v}_j = \sum_{\ell=1}^{m} \bar{\alpha}_{j,\ell}^i \mathbf{g}_\ell(A), \quad \forall 1 \leq i \leq n.$$

Since $\| \begin{pmatrix} \mathbf{g}_j^0(F) \\ \mathbf{v}_j \end{pmatrix} \|_\infty \leq \alpha_{\max}/2$, consequently $\|\mathbf{g}_j^i(F) - \mathbf{v}_j\|_\infty \leq \alpha_{\max}$, and $\bar{\alpha}_{j,\ell}^i \leq \alpha_{\max}$. Consider the cardinality of the set $\{i : \bar{\alpha}_{j,\ell}^i > 0\}$. If $1 \leq |\{i : \bar{\alpha}_{j,\ell}^i > 0\}| \leq \lfloor n/2 \rfloor$, we say ℓ is *unbalanced* for $\mathbf{g}_j(F)$. Let $\bar{\alpha}_{j,\max}^i = \max_{1 \leq \ell \leq m} \bar{\alpha}_{j,\ell}^i$ and UB_j be the set of all unbalanced indices ℓ, we define

$$\mathbf{v}_j^* := \mathbf{v}_j + \sum_{\ell \in UB_j} \bar{\alpha}_{j,\max}^i \mathbf{g}_\ell(A),$$

$$\text{then, } \mathbf{g}_j^i(F) - \mathbf{v}_j^* = \sum_{\ell \in \{1,2,\cdots,m\} \setminus UB_j} \bar{\alpha}_{j,\ell}^i \mathbf{g}_\ell(A) + \sum_{\ell \in UB_j} (\bar{\alpha}_{j,\max}^i - \bar{\alpha}_{j,\ell}^i) \cdot (-\mathbf{g}_\ell(A)), \quad \forall 1 \leq i \leq n.$$

Note that $-\mathbf{g}_\ell(A) \in \mathcal{G}(A)$. For all the $\mathbf{g}_\ell(A)$'s in $\mathcal{G}(A)$ that do not appear in the above equation, we take their coefficients as 0. Furthermore, we have $|\bar{\alpha}_{j,\ell}^i| \leq \alpha_{\max}$ and $|\bar{\alpha}_{j,\max}^i - \bar{\alpha}_{j,\ell}^i| \leq \alpha_{\max}$ for all i, ℓ. As $\|\mathbf{v}_j\|_\infty = \mathcal{O}_{FPT}(1)$, $\|\mathbf{g}_\ell(A)\|_\infty = \mathcal{O}_{FPT}(1)$, we know that $\|\mathbf{v}_j^*\|_\infty = \mathcal{O}_{FPT}(1)$. Thus, the claim is proved. ◁

We call $(\mathbf{g}_j^0(F), \mathbf{v}_j^*, \mathbf{v}_j^*, \cdots, \mathbf{v}_j^*)$ as a canonical vector (of $\mathbf{g}_j(F)$). It is easy to see that $F(\mathbf{g}_j^0(F), \mathbf{v}_j^*, \mathbf{v}_j^*, \cdots, \mathbf{v}_j^*) = 0$. Since $\|\mathbf{v}_j^*\|_\infty = \mathcal{O}_{FPT}(1)$ and $\|\mathbf{g}_j^0(F)\|_\infty = \mathcal{O}_{FPT}(1)$, there are at most $\tau = \mathcal{O}_{FPT}(1)$ different kinds of canonical vectors. This means, there may be different $\mathbf{g}_k(F)$'s with the same canonical vector. We list all the τ possible canonical vectors and let $\mathbf{r}_j := (\mathbf{p}_j^*, \mathbf{v}_j^*, \mathbf{v}_j^*, \cdots, \mathbf{v}_j^*)$ be the j-th one. Let CA_j be the set of indices of all $\mathbf{g}_k(F)$'s whose canonical vector is $\mathbf{r}_j$, then we have

$$\mathbf{g} = \sum_{j=1}^{\tau}\Big(\sum_{k\in CA_j}\alpha_k\Big)\mathbf{r}_j + \sum_{j=1}^{\tau}\sum_{k\in CA_j}\alpha_k\left(\mathbf{g}_k(F) - \mathbf{r}_j\right). \tag{4}$$

We say an n-dimensional vector $\boldsymbol{\alpha} = (\alpha^1, \alpha^2, \cdots, \alpha^n) \in \mathbb{Z}_{\geq 0}^n$ is *balanced*, if $\boldsymbol{\alpha} = 0$, or $\|\boldsymbol{\alpha}\|_\infty \leq \alpha_{\max} = \mathcal{O}_{FPT}(1)$ and $|\{i : \alpha^i > 0\}| \geq n/2$. Then the following observation is true.

▶ **Observation 15.** *For any nonzero balanced vector $\boldsymbol{\alpha}$ it holds that $\|\boldsymbol{\alpha}\|_1 \geq n/2 \cdot \alpha^i/\alpha_{\max}$ for every $1 \leq i \leq n$.*

Using the concept of a balanced vector, Claim 14 indicates that if $\mathbf{r}_j$ is a canonical vector of $\mathbf{g}_k(F)$, then $\mathbf{g}_k^i(F) - \mathbf{v}_j^* = \sum_{\ell=1}^{|\mathcal{G}(A)|}\alpha_{k,\ell}^i\mathbf{g}_\ell(A)$ such that the vector $(\alpha_{k,\ell}^1, \alpha_{k,\ell}^2, \cdots, \alpha_{k,\ell}^n)$ is a balanced vector. The nice thing about balanced vectors is that we can have the following claim, which will be used several times later.

▷ Claim 16. Let $\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_k$ be a sequence of balanced vectors in $\mathbb{Z}_{\geq 0}^n$ such that $\|\sum_{h=1}^k \mathbf{y}_h\|_1 \leq n\Lambda$ where $\Lambda = \mathcal{O}_{FPT}(1)$, then $\|\sum_{h=1}^k \mathbf{y}_h\|_\infty \leq 2\alpha_{\max}\Lambda = \mathcal{O}_{FPT}(1)$.

Proof of Claim 16. We prove by contradiction. Suppose on the contrary that $\|\sum_{h=1}^k \mathbf{y}_h\|_\infty > 2\alpha_{\max}\Lambda$, then there exists some i^* such that $\sum_{h=1}^k \mathbf{y}_h^{i*} > 2\alpha_{\max}\Lambda$. Since $\mathbf{y}_h$'s are balanced vectors, according to Observation 15, we have

$$\|\sum_{h=1}^k \mathbf{y}_h\|_1 = \sum_{h=1}^k \|\mathbf{y}_h\|_1 \geq n \cdot \frac{\sum_{h=1}^k \mathbf{y}_h^{i*}}{2\alpha_{\max}} > n\Lambda,$$

which contradicts the fact that $\|\sum_{h=1}^k \mathbf{y}_h\|_1 \leq n\Lambda$. Hence, the claim is true. ◁

Since $\mathbf{r}_j$ is a canonical vector of $\mathbf{g}_k(F)$, by Claim 14, there exist balanced vectors $\boldsymbol{\beta}_{k,\ell}$ such that Eq (4) can be rewritten as (ignoring $\mathbf{g}^0$):

$$\mathbf{g}^i = \sum_{j=1}^{\tau}\Big(\sum_{k\in CA_j}\alpha_k\Big)\mathbf{v}_j^* + \sum_{j=1}^{\tau}\sum_{k\in CA_j}\alpha_k\left(\sum_{\ell=1}^{|\mathcal{G}(A)|}\beta_{k,\ell}^i\mathbf{g}_\ell(A)\right), \quad \forall 1 \leq i \leq n,$$

$$\text{or equivalently,} \quad \mathbf{g}^i = \sum_{j=1}^{\tau}\alpha_j'\mathbf{v}_j^* + \sum_{\ell=1}^{|\mathcal{G}(A)|}\beta_\ell^i\mathbf{g}_\ell(A), \quad \forall 1 \leq i \leq n, \tag{5}$$

where $\alpha_j' = \sum_{k\in CA_j}\alpha_k$ and each $\beta_\ell = (\beta_\ell^1, \cdots, \beta_\ell^n)$ is the summation of balanced vectors.

$$\text{As } [0, D, D, \cdots, D]\mathbf{g} = 0, \text{ we have } \sum_{j=1}^{\tau} n\alpha_j' D\mathbf{v}_j^* + \sum_{\ell=1}^{|\mathcal{G}(A)|}\Big(\sum_{i=1}^{n}\beta_\ell^i\Big)D\mathbf{g}_\ell(A) = 0. \tag{6}$$

Note that $|\mathcal{G}(A)| = \mathcal{O}_{FPT}(1)$, the equation above can be rewritten as

$$[D\mathbf{v}_1^*, \cdots, D\mathbf{v}_\tau^*, D\mathbf{g}_1(A), \cdots, D\mathbf{g}_{|\mathcal{G}(A)|}(A)] \cdot (n\alpha_1', \cdots, n\alpha_\tau', \sum_{i=1}^{n}\beta_1^i, \cdots, \sum_{i=1}^{n}\beta_{|\mathcal{G}(A)|}^i) = 0. \tag{7}$$

Let $V = [D\mathbf{v}_1^*, D\mathbf{v}_2^*, \cdots, D\mathbf{v}_\tau^*, D\mathbf{g}_1(A), D\mathbf{g}_2(A), \cdots, D\mathbf{g}_{|\mathcal{G}(A)|}(A)]$, which is an $\mathcal{O}_{FPT}(1)\times \mathcal{O}_{FPT}(1)$-matrix with $\|V\|_\infty = \mathcal{O}_{FPT}(1)$, then there exist $\lambda_k \in \mathbb{Z}_+$ and $\mathbf{g}_k(V) \in \mathcal{G}(V)$, such that $(n\alpha'_1, n\alpha'_2, \cdots, n\alpha'_\tau, \sum_{i=1}^n \beta^i_1, \cdots, \sum_{i=1}^n \beta^i_{|\mathcal{G}(A)|}) = \sum_k \lambda_k \mathbf{g}_k(V)$. Note that since $\alpha'_j, \beta^i_\ell \geq 0$, we can restrict that every $\mathbf{g}_k(V) \in \mathbb{Z}^{\tau+|\mathcal{G}(A)|}_{\geq 0}$.

For ease of description, from now on we take the viewpoint of a packing problem. We view each canonical vector $\mathbf{r}^*_j$ and $\mathbf{g}_\ell(A)$ as an item, whereas there are $\tau + |\mathcal{G}(A)|$ different kinds of items. There are $n+1$ different bins. Bin 0 can only be used to pack items $\mathbf{r}^*_j$, $1 \leq j \leq \tau$, and bin i ($1 \leq i \leq n$) can only be used to pack items $\mathbf{g}_\ell(A)$, $1 \leq \ell \leq |\mathcal{G}(A)|$. Currently there are α'_j copies of item $\mathbf{r}^*_j$ in bin 0, and β^i_ℓ copies of item $\mathbf{g}_\ell(A)$ in bin i. This is called a packing profile. Now we want to split this packing profile into several "sub-profiles", i.e., we want to determine integers $\mu^h_j, \sigma^{i,h}_\ell \in \mathbb{Z}_{\geq 0}$ such that the followings are true:

- **(i)** $\mu^h_j, \sigma^{i,h}_\ell = \mathcal{O}_{FPT}(1)$ and $\mu^h_j + \sigma^{i,h}_\ell > 0$.
- **(ii)** $\sum_h \mu^h_j = \alpha'_j$, $\sum_h \sigma^{i,h}_\ell = \beta^i_\ell$;
- **(iii)** $[D\mathbf{v}_1^*, \cdots, D\mathbf{v}_\tau^*, D\mathbf{g}_1(A), \cdots, D\mathbf{g}_{|\mathcal{G}(A)|}(A)]$ $\cdot (n\mu^h_1, \cdots, n\mu^h_\tau, \sum_{i=1}^n \sigma^{i,h}_\ell, \cdots, \sum_{i=1}^n \sigma^{i,h}_{|\mathcal{G}(A)|}) = 0$ for every h.

A packing with μ^h_j copies of $\mathbf{r}^*_j$ in bin 0 and $\sigma^{i,h}_\ell$ copies of $\mathbf{g}_\ell(A)$ in bin i is called a sub-profile. Any sub-profile corresponds to a $(t_A + nt_B)$-dimensional vector $\mathbf{e}_h = (\mathbf{e}^0_h, \mathbf{e}^1_h, \cdots, \mathbf{e}^n_h)$ where

$$\mathbf{e}^0_h = \sum_{j=1}^{\tau} \mu^h_j \mathbf{p}^*_j$$

$$\mathbf{e}^i_h = \sum_{j=1}^{\tau} \mu^h_j \mathbf{v}^*_j + \sum_{\ell=1}^{|\mathcal{G}(A)|} \sigma^{i,h}_\ell \mathbf{g}_\ell(A), \quad \forall 1 \leq i \leq n$$

If all the three conditions on sub-profiles hold, then we know that $\|\mathbf{e}_h\|_\infty = \mathcal{O}_{FPT}(1)$, $\mathbf{g} = \sum_h \mathbf{e}_h$ and $H_0\mathbf{e}_h = 0$ (to see why $H_0\mathbf{e}_h = 0$ holds, simply recall that $F\mathbf{r}^*_j = 0$ and condition (iii) implies that $[0, D, D, \cdots, D]\mathbf{e}_h = 0$), and furthermore, there are at most $\sum_j \alpha'_j + \sum_{i,\ell} \beta^i_\ell$ sub-profiles, which is finite. Hence, $\mathbf{g} = \sum_h \mathbf{e}_h$ and the theorem is proved.

We will construct $\mathbf{e}_h$'s iteratively. Once $\mathbf{e}_h$ is constructed, we continue our decomposition procedure on $\mathbf{g} - \sum_{k=1}^h \mathbf{e}_k$.

Suppose we have constructed $\mathbf{e}_1$ to $\mathbf{e}_{h_0-1}$ where conditions (i) and (iii) are satisfied for each $\mathbf{e}_h$, $\alpha'_j - \sum_{h=1}^{h_0-1} \mu^h_j \geq 0$, $\bar{\beta}^i_\ell := \beta^i_\ell - \sum_{h=1}^{h_0-1} \sigma^{i,h}_\ell \geq 0$ and furthermore, each vector $\bar{\boldsymbol{\beta}}_\ell = (\bar{\beta}^1_\ell, \cdots, \bar{\beta}^n_\ell)$ can be expressed as a summation of all but one balanced vectors, more precisely, there exist balanced vectors $\phi_{\ell,k} \in \mathbb{Z}^n_{\geq 0}$, $1 \leq k \leq k_{\max}$ such that

$$\bar{\beta}_\ell = \sum_{k=1}^{k_{\max}-1} \phi_{\ell,k} + \bar{\phi}_{\ell,k_{\max}}, \quad \text{where } \bar{\phi}_{\ell,k_{\max}} \sqsubseteq \phi_{\ell,k_{\max}}.$$

We show how to construct $\mathbf{e}_{h_0}$. Let $\bar{\alpha}'_j = \alpha'_j - \sum_{h=1}^{h_0-1} \mu^h_j$. According to condition (iii) of each $\mathbf{e}_h$, we know that

$$[D\mathbf{v}_1^*, \cdots, D\mathbf{v}_\tau^*, D\mathbf{g}_1(A), \cdots, D\mathbf{g}_{|\mathcal{G}(A)|}(A)] \cdot (n\bar{\alpha}'_1, \cdots, n\bar{\alpha}'_\tau, \sum_{i=1}^n \bar{\beta}^i_1, \cdots, \sum_{i=1}^n \bar{\beta}^i_{|\mathcal{G}(A)|}) = 0$$

Consequently, there exist $\lambda'_k \in \mathbb{Z}_{\geq 0}$ and $\mathbf{g}_k \in \mathbb{Z}^{\tau+|\mathcal{G}(A)|}_{\geq 0} \cap \mathcal{G}(V)$ such that

$$(n\bar{\alpha}'_1, n\bar{\alpha}'_2, \cdots, n\bar{\alpha}'_\tau, \sum_{i=1}^n \bar{\beta}^i_1, \cdots, \sum_{i=1}^n \bar{\beta}^i_{|\mathcal{G}(A)|}) = \sum_k \lambda'_k \mathbf{g}_k(V).$$

There are two possibilities.

Case 1. If there exists some $\lambda'_k \geq n$, we consider the vector-summand $n\mathbf{g}_k(V)$ out of $\lambda'_k\mathbf{g}_k(V)$. Let $n\mathbf{g}_k(V) = (n\zeta_1, n\zeta_2, \cdots, n\zeta_{\tau+|\mathcal{G}(A)|})$. We set $\mu_j^{h_0} = \zeta_j = \mathcal{O}_{FPT}(1)$ for $1 \leq j \leq \tau$. We set the values of σ_ℓ^{i,h_0} such that $\sum_{i=1}^{n} \sigma_\ell^{i,h_0} = n\zeta_{\tau+\ell}$. Consequently, condition (iii) is satisfied for $\mathbf{e}_{h_0}$. Now it suffices to set the values of each σ_ℓ^{i,h_0} such that they are bounded by $\mathcal{O}_{FPT}(1)$. Equivalently, this means out of the $\bar{\beta}_\ell^i$ copies of $\mathbf{g}_\ell(A)$, our goal is to take σ_ℓ^{i,h_0} copies such that in total we take $n\zeta_{\tau+\ell}$ copies and $\sigma_\ell^{i,h_0} = \mathcal{O}_{FPT}(1)$. We achieve this in a simple greedy way. Let k^* be the index such that

$$\sum_{k=k^*+1}^{k_{\max}-1} \|\phi_{\ell,k}\|_1 + \|\bar{\phi}_{\ell,k_{\max}}\|_1 < n\zeta_{\tau+\ell} \leq \sum_{k=k^*}^{k_{\max}-1} \|\phi_{\ell,k}\|_1 + \|\bar{\phi}_{\ell,k_{\max}}\|_1$$

Let $\bar{\phi}_{\ell,k^*} \sqsubseteq \phi_{\ell,k^*}$ be an arbitrary vector such that

$$\|\bar{\phi}_{\ell,k^*}\|_1 + \sum_{k=k^*+1}^{k_{\max}-1} \|\phi_{\ell,k}\|_1 + \|\bar{\phi}_{\ell,k_{\max}}\|_1 = n\zeta_{\tau+\ell}.$$

We set $\sigma_\ell^{i,h_0} = \bar{\phi}_{\ell,k^*}^i + \sum_{k=k^*+1}^{k_{\max}-1} \phi_{\ell,k}^i + \bar{\phi}_{\ell,k_{\max}}^i$. It is obvious that in total we have taken $n\zeta_{\tau+\ell}$ copies of $\mathbf{g}_\ell(A)$. Now it remains to show that $\|\sigma_\ell^{h_0}\|_\infty = \|\bar{\phi}_{\ell,k^*} + \sum_{k=k^*+1}^{k_{\max}-1} \phi_{\ell,k} + \bar{\phi}_{\ell,k_{\max}}\|_\infty = \mathcal{O}_{FPT}(1)$. To see this, notice that each $\phi_{\ell,k}$ is a balanced vector, hence

$$\|\phi_{\ell,k^*}\|_1 + \sum_{k=k^*+1}^{k_{\max}-1} \|\phi_{\ell,k}\|_1 + \|\phi_{\ell,k_{\max}}\|_1 \leq n\zeta_{\tau+\ell} + 2n\alpha_{\max} = \mathcal{O}_{FPT}(n).$$

According to Claim 16, $\|\phi_{\ell,k^*} + \sum_{k=k^*+1}^{k_{\max}-1} \phi_{\ell,k} + \phi_{\ell,k_{\max}}\|_\infty = \mathcal{O}_{FPT}(1)$. Consequently, $\|\sigma_\ell^{h_0}\|_\infty = \mathcal{O}_{FPT}(1)$.

Also notice that after we take σ_ℓ^{i,h_0} copies of $\mathbf{g}_\ell(A)$, $\bar{\boldsymbol{\beta}}_\ell - \sigma_\ell^{h_0} = \sum_{k=1}^{k^*-1} \phi_{\ell,k} + (\phi_{\ell,k^*} - \bar{\phi}_{\ell,k^*})$, which is still the summation of all but one balanced vector. Hence we can continue to decompose $\mathbf{g} - \sum_{h=1}^{h_0} \mathbf{e}_h$.

Case 2. $\lambda'_k < n$ for every k. We claim that $\|\mathbf{g} - \sum_{h=1}^{h_0-1} \mathbf{e}_h\|_\infty = \mathcal{O}_{FPT}(1)$. If this claim is true, then $\mathbf{g} = \sum_{h=1}^{h_0-1} \mathbf{e}_h + (\mathbf{g} - \sum_{h=1}^{h_0-1} \mathbf{e}_h)$, and Theorem 4 is proved. To show the claim, we use a similar argument as that of case 1. First, $n\bar{\alpha}'_j \leq (\sum_k \lambda_k) \cdot \max_k \|\mathbf{g}_k(V)\|_\infty = \mathcal{O}_{FPT}(n)$, hence $\bar{\alpha}'_j = \mathcal{O}_{FPT}(1)$. Second, we consider the n-dimensional vector $\boldsymbol{\beta} = \sum_{\ell=1}^{|\mathcal{G}(A)|} \boldsymbol{\beta}_\ell$. Recall that $\bar{\beta}_\ell^i := \beta_\ell^i - \sum_{h=1}^{h_0-1} \sigma_\ell^{i,h} \geq 0$ and each vector $\bar{\boldsymbol{\beta}}_\ell$ satisfy that

$$\bar{\beta}_\ell = \sum_{k=1}^{k_{\max}-1} \phi_{\ell,k} + \bar{\phi}_{\ell,k_{\max}}$$

where $\bar{\phi}_{\ell,k_{\max}} \sqsubseteq \phi_{\ell,k_{\max}}$. Let $\bar{\beta}'_\ell = \sum_{k=1}^{k_{\max}} \phi_{\ell,k}$ and $\boldsymbol{\beta}' = \sum_{\ell=1}^{|\mathcal{G}(A)|} \boldsymbol{\beta}'_\ell$. Given that $\bar{\phi}_{\ell,k_{\max}} \sqsubseteq \phi_{\ell,k_{\max}}$ and $\phi_{\ell,k_{\max}}$ is a balanced vector, $\|\bar{\beta}'_\ell\|_1 \leq \|\bar{\beta}_\ell\|_1 + n\alpha_{\max}$. Consequently

$$\begin{aligned} \|\beta'\|_1 \leq \sum_{\ell=1}^{|\mathcal{G}(A)|} \|\bar{\beta}'_\ell\|_1 &\leq \sum_{\ell=1}^{|\mathcal{G}(A)|} \|\bar{\beta}_\ell\|_1 + n\alpha_{\max} \cdot |\mathcal{G}(A)| \\ &\leq \sum_k \lambda'_k \cdot \max_k \|\mathbf{g}_k(V)\|_1 + n\alpha_{\max} \cdot |\mathcal{G}(A)| = \mathcal{O}_{FPT}(n). \end{aligned}$$

Note that $\boldsymbol{\beta}'$ is the summation of balanced vectors. According to Claim 16, $\|\boldsymbol{\beta}'\|_\infty = \mathcal{O}_{FPT}(1)$, consequently $\|\boldsymbol{\beta}\|_\infty \leq \|\boldsymbol{\beta}'\|_\infty = \mathcal{O}_{FPT}(1)$. Combining the fact that $\|\mathbf{p}_j^*\|_\infty = \mathcal{O}_{FPT}(1)$, $\|\mathbf{v}_j^*\|_\infty = \mathcal{O}_{FPT}(1)$ and $\|\mathbf{g}_\ell(A)\|_\infty = \mathcal{O}_{FPT}(1)$, we have $\|\mathbf{g} - \sum_{i=1}^{h_0-1} \mathbf{e}_h\|_\infty = \mathcal{O}_{FPT}(1)$. ◀

Theorem 4 indicates that, there exists some "basis" for 3-block n-fold IP with FPT-bounded ℓ_∞-norms. Unfortunately, this basis need not be Graver basis; indeed, we will show later that the Graver basis of 3-block n-fold IP does not have an FPT-bounded ℓ_∞-norm. However, Theorem 4 provides a new perspective on the structure of the kernel space, which can be utilized to bound the ℓ_∞-norm of the Graver basis through a "merging" technique for the proof of Theorem 5 as we illustrate in the following subsection.

4.2 A sign-compatible decomposition

We have shown in the previous subsection that any element of $\ker_{\mathbb{Z}}(H_0)$ admits a decomposition into lattice elements whose ℓ_∞-norm is bounded by $\mathcal{O}_{FPT}(1)$. However, this decomposition is not necessarily "sign-compatible", meaning that possibly none of its elements is a feasible step on its own, which makes its immediate algorithmic use complicated. Towards the algorithm for 3-block n-fold IP, we resort to Graver basis. The goal of this subsection is to prove the following theorem.

▶ **Theorem 5.** *For any 3-block n-fold matrix H_0, $g_\infty(H_0) \leq \mathcal{O}_{FPT}(n^{t_A^2+1})$.*

Following the line of arguments in previous papers [4, 16, 18, 20], it seems very difficult to derive an upper bound singly exponential in t_A. To prove Theorem 5, we use a completely different approach. We give a brief overview of the proof idea. The reader is referred to the full version of this paper [6] for details.

Proof idea. The basic idea is to show that if $\|\mathbf{g}(H_0)\|_\infty$ is too large for some $\mathbf{g}(H_0) \in \mathcal{G}(H_0)$, then we are able to find some $\mathbf{z} \sqsubset \mathbf{g}(H_0)$ and $H_0\mathbf{z} = 0$, contradicting the fact that $\mathbf{g}(H_0)$ is a Graver basis element. Suppose $\mathbf{y} = \mathbf{g}(H_0)$ and $\|\mathbf{y}\|_\infty$ is very large. The crucial idea is that we do not search directly for $\mathbf{z} \sqsubset \mathbf{y}$, but rather search for $\mathbf{z} \sqsubset \tilde{\mathbf{y}}$ where $\tilde{\mathbf{y}}$ is an "equalization", of $\mathbf{y}$, and then prove that such a $\mathbf{z}$ also satisfies that $\mathbf{z} \sqsubset \mathbf{y}$.

Roughly speaking, we will divide the n bricks of $\mathbf{y}$, i.e., $\mathbf{y}^i$ for $i = 1, 2, \cdots, n$, into $\sigma = \mathcal{O}_{FPT}(1)$ groups $N_1, N_2, \cdots, N_\sigma$ such that for any $k \in N_j$, $\tilde{\mathbf{y}}^k \approx \frac{1}{|N_j|}\sum_{i\in N_j}\mathbf{y}^i$. Why do we need to take such a detour in the proof? The problem is that by directly arguing on $\mathbf{y}$ we run into a bound that is similar as [16]. Therefore, we use a completely different approach – we adopt the decomposition of Theorem 4, and then modify such a decomposition into a sign-compatible one by "merging" summands. Towards this, we first prove a merging lemma (see Lemma 5 of the full version) which states that given a summation of a sequence of vectors, we can always divide them into disjoint subsets such the summation of vectors in each subset becomes sign-compatible. The merging lemma can turn an arbitrary decomposition into a sign-compatible one, despite the fact that the cardinality of each subset is exponential in the dimension of the vectors (which means the ℓ_∞-norm of the summands will explode by a factor that is exponential in the dimension). Consequently, if we directly merge the $\mathcal{O}_{FPT}(n)$-dimensional vectors in the decomposition of Theorem 4, we get a very weak bound. To handle this, we consider an alternative sum $\tilde{\mathbf{y}}$, which is derived by averaging multiple bricks of $\mathbf{y}$ as we mentioned above.

By altering the decomposition of $\mathbf{y}$, we get a decomposition of $\tilde{\mathbf{y}}$ such that the following is true: all the $n+1$ bricks of each vector-summand can be divided into $\mathcal{O}_{FPT}(1)$ subsets where in each subset the bricks are identical. This indicates that, although we are summing up $\mathcal{O}_{FPT}(n)$-dimensional vectors to $\tilde{\mathbf{y}}$, it is essentially the same as summing up $\mathcal{O}_{FPT}(1)$-dimensional vectors. Such a transformation comes at a cost – summands summing up to $\tilde{\mathbf{y}}$ do not have $\mathcal{O}_{FPT}(1)$-bounded ℓ_∞-norms, indeed, each vector-summand consists of n bricks whose ℓ_∞-norm is $\mathcal{O}_{FPT}(1)$, and at most 1 brick (which is a t_A-dimensional vector) whose ℓ_∞-norm is $\mathcal{O}_{FPT}(n)$. Applying our merging lemma, we derive a sign-compatible decomposition of $\tilde{\mathbf{y}}$ where the summands have an ℓ_∞-norm bounded by $\mathcal{O}_{FPT}(n^{t_A^2+1})$.

It remains to show that at least one summand $\mathbf{z}$ in the sign-compatible decomposition of $\tilde{\mathbf{y}}$ also satisfies that $\mathbf{z} \sqsubset \mathbf{y}$. To show this we need to go back to the definition of $\tilde{\mathbf{y}}$. We are averaging bricks of $\mathbf{y}$, but which bricks shall we average? Each brick is a t_A-dimensional vector and we consider each coordinate. We set up a threshold Γ. If the absolute value of a coordinate is larger than Γ, we say it is (positive or negative) large. Otherwise it is small. Therefore, each brick can be characterized by identifying its coordinates being positive large, negative large or small (which is defined as the *quantity type* of a brick). We only average the bricks of the same quantity type. By doing so, we can ensure that $\tilde{\mathbf{y}}^i$ is roughly sign-compatible with $\mathbf{y}^i$ – if the j-th coordinate of $\mathbf{y}^i$ is positive or negative large, then this coordinate of $\tilde{\mathbf{y}}^i$ is also positive or negative. Hence, any $\mathbf{z} \sqsubset \tilde{\mathbf{y}}^i$ is almost sign-compatible with $\mathbf{y}$ – indeed, if we can ensure additionally that the j-th coordinate of $\mathbf{z}^i$ is 0 as long as the j-th coordinate of $\mathbf{y}^i$ is small, then we can conclude that $\mathbf{z} \sqsubset \mathbf{y}$. This "if" can be proved using a counting argument, and we get Theorem 5. ◀

5 4-block n-fold IP reduces to 3-block n-fold IP

In this section, we will show that for any 4-block n-fold IP, there exists an equivalent 3-block n-fold IP which is *kernel preserving*, as we define in the following.

▶ **Definition 17** (Extended formulation). *Let $n' \geq n$, $m' \in \mathbb{N}$, $\mathcal{A} \in \mathbb{Z}^{m \times n}$, $\mathbf{b} \in \mathbb{Z}^m$, $\mathbf{l}, \mathbf{u} \in (\mathbb{Z} \cup \{\pm\infty\})^n$ and $\mathcal{A}' \in \mathbb{Z}^{m' \times n'}$, $\mathbf{b}' \in \mathbb{Z}^{m'}$, $\mathbf{l}', \mathbf{u}' \in (\mathbb{Z} \cup \{\pm\infty\})^{n'}$. We say that*

$$\mathcal{A}'(\mathbf{x}, \mathbf{y}) = \mathbf{b}',\ \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) \leq \mathbf{u}' \tag{EF}$$

is an extended formulation *of*

$$\mathcal{A}\mathbf{x} = \mathbf{b},\ \mathbf{l} \leq \mathbf{x} \leq \mathbf{u} \tag{OrigF}$$

if $\{\mathbf{x} \mid \mathcal{A}\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}\} = \{\mathbf{x} \mid \exists \mathbf{y} : \mathcal{A}'(\mathbf{x}, \mathbf{y}) = \mathbf{b}', \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) \leq \mathbf{u}'\}$.

▶ **Definition 18** (Feasibly kernel-preserving extended formulation). *We say that* (EF) *is a* feasibly kernel preserving *extended formulation of* (OrigF) *if for each* $(\mathbf{x}, \mathbf{y})$ *feasible in* (EF),

$$\mathcal{A}'(\mathbf{g}, \mathbf{h}) = \mathbf{0},\ \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) + (\mathbf{g}, \mathbf{h}) \leq \mathbf{u}' \qquad \Longrightarrow \qquad \mathcal{A}\mathbf{g} = \mathbf{0},\ \mathbf{l} \leq \mathbf{x} + \mathbf{g} \leq \mathbf{u},$$

that is, each element $(\mathbf{g}, \mathbf{h})$ *of* $\ker(\mathcal{A}')$ *which is feasible with respect to* $(\mathbf{x}, \mathbf{y})$ *corresponds to an element* $\mathbf{g} \in \ker(\mathcal{A})$ *which is feasible with respect to* $\mathbf{x}$.

Extended formulations are commonly used to show how a set of solutions can be embedded in an *extended space*, perhaps using less inequalities or obeying some extra structural requirements. The basic observation is that if we take an objective function f over the original formulation (OrigF) and optimize $f'(\mathbf{x}, \mathbf{y}) = f(\mathbf{x})$ over (EF), the optimal solution $(\mathbf{x}, \mathbf{y})$ over (EF) is such that $\mathbf{x}$ is an optimum over (OrigF). In the subsequent theorem we will use it to show that any 4-block n-fold IP can be embedded in a 3-block n-fold IP without blowing up the block sizes too much. The specific notion of a feasibly kernel-preserving extended formulation is useful to show that also our lower bounds on lattice elements are transferred, as we will show subsequently in Theorem 6.

Now we come to the main result of this subsection.

▶ **Theorem 19.** *Any 4-block n-fold IP with parameters $\Delta, s_A, s_B, s_C, s_D, t_A, t_B, t_C, t_D$ has a feasibly kernel-preserving extended formulation whose constraint matrix is a 3-block n-fold matrix with parameters $\hat{\Delta}, \hat{s}_A, \hat{s}_B, \hat{s}_D, \hat{t}_A, \hat{t}_B, \hat{t}_D$ satisfying*

$$\hat{\Delta} = \Delta \quad \hat{t}_A = \hat{t}_D = 2t_C + t_D + s_A \quad \hat{t}_B = t_B \quad \hat{s}_A = \hat{s}_B = s_B + t_C \quad \hat{s}_D = s_D = s_C\ .$$

Proof. Let us construct a 3-block n-fold IP instance which models the given 4-block IP instance. It's matrix $\hat{H}_0$ is a 3-block n-fold matrix composed of blocks $\hat{A}, \hat{B}$ and $\hat{D}$, and the remaining data is $\hat{\mathbf{b}}, \hat{\mathbf{l}}, \hat{\mathbf{u}}$ and $\hat{\mathbf{w}}$. Let the blocks be defined as follows.

$$\hat{D} = (C\ D\ \mathbf{0}\ \mathbf{0}) \qquad \hat{A} = \begin{pmatrix} -I & \mathbf{0} & I & \mathbf{0} \\ \mathbf{0} & A & \mathbf{0} & I \end{pmatrix} \qquad \hat{B} = \begin{pmatrix} I \\ B \end{pmatrix}$$

We call the four block columns of $\hat{A}$ and $\hat{D}$ *subbricks* and index them by greek letters α, β, γ and δ, i.e., $\mathbf{x}^{1\alpha}$ is the α-subbrick of the first brick.

Now, we add an extra brick which we call an *aggregation* brick, denoted $\mathbf{x}^d$ where $d = n+1$. The idea is that the α subbrick is non-zero only at the aggregation brick and corresponds to the first-stage variables of the original 4-block n-fold IP. We shall ensure that this is true using lower and upper bounds. However, to subsequently "assign" the aggregated values to the first stage variables, we also need to modify the B block, which, in turn, forces us to introduce new slack variables. This is the meaning of the γ subbrick (slack variables for bricks $i \neq d$) and δ subbrick (slack variables for the dth brick).

The right hand side $\hat{\mathbf{b}}$ is simply $\hat{\mathbf{b}}^0 = \mathbf{b}^0$ and $\hat{\mathbf{b}}^i = (\mathbf{0}\ \mathbf{b}^i)$ for $i \neq d$ and $\hat{\mathbf{b}}^d = (\mathbf{0}\ \mathbf{0})$. We set the new lower and upper bounds $\hat{\mathbf{l}}, \hat{\mathbf{u}}$ as follows:

- α **subbrick** $\hat{\mathbf{l}}^{i\alpha} = \hat{\mathbf{u}}^{i\alpha} = \mathbf{0}$ for all $i \neq d$, and $\hat{\mathbf{l}}^{d\alpha} = -\infty$, $\hat{\mathbf{u}}^{d\alpha} = +\infty$. This ensures the α subbrick to be only possibly non-zero in brick d.
- β **subbrick** $\hat{\mathbf{l}}^{i\beta} = \mathbf{l}^i$ and $\hat{\mathbf{u}}^{i\beta} = \mathbf{u}^i$ for all $i \neq d$ and $\hat{\mathbf{l}}^{d\beta} = \hat{\mathbf{u}}^{d\beta} = \mathbf{0}$. This ensures that the β subbrick has the meaning of the original variables $\mathbf{x}^i$ for all bricks except brick d, where we enforce $\hat{\mathbf{x}}^{d\beta} = \mathbf{0}$.
- γ **subbrick** $\hat{\mathbf{l}}^{d\gamma} = \hat{\mathbf{u}}^{d\gamma} = \mathbf{0}$ and $\hat{\mathbf{l}}^{i\gamma} = -\infty$, $\hat{\mathbf{u}}^{i\gamma} = +\infty$ for $i \neq d$. Without these variables and due to the structure of $\hat{A}$ and $\hat{B}$, we would be enforcing for *each* brick $i \neq d$ that $\hat{\mathbf{x}}^0 = \hat{\mathbf{x}}^{i\alpha}$, and since $\hat{\mathbf{x}}^{i\alpha} = \mathbf{0}$ this would mean $\hat{\mathbf{x}}^0 = \mathbf{0}$. The γ subbrick relaxes this to $\hat{\mathbf{x}}^0 = \hat{\mathbf{x}}^{i\alpha} + \hat{\mathbf{x}}^{i\gamma} = \mathbf{0} + \hat{\mathbf{x}}^{i\gamma}$ which is trivially satisfiable considering our setting of the bounds $\hat{\mathbf{l}}^{d\gamma}$ and $\hat{\mathbf{u}}^{d\gamma}$.
- δ **subbrick** $\hat{\mathbf{l}}^{i\delta} = \hat{\mathbf{u}}^{i\delta} = \mathbf{0}$ for all $i \neq d$, and $\hat{\mathbf{l}}^{d\delta} = -\infty$, $\hat{\mathbf{u}}^{d\delta} = +\infty$, i.e., the same as for the α subbrick. Similarly to the γ subbrick, without the δ subbrick we would be enforcing $B\hat{\mathbf{x}}^0 + A\hat{\mathbf{x}}^{d\beta} = \mathbf{0}$, however $\hat{\mathbf{x}}^{d\beta} = \mathbf{0}$ so we would be forcing $B\hat{\mathbf{x}}^0 = \mathbf{0}$, which is undesired. Thus we relax it to $B\hat{\mathbf{x}}^0 + A\hat{\mathbf{x}}^{d\beta} + \hat{\mathbf{x}}^{d\delta} = B\hat{\mathbf{x}}^0 + \hat{\mathbf{x}}^{d\delta} = \mathbf{0}$ which is trivially satisfiable.

To show that the constructed system

$$H^0\hat{\mathbf{x}} = \hat{\mathbf{b}},\ \hat{\mathbf{l}} \leq \hat{\mathbf{x}} \leq \hat{\mathbf{u}},\ \hat{\mathbf{x}} \in \mathbb{Z}^{\hat{t}_B + (n+1)\hat{t}_A} \tag{8}$$

is truly an extended formulation of $H\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \mathbf{x} \in \mathbb{Z}^{t_C + nt_A}$, let us define a projection $\pi : \mathbb{Z}^{\hat{t}_B + (n+1)\hat{t}_A} \to \mathbb{Z}^{t_C + nt_A}$ which defines the mapping from the extended formulation to the original instance. Specifically, we let

$$\pi((\hat{x}^0, \hat{x}^{1\alpha}, \hat{x}^{1\beta}, \hat{x}^{1\gamma}, \hat{x}^{1\delta}, \hat{x}^{2\alpha}, \ldots, \hat{x}^{n\delta}, \hat{x}^{d\alpha}, \ldots, \hat{x}^{d\delta}) = (\hat{x}^0, \hat{x}^{1\beta}, \hat{x}^{2\beta}, \ldots, \hat{x}^{n\beta})\ .$$

By the arguments above we see that $\hat{\mathbf{x}}^0$ has precisely the meaning of $\mathbf{x}^0$ and $\hat{\mathbf{x}}^{i\beta}$ for $i \neq d$ has the meaning of $\mathbf{x}^i$.

Finally, let us argue that this extended formulation is also feasibly kernel-preserving. Consider now a feasible solution $\hat{\mathbf{x}}$ of (8), and consider any $\hat{\mathbf{g}}$ in $\ker(H_0)$ such that $\hat{\mathbf{x}} + \hat{\mathbf{g}}$ is again feasible. We have to show that $H\pi(\hat{\mathbf{x}}) = \mathbf{0}$ and $\mathbf{l} \leq \mathbf{x} + \pi(\hat{\mathbf{x}}) \leq \mathbf{u}$. The latter follows easily from the fact that $\hat{\mathbf{l}} \leq \hat{\mathbf{x}} + \hat{\mathbf{g}} \leq \hat{\mathbf{u}}$ and that $\pi(\hat{\mathbf{l}}) = \mathbf{l}$ and $\pi(\hat{\mathbf{u}}) = \mathbf{u}$. To see the former, consider separately first the upper row $(C\ D\ \cdots\ D)$ of H and after that the remaining rows.

We have that

$$C\hat{\mathbf{x}}^{d\alpha} + D\hat{\mathbf{x}}^{d\beta} + \mathbf{0}\hat{\mathbf{x}}^{d\gamma} + \mathbf{0}\hat{\mathbf{x}}^{d\delta} + \sum_{i=1}^{n} C\hat{\mathbf{x}}^{i\alpha} + D\hat{\mathbf{x}}^{i\beta} + \mathbf{0}\hat{\mathbf{x}}^{i\gamma} + \mathbf{0}\hat{\mathbf{x}}^{i\delta} = \mathbf{0} \ .$$

Omitting the zero blocks, we obtain

$$C\hat{\mathbf{x}}^{a\alpha} + D\hat{\mathbf{x}}^{a\beta} + \sum_{i=1}^{n} C\hat{\mathbf{x}}^{i\alpha} + D\hat{\mathbf{x}}^{i\beta} = \mathbf{0} \ .$$

Recall that our bounds enforce $\hat{\mathbf{x}}^{d\beta} = \mathbf{0}$ and $\hat{\mathbf{x}}^{i\alpha} = \mathbf{0}$ for $i \neq d$, and finally $\hat{\mathbf{x}}^{0} = \hat{\mathbf{x}}^{d\alpha}$, so plugging these in we obtain

$$C\hat{\mathbf{x}}^{0} + \sum_{i=1}^{n} D\hat{\mathbf{x}}^{i\beta} = \mathbf{0},$$

which by the definition of π implies that $C\pi(\mathbf{x})^0 + \sum_{i=1}^{n} D\pi(\mathbf{x})^i = \mathbf{0}$ as desired. Now it is left to show that, for each $i \neq d$, $B\pi(\mathbf{x})^0 + A\pi(\mathbf{x})^i = \mathbf{0}$. We have that

$$B\hat{\mathbf{x}}^{0} + \mathbf{0}\hat{\mathbf{x}}^{i\alpha} + A\hat{\mathbf{x}}^{i\beta} + \mathbf{0}\hat{\mathbf{x}}^{i\gamma} + I\hat{\mathbf{x}}^{i\delta} = \mathbf{0} \ .$$

Omitting the zero blocks and recalling that our bounds enforce $\hat{\mathbf{x}}^{i\delta} = \mathbf{0}$ for each $i \neq d$, we have

$$A\hat{\mathbf{x}}^{0} + A\hat{\mathbf{x}}^{i\beta} = \mathbf{0},$$

which, by definition of π, is what we wanted to show. ◀

▶ Remark 20. Theorem 19 has several consequences. One is that 4-block n-fold IP is in FPT if and only if 3-block n-fold IP is in FPT. Furthermore, as the reduction is kernel preserving, we can also utilize Theorem 19 to transfer the Graver basis elements between 4-block n-fold IP and 3-block n-fold IP, as is implied by Theorem 6.

▶ **Theorem 6.** *For arbitrary integer $t \in \mathbb{N}$, there exists a 3-block n-fold IP with a matrix H such that $s_i, t_i \in O(t)$ for $i = A, B, C, D$, and for any* feasible *nonzero $\mathbf{g} \in \ker_{\mathbb{Z}}(H_0)$ we have $\|\mathbf{g}^0\|_\infty = \Omega(n^t)$.*

Proof. Consider the instance constructed in Theorem 2 with H being the 4-block n-fold matrix from the proof. Apply Theorem 19 to this instance to obtain its feasible kernel-preserving extended formulation, which is a 3-block n-fold IP, and consider any $\hat{\mathbf{x}}$ which is a feasible solution for it. Denote by π the projection from the proof of Theorem 19.

Now let $\hat{\mathbf{g}} \in \ker_{\mathbb{Z}}(H_0) \subseteq \ker(H_0)$ be feasible with respect to $\hat{\mathbf{x}}$. By Definition 18, we have $\mathbf{g} = \pi(\hat{\mathbf{g}}) \in \ker_{\mathbb{Z}}(H)$, and by Theorem 2 we have $\|\mathbf{g}\|_\infty = \Omega(n^{t-1})$ and in particular $\|\mathbf{g}^0\|_\infty = \Omega(n^{t-1})$. By the definition of π these lower bounds transfer to $\hat{\mathbf{g}}$ and $\hat{\mathbf{g}}^0$. ◀

▶ Remark 21. The reader may wonder what if we take a "fat" kernel element of a 4-block n-fold IP, which cannot be decomposed into "thin" kernel element whose infinity norm bounded by $\mathcal{O}_{FPT}(1)$, then use Theorem 19 to construct an equivalent 3-block n-fold IP, and apply Theorem 4 to decompose the kernel element of the 3-block n-fold IP into thin elements and transform them back to the original 4-block n-fold IP. This seems to suggest that Theorem 19 is contradicting Theorem 2 and Theorem 4. We emphasize that such a contradiction does not exist. Indeed, our definition of a feasibly-preserving extended formulation is such that it takes kernel elements from 3-block n-fold IP to 4-block n-fold IP

only if they are feasible in the 3-block n-fold IP. Note that the construction of Theorem 19 requires specific lower and upper bounds on the extended variables $\mathbf{y}$. This is where the non-conformality of the decomposition of Thm 4 comes into play: what happens is that we decompose a kernel element of 3-block into "thin" kernel elements, however, we cannot take them back to the 4-block because they do not satisfy the bounds on the extended variables, and thus the definition of feasibly kernel-preserving extended formulation does not guarantee anything for them.

6 Algorithms

Using the upper bound on the Graver basis elements, we can derive algorithms for 3-block and 4-block n-fold IP by combining the idea from [16] and the recent progress in [28, 8], as indicated by Theorem 7 and Theorem 3.

In the following we prove Theorem 7. Theorem 3 can be proved by plugging in the upper bound of 4-block n-fold IP and proceed with the same argument.

▶ **Theorem 7.** *3-block n-fold IP can be solved in time* $\min\{\mathcal{O}_{FPT}(n^{O(s_D t_B)}, \mathcal{O}_{FPT}(n^{O(t_A^2 t_B)})\}$.

Proof. Using the idea of approximate Graver-best oracle introduced by Altmanová et al. [1] and implicitly by Eisenbrand et al. [8], it suffices for us to solve the following IP for each fixed value $\rho_0 = 2^0, 2^1, 2^2, \cdots$:

$$\min\{\mathbf{wx} : H_0\mathbf{x} = 0, \mathbf{l} \leq \mathbf{x}_0 + \rho_0\mathbf{x} \leq \mathbf{u}, \mathbf{x} \in \mathbb{Z}^m, \|\mathbf{x}\|_\infty \leq \min\{\mathcal{O}_{FPT}(n^{s_c}), \mathcal{O}_{FPT}(n^{t_A^2+1})\}\}$$

Let $\mathbf{x}_*$ be the optimal solution. Given that $\|\mathbf{x}_*\|_\infty \leq \mathcal{O}_{FPT}(n^{t_A^2+1})$, we can guess $\mathbf{x}_*^0$ and there are $\mathcal{O}_{FPT}(n^{(t_A^2+1)t_B})$ different possibilities. For each guess, say, $\mathbf{x}_*^0 = \mathbf{v}$, we solve the following problem:

$$\min\{\mathbf{w} \cdot \mathbf{x} : H_0\mathbf{x} = 0, \mathbf{l} \leq \mathbf{x}_0 + \rho_0\mathbf{x} \leq \mathbf{u}, \mathbf{x} \in \mathbb{Z}^m, \mathbf{x}^0 = \mathbf{v}\}$$

By fixing $\mathbf{x}^0$, the above problem becomes exactly an n-fold IP, which can be solved efficiently in $\mathcal{O}_{FPT}(n^2 \log n^2)$ time [8]. Notice that ρ_0 may take $\mathcal{O}_{FPT}(n \log n)$ distinct values, the overall running time is $\min\{\mathcal{O}_{FPT}(n^{s_D t_B+3}) \log^3 n, \mathcal{O}_{FPT}(n^{(t_A^2+1)t_B+3} \log^3 n)\}$. ◀

7 Conclusion

We consider 4-block n-fold IP and its important special case 3-block n-fold IP, both generalizing the two-stage stochastic IP and n-fold IP. We show that lattice elements of 3-block n-fold IP admit a decomposition whose ℓ_∞-norm is bounded in $\mathcal{O}_{FPT}(1)$, while any non-zero integral element in the kernel of 4-block n-fold IP may have an ℓ_∞-norm at least $\Omega(n^{s_c})$. We provide a matching upper bound on the ℓ_∞-norm of the Graver basis for 4-block n-fold IP, which gives an exponential improvement upon the best known result. We also establish an upper bound of $\min\{\mathcal{O}_{FPT}(n^{s_c}), \mathcal{O}_{FPT}(n^{t_A^2}+1)\}$ on the ℓ_∞-norm of the Graver basis for 3-block n-fold IP. A remaining important open problem is whether 4-block n-fold IP, or equivalently, 3-block n-fold IP, is in FPT. Our lower bounds give some indication that this is unlikely.

Abstract

We consider the problem of digitalizing Euclidean segments. Specifically, we look for a constructive method to connect any two points in $\mathbb{Z}^d$. The construction must be *consistent* (that is, satisfy the natural extension of the Euclidean axioms) while resembling them as much as possible. Previous work has shown asymptotically tight results in two dimensions with $\Theta(\log N)$ error, where resemblance between segments is measured with the Hausdorff distance, and N is the L_1 distance between the two points. This construction was considered tight because of a $\Omega(\log N)$ lower bound that applies to any consistent construction in $\mathbb{Z}^2$.

In this paper we observe that the lower bound does not directly extend to higher dimensions. We give an alternative argument showing that any consistent construction in d dimensions must have $\Omega(\log^{1/(d-1)} N)$ error. We tie the error of a consistent construction in high dimensions to the error of similar *weak* constructions in two dimensions (constructions for which some points need not satisfy all the axioms). This not only opens the possibility for having constructions with $o(\log N)$ error in high dimensions, but also opens up an interesting line of research in the tradeoff between the number of axiom violations and the error of the construction. In order to show our lower bound, we also consider a colored variation of the concept of discrepancy of a set of points that we find of independent interest.

The authors would also like to thank the anonymous reviewers for the many comments that helped improve the paper. We would especially like to thank the SODA reviewer that showed us how to improve the lower bound from $\Omega(\log^{1/d} N)$ to $\Omega(\log^{1/(d-1)} N)$.

1 Introduction

Euclidean line segments are one of the most fundamental objects of geometry. Although often loosely referred to as *the shortest path connecting the endpoints*, segments have a clear and unique axiomatic definition out of which many interesting properties follow. For example, it is well-known that the intersection of two segments is always a segment (that could possibly degenerate to a point or even become empty). The definition of other mathematical concepts heavily depends on the definition of segments (such as convex regions).

The definition of segment works very well in a Euclidean or similar spaces with infinite precision. Digital representation (such as pixels in a screen) introduces imprecision. The most common approach used in practice is to somehow *round* the Euclidean segment into the digital space. The digital segments will look very similar to the Euclidean counterparts (that is, the *error* is very small). However, we cannot guarantee the useful properties and concepts that follow from the axiomatic definition of Euclidean segment (see Figure 1).

In the aspect of the consistency of digital segments, we look for a deterministic method to construct digital segments in a way that (i) the analogous of Euclidean axioms are satisfied and (ii) the digital segments resemble the Euclidean ones as much as possible.

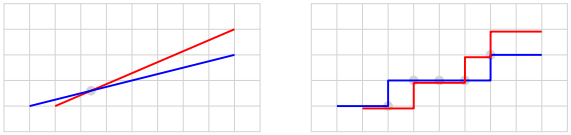

Figure 1 Left: Two Euclidean line segments that intersect in a point. Right: Rounding produces polylines that intersect in three disconnected components.

Preliminaries

Our aim is to construct a digital path $dig(p, q)$ for any two points $p, q \in \mathbb{Z}^d$. Ideally, we want dig to be defined for any pairs of points in $\mathbb{Z}^d$ (full list of requirements is described below), but sometimes we consider the case in which dig is only defined for a subset of $\mathbb{Z}^d \times \mathbb{Z}^d$.

▶ **Definition 1.** *For any $S \subseteq \mathbb{Z}^d \times \mathbb{Z}^d$, let $DS(S)$ be a set of digital segments such that $dig(p, q) \in DS(S)$ for all $(p, q) \in S$. We say that $DS(S)$ forms a* partial set of consistent digital segments *on S (partial CDS for short) if for every pair $(p, q) \in S$ it satisfies the following five axioms:*

(S1) *Grid path property: $dig(p, q)$ is a path between p and q under the $2d$-neighbor topology*[1]*.*
(S2) *Symmetry property: if $(q, p) \in S$, $dig(p, q) = dig(q, p)$.*
(S3) *Subsegment property: for any $r \in dig(p, q)$, $dig(p, r) \in DS(S)$ and $dig(p, r) \subseteq dig(p, q)$.*
(S4) *Prolongation property: $\exists\ r \in \mathbb{Z}^d$ such that $dig(p, r) \in DS(S)$ and $dig(p, q) \subset dig(p, r)$.*
(S5) *Monotonicity property: for all $i \leq d$ such that $p_i = q_i$, it holds that every point $r \in dig(p, q)$ satisfies $r_i = p_i = q_i$.*

These axioms give nice properties of digital segments analogous to Euclidean line segments. For example, (S1) and (S3) imply that the intersection of two digital segments is another segment (that could degenerate to a single point or an empty set). (S5) implies that the intersection of a segment with an axis-aligned halfspace is a segment.

[1] The $2d$-neighbor topology is the natural one that connects to your predecessor and successor in each dimension. Formally speaking, two points are connected if and only if their $||\cdot||_1$ distance is exactly one.

A partial CDS for $S = \mathbb{Z}^d \times \mathbb{Z}^d$ is called a set of *consistent digital segments* (CDS for short). Although our final goal is to have such a construction that works for the case in which $S = \mathbb{Z}^d \times \mathbb{Z}^d$, in this paper we consider subsets of the form $S = \{o\} \times \mathbb{Z}^d$ (where o is the origin or any fixed point in $\mathbb{Z}^d$). We say that a partial CDS on such a set is a *consistent digital ray* system (CDR for short), as it contains all segments (or rays) from o to $\mathbb{Z}^d$.

Another property that we want from partial CDS is that they visually resemble the Euclidean segments. The resemblance between the digital segment $dig(p, q)$ and the Euclidean counterpart $\overline{pq}$ is measured using the *Hausdorff* distance. The Hausdorff distance $H(A, B)$ of two objects A and B is defined by $H(A, B) = \max\{h(A, B), h(B, A)\}$, where $h(A, B) = \max_{a\in A} \min_{b\in B} \delta(a, b)$, and $\delta(a, b)$ is the standard $||\cdot||_\infty$ L-infinity norm.

Thus, the resemblance of a partial CDS on S is defined as $\max_{(p,q)\in S} H(dig(p, q), \overline{pq})$ (that is, the biggest error created between a digital segment and its Euclidean counterpart). This value is simply referred to as the *error* of the partial CDS construction. We are interested to see how the error grows as we enlarge our focus of interest. Thus, we limit the domain to the case in which both points are in the L_1 ball of radius N centered at the origin (i.e. $\mathcal{G}_N = \mathbb{Z}^d \cap B_1(o, N)$). Rather than looking for the exact function, we are interested in the asymptotic behavior of the error as a function of N. For simplicity, we will actually restrict ourselves to the positive orthant $\mathcal{G}_N^+ = \mathcal{G}_N \cap_i H_i$, where $H_i = \{p \in \mathbb{Z}^d : p_i \geq 0\}$ and p_i is the i-th coordinate of p (the results extend to other orthants by symmetry).

Previous Work

Research on the digital representation of line segments has been an active area of research for over half a century [10]. Many different approaches have been considered. Most common techniques look for methods that implicitly encode the properties we desire. For example, a popular approach is to consider a *dynamic* method to digitize line segments. In this setting, the way we transform a Euclidean segment into a digital one will depend on which other segments are present (and their specific coordinates). It is known that a grid of exponential size is needed if we want to preserve the combinatorial types [9]. Another workaround is known as *snap rounding* that represents line segments by polygonal chains: Each segment is carefully rounded to avoid inconsistencies. Note that both of these ideas implicitly keep the error small while making sure that the intersection of two digital segments is a connected component. Although they work well in practice, they have the drawback that they cannot be used to define objects that are based on digital segments (such as digital starshapes or convex region).

The first paper to explicitly look for an axiomatic approach was in 1987 by Luby [11]: in his work he introduced the concept of CDS (under the name of *smooth geometries*) and gave a method to construct CDSs in $\mathbb{Z}^2$ based on a characterization of CDRs in $\mathbb{Z}^2$: any CDR can be uniquely identified by four total orders of the integers (and vice versa). By choosing a proper total order and using it for all points of $\mathbb{Z}^2$ we obtain a CDR with $O(\log N)$ error. Håstad[2] gave a matching lower bound for any such construction. The lower bound is based on discrepancy theory [12]: any CDR is mapped to a sequence of real numbers in $[0, 1)$ in a way that the error of the CDR is proportional to the discrepancy of the sequence (intuitively speaking, a measure on how well shuffled the numbers are).

These results were rediscovered by Chun et al. [8] and Christ et al. [6]. They renewed interest in the topic and sparked other related research: Chowdhury and Gibson [4] gave necessary and sufficient conditions for a collection of CDRs to form a CDS. In a companion

[2] The lower bound was published by Luby, but credit given to Håstad (see Theorem 19 of [11]).

paper, the same authors [5] afterwards provided an alternative characterization together with a constructive algorithm; specifically, they gave an algorithm that, given a collection of segments in an $N \times N$ grid that satisfies the five axioms, computes a CDS that contains those segments. The algorithm runs in polynomial time of N.

Unfortunately, most of these results only work on the digital plane. Out of the previously mentioned results, only the CDR construction of Chun et al. [8] extends to three and higher dimensions. The construction has $O(\log N)$ error regardless of the dimension. Chun et al. [8] also considered the case in which the monotonicity property (S5) is not preserved. They showed that if we remove (S5), we can obtain a CDR with $O(1)$ error in any dimension. Although the error is small, the resulting segments are far from what we would consider similar to the Euclidean segments (because they loop around many times). Recently, Chiu and Korman [2] showed that the problem in higher dimensions behaves very differently from the two dimensional case. Specifically, they studied how to extend the CDS construction of Christ et al. [6] and showed that it is very limiting in three (and higher) dimensions. We can use their method to get arbitrarily many CDRs (with $\Omega(\log N)$ error) and sometimes we can get a CDS. However, whenever the construction yields a CDS, it will have $\Omega(N)$ error.

Our interest in higher dimensions comes motivated by an application in *image segmentation*. Image segmentation is the act of separating an object from its background in an image (that is, determining which pixels are part of the background and which ones not). Chun et al. [8] showed how to combine their CDR construction with the framework of Asano et al. [1] to segment two dimensional images. This idea has been extended to consider other shapes (see [7] for a detailed list), but always two dimensional. The hope is that a high dimensional CDR with low error will produce more accurate segmentation algorithms. Although traditional images taken with a camera are two dimensional, images from a medical equipment such as those taken with an MRI machine can have three or even higher dimensions (say, when we want to track changes of a particular object along time).

Results and paper organization

When approximating some geometric object, it often happens that higher dimensions create a larger error than in a lower dimension setting. Since the high dimensional setting contains a two dimensional subspace, it is common for lower bounds to extend to higher dimensions. However, this is not true for the case of CDRs: although a three dimensional CDR contains two dimensional subspaces, those subspaces need not exactly be CDRs (and thus the $\Omega(\log N)$ lower bound does not directly hold). In this paper, we further explain the reason and investigate the lower bound for the higher dimensional case.

The main reason why a subspace is not a CDR is because of the prolongation property (S4): we require that every segment is extendable, but has no constraints on the dimension in which it does so. In particular, a subspace of a high dimensional CDR need not be a CDR (see an example in Figure 2). Subspaces of CDRs are what we call *weak CDR*: it is a construction that almost always behaves like a CDR but some vertices may not satisfy the prolongation property (S4). Each vertex that does not extend is called an *inner leaf*. In this paper we study weak CDRs in two dimensions and the implications that they have for (proper) CDRs in higher dimensions.

The new found properties of weak CDRs allow us to extend the two-dimensional lower bound to higher dimensions. Håstad's bound was based on a mapping from a (two-dimensional) CDR into a pointset in $[0, 1) \subset \mathbb{R}$ and tied the error of the CDR to the discrepancy of the transformed pointset. Our lower bound uses an additional intermediate step: from any CDR we consider the weak CDR it generates in the x_1x_2-plane. We then

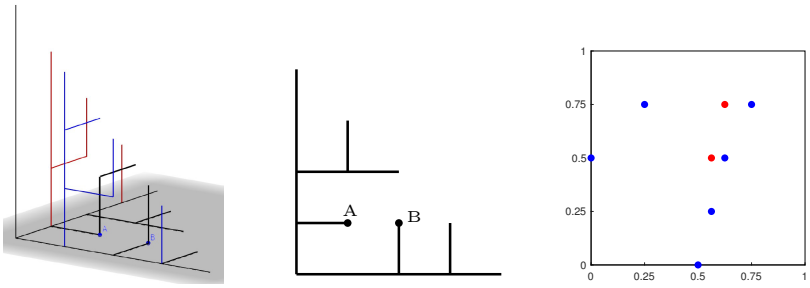

Figure 2 (left) A drawing of a CDR in $\mathcal{G}_N^+ \subset \mathbb{Z}^3$ for $N = 4$. Notice that the CDR is a tree whose leaves are at the plane $x + y + z = N$. (middle) A cross section on the xy-plane of the same CDR. Observe that vertices A and B do not extend within the xy-plane. Thus, the subspace is a weak CDR (rather than a proper CDR). (right) A map of the weak CDR into a two-colored pointset. Regions with many blue points and few red correspond to portions of the CDR with high error.

map this weak CDR into a set of points in the unit square and *then* use discrepancy theory to obtain a lower bound for the weak CDR and eventually to the high dimensional CDR. Overall, we show a very strong link between the three spaces (CDR in high dimensions, weak CDR in the x_1x_2-plane and set of points created by our mapping). Along the paper we will analyze properties of each of the spaces, and see what implications it has for the other two. Specifically, we show the following:

(i) Because we now need to account for more general constructions (weak CDRs instead of proper CDRs), the mapping needs to be changed. Instead of creating points in the $[0, 1)$ interval, in Section 2 we map into a two-colored pointset in $[0, 1) \times [0, 1)$.

(ii) Similar to the two dimensional case, we can tie the error of the weak CDR to the discrepancy of the mapped pointset. First, we extend the discrepancy results [12] to our exact setting. Let R and B be a set of red and blue points in the unit square, respectively. Let $m = |B| - |R|$ and assume $m > 0$. For any set P of points in the unit square and $x, y \in [0, 1]$ let $P[x, y]$ be the number of points in $P \cap [0, x] \times [0, y]$. For any two real numbers $0 \leq x, y \leq 1$ we define the discrepancy of R and B at (x, y) as $D_{R,B}(x, y) = mxy - (B[x, y] - R[x, y])$. The *discrepancy* of R and B is simply defined as $D^*_{R,B} = \max_{(x,y)\in[0,1]^2} |D_{R,B}(x, y)|$ (i.e., the highest discrepancy we can achieve among all possible rectangles). The discrepancy $D^*_{R,B}$ of a two-colored pointset is high if and only if there is an axis-aligned rectangle with the origin as corner in which the difference of the cardinalities is far from the expected difference.

▶ **Theorem 2** (Two colors discrepancy). *For any set R and B of points such that $|B| > |R|$ it holds that $D^*_{R,B} = \Omega\left(\frac{(|B|-|R|)\cdot\log(|B|+|R|)}{|B|+|R|}\right)$.*

The proof is given in Section 3.

(iii) With this new discrepancy result we obtain a trade-off between the error of any weak CDR and the number of inner leaves (i.e., vertices that do not satisfy (S4)). When the weak CDR has zero inner leaves (and thus is a proper CDR) our bound matches the lower bound of Håstad. As the number of inner leaves increases, the lower bound decreases. In Section 4 we prove the following relationship.

▶ **Theorem 3.** *For any $N \in \mathbb{N}$, any weak CDR defined on $\mathcal{G}_N^+ \subset \mathbb{Z}^2$ with κ_2 inner leaves between lines $x + y = \lceil N/2 \rceil$ and $x + y = N$ has $\Omega(\frac{N \log N}{N+\kappa_2})$ error.*

(iv) We then apply Theorem 3 to obtain a lower bound for CDRs in d dimensions: intuitively speaking, if the 2-D subspace has few inner leaves (say, $o(N \log N)$), then it will have $\omega(1)$ error. On the other hand, a weak CDR with many inner leaves in the 2-D

subspace will cause too many points to extend to one of the remaining dimensions, and create large error as well. This gives a lower bound of $\Omega(\log^{1/(d-1)} N)$ for any CDR construction in d dimensions (see Section 5):

▶ **Theorem 4.** *Any CDR in $\mathbb{Z}^d$ has $\Omega(\log^{1/(d-1)} N)$ error.*

Although we believe our analysis to be loose (especially in Theorem 4), we are not certain that the existing CDR constructions with $O(\log N)$ error are tight either. In the full version of the paper in [3], we explore the possibility of having a CDR in high dimensions with $o(\log N)$ error (rather than directly looking at CDRs in high dimensions, we see what properties it would imply in the other two subspaces). Although we cannot explicitly find a construction with $o(\log N)$ error, we provide interesting insight on how further research can solve this question. In particular, we give a weak CDR construction with 5/2 error and $\Theta(N^2)$ inner leaves. In order to further reduce the number of inner leaves in weak CDRs with constant error we instead look at how to create a two-colored pointset with constant discrepancy. We show that it is not possible to have $o(N^2)$ red points in some pattern of the pointset with constant discrepancy, which gives us a condition on any weak CDR with $o(N^2)$ inner leaves.

Further discussion on the implication of these results is given in Section 6.

2 Mapping a weak CDR into a pointset

We start by showing how to transform a weak CDR in two dimensions into a two-colored pointset in $[0,1)^2$. Given any weak CDR, its restriction to $\mathcal{G}_N^+$ forms a spanning tree T of $\mathcal{G}_N^+$ because of axioms (S1) and (S3). Although the tree is undirected, we see it as a directed graph (rooted tree) whose edges are oriented away from the origin (root). Then, (S5) implies that the parent of each vertex (x,y) (except the root) is either $(x-1,y)$ or $(x,y-1)$. For any edge $e=uv$ of T, where u is the parent of v, we define $T(e)$ as the subtree of T that is rooted at the child node v of e. We slightly abuse the notation and use $T(v)$ to denote the subtree that is emanating from v towards the leaves (that is, $T(v)=T(e)$).

For any $n \le N$ let L_n be the points of $\mathcal{G}_N^+$ whose sum of coordinates is n (i.e., $L_n = \{(x,y) \in \mathcal{G}_N^+ \colon x+y=n\}$). We follow the usual terminology that we call a vertex of degree one a *leaf*. We further consider two subcategories: we say that a leaf v of T is an *inner leaf* if it is not in L_N. All the vertices in L_N are called *boundary leaves*. Note that, by properties of CDR, all vertices of L_N are proper leaves (since any children should be in L_{N+1}, which is outside $\mathcal{G}_N^+$). Further note that in a proper CDR there will be no inner leaves. A vertex v of T is a *split vertex* if it has degree three or it is the origin. Let $\mathcal{S}$ be the set of split vertices and $\mathcal{D}$ the set of inner leaves.

2.1 Auxiliary function

Before giving the transformation from a tree to a point set we first define an auxiliary function $M : \mathcal{G}_N^+ \to [0,1]$. For any $p \in L_N$ we set $M(p) = \frac{p_x}{p_x+p_y}$. For any subtree $T'(v)$ of T we define two more functions inductively for $v \in L_n$ from $n=N$ to 0 as follows:

$$\max(T'(v)) = \max_{p \in T'(v) \cap (\mathcal{D} \cup L_N)} M(p) \quad \text{and} \quad \min(T'(v)) = \min_{p \in T'(v) \cap (\mathcal{D} \cup L_N)} M(p),$$

where $M(p)$ for $p \in \mathcal{D}$ is defined in the next paragraph.

For any inner leaf $\ell \in \mathcal{D}$, we know that the edges $e_1 = (\ell_x - 1, \ell_y + 1)(\ell_x, \ell_y + 1)$ and $e_2 = (\ell_x + 1, \ell_y - 1)(\ell_x + 1, \ell_y)$ must be present in T. Thus, we define $M(\ell)$ as $M(\ell) = \frac{\max(T(e_1)) + \min(T(e_2))}{2}$. Intuitively speaking, we look at the leaves above and to the right of ℓ, and assign a value that is in between the two of them (see Figure 3, left). The following statement shows that these values are sorted along L_n.

▶ **Lemma 5.** *Let $T(u), T(v) \subset T$ be two subtrees of T rooted at the vertices $u, v \in L_n$ (respectively) for some $n \leq N$ such that $u_x < v_x$. Then, it holds that* $\max(T(u)) < \min(T(v))$.

Proof. We prove this statement by induction on n from N to 1. If both $u, v \in L_N$ then both $T(u)$ and $T(v)$ consist of a single vertex and the proof trivially follows. Now, assume that the statement is true for any two vertices $u', v' \in L_i$ for $i > n$. We need to show that the statement holds for any two vertices $u, v \in L_n$ such that $u_x < v_x$.

First observe that if we have two descendants u' and v' from u and v respectively such that $u', v' \in L_{n'}$ for some $n' > n$, then it holds that $u'_x < v'_x$. Indeed, this follows from the fact that when we embed T in the natural way with edges drawn as straight segments, the result is a tree with no crossings. Thus, if $v'_x < u'_x$ happened for some descendants, then the two paths in T from u to u' and from v to v' would either cross or form a cycle. Any of those two situations would contradict with the fact that T is a weak CDR.

Back to our original proof, consider the case in which neither u nor v are inner leaves. By the above argument we have that the x-coordinate of any child $u' \in L_{n+1}$ of u must be smaller than any child $v' \in L_{n+1}$ of v. By induction, this implies that $\max(T(u')) < \min(T(v'))$ and thus $\max(T(u)) < \min(T(v))$.

The cases in which u or v are inner leaves are similar: if u is an inner leaf, we have $\max(T(u)) = M(u) = \frac{\max(T(u_1))+\min(T(u_2))}{2}$, where $u_1 = (u_x, u_y + 1) \in L_{n+1}$ and $u_2 = (u_x + 1, u_y) \in L_{n+1}$. By induction on u_1 and u_2 we have $\max(T(u_1)) < \min(T(u_2))$ and $\max(T(u)) < \min(T(u_2))$, thus we need to compare $\min(T(u_2))$ with any children of v. If v is also an inner leaf, we can do a similar argument and have that $\max(T(v_1)) < \min(T(v))$ where $v_1 = (v_x, v_y + 1)$.

In general, given u, let $u' \in L_{n+1}$ be the child of u with the largest x-coordinate (or $u' = u_2$ if u is an inner leaf). Similarly, we define v' as the child of v with the smallest x-coordinate (or $v' = v_1$ if v is an inner leaf). Again, by planarity of the natural embedding, we have that $u'_x \leq v'_x$ if at least one of u, v is an inner leaf. In either case, we can use induction and get that $\max(T(u')) \leq \min(T(v'))$ which implies $\max(T(u)) < \max(T(u')) \leq \min(T(v')) \leq \min(T(v))$ (if u is an inner leaf) or $\max(T(u)) \leq \max(T(u')) \leq \min(T(v')) < \min(T(v))$ (if v is an inner leaf) completing the proof. ◀

For any subtree T' of T, its *depth* is the longest possible length of a path from its root to any of its leaves. Any split vertex $s \in \mathcal{S}$ has two branching edges e_1 and e_2, each defining a subtree. The subtree of higher depth is the *preferred* subtree of s (in case of tie, we choose the tree emanating from $(s_x + 1, s_y)$). For any point $p \in \mathcal{G}_N^+$ we define a walk from p to some leaf of T. If $p \in L_n$ has degree two, we follow the single edge to L_{n+1}. If $p \in \mathcal{S}$, we follow the edge to the preferred subtree. This process is continued until we reach a leaf $\gamma(p)$.

With this virtual walk we can define the function M to all points $p \in \mathcal{G}_N^+$ (not only leaves) of the domain as follows. If p is neither a split nor a leaf, we define $M(p)$ as $M(p) = M(\gamma(p))$. For a split vertex s, let s' be the child of s that is not on the preferred subtree of s. Then, we define $M(s)$ as $M(s) = M(\gamma(s'))$.

Intuitively speaking, from any vertex we always follow its only edge away from the root (if it has degree 2) or the preferred edge (if it has degree 3) until we reach a leaf. The only exception is if we start on a split vertex, in which case we do not follow the preferred edge at the first step. This exception is needed to make sure that the end points of the walk starting from split vertices are distinct.

▶ **Lemma 6.** *For any split vertex $s \in \mathcal{S}$, there exists a unique leaf $\ell \in \mathcal{D} \cup L_N$ such that $M(s) = M(\ell)$. And for any leaf $\ell \in \mathcal{D} \cup L_N \setminus \{(N, 0)\}$, there exists a unique split vertex $s \in \mathcal{S}$ such that $M(s) = M(\ell)$.*

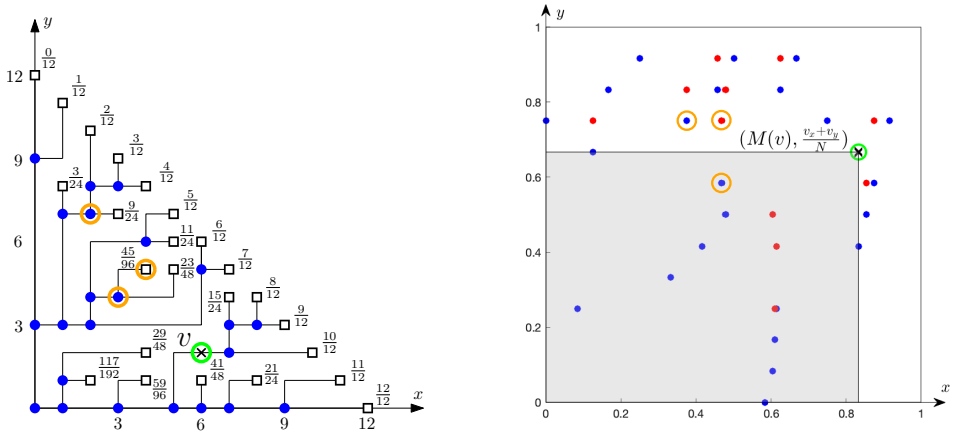

Figure 3 (left) A tree of a weak CDR and the value of the auxiliary function M applied to all leaves of the tree. (right) The tree transformed into blue and red point sets. Two vertices of the same layer are mapped to points with the same y-coordinate and an inner leaf and its corresponding split vertex are mapped to points with the same x-coordinate (see the highlighted orange circles). (For Theorem 8) The x-coordinate of $v = (6, 2)$ (green circle) can be bounded in terms of the difference between blue and red point in the axis-aligned rectangle with corners $(0, 0)$ and $\pi(v) = (M(v), \frac{v_x+v_y}{N}) = (\frac{10}{12}, \frac{8}{12})$. The rectangle contains 11 blue points and 3 red ones.

Proof. By definition of the auxiliary function, two leaves do not have the same mapping. Thus, it remains to show that the walk of two different split vertices cannot end at the same leaf. Imagine doing the walk backwards: start at any leaf, walk towards the origin and stop as soon as you reach a split vertex by traversing its non-preferred edge. Since each split vertex has exactly two children, it follows that exactly one leaf will stop at each split vertex. The exceptional case is the leaf $(N, 0)$, from which walking backwards to the origin is a horizontal path and the path does not contain any non-preferred edge. That is, in the inverse walk we follow preferred edges until we reach a non-preferred edge. This is equivalent to starting at a split vertex and follow the non-preferred edge once and continue with the preferred edges, which is the exact definition of our auxiliary function. ◀

2.2 Transforming the tree into a pointset

With the auxiliary function M we can define the mapping between a weak CDR into a bicolored pointset in the unit square. For any vertex $v = (v_x, v_y) \in \mathcal{G}_N^+$ we define its *transformation* as $\pi(v) = (M(v), \frac{v_x+v_y}{N})$. Given any weak CDR, we look at the tree T it defines in $\mathcal{G}_N^+$. Each vertex $v \in \mathcal{D}$ creates a red point $\pi(v)$ and each split vertex $w \in \mathcal{S}$ creates a blue point $\pi(w)$ (note that we do not transform the boundary leaves in L_N into points). We define the *mapping* of T as the union of the sets $R = \{\pi(v) \colon v \in \mathcal{D}\}$ and $B = \{\pi(v) \colon v \in \mathcal{S}\}$ (see Figure 3, right). Note that the two sets depend on the tree T (and thus $R = R(T)$ and $B = B(T)$). From now on we assume that T is fixed, and thus we simplify the notation for ease of reading. For any set P of points in the unit square and $x, y \in [0, 1]$ let $P[x, y]$ be the number of points in $P \cap [0, x] \times [0, y]$.

▶ **Lemma 7.** *For any weak CDR T in $\mathcal{G}_N^+ \subset \mathbb{Z}^2$ and $n < N$, the red and blue points on the horizontal line $y = n/N$ alternate in color starting and ending with a blue point. In particular, we have $B[1, n/N] - R[1, n/N] = n + 1$.*

Proof. For the first statement we observe that only points that lie in L_n will have y-coordinates equal to n/N. Moreover, since L_{n+1} has one more vertex than L_n, each diagonal must have exactly one more split vertex than inner leaves. Indeed, Chun et al. showed that in proper CDRs each diagonal has exactly one split vertex (and of course, zero inner leaves).

Now we need to show that split vertices and inner leaves appear alternatingly on the diagonal line. Consider two consecutive split vertices $u, v \in L_n$ such that $u_x < v_x$. By definition of split, the edges $e_u = (u_x, u_y)(u_x + 1, u_y)$ and $e_v = (v_x, v_y)(v_x, v_y + 1)$ are all in T. Observe that there are $v_x - u_x - 1$ vertices in L_n and $v_x - u_x - 2$ vertices in L_{n+1} between e_u and e_v. Since two different vertices of L_n cannot connect to the same vertex of L_{n+1}, one of them will not reach L_{n+1}. That vertex will be an inner leaf and will be between u and v as claimed.

That is, the blue pointset has one more point than the red pointset in each horizontal line $y = i/N$. Summing up the differences from $i = 0$ to n, we get that in total there are $n + 1$ additional blue points $p = (x, y)$ with $y \leq n/N$. ◀

With the above observations we can now state the main relationship between the weak CDR and its mapped pointset. For any vertex $v \in L_n$, its path to the origin splits the tree into two portions. Consider the portion of the tree up to L_n that is above the path from v to the origin. In L_0, the subtree contains a single vertex (the root) whereas at the diagonal L_n contains $v_x + 1$ vertices. Since the number of leaves grows with split vertices and shrinks with inner leaves, this means that in the portion of the tree that we are looking at, the difference between split vertices and inner leaves must be v_x, see Figure 3. Note that if the two children of a split vertex (e.g., $(5, 0)$ in Figure 3) are not in the same portion, the number of leaves does not grow with that split vertex. However, these split vertices may be still contained in the rectangle that we consider in the mapped pointset. This is the reason why we do not have an equality in Theorem 8.

▶ **Theorem 8.** *For any vertex $v \in \mathcal{G}_N^+$ it holds that $B[M(v), \frac{v_x+v_y}{N}] - R[M(v), \frac{v_x+v_y}{N}] - 2 \leq v_x \leq B[M(v), \frac{v_x+v_y}{N}] - R[M(v), \frac{v_x+v_y}{N}]$.*

Proof. We split the proof into two auxiliary lemmas.

▶ **Lemma 9.** *Let $v \in L_n$ be a split vertex such that $v_x < n$. If $M(v) < M(\gamma(v))$ the rectangle $[M(v), M(\gamma(v))] \times \left[0, \frac{n-1}{N}\right]$ contains exactly one point, which is blue and has $M(\gamma(v))$ as x-coordinate. If $M(\gamma(v)) < M(v)$ the rectangle $[M(\gamma(v)), M(v)] \times \left[0, \frac{n-1}{N}\right]$ contains exactly one point, which is blue and has $M(\gamma(v))$ as x-coordinate. When $v = (n, 0) \in L_n$ the rectangle $[M(v), M(\gamma(v))] \times \left[0, \frac{n-1}{N}\right]$ is empty.*

Proof. We first consider the case of $M(v) < M(\gamma(v))$. When we keep following from v to the preferred subtree, we end up in a leaf, called ℓ. By definition of M we have $M(\ell) = M(\gamma(v))$. Since $v_x < n$ we have $M(\gamma(v)) \neq 1$. By Lemma 6 there is a unique split vertex $s \in \mathcal{S}$ such that $M(s) = M(\ell)$. This split vertex is below layer L_n (indeed, we reach L_n from ℓ by following only preferred edges and the inverse walk has to stop when we traverse a non-preferred edge of s) and therefore s is transformed to a blue point in the rectangle. Now let s' be a split vertex which is mapped to a blue point in the rectangle. We will show that $s' = s$. Let ℓ' be the unique leaf such that $M(\ell') = M(s')$. Consider first the case in which ℓ' is below layer L_n (that is, $\ell'_x + \ell'_y < n$). Then let v' be the vertex on $dig(o, v)$ and $L_{\ell'_x+\ell'_y}$. If $\ell'_x < v'_x$ (resp. $v'_x < \ell'_x$) then Lemma 5 implies that $M(\ell') < min(T_{v'}) \leq M(v)$ (resp. $M(\gamma(v)) \leq max(T_{v'}) < M(\ell')$). This would be a contradiction to s' being mapped to a blue point in the rectangle.

It remains to consider the case in which ℓ' is above layer L_n. Define ℓ'' to be the vertex on $dig(o, \ell')$ and L_n. Lemma 5 implies that $\ell'' = v$ (otherwise we have either $M(\ell') < M(v)$ or $M(\gamma(v)) < M(\ell')$ which would again be a contradiction). Recall that there is only one split vertex whose walk to its corresponding leaf through preferred subtrees passes through v. Hence $s' = s$ and there is exactly one blue point in the rectangle.

We now show that there cannot be any red point either. Indeed, recall that for every red point there is a blue point with the same x-coordinate and smaller y-coordinate because for each inner leaf ℓ there is a unique split vertex s defined by the walk from s to ℓ such that $M(\ell) = M(s)$. From the previous argument, we know that s with $M(s) = M(\gamma(v))$ is mapped to the only one blue point in the rectangle and its corresponding leaf ℓ defined by the walk is above L_n. Hence, even if ℓ is an inner leaf, the mapped red point is not in the rectangle. Moreover, there cannot be any other red point in the rectangle (since it would imply that the corresponding blue point would also be in and we already ruled out this case).

In the same way we can also prove that if $M(\gamma(v)) < M(v)$ the rectangle $[M(\gamma(v)), M(v)] \times \left[0, \frac{n-1}{N}\right]$ contains exactly one point, which is blue and has $M(\gamma(v))$ as x-coordinate. If $v_x = n$ then ℓ as defined above is the leaf $(N, 0)$ and $M(\ell) = 1$. Lemma 6 implies that there is no split vertex s with $M(s) = 1$. ◀

▶ **Lemma 10.** *For any vertex $v \in \mathcal{G}_N^+$ it holds that*

$$v_x - B\left[M(v), \frac{v_x + v_y - 1}{N}\right] + R\left[M(v), \frac{v_x + v_y - 1}{N}\right] + 1 \in \{0, 1\}. \tag{1}$$

Proof. We first prove by induction over n that $\forall n \in \{0, 1, ..., N\}$ the following statement holds.

$$\begin{aligned} & \{M(\gamma(p)) | p \in L_n\} \\ = \; & \left\{x \in [0,1] : \left|B \cap \{x\} \times \left[0, \frac{n-1}{N}\right]\right| - \left|R \cap \{x\} \times \left[0, \frac{n-1}{N}\right]\right| = 1\right\} \cup \{1\}. \end{aligned} \tag{2}$$

The quantity $|B \cap \{x\} \times [0, \frac{n-1}{N}]| - |R \cap \{x\} \times [0, \frac{n-1}{N}]|$ counts the difference between the number of blue points and red points on the vertical segment with x-coordinate x and length $\frac{n-1}{N}$. Because of Lemma 6 we know that each split vertex shares the same value with a leaf in the auxiliary function M. If the leaf is an inner leaf, both blue (split) and red (inner) points lie on the same unit segment $\{x\} \times [0, 1]$. Otherwise, there is only one blue point on $\{x\} \times [0, 1]$ because $M(p)$ for $p \in L_N$ are all different. Hence the quantity $|B \cap \{x\} \times [0, \frac{n-1}{N}]| - |R \cap \{x\} \times [0, \frac{n-1}{N}]|$ can either be 0 or 1.

The base case $n = 0$ trivially holds. We have $\{M(\gamma(p)) | p \in L_0\} = \{1\}$ and

$$B \cap \{x\} \times \left[0, \frac{n-1}{N}\right] = R \cap \{x\} \times \left[0, \frac{n-1}{N}\right] = \emptyset$$

We assume that Section 2.2 holds for layer L_n and we prove that it also holds for L_{n+1}. We distinguish 3 cases for any vertex q in layer L_n.

- If q has degree 2 then q and its child $r \in L_{n+1}$ are mapped by $M \circ \gamma$ to the same value. Moreover q does not create any vertex in the set B nor R.
- If q is an inner leaf, then the value $M(\gamma(q))$ will not appear in $\{M(\gamma(p)) | p \in L_{n+1}\}$ any more. The value $M(\gamma(q))$ also disappears in

  $$\left\{x \in [0,1] : \left|B \cap \{x\} \times \left[0, \frac{n}{N}\right]\right| - \left|R \cap \{x\} \times \left[0, \frac{n}{N}\right]\right| = 1\right\} \cup \{1\}.$$

  because q created a red point in R with the coordinates $(M(\gamma(q)), \frac{n}{N}) = (M(q), \frac{n}{N})$.

- If q is a split vertex, then the value $M(\gamma(q))$ will stay in $\{M(\gamma(p))|p \in L_{n+1}\}$. Moreover $\{M(\gamma(p))|p \in L_{n+1}\}$ contains the additional value $M(q)$. The value $M(q)$ also appears in

$$\left\{x \in [0,1] : \left|B \cap \{x\} \times \left[0, \frac{n}{N}\right]\right| - \left|R \cap \{x\} \times \left[0, \frac{n}{N}\right]\right| = 1\right\} \cup \{1\}$$

because q creates a blue point in B with the coordinates $(M(q), \frac{n}{N})$.

Hence Section 2.2 holds.

Let v be a vertex in layer L_n, i.e. $n = v_x + v_y$. By Lemma 5 we know that a vertex $u \in L_n$ with $u_x < v_x$ satisfies $M(\gamma(u)) < M(\gamma(v))$. By Lemma 5 we also know that a vertex $w \in L_n$ with $v_x < w_x$ satisfies $M(\gamma(v)) < M(\gamma(w))$. Hence the number of vertices in layer L_n with smaller x-coordinate than that of v is exactly the number of vertices which are mapped by $M \circ \gamma$ to a smaller value than that of v. If $v_x < n$:

$$\begin{aligned} v_x &= |\{u \in L_n | u_x < v_x\}| \overset{\text{Lemma 5}}{=} |\{u \in L_n | M(\gamma(u)) < M(\gamma(v))\}| \\ &= |\{u \in L_n | M(\gamma(u)) \le M(\gamma(v))\}| - 1 \\ &\overset{(2)}{=} B\left[M(\gamma(v)), \frac{n-1}{N}\right] - R\left[M(\gamma(v)), \frac{n-1}{N}\right] - 1 \\ &\overset{\text{Lemma 9}}{=} \begin{cases} B[M(v), \frac{n-1}{N}] - R\left[M(v), \frac{n-1}{N}\right] - 1 & \text{if } M(\gamma(v)) \le M(v) \\ B[M(v), \frac{n-1}{N}] - R\left[M(v), \frac{n-1}{N}\right] & \text{if } M(v) < M(\gamma(v)) \end{cases} \end{aligned}$$

If $v_x = n$ then:

$$\begin{aligned} v_x &= |\{u \in L_n | M(\gamma(u)) \le M(\gamma(v))\}| - 1 \overset{(2)}{=} B\left[M(\gamma(v)), \frac{n-1}{N}\right] - R\left[M(\gamma(v)), \frac{n-1}{N}\right] \\ &\overset{\text{Lemma 9}}{=} B\left[M(v), \frac{n-1}{N}\right] - R\left[M(v), \frac{n-1}{N}\right] \end{aligned}$$

◀

By Lemma 7, the red and blue points on the line $y = v_x + v_y$ alternate in color starting and ending with a blue point. Hence, any interval $[0, x]$ on the line $y = v_x + v_y$ contains at most one more blue points. Therefore, $B[M(v), \frac{v_x+v_y}{N}] - R[M(v), \frac{v_x+v_y}{N}] - (B[M(v), \frac{v_x+v_y-1}{N}] - R[M(v), \frac{v_x+v_y-1}{N}])$ is at most one. Lemmas 10 and 7 directly imply Theorem 8. ◀

3 Bichromatic discrepancy

Let R and B be a set of red and blue points in the unit square, respectively. Let $r = |R|$ and $b = |B|$, and further assume that $b > r$. Let $m = b - r$ (which is positive since $b > r$). For any set P of points in the unit square and $x, y \in [0, 1]$ let $P[x, y]$ be the number of points in $P \cap [0, x] \times [0, y]$.

For any two sets R and B and real numbers $x, y \le 1$ we define the discrepancy of R and B at (x, y) as

$$D_{R,B}(x, y) = (b - r)xy - (B[x, y] - R[x, y]). \tag{3}$$

The *discrepancy* of R and B is simply defined as $D^*_{R,B} = \max_{(x,y)\in[0,1]^2} |D_{R,B}(x, y)|$ (i.e., the highest discrepancy we can achieve among all possible rectangles).

▶ **Theorem 2** (Two colors discrepancy). *For any set R and B of points such that $|B| > |R|$ it holds that $D^*_{R,B} = \Omega\left(\frac{(|B|-|R|)\cdot\log(|B|+|R|)}{|B|+|R|}\right)$.*

Note that if we set $R = \emptyset$ we get the classic two dimensional discrepancy result for which there are several proofs (see [12] for a detailed survey). In order to extend the bound for the case of $R \neq \emptyset$, we make minor changes to Schmidt's proof [13]. We start by using an auxiliary function G (defined below) and combining it with the trivial inequality

$$\int_{(x,y)\in[0,1]^2} D_{R,B}(x,y)G(x,y)dxdy \leq \max_{(x,y)\in[0,1]^2} |D_{R,B}(x,y)| \int_{(x,y)\in[0,1]^2} |G(x,y)|dxdy$$

to obtain $D^*_{R,B} = \max_{(x,y)\in[0,1]^2} |D_{R,B}(x,y)| \geq \frac{\int D_{R,B}G}{\int |G|}$.

Note that for simplicity in the notation we removed the integration limits. Our definition of G is identical to the one used by Schimdt: Let $m = \lceil \log_2(b+r) \rceil + 1$ and observe that, by definition of m we have $2(b+r) \leq 2^m \leq 4(b+r)$. For any $j \in \{0,\ldots,m\}$ we define function $f_j : [0,1]^2 \to \{-1,0,1\}$ as follows: subdivide the unit square with 2^j equally spaced vertical lines and 2^{m-j} horizontal lines.

For any value of j we subdivide the unit square into rectangles of area 2^{-m} (larger values of j will result in thinner but wider rectangles). Let A be a rectangle of subdivision associated to f_j. We define f_j within the rectangle to be 0 if A contains any point of $R \cup B$. If A does not have neither red nor blue points, we further subdivide it into four congruent quadrants. The function value of f_j is equal to 1 in the upper right and lower left quadrants, and -1 in upper left and lower right quadrants (see a visual representation of f_j in [12], page 173).

Then, we define G as $G = (1+cf_0)(1+cf_1)\ldots(1+cf_m) - 1$, where $c > 0$ is a small constant (whose value will be chosen afterwards). Note that G can also be expressed as $G = G_1 + \ldots G_m$, where $G_k = c^k \sum_{0\leq j_1 \leq \ldots \leq j_m \leq m} f_{j_1} f_{j_2} \cdots f_{j_k}$.

Schmidt showed that $\int |G| \leq 2$ (regardless of the value of m). Thus, we now focus in giving an upper bound for $\int D_{R,B}G$.

▶ **Lemma 11.** *There exists a constant c_1 such that $\int D_{R,B}G_1 \geq cc_1 \frac{b-r}{b+r} \log(b+r)$.*

Proof. By definition of G_1 we have $\int D_{R,B}G_1 = c\sum_{j=0}^{m} \int D_{R,B}f_j$. Thus, it suffices to show that for any value of j it holds that $\int D_{R,B}f_j \geq c' \frac{b-r}{b+r}$ (for some other constant $c' > 0$).

Recall that, when defining f_j, we subdivided the unit square into at least $2(b+r)$ rectangles. For the rectangles that contain at least one point of $R \cup B$, f_j is set to zero, and thus they do not contribute to the integral. Since we have $b+r$ many points, we know that there must exist at least $b+r$ rectangles that do not contain any point of R or B. Let A be any such rectangle, and let $A_{SW}, A_{NW}, A_{SE}, A_{NE}$ be the four subquadrants of A (where the subindex refers to the cardinal position of the quadrant). Recall that f_j is equal to 1 for any point of $A_{SW} \cup A_{NE}$ and -1 for points of $A_{SE} \cup A_{NW}$.

Let w and h be vectors defined by the horizontal and vertical sides of A_{SW}, respectively. Observe that their lengths are 2^{-j-1} and 2^{j-m-1}, respectively. Then, we have

$$\begin{aligned}
&\int_A f_j D_{R,B} \\
=\ &\int_{A_{SW}} D_{R,B} - \int_{A_{NW}} D_{R,B} + \int_{A_{NE}} D_{R,B} - \int_{A_{SE}} D_{R,B} \\
=\ &\int_{A_{SW}} [D_{R,B}(x,y) + D_{R,B}(x+\mathsf{w}, y+\mathsf{h}) - D_{R,B}(x, y+\mathsf{h}) - D_{R,B}(x+\mathsf{w}, y)]dxdy.
\end{aligned}$$

If we apply the definition of $D_{R,B}$ (Eq. (3)) to the four terms inside the integral we get

$$\begin{aligned}\int_A f_j D_{R,B} &= \int_{A_{SW}} ((b-r)[xy+(x+\mathsf{w})(y+\mathsf{h})-x(y+\mathsf{h})-(x+\mathsf{w})y])dxdy \\ &- \int_{A_{SW}} (B[x,y]+B[x+\mathsf{w},y+\mathsf{h}]-B[x,y+\mathsf{h}]-B[x+\mathsf{w},y])dxdy \\ &+ \int_{A_{SW}} (R[x,y]+R[x+\mathsf{w},y+\mathsf{h}]-R[x,y+\mathsf{h}]-R[x+\mathsf{w},y])dxdy.\end{aligned}$$

Observe that we are integrating twice positively and twice negatively over almost identical functions. In fact, the terms of the first integral all cancel out except along the rectangle $[x,x+\mathsf{w})\times[y,y+\mathsf{h})$. Similarly, when we look at the second and third terms, the contribution of any point in $R\cup B$ is cancelled out unless it is in the rectangle $[x,x+\mathsf{w})\times[y,y+\mathsf{h})$. However, by definition of A there are no such points. Thus, we obtain

$$\int_A f_j D_{R,B} = \int_{A_{SW}} (b-r)\mathsf{w}\cdot\mathsf{h}\,dxdy = \int_{A_{SW}} (b-r)2^{-m-2}dxdy = (b-r)2^{-2m-4}$$

That is, when we integrate $f_j D_{R,B}$ over a rectangle A containing no point of $R\cup B$, the result is $(b-r)2^{-2m-4}$. We know that there are at least $b+r$ rectangles not containing points of $R\cup B$, thus their contribution is at least $\frac{(b+r)(b-r)}{2^{2m+4}} = \frac{(b+r)}{2^m}\frac{(b-r)}{16\cdot 2^m} \geq \frac{1}{4}\frac{(b-r)}{16\cdot 4(b+r)} = \Omega(\frac{b-r}{b+r})$. ◀

▶ **Lemma 12.** *There exists a constant c_2 such that $\sum_{k=2}^{m}\int D_{R,B}G_k \leq c^2 c_2 \frac{b-r}{b+r}\log(b+r)$.*

Proof. Recall that $G_k = c^k \sum_{0\leq j_1<j_2<\ldots<j_k\leq m} f_{j_1}\ldots f_{j_k}$. Fix any valid set of indices and consider the value of $\int f_{j_1}\ldots f_{j_k}D_{R,B}$.

As shown in [12], function $f_{j_1}\ldots f_{j_k}$ is largely defined by f_{j_1} and f_{j_k}. Indeed, if we overlay the rectangular partition defined by functions $f_{j_1},\ldots,f_{j_k}$ we obtain a grid of rectangles whose width is 2^{-j_k} and height $2^{-(m-j_1)}$. In each of these rectangles, the function is zero (if any of the rectangles associated to the f_{j_i} functions contains a point of $R\cup B$), or is further subdivided into four equal sized quadrants and in each one it is $+1$ or -1 alternatively.

Let A be one of the rectangles of the refined grid. As shown in Lemma 11, we have that

$$\int_A f_{j_1}\ldots f_{j_k}D_{R,B} = \tau(b-r)2^{-2(m+j_k-j_1)-4},$$

where $\tau\in\{-1,1\}$. This extra term appears because the product of the different functions involved can change the sign of each of the four quadrants. In any case, we have $\int_A f_{j_1}\ldots f_{j_k}D_{R,B} \leq (b-r)2^{-2(m+g)-4}$ where $g=j_k-j_1$.

By the way the grid is constructed, there are $2^{m-j_1}\times 2^{j_k} = 2^{m+g}$ many rectangles, and thus we conclude that $\int f_{j_1}\ldots f_{j_k}D_{R,B} \leq (b-r)2^{-m-g-4}$. In order to obtain a bound $\int D_{R,B}G_k$ we sum over all possible indices.

$$\int D_{R,B}G_k = c^k \sum_{0\leq j_1<\ldots<j_k\leq m}\int f_{j_1}\ldots f_{j_k}D_{R,B} \leq \frac{c^k(b-r)}{2^{m+4}}\sum_{0\leq j_1<\ldots<j_k\leq m} 2^{-(j_k-j_1)}.$$

Note that in the sum, the indices $j_2,\ldots j_{k-1}$ do not matter. Thus, we group the terms by the gap between the indices j_1 and j_k (say, if $j_1=3$ and $j_k=7$ the gap is 4). Note that the minimum gap is at least $k-1$ (since otherwise we do not have enough space to choose the $k-2$ indices in between) and at most m. Once we have a gap of g there are $m-g$ options for index j_1.

$$\begin{aligned}\int D_{R,B}G_k &\leq \frac{c^k(b-r)}{2^{m+4}} \sum_{g=k-1}^{m} \sum_{j_1=0}^{m-g} \sum_{j_1<j_2<\ldots<j_{k-1}<j_1+g} 2^{-g} \\ &= \frac{c^k(b-r)}{2^{m+4}} \sum_{g=k-1}^{m} \sum_{j_1=0}^{m-g} \binom{g-1}{k-2} 2^{-g} \leq \frac{c^k(b-r)m}{2^{m+4}} \sum_{g=k-1}^{m} \binom{g-1}{k-2} 2^{-g}.\end{aligned}$$

In order to upper bound the sum over all G_k, we first reorder the summation order.

$$\begin{aligned}\sum_{k=2}^{m} \int D_{R,B}G_k &\leq \sum_{k=2}^{m} \frac{c^k(b-r)m}{2^{m+4}} \sum_{g=k-1}^{m} \binom{g-1}{k-2} 2^{-g} \\ &= \frac{(b-r)m}{2^{m+4}} \sum_{g=1}^{m} 2^{-g} c^2 \sum_{k=2}^{g+1} \binom{g-1}{k-2} c^{k-2} \\ &= \frac{(b-r)m}{2^{m+4}} \sum_{g=1}^{m} 2^{-g} c^2 (1+c)^{g-1} \\ &= \frac{(b-r)mc^2}{2^{m+5}} \sum_{g=1}^{m} \left(\frac{1+c}{2}\right)^{g-1}.\end{aligned}$$

The sum contains the first terms of the geometric sum $\sum_{g=1}^{\infty} \left(\frac{1+c}{2}\right)^{g-1} \leq \frac{2}{1-c}$ (for any $c < 1$). In particular, if we set $c \leq 1/2$ we can upper bound the partial sum by 4. Recall that $m = \Theta(\log(b+r))$ and $2^m = \Theta(b+r)$. Thus, the lemma is proven. ◀

▶ **Corollary 13.** *There exists a constant $\kappa > 0$ such that $\int D_{R,B}G \geq \kappa \left(\frac{(b-r)\cdot\log(b+r)}{b+r}\right)$.*

Proof. Apply the inequality $\int(A+B) \geq \int A - \int |B|$ and Lemmas 11 and 12 to obtain:

$$\int D_{R,B}G = \int D_{R,B}G_1 + \sum_{k=2}^{m} \int D_{R,B}G_k \geq c(c_1 - cc_2) \left(\frac{(b-r)\cdot\log(b+r)}{b+r}\right)$$

Note that Lemmas 11 and 12 holds for any value of c such that $c \in (0, 1/2]$. By choosing a sufficiently small value of c (say, $c = \min\{\frac{1}{2}, \frac{c_1}{2c_2}\}$) we obtain $\int D_{R,B}G \geq \frac{cc_1}{2} \left(\frac{(b-r)\cdot\log(b+r)}{b+r}\right)$. ◀

This completes the proof of Theorem 2.

When $R = \emptyset$, it would be expected that we need to distribute the blue points uniformly in the unit square to have a low discrepancy. Indeed, it is also held for the red points. The following theorem implies that even if there are many red points, but the red points are concentrated in the lower half of the unit square, the discrepancy cannot be reduced. For simplicity, we only show a special case of how the discrepancy is depended on the points in $[0,1] \times [1/2,1]$, which is good enough for our purpose in Section 5. Notice that the same argument can be applied in a more general case.

▶ **Theorem 14.** *For any set R and B of points in the unit square such that $|R| = r$, $|B| = b$ and $b > r$. Let r_2 and b_2 be the number of red and blue points in $[0,1] \times [1/2,1]$ respectively. It holds that*

$$D^*_{R,B} = \Omega\left(\frac{(b_2 - r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right).$$

Proof. Let R_2 and B_2 be the set of red and blue points in $[0,1] \times [1/2,1]$ respectively. Consider the upper half of the unit square $[0,1] \times [1/2,1]$ and rescale the vertical length to be 1. By Theorem 2, there exists a point $(x,2y)$ such that $|D_{R_2,B_2}(x,2y)| = |2xy(b_2 - r_2) - (B_2[x,2y] - R_2[x,2y])| \geq 2c\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$ for some constant c.

Then, we map the point $(x,2y)$ back to a point $(x,1/2+y)$ in the original unit square. We will show that either $D_{R,B}(x,1/2+y)$ or $D_{R,B}(x,1/2-\epsilon)$ would give us the desired lower bound, where ϵ is an arbitrarily small constant such that rectangle $[0,1] \times [0,1/2-\epsilon]$ only contains $B \setminus B_2$ and $R \setminus R_2$.

If $|D_{R,B}(x,1/2+y)| \geq c\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$, we are done.

If $|(b-r)/2 - (b_2-r_2)| \geq c/4\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$, the proof is also done. Because

$$\begin{aligned}
& |D_{R,B}(1,1/2-\epsilon)| \\
\overset{(3)}{=} \; & |(b-r)(1/2-\epsilon) - (B[1,1/2-\epsilon] - R[1,1/2-\epsilon])| \\
= \; & |(b-r)(1/2-\epsilon) - (b-r-(b_2-r_2))| \\
= \; & |(b-r)/2 - (b_2-r_2) - (b-r)\epsilon| \\
> \; & c/8\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right).
\end{aligned}$$

Suppose that the two cases do not hold, we have $|D_{R,B}(x,1/2+y)| < c\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$ and $|(b-r)/2 - (b_2-r_2)| < c/4\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$. Let $R_1 = R \setminus R_2$ and $B_1 = B \setminus B_2$, which are inside the rectangle $[0,1] \times [0,1/2-\epsilon]$. Consider

$$\begin{aligned}
& D_{R,B}(x,1/2+y) \\
= \; & (b-r)x(1/2+y) - (B[x,1/2+y] - R[x,1/2+y]) \\
= \; & (b-r)x(1/2+y) - (B_2[x,1/2+y] - R_2[x,1/2+y] + B_1[x,1/2-\epsilon] - R_1[x,1/2-\epsilon]) \\
= \; & (b-r)x(1/2-\epsilon) - (B_1[x,1/2-\epsilon] - R_1[x,1/2-\epsilon]) + (b-r)x\epsilon \\
& +(b-r)xy - (B_2[x,1/2+y] - R_2[x,1/2+y]) \\
= \; & D_{R,B}(x,1/2-\epsilon) + (b-r)xy - (B_2[x,1/2+y] - R_2[x,1/2+y]) + (b-r)x\epsilon \\
> \; & D_{R,B}(x,1/2-\epsilon) + 2(b_2-r_2)xy - (B_2[x,1/2+y] - R_2[x,1/2+y]) \\
& -c/2\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right) + (b-r)x\epsilon \\
= \; & D_{R,B}(x,1/2-\epsilon) + D_{R_2,B_2}(x,2y) - c/2\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right) + (b-r)x\epsilon
\end{aligned}$$

The first inequality is given by $b-r > 2(b_2-r_2) - c/2\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$. Since $|D_{R,B}(x,1/2+y)| < c\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$ and $|D_{R_2,B_2}(x,2y)| \geq 2c\left(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2}\right)$, we can conclude that $|D_{R,B}(x,1/2-\epsilon)| = \Omega(\frac{(b_2-r_2)\cdot\log(b_2+r_2)}{b_2+r_2})$. ◀

4 Lower bound for two dimensional weak CDRs

Before giving the proof of Theorem 3, we recall that a proof for a proper CDR (i.e., one without inner leaves) was given in [8]. Our proof follows the same spirit, so we first give an overview of their proof and describe what changes when we introduce inner leaves.

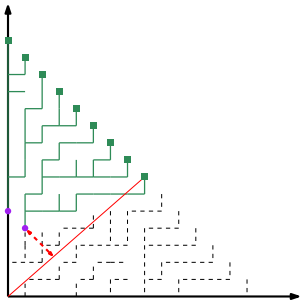

Figure 4 Illustration of why the two sets I (purple disks) and $\mathcal{L}(I)$ (green squares) should have proportional sizes. If the size of $\mathcal{L}(I)$ grows drastically (as shown in the figure), the point of the highest x-coordinate in $\mathcal{L}(I)$ must make a significant detour to pass through I, causing a large error. A similar effect happens if the size of $\mathcal{L}(I)$ is comparatively small.

▶ **Lemma 15.** *Given a CDR, a point $p = (x, y) \in L_N$, and an integer $n < N$, let $p' = (x', y') \in L_n$ be the unique point of L_n that is in $dig(o, p)$. The Hausdorff error of the CDR is at least $|x' - x \cdot \frac{n}{N}|$.*

Proof. This result was shown by Chun et al. [8] (Lemma 3.5, in Cases 1 and 2). We give the proof for completeness. Consider the L-infinity ball of radius $|x' - x \cdot \frac{n}{N}|$ centered at $p \cdot \frac{n}{N}$. By construction, this ball contains p' in its boundary. Because of the monotonicity axiom, no vertex of $dig(o, p)$ can be in the interior of the ball. In particular, when measuring the Hausdorff distance of point $p \cdot \frac{n}{N} \in \overline{op}$ we get an error of at least $|x' - x \cdot \frac{n}{N}|$. ◀

Consider any point $p \in L_N$ and virtually sweep a line of slope -1 from the origin all the way to L_N. During the sweep, the intersection between the diagonal line and either the Euclidean segment $\overline{op}$ or the digital one $dig(o, p)$ will be a point. Lemma 15 says that if we can find an instant of time for which two intersection points are at distance ∂ from each other, then the Hausdorff error of the whole CDR must be $\Omega(\partial)$ (see Figure 4).

In order to find this instant of time we see how much the subtrees grow. Consider a consecutive set of I vertices in some intermediate layer L_n. Let $\mathcal{L}(I)$ be the vertices of L_N whose digital path to the origin passes through some vertex of I. If the CDR has small error, we need $\mathcal{L}(I)$ to have roughly $\frac{N}{n}|I|$ many points. The difference between the expected number of vertices and $|\mathcal{L}(I)|$ combined with Lemma 15 will give a lower bound on the Hausdorff error.

Our proof follows the same spirit (transform the tree into a pointset, use discrepancy to find a subset with too many/too few children and use Lemma 15 to find a large error). Although all three steps follow the same spirit, they need major changes to account for the possibility of inner leaves.

The biggest change is how we map the tree. In proper CDRs each line has a unique split vertex and always extends to L_N. Thus, a region with a large number of split vertices directly implies a large error. In our setting, we could potentially have a region with many split vertices followed by a large number of inner leaves to cancel out the growth. This is why we need two major changes: first we now color the points red and blue depending on whether they are split vertices or inner leaves. We also introduce a second dimension to track when the children of a split vertex stop extending. Intuitively speaking, the x-coordinate of our mapping will be similar to the mapping done by Chun et al. [8] whereas the y-coordinate represents time. Thus, the difference in y-coordinates between red and blue points can be used to determine for how long are the two children of a split vertex alive (the longer the difference in y-coordinates, the further away that the two children extend).

We now use the mapping of Section 2 together with the two colors discrepancy (Theorems 2 and 14) to show a lower bound on the error of weak CDRs. The discrepancy result in Theorem 2 considers the points in the whole unit square. Due to some technical reasons, in Section 5 we will need a discrepancy result for the points in the *upper half* of the unit square instead (Theorem 14). The difference between the two theorems is just a constant factor and thus would have little implication. Here we use Theorem 14 and prove the result in terms of the number of inner leaves in the upper half. Specifically, we show the following result.

▶ **Theorem 3.** *For any $N \in \mathbb{N}$, any weak CDR defined on $\mathcal{G}_N^+ \subset \mathbb{Z}^2$ with κ_2 inner leaves between lines $x+y=\lceil N/2 \rceil$ and $x+y=N$ has $\Omega(\frac{N \log N}{N+\kappa_2})$ error.*

Proof. Given a weak CDR and its associated tree T, consider its transformation into the sets R and B of red and blue points defined by π. Let b_2 and r_2 be the numbers of blue and red points in the rectangle $[0,1] \times [1/2,1]$ respectively. By Lemma 7, we have $b_2 - r_2 = \lfloor N/2 \rfloor$. We apply the discrepancy result (Theorem 14) with $b_2 - r_2 = \lfloor N/2 \rfloor$ and $r_2 = \kappa_2$, and obtain that there exists $\alpha, \beta \in [0,1]$ such that $|B[\alpha,\beta] - R[\alpha,\beta] - N \cdot \alpha \cdot \beta| > c' \cdot \frac{N \cdot \log N}{N+\kappa_2}$.

We want to use Theorem 8 on the vertex of T whose image is (α, β). Naturally, such a vertex need not exist, but we will find one nearby whose associated discrepancy is also high. Let $n = \lfloor N \cdot \beta \rfloor$ and observe that $B[\alpha,\beta] = B[\alpha, \frac{n}{N}]$; indeed, by the way we transform points, their y-coordinates are of the form i/N. However, by definition of n we know that β is between n/N and $(n+1)/N$ and thus no point can lie in the horizontal strip $y \in (n/N, \beta]$ (by the same argument we also have $R[\alpha,\beta] = R[\alpha, \frac{n}{N}]$).

If we substitute β in the previous equation we get

$$\left| B\left[\alpha, \frac{n}{N}\right] - R\left[\alpha, \frac{n}{N}\right] - \alpha n \right| > c' \cdot \frac{N \log N}{N+\kappa_2} - 1 \geq c'' \cdot \frac{N \cdot \log N}{N+\kappa_2}$$

for a large enough N, $\kappa_2 \in O(N \log N)$ and for some $c'' > 0$. We get the additional 1 term because of the rounding in the definition of n.

Now we need to do a similar operation for α. Let $q_i = (i, n-i)$ be a vertex of L_n. By Lemma 5 the image of the auxiliary function $M(q_i)$ monotonically increases as i grows. Let $Q = \{q_i \colon M(q_i) \leq \alpha\}$ and $\alpha' = max_{q_i \in Q} M(q_i)$. Note that, by definition of the set Q, it trivially holds that $\alpha' \leq \alpha$.

▶ **Lemma 16.** $B[\alpha, \frac{n}{N}] - R[\alpha, \frac{n}{N}] = B[\alpha', \frac{n}{N}] - R[\alpha', \frac{n}{N}]$

Proof. The difference between the two rectangles is the rectangle Δ whose opposite corners are $(\alpha', 0)$ and $(\alpha, n/N)$, and one of the boundary $\overline{(\alpha',0)(\alpha', \frac{n}{N})}$ is open. We claim that red and blue points are paired (sharing the same x-coordinate) in Δ (and thus, for each red point that we remove we are also removing a blue one). By Lemma 6, we know that all the blue points have different x-coordinates, so do red points. Hence, if there are red and blue points on the same vertical line, they must be the only pair in that vertical line. First notice that if there is a red point in Δ, there also exists a blue point in Δ with the same x-coordinate and below the red point. By the virtual walk that we define the auxiliary function, every split vertex is closer to the origin than the corresponding leaf. Hence, after the transformation π, if there is a red point, then there must exist a blue point with the same x-coordinate (by Lemma 6) and smaller y-coordinate. Then, we will show that if there is a blue point in Δ, there also exists a red point in Δ with the same x-coordinate.

Assume, for the sake of contradiction that there exists a blue point p in Δ such that there does not exist a red point q with the same x-coordinate as p in Δ. Let s be the split vertex whose image is p. By definition of the transformation π, the x-coordinate of p is $M(s)$, which

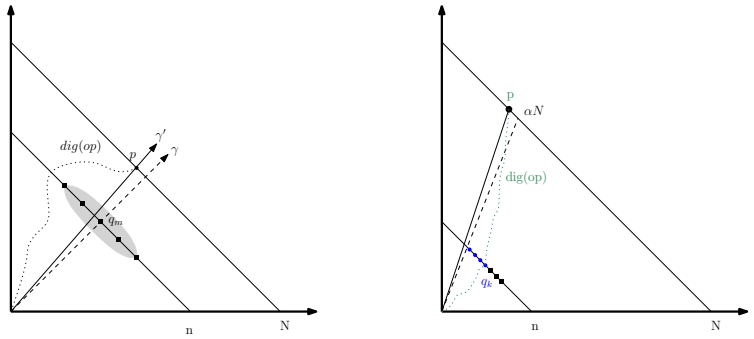

Figure 5 (left) When k is small we have $\Omega(\frac{N \log N}{N+\kappa_2})$ consecutive vertices in L_n that are not productive (shown as squares). In particular, the ray γ through the middle point must make a large detour. (right) When k is large, there is a digital path through q_k with a big detour.

is between α' and α. We apply Lemma 6 to find the unique leaf ℓ such that $M(s) = M(\ell)$. Since $\pi(\ell) \notin \Delta$, we have that $\ell_x + \ell_y > n$. Let m be the unique vertex of L_n that is in the path from s to ℓ. It follows that $\pi(m) = (M(\ell), \frac{n}{N}) \in \Delta$. This gives a contradiction with the definition of α', and thus implies that if there exists a blue point in Δ, then there also exists a red point in Δ with the same x-coordinate. ◀

Thus, given a pair (α, β) whose associated rectangle has high discrepancy, we have *snapped* it to the pair $(\alpha', \frac{n}{N})$ that defines another rectangle with high discrepancy. More importantly, by definition of Q, we know that $\pi(q_{|Q|-1}) = (\alpha', \frac{n}{N})$. Note that $q_{|Q|-1}$ need not be a split vertex or an inner leaf (and thus, $(\alpha', \frac{n}{N})$ may not be a point of $R \cup B$).

Let $b' = B[\alpha', \frac{n}{N}]$ and $r' = R[\alpha', \frac{n}{N}]$. If we apply Theorem 8 to point $q_{|Q|-1}$ we get that $b' - r' - 2 \leq |Q| - 1 \leq b' - r'$. This set Q is the one that makes the role of I in the proof overview: we know that vertices of Q are the ones that extend to cover all the vertices of L_N whose image is α' or less. As such, we would expect $|Q|$ to contain roughly $n\alpha'$ elements. However, the discrepancy result tells us that the size of Q is $c'' \frac{N \log N}{N+\kappa_2}$ units away from that value. We say that p is *productive* if some point of $T(p)$ is in L_N (this is equivalent to the fact that p can be extended to reach the boundary). Let $k \leq b' - r' - 2$ be the biggest integer such that q_k is productive. Note that k is well defined because q_0 is always productive ($(0, n)$ always extends to $(0, N)$). The proof now considers a few cases depending on whether k is small or large (specifically, we say that k is *small* if $|Q| - 1 - k \geq (b' - r' - 2) - k > \frac{c''}{2} \cdot \frac{N \log N}{N+\kappa_2}$, *large* otherwise) and if Q contains too few or too many points.

k is small. Recall that we looked for the largest possible k (such that q_k is productive). Thus, if k is small, we have many points in layer L_n that are consecutive and not productive. In particular, none of the vertices in $q_{b'-r'-\lfloor \frac{c''}{2} \cdot \frac{N \log N}{N+\kappa_2} \rfloor}, \ldots, q_{b'-r'-2}$ are productive. Let $q_m = q_{b'-r'-\lfloor \frac{c''}{4} \cdot \frac{N \log N}{N+\kappa_2} \rfloor}$ (note that this point is surrounded by non-productive points in both sides along L_n).

Shoot a ray γ from o towards q_m. Let p be the vertex on L_N that is closest to γ. Observe that the $||\cdot||_\infty$ distance between γ and p is at most $1/2$. Let γ' be the ray shooting from o towards p. Similarly, the $||\cdot||_\infty$ distance between γ' and q_m is at most $1/2$ (see Figure 5, left).

We now apply Lemma 15 to $dig(o, p)$. We know that the Euclidean segment $\overline{op}$ is close to q_m. The digital segment must cross L_n and is far from q_m (the closest it can pass is either $q_{b'-r'-\lfloor \frac{c''}{2} \cdot \frac{N \log N}{N+\kappa_2} \rfloor - 1}$ or $q_{b'-r'-1}$). That is, we know that the intersection of $\overline{op}$

with the line $x + y = n$ is at most half a unit away from q_m. Similarly, the intersection with $dig(o, p)$ is at least $\lfloor \frac{c''}{4} \cdot \frac{N \log N}{N+\kappa_2} \rfloor$ from q_m. Thus, by triangle inequality the $||\cdot||_\infty$ distance between $dig(o, p)$ and $\overline{op}$ is at least $\lfloor \frac{c''}{4} \cdot \frac{N \log N}{N+\kappa_2} \rfloor - 3/2 \in \Omega(\frac{N \log N}{N+\kappa_2})$.

k is large and $b' - r' \geq n\alpha + c'' \cdot \frac{N \log N}{N+\kappa_2}$. Look at the x-coordinate of q_k. We know that Q has at least $b' - r' - 1 \geq n\alpha + c'' \cdot \frac{N \log N}{N+\kappa_2} - 1$ many elements, and k is among the productive vertices with the largest x-coordinate. In particular, the x-coordinate of q_k is at least $b' - r' - 2 \geq n\alpha + \frac{c''}{2} \cdot \frac{N \log N}{N+\kappa_2} - 2$.

Let p be the unique leaf of L_N such that $M(p) = M(q_k)$. We now apply Lemma 15 to $dig(o, p)$ at the line $x + y = n$. By definition of p, we have that $dig(o, p)$ passes through q_k. Now, by definition of Q, we know that $M(q_k) \leq \alpha$ and in particular the x-coordinate of p is at most αN (see Figure 5, right). Thus, the Euclidean segment $\overline{op}$ must intersect at a point whose x-coordinate is at most αn.

That is, when we look at the Euclidean and the digital segments along line $x + y = n$, the Euclidean crossing happens at x-coordinate at most αn. However, the x-coordinate of the digital crossing is at least $\alpha n + \frac{c''}{2} \cdot \frac{N \log N}{N+\kappa_2} - 1$. By Lemma 15 we conclude that the error must be $\Omega(\frac{N \log N}{N+\kappa_2})$ as claimed.

$b' - r' < n\alpha - c'' \cdot \frac{N \log N}{N+\kappa_2}$. This proof is very similar to the previous case. Consider the vertex $p = (\lfloor \alpha N \rfloor, N - \lfloor \alpha N \rfloor) \in L_N$ and apply Lemma 15 to $dig(o, p)$ and $\overline{op}$.

At line $x + y = n$ the Euclidean segment $\overline{op}$ passes through a point whose x-coordinate is $\lfloor \alpha N \rfloor \cdot \frac{n}{N} \geq \lfloor \alpha n \rfloor - 1$. By definition, $M(p) \leq \alpha$ and thus $dig(o, p)$ must pass through some vertex q of Q. In particular, the x-coordinate of q is at most $b' - r' < n\alpha - c'' \cdot \frac{N \log N}{N+\kappa_2}$, giving the $\Omega(\frac{N \log N}{N+\kappa_2})$ error and completing the proof of Theorem 3. ◀

Note that if we use Theorem 2 instead, the same argument follows and we would get the following result.

▶ **Theorem 17.** *For any $N \in \mathbb{N}$, any weak CDR defined on $\mathcal{G}_N^+ \subset \mathbb{Z}^2$ with κ_1 inner leaves has $\Omega(\frac{N \log N}{N+\kappa_1})$ error.*

5 Lower bound for CDRs in high dimensions

We now use the lower bound of weak CDRs to obtain a lower bound for CDRs in three or higher dimensions. Consider the restriction of any d-dimensional CDR T to the x_1x_2-plane (we call this restriction the *x_1x_2-restriction of T* and denote it by $T_{x_1x_2}$). Recall that the key observation is that $T_{x_1x_2}$ is a (possibly weak) CDR and that any inner leaf in $T_{x_1x_2}$ must extend in some x_i-direction in T for some $i \in [3..d]$. We have seen that $T_{x_1x_2}$ needs to have a large number of inner leaves to have $o(\log N)$ error. In the following, we will show that a large number of inner leaves will cause constraints for $\mathbb{Z}^d$ and have an impact in the overall error of T.

We do a slight abuse of notation and use the same terms as in two dimensions. For simplicity of the notation, we assume that N is a positive even number. For any $n \leq N$, let $L_n = \{(x_1, x_2, \ldots, x_d) \in \mathcal{G}_N^+ \colon \sum_{i=1}^d x_i = n\}$. Given any CDR in $\mathcal{G}_N^+$, we consider the CDR as a tree rooted at the origin. Let $T(v)$ be the subtree rooted at v.

From Theorem 3, we already know that in order for $T_{x_1x_2}$ to have sublogarithmic error we must have $\kappa_2 \in \omega(N)$ inner leaves. However, each inner leaf ties to a boundary leaf in L_N in d dimensions. In other words, the subtrees rooted at the vertices in $L_{N/2-1} \cap T_{x_1x_2}$ must cover all these boundary vertices. We now observe that a weak CDR with inner leaves in the x_1x_2-plane induces subtrees which are too big for the high dimensional proper CDR (See Figure 6).

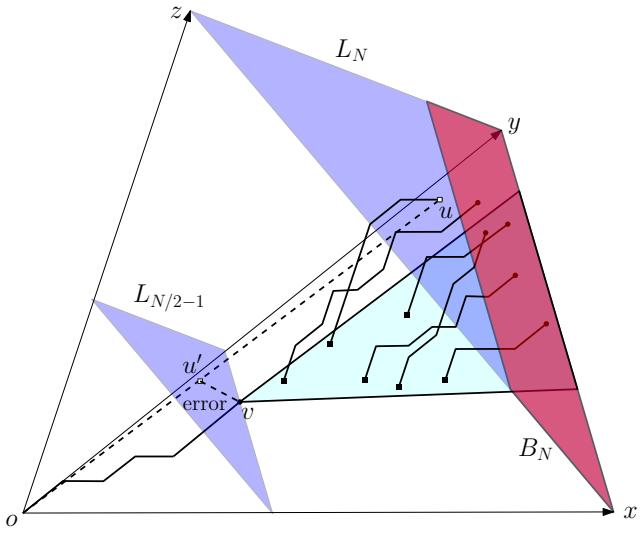

Figure 6 Illustration of Lemmas 18 and 19: the red region represents the region of B_N. If we have lots of inner leaves in T_{xy}, it will have many descendants in the three dimensional CDR at layer L_N so that the height of the red region attempting to contain them is large. In particular, we can find a vertex v on the xy-plane such that v is on the $dig(o, u)$ and u is far away from the xy-plane. For simplicity, we show the Euclidean error between v and u', but we note that the proof argues under the $||\cdot||_\infty$ metric.

▶ **Lemma 18.** *Given any CDR in $\mathcal{G}_N^+$, let κ_2 be the number of inner leaves in $T_{x_1x_2}$ between $L_{N/2}$ and L_N. There exists a vertex $v \in L_{N/2-1}$ such that $v_i = 0$ for $i = 3, \ldots, d$ and some boundary leaf $u \in T(v) \cap L_N$ has $u_j \geq (\kappa_2/N)^{\frac{1}{d-2}} - 1$ for some $j \in [3..d]$.*

Proof. The proof follows from a packing argument. Consider the set $V = \{(0, N/2 - 1, 0, \ldots, 0), (1, N/2 - 2, 0, \ldots, 0), \ldots, (N/2 - 1, 0, 0, \ldots, 0)\}$. Note that these vertices lie in the x_1x_2-plane and thus are in $T_{x_1x_2}$. Because they are the two dimensional equivalent of $L_{N/2-1}$, the union of their subtrees covers $T_{x_1x_2}$ between $N/2$ and N. In this region we know that we have κ_2 many inner leaves, which will extend to L_N with the first step in the x_i-direction for some $i \in [3..d]$. Let Y_N be the extended vertices on L_N from these κ_2 inner leaves, i.e., $|Y_N| \geq \kappa_2$.

Let $B_N = \{(x_1, x_2, \ldots, x_d) \in \mathcal{G}_N^+ \colon \sum_{i=1}^d x_i = N, x_1 + x_2 < N \text{ and } \forall i \in [3..d], x_i < (\kappa_2/N)^{\frac{1}{d-2}} - 1\}$, see Figure 6. Since we have less than $(\kappa_2/N)^{\frac{1}{d-2}}$ choices for $x_3, \ldots, x_d$, at most N choices for x_1 and the value of x_2 is adjusted to satisfy the constraint $\sum_{i=1}^d x_i = N$, the size of B_N is less than κ_2. Hence, B_N cannot contain all vertices of Y_N. Moreover, no vertices of Y_N lie on x_1x_2-plane, so there exists some vertex $u \in Y_N$ such that $u_j \geq (\kappa_2/N)^{\frac{1}{d-2}} - 1$ for some $j \in [3..d]$, which is in $T(v) \cap L_N$ for some $v \in V$. ◀

The existence of this vertex v is the root of the problem. We conclude with the following statement.

▶ **Lemma 19.** *Any CDR defined on $\mathcal{G}_N^+ \subset \mathbb{Z}^d$ with κ_2 inner leaves in $T_{x_1x_2}$ between $L_{N/2}$ and L_N has $\Omega((\kappa_2/N)^{\frac{1}{d-2}})$ error.*

Proof. Apply Lemma 18 to obtain a vertex $v \in L_{N/2-1} \cap T_{x_1x_2}$ that satisfies some $u \in T(v) \cap L_N$ with $u_j \geq (\kappa_2/N)^{\frac{1}{d-2}} - 1$ for some $j \in [3..d]$. Let u' be the intersection of $\overline{ou}$ and the affine plane containing $L_{N/2-1}$, see Figure 6. As L_N and $L_{N/2-1}$ are parallel, $\frac{u'_j - o_j}{u_j - o_j} \geq \frac{1}{3}$ for $N \geq 6$, this implies that $u'_j = \Omega((\kappa_2/N)^{\frac{1}{d-2}})$. By construction, we have that v is on the $dig(o, u)$ and $v_j = 0$, hence $||\cdot||_\infty$ distance between $dig(o, u)$ and $\overline{ou}$ is $\Omega((\kappa_2/N)^{\frac{1}{d-2}})$. ◀

Combining with Theorem 3 gives us a lower bound for CDRs in d dimensions.

▶ **Theorem 4.** *Any CDR in $\mathbb{Z}^d$ has $\Omega(\log^{1/(d-1)} N)$ error.*

Proof. By Theorem 3 and Lemma 19, the error is $\Omega(\frac{N \log N}{N+\kappa_2})$ and $\Omega((\kappa_2/N)^{\frac{1}{d-2}})$, where κ_2 is the number of inner leaves in $T_{x_1x_2}$ between $L_{N/2}$ and L_N. The balance between the two is obtained by choosing $\kappa_2 = \Theta(N \log^{\frac{d-2}{d-1}} N)$, giving the $\Omega(\log^{1/(d-1)} N)$ lower bound. ◀

6 Final remarks

Common intuition would say that the $\Omega(\log N)$ lower bound for the error of two-dimensional CDR and CDS automatically extends to higher dimensions. The observation that this is not true opens up new ways in which research can continue. We believe that further analysis of the mapping between the three spaces (from CDR in high dimensions to the 2-D weak CDR to the two-colored pointset) and the high interdependence between the three spaces can help in designing better lower and upper bounds.

Our lower bound $\Omega(\log^{1/(d-1)} N)$ extends the previous lower bound. The next step would be to close the gap between $\Omega(\log^{1/2} N)$ and $O(\log N)$ bounds in three dimensions. Even if the final answer ends up being $\Theta(\log N)$ we believe that the relationship between high dimensional CDRs, weak CDRs induced in subspaces and the mapping to pointset gives a better understanding of CDRs.

We also find that weak CDRs are an interesting research topic on their own. In particular, we would like to find the relationship between the number of inner leaves and the error of the construction. That is, say that we want a CDR with $O(e)$ error (for some $e \leq \log n$). What is the minimum number of leaves $\ell = \ell(e)$ that such a CDR must have? Can we find such a construction?

Theorem 3 seems to indicate a linear relationship between the two, and it is not hard to obtain one (an example is given in [3]). However, this construction is most likely not the best possible one. Indeed, even if we are interested in $O(\log N)$ error, this construction creates a large number of inner leaves, but we know of CDRs with the same error and no inner leaves. Thus, the question becomes, can we significantly improve upon the greedy construction, which can be found in the full version of the paper in [3]? Or is there some exponential dependency between the number of inner leaves and the error of the weak CDR?

Abstract

We study the Max Partial H-Coloring problem: given a graph G, find the largest induced subgraph of G that admits a homomorphism into H, where H is a fixed pattern graph without loops. Note that when H is a complete graph on k vertices, the problem reduces to finding the largest induced k-colorable subgraph, which for $k = 2$ is equivalent (by complementation) to Odd Cycle Transversal.

We prove that for every fixed pattern graph H without loops, Max Partial H-Coloring can be solved:

- in $\{P_5, F\}$-free graphs in polynomial time, whenever F is a threshold graph;
- in $\{P_5, \text{bull}\}$-free graphs in polynomial time;
- in P_5-free graphs in time $n^{\mathcal{O}(\omega(G))}$;
- in $\{P_6, \text{1-subdivided claw}\}$-free graphs in time $n^{\mathcal{O}(\omega(G)^3)}$.

Here, n is the number of vertices of the input graph G and $\omega(G)$ is the maximum size of a clique in G. Furthermore, by combining the mentioned algorithms for P_5-free and for $\{P_6, \text{1-subdivided claw}\}$-free graphs with a simple branching procedure, we obtain subexponential-time algorithms for Max Partial H-Coloring in these classes of graphs.

Finally, we show that even a restricted variant of Max Partial H-Coloring is NP-hard in the considered subclasses of P_5-free graphs, if we allow loops on H.

1 Introduction

Many computational graph problems that are (NP-)hard in general become tractable in restricted classes of input graphs. In this work we are interested in *hereditary* graph classes, or equivalently classes defined by forbidding induced subgraphs. For a set of graphs $\mathcal{F}$, we say that a graph G is *$\mathcal{F}$-free* if G does not contain any induced subgraph isomorphic to a graph from $\mathcal{F}$. By forbidding different sets $\mathcal{F}$ we obtain graph classes with various structural properties, which can be used in the algorithmic context. This highlights an interesting interplay between structural graph theory and algorithm design.

Perhaps the best known example of this paradigm is the case of the Maximum Independent Set problem: given a graph G, find the largest set of pairwise non-adjacent vertices in G. It is known that the problem is NP-hard on F-free graphs unless F is a forest whose every component is a path or a subdivided claw [2]; here, a *claw* is a star with 3 leaves. However, the remaining cases, when F is a *subdivided claw forest*, remain largely unexplored despite significant effort. Polynomial-time algorithms have been given for P_5-free graphs [24], P_6-free graphs [20], claw-free graphs [26, 29], and fork-free graphs [3, 25]. While the complexity status in all the other cases remains open, it has been observed that relaxing the goal of polynomial-time solvability leads to positive results in a larger generality. For instance, for every $t \in \mathbb{N}$, Maximum Independent Set can be solved in time $2^{\mathcal{O}(\sqrt{tn \log n})}$ in P_t-free graphs [4]. The existence of such a *subexponential-time algorithm* for F-free graphs is excluded under the Exponential Time Hypothesis whenever F is not a subdivided claw forest (see e.g. the discussion in [27]), which shows a qualitative difference between the negative and the potentially positive cases. Also, Chudnovsky et al. [10] recently gave a quasi-polynomial-time approximation scheme (QPTAS) for Maximum Independent Set in F-free graphs, for every fixed subdivided claw forest F.

The abovementioned positive results use a variety of structural techniques related to the considered graph classes, for instance: the concept of *Gyárfás path* that gives useful separators in P_t-free graphs [4, 6, 10], the dynamic programming approach based on potential maximal cliques [24, 20], or structural properties of claw-free and fork-free graphs that relate them to line graphs [25, 26, 29]. Some of these techniques can be used to give algorithms for related problems, which can be expressed as looking for the largest (in terms of the number of vertices) induced subgraph satisfying a fixed property. For Maximum Independent Set this property is being edgeless, but for instance the property of being acyclic corresponds to the Maximum Induced Forest problem, which by complementation is equivalent to Feedback Vertex Set. Work in this direction so far focused on properties that imply bounded treewidth [1, 17] or, more generally, that imply sparsity [27].

A different class of problems that admits an interesting complexity landscape on hereditary graphs classes are coloring problems. For fixed $k \in \mathbb{N}$, the k-Coloring problem asks whether the input graph admits a proper coloring with k colors. For every $k \geqslant 3$, the problem is NP-hard on F-free graphs unless F is a forest of paths (a *linear forest*) [18]. The classification of the remaining cases is more advanced than in the case of Maximum Independent Set, but not yet complete. On one hand, Hoàng et al. [22] showed that for every fixed k, k-Coloring

is polynomial-time solvable on P_5-free graphs. On the other hand, the problem becomes NP-hard already on P_6-free graphs for all $k \geqslant 5$ [23]. The cases $k = 3$ and $k = 4$ turn out to be very interesting. 4-Coloring is polynomial-time solvable on P_6-free graphs [14] and NP-hard in P_7-free graphs [23]. While there is a polynomial-time algorithm for 3-Coloring in P_7-free graphs [5], the complexity status in P_t-free graphs for $t \geqslant 8$ remains open. However, relaxing the goal again leads to positive results in a wider generality: for every $t \in \mathbb{N}$, there is a subexponential-time algorithm with running time $2^{\mathcal{O}(\sqrt{tn \log n})}$ for 3-Coloring in P_t-free graphs [19], and there is also a polynomial-time algorithm that given a 3-colorable P_t-free graph outputs its proper coloring with $\mathcal{O}(t)$ colors [12].

We are interested in using the toolbox developed for coloring problems in P_t-free graphs to the setting of finding maximum induced subgraphs with certain properties. Specifically, consider the following Maximum Induced k-Colorable Subgraph problem: given a graph G, find the largest induced subgraph of G that admits a proper coloring with k colors. While this problem clearly generalizes k-Coloring, for $k = 1$ it boils down to Maximum Independent Set. For $k = 2$ it can be expressed as Maximum Induced Bipartite Subgraph, which by complementation is equivalent to the well-studied Odd Cycle Transversal problem: find the smallest subset of vertices that intersects all odd cycles in a given graph. While polynomial-time solvability of Odd Cycle Transversal on P_4-free graphs (also known as *cographs*) follows from the fact that these graphs have bounded cliquewidth (see [15]), it is known that the problem is NP-hard in P_6-free graphs [16]. The complexity status of Odd Cycle Transversal in P_5-free graphs remains open [9, Problem 4.4]: resolving this question was the original motivation of our work.

Our contribution. Following the work of Groenland et al. [19], we work with a very general form of coloring problems, defined through homomorphisms. For graphs G and H, a *homomorphism* from G to H, or an *H-coloring* of G, is a function $\phi\colon V(G) \to V(H)$ such that for every edge uv in G, we have $\phi(u)\phi(v) \in E(H)$. We study the Max Partial H-Coloring problem defined as follows: given a graph G, find the largest induced subgraph of G that admits an H-coloring. Note that if H is the complete graph on k vertices, then an H-coloring is simply a proper coloring with k colors, hence this formulation generalizes the Maximum Induced k-Colorable Subgraph problem. Unless stated explicitly, we will always assume that the pattern graph H does not have loops, hence an H-coloring is a proper coloring with $|V(H)|$ colors.

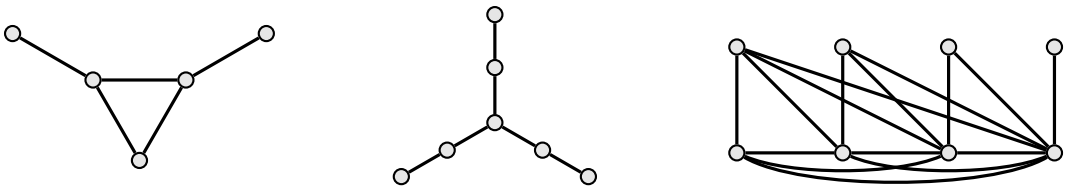

Figure 1 A bull, a 1-subdivided claw, and an example threshold graph.

Fix a pattern graph H without loops. We prove that Max Partial H-Coloring can be solved:

(R1) in $\{P_5, F\}$-free graphs in polynomial time, whenever F is a threshold graph;
(R2) in $\{P_5, \text{bull}\}$-free graphs in polynomial time;
(R3) in P_5-free graphs in time $n^{\mathcal{O}(\omega(G))}$; and
(R4) in $\{P_6, \text{1-subdivided claw}\}$-free graphs in time $n^{\mathcal{O}(\omega(G)^3)}$.

Here, n is the number of vertices of the input graph G and $\omega(G)$ is the size of the maximum clique in G. Also, recall that a graph G is a *threshold graph* if $V(G)$ can be partitioned into an independent set A and a clique B such that for each $a, a' \in A$, we have either $N(a) \supseteq N(a')$ or $N(a) \subseteq N(a')$. There is also a characterization via forbidden induced subgraphs: threshold graphs are exactly $\{2P_2, C_4, P_4\}$-free graphs, where $2P_2$ is an induced matching of size 2. Figure 1 depicts a bull, a 1-subdivided claw, and an example threshold graph.

Further, we observe that by employing a simple branching strategy, an $n^{\mathcal{O}(\omega(G)^\alpha)}$-time algorithm for Max Partial H-Coloring in $\mathcal{F}$-free graphs can be used to give also a subexponential-time algorithm in this setting, with running time $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$. Thus, results (R3) and (R4) imply that for every fixed irreflexive H, the Max Partial H-Coloring problem can be solved in time $n^{\mathcal{O}(\sqrt{n})}$ in P_5-free graphs and in time $n^{\mathcal{O}(n^{3/4})}$ in $\{P_6, \text{1-subdivided claw}\}$-free graphs. This in particular applies to the Odd Cycle Transversal problem. We note here that Dabrowski et al. [16] proved that Odd Cycle Transversal in $\{P_6, K_4\}$-free graphs is NP-hard and does not admit a subexponential-time algorithm under the Exponential Time Hypothesis. Thus, it is unlikely that any of our algorithmic results – the $n^{\mathcal{O}(\omega(G))}$-time algorithm and the $n^{\mathcal{O}(\sqrt{n})}$-time algorithm – can be extended from P_5-free graphs to P_6-free graphs.

All our algorithms work in a weighted setting, where instead of just maximizing the size of the domain of an H-coloring, we maximize its total *revenue*, where for each pair $(u, v) \in V(G) \times V(H)$ we have a prescribed revenue yielded by sending u to v. This setting allows encoding a broader range of coloring problems. For instance, list variants can be expressed by giving negative revenues for forbidden assignments (see e.g. [21, 28]). Also, our algorithms work in a slightly larger generality than stated above, see Section 5 for precise statements.

Finally, we investigate the possibility of extending our algorithmic results to pattern graphs with possible loops. We show an example of a graph H with loops, for which Max Partial H-Coloring is NP-hard and admits no subexponential-time algorithm under the ETH even in very restricted subclasses of P_5-free graphs, including $\{P_5, \text{bull}\}$-free graphs. This shows that whether the pattern graph is allowed to have loops has a major impact on the complexity of the problem.

Full version. In this extended abstract we focus on proving results (R3) and (R4). Results (R1) and (R2), as well as of the abovementioned lower bound, are proved in the full version of the paper, which is available on arXiv [8]. Also, the main branching step is given here in a simplified form that is sufficient for results (R3) and (R4), but not for results (R1) and (R2).

Our techniques. The key element of our approach is a branching procedure that, given an instance (G, rev) of Max Partial H-Coloring, where rev is the revenue function, produces a relatively small set of instances Π such that solving (G, rev) reduces to solving all the instances in Π. Moreover, every instance $(G', \mathsf{rev}') \in \Pi$ is simpler in the following sense: either it is an instance of Max Partial H'-Coloring for H' being a proper induced subgraph of H (hence it can be solved by induction on $|V(H)|$), or for any connected graph F on at least two vertices, G' is F-free provided we assume that G is $F^{\bullet\!-\!\circ}$-free. Here, $F^{\bullet\!-\!\circ}$ is the graph obtained from F by adding a universal vertex y and a degree-1 vertex x adjacent only to y. In particular we have $\omega(G') < \omega(G)$, so applying the branching procedure exhaustively in a recursion scheme yields a recursion tree of depth bounded by $\omega(G)$. Now, for results (R3) and (R4) we respectively have $|\Pi| \leqslant n^{\mathcal{O}(1)}$ and $|\Pi| \leqslant n^{\mathcal{O}(\omega(G)^2)}$, giving bounds of $n^{\mathcal{O}(\omega(G))}$ and $n^{\mathcal{O}(\omega(G)^3)}$ on the total size of the recursion tree and on the overall time complexity.

For result (R1) we apply the branching procedure not exhaustively, but a constant number of times: if the original graph G is $\{P_5, F\}$-free for some threshold graph F, it suffices to apply the branching procedure $\mathcal{O}(|V(F)|)$ times to reduce the original instances to a set of edgeless instances, which can be solved trivially. As $\mathcal{O}(|V(F)|) = \mathcal{O}(1)$, this gives recursion tree of polynomial size, and hence a polynomial-time complexity due to always having $|\Pi| \leqslant n^{\mathcal{O}(1)}$ in this setting. For result (R2), we show that two applications of the branching procedure reduce the input instance to a polynomial number of instances that are P_4-free, which can be solved in polynomial time due to P_4-free graphs (also known as *cographs*) having cliquewidth at most 2. However, these applications are interleaved with a reduction to the case of *prime graphs* – graphs with no non-trivial modules – which we achieve using dynamic programming on the modular decomposition of the input graph. This is in order to apply some results on the structure of prime bull-free graphs [11, 13], so that P_4-freeness is achieved at the end.

Let us briefly discuss the key branching procedure. The first step is finding a useful dominating structure that we call a *monitor*: a subset of vertices M of a connected graph G is a monitor if for every connected component C of $G - M$, there is a vertex in M that is complete to C. We prove that in a connected P_6-free graph there is always a monitor that is the closed neighborhood of a set of at most three vertices. After finding such a monitor $N[X]$ for $|X| \leqslant 3$, we perform a structural analysis of the graph centered around the set X. This analysis shows that there exists a subset of $\mathcal{O}(|V(H)|)$ vertices such that after guessing this subset and the H-coloring on it, the instance can be partitioned into several separate subinstances, each of which has a strictly smaller clique number. This structural analysis, and in particular the way the separation of subinstances is achieved, is inspired by the polynomial-time algorithm of Hoàng et al. [22] for k-Coloring in P_5-free graphs.

Other related work. We remark that very recently and independently of us, Brettell et al. [7] proved that for every fixed $s, t \in \mathbb{N}$, the class of $\{K_t, sK_1 + P_5\}$-free graphs has bounded mim-width. Here, *mim-width* is a graph parameter that is less restrictive than cliquewidth, but the important aspect is that a wide range of vertex-partitioning problems, including the Max Partial H-Coloring problem considered in this work, can be solved in polynomial time on every class of graphs where the mim-width is universally bounded and a corresponding decomposition can be computed efficiently. The result of Brettell et al. thus shows that in P_5-free graphs, the mim-width is bounded by a function of the clique number. This gives an $n^{f(\omega(G))}$-time algorithm for Max Partial H-Coloring in P_5-free graphs (for fixed H), for some function f. However, the proof presented in [7] gives only an exponential upper bound on the function f, which in particular does not imply the existence of a subexponential-time algorithm. To compare, our reasoning leads to an $n^{\mathcal{O}(\omega(G))}$-time algorithm and a subexponential-time algorithm with complexity $n^{\mathcal{O}(\sqrt{n})}$.

We remark that the techniques used by Brettell et al. [7] also rely on revisiting the approach of Hoàng et al. [22], and they similarly observe that this approach can be used to apply induction based on the clique number of the graph.

2 Preliminaries

Graphs. For a graph G, the vertex and edge sets of G are denoted by $V(G)$ and $E(G)$, respectively. The *open neighborhood* of a vertex u is the set $N_G(u) := \{v \colon uv \in E(G)\}$, while the *closed neighborhood* is $N_G[u] := N_G(u) \cup \{u\}$. This notation is extended to sets of vertices: for $X \subseteq V(G)$, we set $N_G[X] := \bigcup_{u \in X} N_G[u]$ and $N_G(X) := N_G[X] - X$. We may omit the subscript if the graph G is clear from the context. By C_t, P_t, and K_t we respectively denote the cycle, the path, and the complete graph on t vertices.

The *clique number* $\omega(G)$ is the size of the largest clique in a graph G. A clique K in G is *maximal* if no proper superset of K is a clique.

For $s, t \in \mathbb{N}$, the *Ramsey number* of s and t is the smallest integer k such that every graph on k vertices contains either a clique of size s or an independent set of size t. It is well-known that the Ramsey number of s and t is bounded from above by $\binom{s+t-2}{s-1}$, hence we will denote $\mathsf{Ramsey}(s,t) \coloneqq \binom{s+t-2}{s-1}$.

For a graph G and $A \subseteq V(G)$, by $G[A]$ we denote the subgraph of G induced by A. We write $G - A \coloneqq G[V(G) - A]$. We say that F is an *induced subgraph* of G if there is $A \subseteq V(G)$ such that $G[A]$ is isomorphic to F; this containment is *proper* if in addition $A \neq V(G)$. For a family of graphs $\mathcal{F}$, a graph G is *$\mathcal{F}$-free* if G does not contain any induced subgraph from $\mathcal{F}$. If $\mathcal{F} = \{H\}$, then we may speak about *H-free* graphs as well.

If G is a graph and $A \subseteq V(G)$ is a subset of vertices, then a vertex $u \notin A$ is *complete* to A if u is adjacent to all the vertices of A, and u is *anti-complete* to A if u has no neighbors in A. We will use the following simple claim several times.

▶ **Lemma 1.** *Suppose G is a graph, A is a subset of its vertices such that $G[A]$ is connected, and $u \notin A$ is a vertex that is neither complete nor anti-complete to A in G. Then there are vertices $a, b \in A$ such that $u - a - b$ is an induced P_3 in G.*

Proof. Since u is neither complete nor anticomplete to A, both the sets $A \cap N(u)$ and $A - N(u)$ are non-empty. As A is connected, there exist $a \in A \cap N(u)$ and $b \in A - N(u)$ such that a and b are adjacent. Now $u - a - b$ is the desired induced P_3. ◀

For a graph F, by $F^\bullet$ we denote the graph obtained from F by adding a *universal vertex*: a vertex adjacent to all the other vertices. Similarly, by $F^{\bullet-\circ}$ we denote the graph obtained from F by adding first an isolated vertex, say x, and then a universal vertex, say y. Note that thus y is adjacent to all the other vertices of $F^{\bullet-\circ}$, while x is adjacent only to y.

***H*-colorings.** For graphs H and G, a function $\phi\colon V(G) \to V(H)$ is a *homomorphism* from G to H if for every $uv \in E(G)$, we also have $\phi(u)\phi(v) \in E(H)$. Note that a homomorphism from G to the complete graph K_t is nothing else than a proper coloring of G with t colors. Therefore, a homomorphism from G to H will be also called an *H-coloring* of G, and we will refer to vertices of H as colors. Note that we will always assume that H is a simple graph without loops, so no two adjacent vertices of G can be mapped by a homomorphism to the same vertex of H. To stress this, we will call such H an *irreflexive pattern graph*.

A *partial homomorphism* from G to H, or a *partial H-coloring* of G, is a partial function $\phi\colon V(G) \rightharpoonup V(H)$ that is a homomorphism from $G[\mathsf{dom}\,\phi]$ to H, where $\mathsf{dom}\,\phi$ denotes the domain of ϕ.

Suppose that with graphs G and H we associate a *revenue function* $\mathsf{rev}\colon V(G) \times V(H) \to \mathbb{R}$. Then the *revenue* of a partial H-coloring ϕ is defined as

$$\mathsf{rev}(\phi) \coloneqq \sum_{u \in \mathsf{dom}\,\phi} \mathsf{rev}(u, \phi(u)).$$

In other words, for $u \in V(G)$ and $v \in V(H)$, $\mathsf{rev}(u,v)$ denotes the revenue yielded by assigning $\phi(u) \coloneqq v$.

We now define the main problem studied in this work. In the following, we consider the graph H fixed.

Max Partial H-Coloring
Input: Graph G and a revenue function $\mathsf{rev}\colon V(G) \times V(H) \to \mathbb{R}$
Output: A partial H-coloring ϕ of G that maximizes $\mathsf{rev}(\phi)$

An *instance* of the Max Partial H-Coloring problem is a pair (G, rev) as above. A *solution* to an instance (G, rev) is a partial H-coloring of G, and it is *optimum* if it maximizes $\mathsf{rev}(\phi)$ among solutions. By $\mathrm{OPT}(G, \mathsf{rev})$ we denote the maximum possible revenue of a solution to the instance (G, rev).

Let us note one aspect that will be used later on. Observe that in revenue functions we allow negative revenues for some assignments. However, if we are interested in maximizing the total revenue, there is no point in using such assignments: if $u \in \mathsf{dom}\,\phi$ and $\mathsf{rev}(u, \phi(u)) < 0$, then just removing u from the domain of ϕ increases the revenue. Thus, optimal solutions never use assignments with negative revenues. Note that this feature can be used to model list versions of partial coloring problems, where each vertex $v \in V(G)$ is assigned a list of colors $L(v) \subseteq V(H)$ and can only be mapped to a vertex from $L(v)$.

3 Monitors in P_6-free graphs

In this section we prove an auxiliary result about finding useful separators in P_6-free graphs. The desired property is expressed in the following definition.

▶ **Definition 2.** *Let G be a connected graph. A subset of vertices $M \subseteq V(G)$ is a* monitor *in G if for every connected component C of $G - M$, there exists a vertex $w \in M$ that is complete to C.*

Let us note the following property of monitors.

▶ **Lemma 3.** *If M is a monitor in a connected graph G, then every maximal clique in G intersects M. In particular, $\omega(G - M) < \omega(G)$.*

Proof. If K is a clique in $G - M$, then K has to be entirely contained in some connected component C of $G - M$. Since M is a monitor, there exists $w \in M$ that is complete to C. Then $K \cup \{w\}$ is also a clique in G, hence K cannot be a maximal clique in G. ◀

We now prove that in P_6-free graphs we can always find easily describable monitors.

▶ **Lemma 4.** *Let G be a connected P_6-free graph. Then for every $u \in V(G)$ there exists a subset of vertices X such that $u \in X$, $|X| \leqslant 3$, $G[X]$ is a path whose one endpoint is u, and $N_G[X]$ is a monitor in G.*

Lemma 4 follows immediately from the following statement applied for $t = 6$.

▶ **Lemma 5.** *Let $t \in \{4, 5, 6\}$, G be a connected P_6-free graph, and $u \in V(G)$ be a vertex such that in G there is no induced P_t with u being one of the endpoints. Then there exists a subset X of vertices such that $u \in X$, $|X| \leqslant t - 3$, $G[X]$ is a path whose one endpoint is u, and $N_G[X]$ is a monitor in G.*

Proof. We proceed by induction on t. The base case for $t = 4$ will be proved directly within the analysis.

In the following, by *slabs* we mean connected components of the graph $G - N_G[u]$. We shall say that a vertex $w \in N_G(u)$ is *mixed* on a slab C if w is neither complete nor anti-complete to C. A slab C is *simple* if there exists a vertex $w \in N_G(u)$ that is complete to C, and *difficult* otherwise.

Note that since G is connected, for every difficult slab D there exists some vertex $w \in N_G(u)$ that is mixed on D. Then, by Lemma 1, we can find vertices $a, b \in D$ such that $u - w - a - b$ is an induced P_4 in G. If $t = 4$ then no such induced P_4 can exists, so we infer that in this case there are no difficult slabs. Then $N_G[u]$ is a monitor, so we may set $X := \{u\}$. This proves the claim for $t = 4$; from now on we assume that $t \geqslant 5$.

Let us choose a vertex $v \in N_G(u)$ that maximizes the number of difficult slabs on which v is mixed. Suppose there is a difficult slab D' such that v is anti-complete to D'. As we argued, there exists a vertex $v' \in N_G(u)$ such that v' is mixed on D'; clearly $v' \neq v$. By the choice of v, there exists a difficult slab D such that v is mixed on D and v' is anti-complete to D. By applying Lemma 1 twice, we find vertices $a, b \in D$ and $a', b' \in D'$ such that $v - a - b$ and $v' - a' - b'$ are induced P_3s in G. Now, if v and v' were adjacent, then $b - a - v - v' - a' - b'$ would be an induced P_6 in G, a contradiction. Otherwise $b - a - v - u - v' - a' - b'$ is an induced P_7 in G, again a contradiction (see Figure 2).

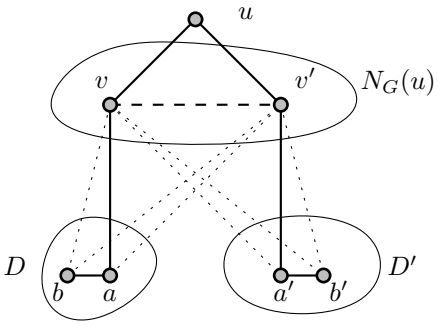

Figure 2 The graph G in the proof of Lemma 5 when v anti-complete to some difficult slab D'. Dotted lines show non-edges. The edge vv' might be present.

We conclude that v is mixed on every difficult slab. Let

$$A := \{v\} \cup \bigcup_{D\colon \text{difficult slab}} V(D).$$

Then $G[A]$ is connected and P_6-free. Moreover, in $G[A]$ there is no P_{t-1} with one endpoint being v, because otherwise we would be able to extend such an induced P_{t-1} using u, and thus obtain an induced P_t in G with one endpoint being u. Consequently, by induction we find a subset $Y \subseteq A$ such that $|Y| \leqslant (t-1) - 3 = t - 4$, $G[Y]$ is a path with one of the endpoints being v, and $N_{G[A]}[Y]$ is a monitor in $G[A]$. Let $X := Y \cup \{u\}$. Then $|X| \leqslant t - 3$ and $G[X]$ is a path with u being one of the endpoints.

We verify that $N_G[X]$ is a monitor in G. Consider any connected component C of $G - N_G[X]$. As $N_G[X] \supseteq N_G[u]$, C is contained in some slab D. If D is simple, then by definition there exists a vertex $w \in N_G[u] \subseteq N_G[X]$ that is complete to D, hence also complete to C. Otherwise D is difficult, hence C is a connected component of $G[A] - N_{G[A]}[Y]$. Since $N_{G[A]}[Y]$ is a monitor in $G[A]$, there exists a vertex $w \in N_{G[A]}[Y] \subseteq N_G[X]$ that is complete to C. This completes the proof. ◀

We remark that no statement analogous to Lemma 4 can hold for P_7-free graphs, even if from X we only require that $N_G[X]$ intersects all the maximum-size cliques in G (which is implied by the property of being a monitor, see Lemma 3). Consider the following example. Let G be a graph obtained from the union of $n+1$ complete graphs $K^{(0)}, \ldots, K^{(n)}$, each on n vertices, by making one vertex from each of the graphs $K^{(1)}, \ldots, K^{(n)}$ adjacent to a different vertex of $K^{(0)}$. Then G is P_7-free, but the minimum size of a set $X \subseteq V(G)$ such that $N_G[X]$ intersects all maximum-size cliques in G is n.

4 Branching

We now present the core branching step that is used by all our algorithms. This part is inspired by the approach of Hoàng et al. [22]. We will rely on the following two graph families; see Figure 3. For $t \in \mathbb{N}$, the graph S_t is obtained from the star $K_{1,t}$ by subdividing every edge once. Then $L_1 := P_3$ and for $t \geqslant 2$ the graph L_t is obtained from S_t by making all the leaves of S_t pairwise adjacent.

Figure 3 Graphs S_4 and L_4.

▶ **Lemma 6.** *Let H be a fixed irreflexive pattern graph. Suppose we are given integers s, t and an instance (G, rev) of Max Partial H-Coloring such that G is connected and $\{P_6, L_s, S_t\}$-free. Denoting $n := |V(G)|$, one can in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ construct a subgraph G' of G with $V(G') = V(G)$ and a set Π consisting of at most $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ revenue functions with domain $V(G) \times V(H)$ such that the following conditions hold:*

(C1) *The graph G' is $\{P_6, L_s, S_t\}$-free. Moreover, if G is $F^\bullet$-free for some connected graph F on at least two vertices, then G' is F-free.*

(C2) *We have $\mathrm{OPT}(G, \mathsf{rev}) = \max_{\mathsf{rev}' \in \Pi} \mathrm{OPT}(G', \mathsf{rev}')$. Moreover, for any $\mathsf{rev}' \in \Pi$ for which the maximum is reached, every optimum solution ϕ to (G', rev') is also an optimum solution to (G, rev) with $\mathsf{rev}(\phi) = \mathsf{rev}'(\phi)$.*

We remark that the statement above is a simplified variant of the lemma, and it is sufficient for proving results (R3) and (R4), but not for results (R1) and (R2). In the full variant, presented in the full version of the paper, solving the instance (G, rev) is reduced to solving a list Π of *pairs* of instances. Each pair $((G_1, \mathsf{rev}_1), (G_2, \mathsf{rev}_2)) \in \Pi$ satisfies the following: (G_1, rev_1) is an instance of Max Partial H'-Coloring for some proper induced subgraph H' of G; and if G_2 contains some induced connected graph F on at least two vertices, then G contains not only an induced $F^\bullet$, but even an induced $F^{\bullet\text{-}\circ}$. This gives a stronger reduction of structure upon application of Lemma 6, which is vitally used in the proofs of results (R1) and (R2).

The remainder of this section is devoted to the proof of Lemma 6. We fix the irreflexive pattern graph H and consider an input instance (G, rev). We find it more didactic to first perform an analysis of (G, rev), and only provide the algorithm at the end. Thus, the correctness will be clear from the previous observations.

Since G is connected, by Lemma 4 there exists $X \subseteq V(G)$ such that $|X| \leqslant 3$ and $N[X]$ is a monitor in G. Note that such a set X can be found in polynomial time by checking all subsets of $V(G)$ of size at most 3. In case $|X| < 3$, we may add arbitrary vertices to X so that $|X| = 3$, note that the property of being a monitor still holds. Let us arbitrarily enumerate the vertices of X as $\{x_1, x_2, x_3\}$.

We partition $V(G) - X$ into A_1, A_2, A_3, A_4 as follows (see Figure 4):

$$A_1 := N(x_1) - X,\ A_2 := N(x_2) - (X \cup A_1),\ A_3 := N(x_3) - (X \cup A_1 \cup A_2),\ A_4 := V(G) - N[X].$$

Note that $\{A_1, A_2, A_3\}$ is a partition of $N(X)$. For $i \in \{1,2,3\}$, denote $A_{>i} \coloneqq \bigcup_{j=i+1}^{4} A_j$ and observe that x_i is complete to A_i and anti-complete to $A_{>i}$. Moreover, we have the following.

▷ Claim 7. For every connected graph F and $i \in \{1,2,3,4\}$, if $G[A_i]$ contains an induced F, then G contains an induced $F^\bullet$.

Proof. Suppose $B \subseteq A_i$ induces F in G. If $i \in \{1,2,3\}$ then $B \cup \{x_i\}$ induces $F^\bullet$ in G, hence assume that $i = 4$. Since F is connected, B is entirely contained in one connected component C of $G[A_4]$. As $N[X]$ is a monitor in G, there exists a vertex $w \in N[X]$ that is complete to C. Now $B \cup \{w\}$ induces $F^\bullet$ in G. ◁

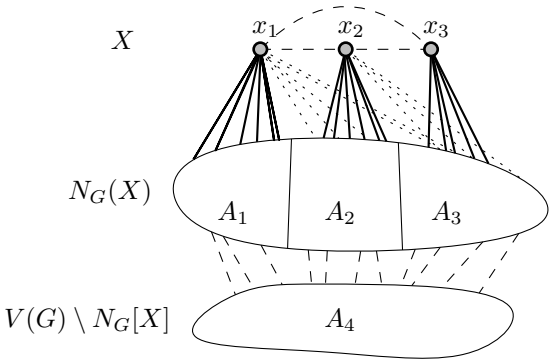

Figure 4 The partition on $V(G)$ in the proof of Lemma 6. Solid and dotted lines respectively indicate that a vertex is complete or anti-complete to a set. Dashed edges might, but do not have to exist.

The next claim contains the core combinatorial observation of the proof.

▷ Claim 8. Let ϕ be a solution to the instance (G, rev). Then for every $i \in \{1,2,3\}$ and $v \in V(H)$, there exists a set $S \subseteq A_i$ such that:

- $|S| < \mathsf{Ramsey}(s,t)$ and $S \subseteq A_i \cap \phi^{-1}(v)$; and
- every vertex $u \in A_{>i}$ that has a neighbor in $A_i \cap \phi^{-1}(v)$, also has a neighbor in S.

Proof. Let S be the smallest set contained in $A_i \cap \phi^{-1}(v)$ and satisfying the second condition, it exists, as this condition is satisfied by $A_i \cap \phi^{-1}(v)$. Note that since H is irreflexive, it follows that $\phi^{-1}(v)$ is an independent set in G, hence S is independent as well.

Suppose for contradiction that $|S| \geqslant \mathsf{Ramsey}(s,t)$. By minimality, for every $u \in S$ there exists $u' \in A_{>i}$ such that u is the only neighbor of u' in S. Let $S' \coloneqq \{u' \colon u \in S\}$. Since $|S'| = |S| \geqslant \mathsf{Ramsey}(s,t)$, in $G[S']$ we can either find a clique K' of size s or an independent set I' of size t; denote $K \coloneqq \{u \colon u' \in K'\}$ and $I \coloneqq \{u \colon u' \in I'\}$. In the former case, we find that $\{x_i\} \cup K \cup K'$ induces the graph L_s in G, a contradiction. Similarly, in the latter case we have that $\{x_i\} \cup I \cup I'$ induces S_t in G, again a contradiction. This completes the proof of the claim. ◁

Claim 8 suggests the following notion. A *guess* is a function $R \colon V(H) \to 2^{N[X]}$ satisfying that:

- for each $v \in V(H)$, $R(v)$ is a subset of $N[X]$ such that $|R(v) \cap A_i| < \mathsf{Ramsey}(s,t)$ for all $i \in \{1,2,3\}$; and
- sets $R(v)$ are pairwise disjoint for different $v \in V(H)$.

Let $\mathcal{R}$ be the family of all possible guesses; then we easily have the following.

▷ Claim 9. We have that $|\mathcal{R}| \leqslant n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ and $\mathcal{R}$ can be enumerated in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$.

Proof. For each $v \in V(H)$, the number of choices for $R(v)$ in a guess R is bounded by $2^3 \cdot n^{3\cdot\mathsf{Ramsey}(s,t)}$: the first factor corresponds to the choice of $R(v) \cap X$, while the second factor bounds the number of choices of $R(v) \cap A_i$ for $i \in \{1,2,3\}$. Since the guess R is determined by choosing $R(v)$ for each $v \in V(H)$ and $|V(H)|$ is considered a constant, the number of different guesses is bounded by $\left(2^3 \cdot n^{3\cdot\mathsf{Ramsey}(s,t)}\right)^{|V(H)|} = n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$. Clearly, they can be also enumerated in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$. ◁

Now, we say that a guess R is *compatible* with a solution ϕ to (G, rev) if the following conditions hold for every $v \in V(H)$:

(C1) $R(v) \subseteq \phi^{-1}(v)$;
(C2) $R(v) \cap X = \phi^{-1}(v) \cap X$; and
(C3) for all $i \in \{1,2,3\}$ and $u \in A_{>i}$, if u has a neighbor in $\phi^{-1}(v) \cap A_i$, then u also has a neighbor in $R(v) \cap A_i$.

The following statement follows immediately from Claim 8.

▷ Claim 10. For every solution ϕ to the instance (G, rev), there exists a guess $R \in \mathcal{R}$ that is compatible with ϕ.

Consider a guess $R \in \mathcal{R}$. We define a set $B^R \subseteq V(G) \times V(H)$ of *disallowed pairs* for R as follows. We include a pair $(u,v) \in V(G) \times V(H)$ in B^R if any of the following conditions holds:

(D1) $u \in X$ and $u \notin R(v)$;
(D2) $u \in R(v')$ for some $v' \in V(H)$ that is different from v;
(D3) u has a neighbor in G that belongs to $R(v')$ for some $v' \in V(H)$ such that $vv' \notin E(H)$; or
(D4) $u \in A_i - R(v)$ for some $i \in \{1,2,3\}$ and there exists $u' \in A_{>i}$ such that $uu' \in E(G)$ and $N_G(u') \cap A_i \cap R(v) = \emptyset$.

Intuitively, B^R contains assignments that contradict the supposition that R is compatible with a considered solution.

Based on B^R, we define a new revenue function $\mathsf{rev}^R \colon V(G) \times V(H) \to \mathbb{R}$ as follows:

$$\mathsf{rev}^R(u,v) = \begin{cases} -1 & \text{if } (u,v) \in B^R; \\ \mathsf{rev}(u,v) & \text{otherwise.} \end{cases}$$

The intuition is that disallowing a pair (u,v) is modelled by assigning a negative revenue to the corresponding assignment. This forbids optimum solutions from using this assignment.

We define a subgraph G' of G as follows: $V(G') \coloneqq V(G)$ and $E(G')$ comprises all edges of G whose both endpoints belong to the same set A_i, for some $i \in \{1,2,3,4\}$. Thus, in G' the vertices of X are isolated, and there are no edges between any A_i and A_j for $i \neq j$, nor between any A_i and X. For every guess $R \in \mathcal{R}$, we may consider a new instance (G', rev^R) of Max Partial H-Coloring. In the following two claims we establish the relationship between solutions to the instance (G, rev) and solutions to instances (G', rev^R) for $R \in \mathcal{R}$. The proofs essentially boil down to a verification that all the previous definitions work as expected. In particular, the key point is that the modification of revenues applied when constructing rev^R implies automatic satisfaction of all the constraints associated with edges that were present in G, but got removed in G'.

▷ Claim 11. For every guess $R \in \mathcal{R}$, every optimum solution ϕ to the instance (G', rev^R) is also a solution to the instance (G, rev), and moreover $\mathsf{rev}^R(\phi) = \mathsf{rev}(\phi)$.

Proof. Recall that ϕ is a solution to (G, rev) if and only if ϕ is a partial H-coloring of G. Hence, we need to prove that for every $uu' \in E(G)$ with $u, u' \in \mathsf{dom}\,\phi$, we have $\phi(u)\phi(u') \in E(H)$. Denote $v \coloneqq \phi(u)$ and $v' \coloneqq \phi(u')$ and suppose for contradiction that $vv' \notin E(H)$. Since ϕ is an optimum solution to (G', rev^R), we have $\mathsf{rev}^R(u, v) \geqslant 0$, which implies that $(u, v) \notin B^R$. Similarly $(u', v') \notin B^R$. We now consider cases depending on the alignment of u and u' in G.

If $u, u' \in A_i$ for some $i \in \{1, 2, 3, 4\}$ then $uu' \in E(G')$, so the supposition $vv' \notin E(H)$ would contradict the assumption that ϕ is a solution to (G', rev^R).

Suppose $u \in A_i$ and $u' \in A_j$ for $i, j \in \{1, 2, 3, 4\}$, $i \neq j$; by symmetry, assume $i < j$. As $vv' \notin E(H)$, we infer that u' does not have any neighbors in $R(v)$ in G, for otherwise we would have $(u', v') \in B^R$ by (D3). As $uu' \in E(G)$, $u \in A_i$, and $u' \in A_{>i}$, this implies that $(u, v) \in B^R$ by (D4), a contradiction.

Finally, suppose that $\{u, u'\} \cap X \neq \emptyset$, say $u \in X$. Since $(u, v) \notin B^R$, by (D1) we infer that $u \in R(v)$. Then, by (D3), $vv' \notin E(H)$ and $uu' \in E(G)$ together imply that $(u', v') \in B^R$, a contradiction.

This completes the proof that ϕ is a solution to (G, rev). To see that $\mathsf{rev}^R(\phi) = \mathsf{rev}(\phi)$ note that ϕ, being an optimum solution to (G', rev^R), does not use any assignments with negative revenues in rev^R, while $\mathsf{rev}(u, v) = \mathsf{rev}^R(u, v)$ for all (u, v) satisfying $\mathsf{rev}^R(u, v) \geqslant 0$. ◁

▷ Claim 12. If ϕ is a solution to (G, rev) that is compatible with a guess $R \in \mathcal{R}$, then ϕ is also a solution to (G', rev^R) and $\mathsf{rev}^R(\phi) = \mathsf{rev}(\phi)$.

Proof. As ϕ is a solution to (G, rev), it is a partial H-coloring of G. Since G' is a subgraph of G with $V(G') = V(G)$, ϕ is also a partial H-coloring of G'. Hence ϕ is a solution to (G', rev^R).

To prove that $\mathsf{rev}^R(\phi) = \mathsf{rev}(\phi)$ it suffices to show that $(u, \phi(u)) \notin B^R$ for every $u \in \mathsf{dom}\,\phi$, since functions rev^R and rev differ only on the pairs from B^R. Suppose otherwise, and consider cases depending on the reason for including $(u, \phi(u))$ in B^R. Denote $v \coloneqq \phi(u)$.

First, suppose $u \in X$ and $u \notin R(v)$. By (C2) we have $u \notin R(v) \cap X = \phi^{-1}(v) \cap X \ni u$, a contradiction.

Second, suppose $u \in R(v')$ for some $v' \neq v$. By (C1) we have $v = \phi(u) = v'$, again a contradiction.

Third, suppose that u has a neighbor u' in G such that $u' \in R(v')$ for some $v' \in V(H)$ satisfying $vv' \notin E(H)$. By (C1), we have $u' \in \mathsf{dom}\,\phi$ and $\phi(u') = v'$. But then $\phi(u)\phi(u') = vv' \notin E(H)$ even though $uu' \in E(G)$, a contradiction with the assumption that ϕ is a partial H-coloring of G.

Fourth, suppose that $u \in A_i - R(v)$ for some $i \in \{1, 2, 3\}$ and there exists $u' \in A_{>i}$ such that $uu' \in E(G)$ and $N_G(u') \cap R(v) \cap A_i = \emptyset$. Observe that since $u \in A_i \cap \phi^{-1}(v)$ and $uu' \in E(G)$, by (C3) u' has a neighbor in $R(v) \cap A_i$ in the graph G. This contradicts the supposition that $N_G(u') \cap R(v) \cap A_i = \emptyset$.

As in all the cases we have obtained a contradiction, this concludes the proof of the claim. ◁

Let now $\Pi \coloneqq \{\mathsf{rev}^R \colon R \in \mathcal{R}\}$. Then, condition (C2) can be easily derived from Claim 11 and Claim 12, while condition (C1) is implied by Claim 7. Note here that G' is $\{P_6, L_s, S_t\}$-free, because it is a disjoint union of induced subgraphs of G. Finally, from Claim 9 we infer that $|\Pi| = |\mathcal{R}| \leqslant n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ and Π can be constructed in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$, because given $R \in \mathcal{R}$ it is straightforward to construct rev^R in polynomial time. Hence Π satisfies all the requested properties, and this completes the proof of Lemma 6.

5 Corollaries for subclasses of P_6-free graphs

In this section we prove results (R3) and (R4) promised in Section 1. The idea is to apply Lemma 6 exhaustively, until the considered instance becomes trivial. The main point is that with each application the clique number of the graph drops, hence we naturally obtain an upper bound of the form $n^{f(\omega(G))}$ for the total size of the recursion tree, hence also on the running time.

The following statement captures the idea of exhaustive applying Lemma 6 in a recursive scheme. For convenience, we formulate the statement so that s and t are given on input.

▶ **Theorem 13.** *Let H be a fixed irreflexive pattern graph. There exists an algorithm that given $s,t \in \mathbb{N}$ and an instance (G, rev) of Max Partial H-Coloring where G is $\{P_6, L_s, S_t\}$-free, solves this instance in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t)\cdot\omega(G))}$.*

Proof. If G is not connected, then for every connected component C of G we apply the algorithm recursively to $(C, \mathsf{rev}|_{V(C)})$. If ϕ_C is the obtained optimum solution to this instance, we may output $\phi := \bigcup_C \phi_C$. It is clear that ϕ constructed in this way is an optimum solution to (G, rev).

Assume then that G is connected. If G consists of only one vertex, say u, then we may simply output $\phi := \{(u,v)\}$ where v maximizes $\mathsf{rev}(u,v)$, or $\phi := \emptyset$ if $\mathsf{rev}(\cdot)$ has no positive value in its range. Hence, assume that G has at least two vertices, in particular $\omega(G) \geqslant 2$. We now apply Lemma 6 to G. Thus, in time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ we obtain a subgraph G' of G with $V(G) = V(G')$ and a suitable set of revenue functions Π satisfying $|\Pi| \leqslant n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$. Recall here that G' is $\{P_6, L_s, S_t\}$-free. Moreover, if we set $F = K_{\omega(G)}$ then G is $F^\bullet$-free, so Lemma 6 implies that G' is F-free. This means that $\omega(G') < \omega(G)$.

Next, for every $\mathsf{rev}' \in \Pi$ we recursively solve the instance (G', rev'). Lemma 6 implies that if among the obtained optimum solutions to instances (G', rev') we pick the one with the largest revenue, then this solution is also an optimum solution to (G, rev).

We are left with analyzing the running time. Recall that every time we recurse into subproblems constructed using Lemma 6, the clique number of the currently considered graph drops by at least one. Since recursing on a disconnected graph yields connected graphs in subproblems, we conclude that the total depth of the recursion tree is bounded by $2\cdot\omega(G)$. In every recursion step we branch into $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$ subproblems, hence the total number of nodes in the recursion tree is bounded by $\left(n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}\right)^{2\cdot\omega(G)} = n^{\mathcal{O}(\mathsf{Ramsey}(s,t)\cdot\omega(G))}$. The internal computation in each subproblem take time $n^{\mathcal{O}(\mathsf{Ramsey}(s,t))}$, hence the total running time is indeed $n^{\mathcal{O}(\mathsf{Ramsey}(s,t)\cdot\omega(G))}$. ◀

Note that since both L_3 and S_2 contain P_5 as an induced subgraph, every P_5-free graph is $\{P_6, L_3, S_2\}$-free. Hence, from Theorem 13 we may immediately conclude the following statement, where the setting of P_5-free graphs is covered by the case $s = 3$ and $t = 2$.

▶ **Corollary 14.** *For any fixed $s,t \in \mathbb{N}$ and irreflexive pattern graph H, Max Partial H-Coloring can be solved in $\{P_6, L_s, S_t\}$-free graphs in time $n^{\mathcal{O}(\omega(G))}$. This in particular applies to P_5-free graphs.*

Next, we observe that the statement of Theorem 13 can be also used for non-constant s to obtain an algorithm for the case when the graph L_s is not excluded.

▶ **Corollary 15.** *For any fixed $t \in \mathbb{N}$ and irreflexive pattern graph H, Max Partial H-Coloring can be solved in $\{P_6, S_t\}$-free graphs in time $n^{\mathcal{O}(\omega(G)^t)}$.*

Proof. Observe that since the graph L_s contains a clique of size s, every graph G is actually $L_{\omega(G)+1}$-free. Therefore, we may apply the algorithm of Theorem 13 for $s := \omega(G)+1$. Note here that $\omega(G)$ can be computed in time $n^{\omega(G)+\mathcal{O}(1)}$ by verifying whether G has cliques of size $1, 2, 3, \ldots$ up to the point when the check yields a negative answer. Since for $s = \omega(G)+1$ and fixed t we have

$$\mathsf{Ramsey}(s,t) = \binom{s+t-2}{t-1} \leqslant \mathcal{O}(\omega(G)^{t-1}),$$

the obtained running time is $n^{\mathcal{O}(\mathsf{Ramsey}(s,t)\cdot\omega(G))} \leqslant n^{\mathcal{O}(\omega(G)^t)}$. ◀

Let us note that an algorithm with running time $n^{\mathcal{O}(\omega(G)^\alpha)}$, for some constant α, can be used within a simple branching strategy to obtain a subexponential-time algorithm.

▶ **Lemma 16.** *Let H be a fixed irreflexive graph and suppose Max Partial H-Coloring can be solved in time $n^{\mathcal{O}(\omega(G)^\alpha)}$ on $\mathcal{F}$-free graphs, for some family of graphs $\mathcal{F}$ and some constant $\alpha \geqslant 1$. Then Max Partial H-Coloring can be solved in time $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$ on $\mathcal{F}$-free graphs.*

Proof. Let (G, rev) be the input instance, where G has n vertices. We define threshold $\tau := \left\lfloor n^{\frac{1}{\alpha+1}} \right\rfloor$.

The algorithm first checks whether G contains a clique on τ vertices. This can be done in time $n^{\tau+\mathcal{O}(1)} \leqslant n^{\mathcal{O}(n^{1/(\alpha+1)})}$ by verifying all subsets of τ vertices in G. If there is no such clique then $\omega(G) < \tau$, so we can solve the problem using the assumed algorithm in time $n^{\mathcal{O}(\omega(G)^\alpha)} \leqslant n^{\mathcal{O}(\tau^\alpha)} \leqslant n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$. Hence, suppose that we have found a clique K on τ vertices.

Observe that since H is irreflexive, in any partial H-coloring ϕ of G only at most $|V(H)|$ vertices of K can be colored, that is, belong to $\mathsf{dom}\,\phi$. We recurse into $\binom{\tau}{\leqslant |V(H)|} \leqslant n^{|V(H)|}$ subproblems: in each subproblem we fix a different subset $A \subseteq K$ with $|A| \leqslant |V(H)|$ and recurse on the graph $G_A := G - (K - A)$ with revenue function $\mathsf{rev}_A := \mathsf{rev}|_{V(G_A)}$. Note here that G_A is $\mathcal{F}$-free. From the above discussion it is clear that $\mathrm{OPT}(G, \mathsf{rev}) = \max_{A\subseteq K, |A|\leqslant|V(H)|} \mathrm{OPT}(G_A, \mathsf{rev}_A)$. Therefore, the algorithm may return the solution with the highest revenue among those obtained in recursive calls.

As for the running time, observe that in every recursive call, the algorithm either solves the problem in time $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$, or recurses into $n^{|V(H)|} = n^{\mathcal{O}(1)}$ subcalls, where in each subcall the vertex count is decremented by at least $\left\lfloor n^{\frac{1}{\alpha+1}} \right\rfloor$. It follows that the depth of the recursion is bounded by $\mathcal{O}(n^{\alpha/(\alpha+1)})$, hence the total number of nodes in the recursion tree is at most $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$. Since the time used for each node is bounded by $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$, the total running time of $n^{\mathcal{O}(n^{\alpha/(\alpha+1)})}$ follows. ◀

By combining Corollary 14 and Corollary 15 with Lemma 16 we conclude the following.

▶ **Corollary 17.** *For any fixed $s, t \in \mathbb{N}$ and irreflexive pattern graph H, Max Partial H-Coloring can be solved in*

1. *$\{P_6, L_s, S_t\}$-free graphs in time $n^{\mathcal{O}(\sqrt{n})}$ (this in particular applies to P_5-free graphs),*
2. *$\{P_6, S_t\}$-free graphs in time $n^{\mathcal{O}\left(n^{t/(t+1)}\right)}$.*

6 Open problems

The following question, which originally motivated our work, still remains unresolved.

▶ **Question 1.** *Is* Odd Cycle Transversal *polynomial-time solvable in P_5-free graphs?*

Note that our work stops short of giving a positive answer to this question: we give an algorithm with running time $n^{\mathcal{O}(\omega(G))}$, a subexponential-time algorithm, and polynomial time algorithms for the cases when either a threshold graphs or a bull is additionally forbidden. Therefore, we are hopeful that the answer to the question is indeed positive.

One aspect of our work that we find particularly interesting is the possibility of treating the clique number $\omega(G)$ as a progress measure for an algorithm, which enables bounding the recursion depth in terms of $\omega(G)$. This approach naturally leads to algorithms with running time of the form $n^{f(\omega(G))}$ for some function f, that is, polynomial-time for every fixed clique number. By Lemma 16, having a polynomial function f in the above gives a subexponential-time algorithm, at least in the setting of Max Partial H-Coloring for irreflexive H. However, looking for algorithms with time complexity $n^{f(\omega(G))}$ seems to be another relaxation of the goal of polynomial-time solvability, somewhat orthogonal to subexponential-time algorithms [4, 6, 19] or approximation schemes [10]. Note that our work and the recent work of Brettell et al. [7] actually show two different methods of obtaining such algorithms: using direct recursion, or via dynamic programming on branch decompositions of bounded mim-width. It would be interesting to investigate this direction in the context of Maximum Independent Set in P_t-free graphs. A concrete question would be:

▶ **Question 2.** *Is there a polynomial-time algorithm for* Maximum Independent Set *in $\{P_t, K_t\}$-free graphs, for every fixed t?*

In all our algorithms, we state the time complexity assuming that the pattern graph H is fixed. This means that the constants hidden in the $\mathcal{O}(\cdot)$ notation in the exponent may – and do – depend on the size of H. In the language of parameterized complexity, this means that we give XP algorithms for the parameterization by the size of H. It is natural to ask whether this state of art can be improved to the existence of FPT algorithms, that is, with running time $f(H) \cdot n^c$ for some computable function f and universal constant c, independent of H. This is not known even for the case of k-Coloring P_5-free graphs, so let us re-iterate the old question of Hoàng et al. [22].

▶ **Question 3.** *Is there an* FPT *algorithm for k-*Coloring *in P_5-free graphs parameterized by k?*

While the above question seems hard, it is conceivable that FPT results could be derived in some more restricted settings considered in this work, for instance for $\{P_5, \text{bull}\}$-free graphs.

Compact Oblivious Routing in Weighted Graphs

Abstract

The space-requirement for routing-tables is an important characteristic of routing schemes. For the cost-measure of minimizing the total network load there exist a variety of results that show tradeoffs between stretch and required size for the routing tables. This paper designs compact routing schemes for the cost-measure congestion, where the goal is to minimize the maximum relative load of a link in the network (the relative load of a link is its traffic divided by its bandwidth). We show that for arbitrary undirected graphs we can obtain oblivious routing strategies with competitive ratio $\tilde{\mathcal{O}}(1)$ that have header length $\tilde{\mathcal{O}}(1)$, label size $\tilde{\mathcal{O}}(1)$, and require routing-tables of size $\tilde{\mathcal{O}}(\deg(v))$ at each vertex v in the graph.

This improves a result of Räcke and Schmid who proved a similar result in *unweighted* graphs.

1 Introduction

Oblivious routing strategies choose routing paths independent of the traffic in the network and are therefore usually much easier to implement than adaptive routing solutions that might require centralized control and/or lead to frequent reconfigurations of traffic routes. Because of this simplicity a lot of research in recent years has been performed on the question whether the quality of route allocations performed by oblivious algorithms is comparable to that of adaptive solutions (see e.g. [2, 5, 6, 17, 19, 20, 21, 26]). For some cost-metrics this is indeed the case. For example for minimizing the total traffic in the network (a.k.a. total load), shortest path routing is a simple optimal oblivious strategy. When one aims to minimize the congestion, i.e., the maximum (relative) load of a network link, one can still obtain strategies with a competitive ratio of $\mathcal{O}(\log n)$, i.e., the congestion generated by these strategies is at most an $\mathcal{O}(\log n)$-factor than the best possible congestion [21].

However, another important aspect for implementing oblivious routing strategies on large networks is the size of the required routing tables. This aspect has been investigated thoroughly for the cost-measure total load (see e.g. [7, 9, 11, 18, 24, 25, 29]), and various trade-offs between competitive ratio (also called stretch for the total load scenario) and the table-size have been discovered.

If for example every vertex stores the next hop on a shortest path to a target one can obtain a stretch of 1 at the cost of having routing tables of size $\mathcal{O}(n \log n)$ per node. If one allows non-optimal solutions Thorup and Zwick [25] have shown how to obtain a stretch of $4k - 5$ for any $k > 2$ with routing tables of size $\tilde{\mathcal{O}}(n^{1/k})$. This routing scheme works for the so-called labeled scenario in which the designer of the routing-scheme is allowed to relabel the vertices of the network in order to make routing decisions easier. Of course, there is still a restriction on the label-size as otherwise the power of being able to assign labels to vertices could be abused.

In the (more difficult) so-called *name-independent* model the designer is not allowed to relabel the vertices. Abraham et al. [1] have shown that for general undirected graphs one can asymptotically match the bounds for the labeled variant. They obtain a stretch of $\mathcal{O}(k)$ and routing tables of size $\tilde{\mathcal{O}}(n^{1/k})$. If a famous conjecture due to Erdős [8] about the existence of low-girth graphs holds then there is also a lower bound that says that obtaining a stretch better than $2k+1$ requires routing tables of size $\Omega(n^{1/k})$. This means that for general undirected graphs the existing tradeoffs between stretch and space are fairly tight.

There exist many more results that analyze problem variants as e.g. obtained by restricting the graph representing the network (see e.g. [18, 7, 10, 12, 13, 24]); so the problem of designing compact routing schemes is very well studied for the cost-measure *total load*.

However, for the cost-measure congestion this is not the case. Räcke and Schmid [22] gave the first oblivious routing scheme that combines a guarantee w.r.t. the congestion with small routing-tables. They consider the labeled model and design an oblivious routing scheme that for a general undirected, unweighted graph G requires routing tables of size $\tilde{\mathcal{O}}(\deg(v))$ at each vertex v and obtains a competitive ratio of $\tilde{\mathcal{O}}(1)$ w.r.t. congestion.

There are important differences when comparing this result to its counter-parts for the total-load scenario. Firstly, the space used at a vertex v may depend on the degree of v. This is a reasonable assumption from a practical perspective as a node corresponds to a router in the network and it is reasonable to assume that the memory at a router (node) grows with the number of ports (number of incident edges). However, this assumption seems also crucial for getting any reasonable guarantees. In order to minimize congestion it is important to distribute the traffic among all network resources. It seems very difficult to do this if the routing table at a vertex is a lot smaller than the number of outgoing edges.

Another difference is that there is no tradeoff parameter k that gives a smooth transition from optimal routing with large tables to more compact routing. The reason is that for *congestion* the competitive ratio may be $\Omega(\log n)$ even for unlimited routing tables [3].

One important shortcoming of the result by Schmid and Räcke [22] is that it only applies to unweighted graphs (there is a straightforward generalization that obtains routing tables of size $\mathcal{O}(W \operatorname{polylog} n)$ where W is the largest weight of an edge, but this is undesirable). This restriction is due to the fact that the result by Schmid and Räcke uses *paths* to route within well-connected clusters, which they obtain by randomized rounding.

There are two major obstacles in generalizing this result to the weighted case:

(1) In unweighted graphs, low congestion also ensures a low number of paths using an edge. However, an edge of weight W might be used by W small paths, which cannot be stored in a compact manner.

(2) Even within a well-connected cluster, it is not sufficient to route a commodity using a small number of paths, if the nodes are connected by many low-weight edges (illustrated in Figure 1). Hence a source node may have to route (and store) W small paths.

In this paper we give a construction of an oblivious routing scheme that avoids both problems, by storing aggregate routing information for many paths at once, as well as distributing storage across nodes for commodities that need to spread out over multiple paths. In this manner we obtain a polylogarithmic competitive ratio with polylogarithmic space requirement per edge in the network. Our main result is the following.

▶ **Theorem 13.** *There is a compact oblivious routing scheme with competitive ratio at most* $\mathcal{O}(\log^6 n \log^3 W)$*, that uses routing tables of size* $\mathcal{O}(\log^5 n \log W \log^3(nW) \cdot \deg(v))$ *at a node* v*, packet headers of length* $\mathcal{O}(\log^3(nW))$*, and node labels of length* $\mathcal{O}(\log^2 n)$*.*

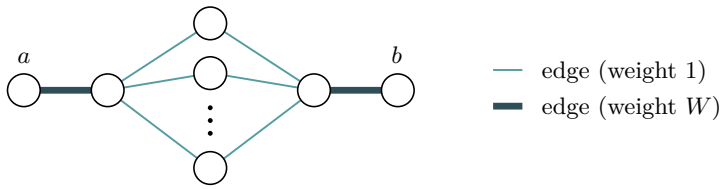

Figure 1 Routing a single demand over multiple edges. Sending data from a to b requires roughly W paths, but a has degree 1 and can store only $\tilde{\mathcal{O}}(1)$ bits.

In particular this result shows that if we can route some demand in a network with a multicommodity flow f of congestion C, then it is possible to route the demands *space-efficiently*, i.e., one can set up small routing tables so that packets follow a (maybe) different flow f' that routes the same demands with a slightly worse congestion. This question of space-efficiently routing demands in a network is orthogonal to oblivious routing and it is not clear by how much the performance (i.e., the congestion) degrades because of the space-requirement. The above theorem gives a polylogarithmic upper bound but to the best of our knowledge this problem has not been studied before.

1.1 Further Work

Oblivious routing with the goal of either minimizing the total load (or stretch), minimizing the congestion or a combination of both is a well studied problem. The research started with deterministic algorithms and it was shown by Borodin and Hopcroft [5] that on *any* bounded degree graph G for *any* deterministic routing scheme there exists a permutation routing instance that incurs congestion $\Omega(\sqrt{n}/\Delta^{3/2})$. This result was improved by Kaklamanis et al. [15] to a lower bound of $\Omega(\sqrt{n}/\Delta)$. As there exist bounded degree graphs that can route any permutation with small congestion this gives a large lower bound on the competitive ratio of deterministic oblivious routing schemes.

For randomized algorithms Valiant and Brebner [28] showed how to obtain a polylogarithmic competitive ratio for the hypercube by routing to random intermediate destinations (known as Valiant's trick).

Räcke [20] presented the first oblivious routing scheme with a polylogarithmic competitive ratio of $\mathcal{O}(\log^3 n)$ in general undirected networks. This routing scheme is based on a hierarchical decomposition of a graph and forms the basis for the compact routing schemes that we construct in this paper. The construction in [20] was not polynomial time. This drawback was independently addressed by Bienkowski et al. [4] and Harrelson et al. [14]. Both papers give a polynomial-time algorithm for constructing the hierarchical decomposition (and, hence, the routing scheme) – the first with a competitive ratio of $\mathcal{O}(\log^4 n)$, and the second with a competitive ratio of $\mathcal{O}(\log^2 n \log\log n)$.

In 2014 Räcke et al. [23] presented another construction of the hierarchy that runs in time $\mathcal{O}(m \operatorname{polylog} n)$ and guarantees a competitive ratio of $\mathcal{O}(\log^5 n)$ (however, going from the hierarchy to the actual routing scheme may require superlinear time).

The above oblivious routing schemes that are based on hierarchical tree decompositions do not give the best possible competitive ratio. In [21] Räcke presents an oblivious routing scheme that is based on embedding a convex combination of trees into the graph G. This scheme obtains a competitive ratio of $\mathcal{O}(\log n)$, which is optimal due to a lower bound of Bartal and Leonardi for online routing in grids [3].

However, the number of trees that are used in the above result [21] is fairly large ($\Theta(m)$). Therefore, it seems difficult to design a compact routing scheme based on the tree embedding approach, and, therefore we use the earlier results that are based on hierarchical decompositions (a single tree!) but only guarantee slightly weaker competitive ratios.

1.2 Preliminaries

Throughout the paper we use $G = (V, E, w)$ to denote an undirected weighted graph with n node and m edges. We will refer to the weight of an edge also as the *capacity* of the edge. Wlog. we assume that the minimum edge weight is 1, that edge-weights are a power of 2, and that the largest edge weight is W. We call an edge of capacity/weight 2^i a *class* i edge and use $N_{\text{class}} := 1 + \log_2 W$ to denote the total number of classes. Further, we use $\Gamma(v)$ to denote the neighborhood of a vertex v, i.e., $\Gamma(v) = \{u \in V \mid \{u, v\} \in E\}$.

The degree of a node v in the graph G will be referred to as $\deg_G(v)$, that is $\deg_G(v) := |\Gamma(v)|$. We apply that to directed graphs as well, where it refers to the number of outgoing edges.

While the edges E are undirected, it will be convenient to refer to a certain orientation of an edge, so we define $E_{\text{or}} := \{(u, v) \in V^2 : \{u, v\} \in E\}$. A mapping $f : E_{\text{or}} \to \mathbb{R}$ with $f((u, v)) = -f((v, u))$ for $(u, v) \in E_{\text{or}}$ is called a (single-commodity) flow. If $f(u, v) > 0$ for some edge $(u, v) \in E$, this indicates flow from u to v. The reverse flow of f is simply $-f$. For the sake of readability we omit double parentheses and write, e.g., $f(u, v)$ instead of $f((u, v))$.

A flow f may have multiple sources and sinks. The balance of a node $v \in V$ is denoted by $\text{bal}_f(v) := \sum_{u \in \Gamma(v)} f(u, v)$, so a positive balance indicates that the node is receiving more flow than sending out. A flow is *acyclic*, if there is no path $(p_0, ..., p_k)$ in G with $p_0 = p_k$ and $f(p_i, p_{i+1}) > 0$ for all i. Its congestion is the maximum ratio between the flow over an edge and its weight, denoted by $\text{cong}(f) := \max_{\{u,v\} \in E} |f(u, v)|/w(u, v)$. Given a multi-set of flows $F := \{f_1, f_2, ..., f_k\}$, its *total congestion* is $\text{cong}(F) := \max_{\{u,v\} \in E} \sum_k |f_k(u, v)|/w(u, v)$.

If a flow f has all flow originating at a single node s, i.e., $\text{bal}_f(s) \leq 0$ and $\text{bal}_f(u) \geq 0$ for $u \neq s$, we say that f is an s-flow. If additionally $\text{bal}_f(s) = -1$, we call f a *unit* s-flow. The set of all unit s-flows is denoted with $\text{flow}(s)$. If a flow f only sends from s to t, i.e., f is an s-flow and $-f$ is a t-flow we call f an s-t flow.

We use $\tilde{\mathcal{O}}$ to disregard logarithmic factors, so $g = \tilde{\mathcal{O}}(h)$ iff $g = \mathcal{O}(h \log^c(nW))$ for some constant c.

Oblivious Routing Scheme

Now we define the concept of an oblivious routing scheme. The idea is to fix a single flow between each pair of nodes (u, v), and then multiply that flow with the actual demand from u to v to get the route. This flow can be interpreted probabilistically or fractionally, so if we have $f(e) = \frac{1}{2}$ for some edge e it means that the probability of the packet being routed across edge e is $\frac{1}{2}$; or that half a packet travels along that edge. We will use both interpretations interchangeably.

▶ **Definition 1.** *An* oblivious routing scheme $S = (f_{u,v})_{u,v \in V}$ *consists of a unit u-v-flow for each pair of nodes $u, v \in V$. Given demands $d : V \times V \to \mathbb{R}_{\geq 0}$ the congestion of S w.r.t. d, denoted* $\text{cong}(S, d)$*, is the total congestion of the set of flows $\{d(u, v)f_{u,v} : u, v \in V\}$. The* competitive ratio *of S is* $\max_d \text{cong}(S, d)/\text{cong}_{\text{opt}}(d)$*, where* $\text{cong}_{\text{opt}}(d)$ *denotes the optimal congestion that can be obtained for demands d by any routing scheme.*

Defining a compact oblivious routing scheme formally is a bit more involved, as we have to clarify where information is stored and how it is used. Before we do so, we introduce the notion of a *routing algorithm*, which defines formally how packets are sent through the network. The intuition is that each packet carries a *packet header*, storing per-packet information. Each node stores a *routing table*, containing arbitrary information for the routing algorithm to use.

The routing algorithms forwards a packet in a local manner, meaning that it reads both the packet header and the routing table before choosing an outgoing edge on which to sent the packet. At the same time, it may modify the packet header. This procedure repeats, until routing algorithm indicates that the packet has reached its destination, by outputting no outgoing edge.

It remains to describe how the packet header is initialized. For oblivious routing schemes, we simply use the name of the target node as initial packet header. However, we will later define more general building blocks, namely transformation schemes. Hence a routing algorithm works with a set of abstract *input labels* as possible initial packet headers (and thus as input to the routing algorithm). For the purposes of a routing algorithm these are simply some set, but later definitions will describe their structure more concretely.

▶ **Definition 2.** *A* routing algorithm $A = (\mathcal{A}, \mathcal{L}, \mathcal{T})$ *is a tuple,* $\mathcal{L} \subset \{0,1\}^*$ *denoting a finite set of* input labels *and* $\mathcal{T} : V \to \{0,1\}^*$ *a* routing table *for each node. Additionally,* $\mathcal{A} : \mathcal{T}(V) \times \{0,1\}^* \to (E \cup \{\emptyset\}) \times \{0,1\}^*$ *is a (possibly randomized) algorithm, taking both a routing table and a packet header as input, which calculates both the outgoing edge (if any) and the new packet header.*

We remark that the outgoing edge given by $\mathcal{A}$ has to be encoded in some manner, and it must be adjacent to the node the routing table belongs to. The routing table $\mathcal{T}(v)$ for a node v can contain information about v, such as a list of adjacent nodes, so any straightforward encoding, e.g., the index in this list, will work.

Given a routing algorithm $A = (\mathcal{A}, \mathcal{L}, \mathcal{T})$, a start vertex $v \in V$, and an input label $l \in \mathcal{L}$, the above mechanism defines a process for probabilistically distributing packets from v to targets in the network. We use $A(v, l)$ to denote a flow that describes the associated routing paths. This is defined as follows: We inject a packet at v, with l as packet header and execute $\mathcal{A}$ until no outgoing edge is returned. Then $A(v, l)(e)$ is the probability that the packet is routed over e (note that $\mathcal{A}$ may be randomized).

A routing algorithm $A = (\mathcal{A}, \mathcal{L}, \mathcal{T})$ is *compact*, if packet headers and input labels have size $\tilde{\mathcal{O}}(1)$, and the routing table of a node $v \in V$ has size $\tilde{\mathcal{O}}(\deg(v))$.

Recall that an oblivious routing scheme corresponds to a routing algorithm where the input labels are names of nodes in the graph. Consequently, we say that such a scheme is compact if its routing algorithm is compact.

Formally, we assign a name to each vertex in the graph, which we call *node label*, i.e., we have some function $\text{node} : V \to \{0,1\}^*$. For an oblivious routing scheme $S = (f_{u,v})_{u,v \in V}$ we use the set of all node labels $\text{node}(V)$ as input labels, so the initial packet header is the node label of the target node.

We say that S is *compact* if there exists a compact routing algorithm $A = (\mathcal{A}, \text{node}(V), \mathcal{T})$ with $f_{u,v} = A(u, \text{node}(v))$. This definition matches the one used by Räcke and Schmid [22], although it is more explicit.

The main result of this paper is the existence of a compact oblivious routing scheme, with competitive ratio $\tilde{\mathcal{O}}(1)$.

Transformation Schemes

Our routing scheme will be composed out of several building blocks, which we call *transformation schemes*. Loosely speaking, they correspond to single-commodity flows which we are able to route.

We consider *distributions* or *weight functions* of the form $\mu : V \to \mathbb{R}_{\geq 0}$ that assign a non-negative weight to vertices in V. If we only specify a weight function on a subset $S \subseteq V$ we assume that it is 0 on $V \setminus S$. We use $\mu(S) := \sum_{v \in S} \mu(v)$ to denote the weight of a subset S, and $\mathbf{1}_v : V \to \mathbb{N}$ to denote the special weight function that has weight 1 on v and 0 elsewhere. For a distribution μ we use $\bar{\mu} := \frac{1}{\mu(V)}\mu$ to denote the corresponding *normalized distribution*.

▶ **Definition 3.** *A* (compact[1]) transformation scheme (TS) *is a compact routing algorithm with a single input label.*

The above definition is not very useful by itself. The underlying idea is that we view a transformation scheme TS as on operation to transform one distribution of packets into another, by executing the routing algorithm. More precisely, given P packets each packet follows the flow $TS(v)$ at its source location $v \in V$. This will send it to some target node (probabilistically, according to $TS(v)$).

We say that a transformation scheme routes from some *input distribution* μ_{in} to an *output distribution* μ_{out}, if the above process transforms a set of P packets that are distributed according to $\bar{\mu}_{\text{in}}$ (i.e., a node v has $\mu_{\text{in}}(v)/\mu_{\text{in}}(V) \cdot P$ packets in expectation) into a set of packets that are distributed according to $\bar{\mu}_{\text{out}}$, i.e., afterwards a node has $\mu_{\text{out}}/\mu_{\text{out}}(V) \cdot P$ packets in expectation.

In addition we associate a *demand* $d(TS)$ and *congestion* $\text{cong}(TS)$ with a transformation scheme TS. We say a tranformation scheme routes demand $d(TS)$ from μ_{in} to μ_{out} with congestion $\text{cong}(TS)$ if the expected load on an edge e for the above process is at most $\text{cong}(TS) \cdot w(e)$ when $P = d(TS)$ (we allow P to be non-integral).

Note that, of course, the input for a transformation scheme could be any packet distribution. However, the congestion of the scheme is stated w.r.t. some fixed input distribution μ_{in} (its *natural input distribution*) and some total demand $d(TS)$.

From the congestion-value for μ_{in} and its demand d, one can then deduce the congestion-value for other inputs. If we, e.g., use the transformation scheme on a demand d' that is distributed according to ν we experience congestion at most $\max_{v \in V} d'\bar{\nu}(v)/d\bar{\mu}_{\text{in}}(v)$.

To make our notation more concise, we write a statement like "*TS routes* μ_{in} *to* μ_{out} *with demand* d *and congestion at most* C" as "*TS routes* $\mu_{\text{in}} \xrightarrow{d} \mu_{\text{out}}$ with congestion (at most) C". We omit the demand d if it equals 1.

It may happen that for some transformation scheme TS we cannot exactly specify the output distribution that corresponds to its natural input distribution μ_{in}. We say TS routes $\mu_{\text{in}} \to \mu_{\text{out}}$ with *approximation* σ if the real output distribution μ'_{out} fulfills $\bar{\mu}_{\text{out}}(v)/\sigma \leq \bar{\mu}'_{\text{out}}(v) \leq \bar{\mu}_{\text{out}} \cdot \sigma$.

Finally, in some proofs we will view packets as discrete entities and specify that the transformation scheme does not split them up.

However, this collides with the fractional nature of the transformation scheme, which is caused by randomization. Therefore we introduce the following definition of a deterministic transformation scheme, that extracts this randomness and makes it explicit.

[1] As all of our transformation schemes are compact (the later variants of deterministic and concurrent transformation schemes will be as well), we may drop the 'compact' when appropriate.

▶ **Definition 4.** *A* (compact) deterministic transformation scheme $TS = (\mathcal{A}, \mathcal{P}(V), \mathcal{T})$ *is a compact routing algorithm where* $\mathcal{A}$ *is deterministic and* $\mathcal{P}(v) = \{1, ..., N_v\}$ *is a set of* path-ids *valid for a node* $v \in V$*.*

The idea of the above definition is that we can specify a"random seed" as input label, which will determine precisely how a packet is routed. The ordinary transformation scheme will correspond to choosing an input label u.a.r. from sets $\mathcal{P}(v)$. In this sense the above definition makes the random choices of a transformation scheme explicit.

Note that, technically, the definition of routing algorithms allows any path id in $\mathcal{P}(V)$ to be specified at a node v, not only the ones in $\mathcal{P}(v)$. We ensure that this does not occur.

As $\mathcal{A}$ is deterministic, the path id indeed determines the exact route a packet will take when starting at a certain node. More precisely, each flow $TS(v, l)$ for $v \in V, l \in \{1, ..., N_v\}$ is simply a path starting at v. Still, there is no guarantee that different path-ids send the packet to the same node.

We associate a transformation scheme with each deterministic TS, by choosing the path-id uniformly at random. In this fashion we extend the notions, such as congestion, input/output distributions, etc., that were defined above for ordinary transformation schemes to also cover deterministic transformation schemes.

Concurrent Transformation Schemes

While a transformation scheme can mix packets arbitrarily, often we want to distribute several commodities at the same time, with separate input and output distributions for each commodity. This allows us to analyze the congestion more precisely and aggregate the routing information for different commodities. Hence we define the notion of a *concurrent transformation scheme*, which executes multiple transformation schemes in parallel.

The idea is that we take a transformation scheme and additionally specify a commodity as input.

▶ **Definition 5.** *Let* I *denote a set of commodities. A* (compact) concurrent [deterministic] transformation scheme (CTS) *is a compact routing algorithm* $TS = (\mathcal{A}, I \times \mathcal{L}, \mathcal{T})$*, s.t.* $TS_i := (\mathcal{A}, \{i\} \times \mathcal{L}, \mathcal{T})$ *is a [deterministic] transformation scheme for each commodity* $i \in I$*.*

Note that transformation schemes have a single input label, in which case the $\mathcal{L}$ in the above definition is superfluous and the input to the concurrent transformation scheme is just the commodity. If it is deterministic, we need the path id as input, and $\mathcal{L}$ would be the set of possible path ids. Similar to before, any combination of commodity and path id may be specified at a node, according to the definition of a routing algorithm, but for our purpose only some of these make sense.

The congestion of such a concurrent transformation scheme is defined as follows. Let μ_i and d_i denote the input distribution and demand of TS_i, respectively. Let $X_i(e)$ denote the expected load on an edge e if we execute TS_i on d_i packets distributed according to μ_i. The congestion of the CTS D is defined as $\text{cong}(D) := \max_e \frac{1}{w(e)} \sum_i X_i(e)$.

As an input to the routing algorithm, a commodity $i \in I$ has to be encoded in some fashion. Often, the commodity is determined by the source node (i.e., for each node v at most one input distributions μ_i is nonzero) and does not need to be specified. Otherwise, we will explicitly describe the necessary encoding as a property of the CTS.

Analogous to transformation schemes, we write "TS *routes* $\mu_i \xrightarrow{d_i} \nu_i$ with congestion (at most) C" for each commodity $i \in I$ for a CTS, and extend this notation to deterministic CTS by considering the associated transformation schemes.

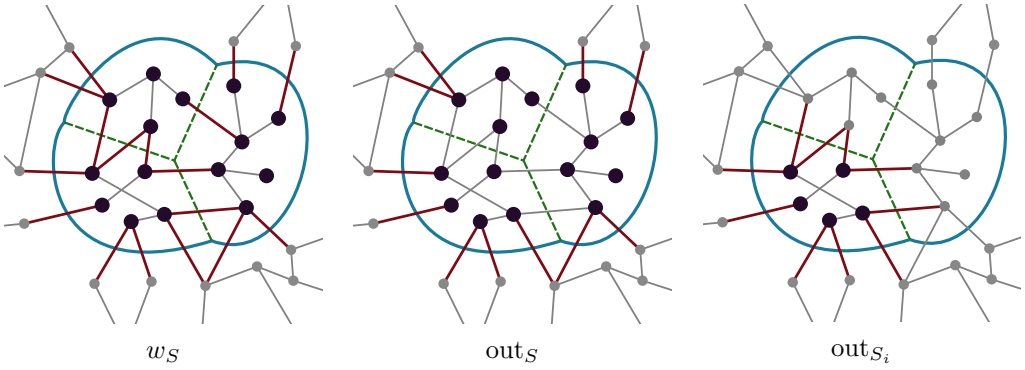

Figure 2 Distributions inside a cluster S with child S_i. The child clusters are separated by dashed lines. The respective distribution is nonzero only on the highlighted nodes and counts the total weight of highlighted edges adjacent to a node.

2 Overview

In this section we give a high-level overview of the most important steps in our construction. The first part gives a rough outline of the general approach of routing along a decomposition tree that forms the basis for some oblivious routing schemes (e.g. [20, 4, 14]), and has also been used by Räcke and Schmid [22] to obtain compact routing schemes.

2.1 The Decomposition Tree

The result by Räcke and Schmid [22] as well as our extension of it use a decomposition tree, in particular the one described in [20]. We refer the reader to these for a more detailed description and just briefly mention the key ideas here. We start with a single cluster containing all nodes, and then further refine that until all clusters consist of just a single node. Hence we get a tree T where nodes are subsets of V, which we call *clusters*. The tree T has root V, i.e., the cluster containing all nodes, and leaves $\{v\}$ for each $v \in V$. For a cluster S with children $S_1, ..., S_r$ we have $S = S_1 \dot\cup ... \dot\cup S_r$, so the children are a partition of the parent. We use $\text{height}(T)$ to denote the maximum distance from any leaf to the root, and $\deg(T)$ to denote the largest number of children of any cluster.

Now we introduce a number of distributions, which will be important for routing within the decomposition tree. For any cluster S we define the *border-weight* $\text{out}_S : S \to \mathbb{N}$ by $\text{out}_S(v) := \sum_{u \notin S} w(v,u)$ for $v \in S$, counting the total weight of edges leaving the cluster adjacent to a node. Additionally, for any cluster S with child clusters $S_1, ..., S_r$ we define the *cluster-weight* $w_S : S \to \mathbb{N}$ as $w_S := \sum_i \text{out}_{S_i}$, which also counts edges between children of S. These distributions are shown schematically in Figure 2.

The decomposition from [20] has two essential properties:

- For each cluster S we can solve the multi-commodity flow problem with demands $d(u,v) := w_S(u)w_S(v)/w_S(S)$ for $u, v \in S$ with congestion $C \in \mathcal{O}(\log^2 n)$ *within* S, and
- the tree has logarithmic height, i.e., $\text{height}(T) \in \mathcal{O}(\log n)$.

The essential idea for oblivious routing is that in order to route between two nodes s and t in the graph we determine the path $\{s\} = S_1, S_2, \ldots, S_k = \{t\}$ in the tree and then we route a packet successively along this path by routing it from distribution $\bar w_{S_i}$ to distribution $\bar w_{S_{i+1}}$ for $i = 1, \ldots, k-1$. Note that distribution $\bar w_{S_1} = \bar w_{S_{\{s\}}} = \mathbf{1}_s$ and distribution $\bar w_{S_k} = \bar w_{S_{\{t\}}} = \mathbf{1}_t$, i.e., we indeed route from s to t.

Now suppose that the optimal congestion for the given demand d is $C_{\text{opt}}(d)$. How much demand does the above process induce for routing from w_{S_i} to w_S for a child-cluster S_i of some cluster S (for all packets)? Each packet that uses the tree edge (S_i, S) in its path has to leave the cluster S_i and thus create a load of 1 in out_{S_i}. Conversely, OPT has congestion $C_{\text{opt}}(d)$, i.e., a load of at most $\text{out}_{S_i}(S_i) \cdot C_{\text{opt}}(d)$ on out_{S_i}. Therefore the total demand that has to be routed for $w_{S_i} \to w_S$ is at most $\text{out}_{S_i}(S_i) \cdot C_{\text{opt}}(d) = w_S(S_i) \cdot C_{\text{opt}}(d)$. An analogous argument holds for sending from w_S to w_{S_i}.

Now, we define a CTS for every cluster S that concurrently routes $w_{S_i} \xrightarrow{w_S(S_i)} w_S$ for all child-clusters with small congestion. If these schemes have congestion at most C then the overall competitive ratio of the compact oblivious routing scheme is $\text{height}(T)C$ as an edge is contained in at most $\text{height}(T)$ many clusters. Hence, we can restate our goal as follows. For every cluster S find

Mixing CTS
A CTS that routes $w_{S_i} \xrightarrow{w_S(S_i)} w_S$ for each child S_i, with congestion $\tilde{\mathcal{O}}(1)$.

Unmixing CTS
A CTS that routes $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ for each child S_i, with congestion $\tilde{\mathcal{O}}(1)$.

Here, we have to think about the encoding of the commodities, i.e., the indices of child clusters S_i. For our oblivious routing scheme we relabel the vertices so that the new name of a vertex v encodes the path from the root to the leaf $\{v\}$ in the decomposition tree. Then when we are given a packet with a source and a target node we can determine the path in the tree. For routing along an edge (S_i, S_{i+1}) of this path we extract the name of the child cluster and use this as commodity for the CTS. Furthermore, we will fix a specific name for each child cluster, incorporating a little bit of information for the CTS. (As in the scheme by Räcke and Schmid [22], the name will be the index in the list of child clusters, sorted by size.)

2.2 Constructing Transformation Schemes

In this section we give an overview of the steps for constructing transformation schemes that for some cluster S route $w_{S_i} \xrightarrow{w_S(S_i)} w_S$ and $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ with small congestion. For this we use simplified versions of the main lemmata that are proven in the technical analysis in Section A. We mark these simplified version with a " $'$ ", so Lemma 3$'$ would be the simplified version of Lemma 3 in Section A.

Single-commodity flows

The first lemma that we show is how to construct a transformation scheme from a given flow, to route between *integral* distributions.

▶ **Lemma 3$'$** (Single-commodity flow routing). *Let f denote a flow with congestion at most $\mathcal{O}(\text{poly}(nW))$, and μ, μ' integral distributions with $\mu' - \mu = \text{bal}_f$.*[2] *Then there exists a compact, deterministic transformation scheme that routes $\mu \xrightarrow{\mu(V)} \mu'$ with congestion $\mathcal{O}(\text{cong}(f))$ and has $N_v := \mu(v)$ valid path-ids at node v.*

This means that if we are given a flow then we can construct a transformation scheme that allows us to send packets from sources (outgoing net-flow) to targets (incoming net-flow). Note that there is no guarantee which target a packet will be sent to if the flow contains several targets.

[2] We remark that due to flow conservation, $\mu(V) = \mu'(V)$ holds.

Product multicommodity flow

The second step of our approach is to obtain a concurrent transformation scheme that routes a *product multicommodity flow* (PMCF). Suppose that we are given a weight function $c : V \to \mathbb{N}$ on the vertices of the graph. We associate a multicommodity flow problem with this weight function by defining a demand $d(u, v) = c(u)c(v)/c(V)$ for any pair (u, v) of vertices. One can view this demand as each vertex u generating a flow of $c(u)$ and distributing it according to $\bar{c}$. Suppose that we can solve this multicommodity flow problem with some congestion $C = \mathcal{O}(\text{poly}(nW))$. We show that we can then obtain a CTS that routes a solution to the PMCF.

▶ **Lemma 6′** (PMCF-routing). *Given a graph G together with a weight function $w : V \to \mathbb{N}$ on the vertices there exists a compact, deterministic CTS that routes $\mathbf{1}_u \xrightarrow{c(u)} c$ for each $u \in V$ with approximation $1 + \mathcal{O}(n^{-1})$ and congestion $\tilde{\mathcal{O}}(C)$.*

We obtain this result by making use of the KRV-framework [16]. One way to view this framework is that it tries to embed an expander into a graph by solving a small number of single-commodity maximum flow problems. Each maximum flow solution gives rise to a matching. One can then route to a random vertex by following the "*matching random walk*", i.e., in the i-th step the packet takes the (embedded) matching edge with probability $1/2$.

We proceed slightly differently. Instead of decomposing the flow into matchings and then route along the matchings (which seems difficult to do with small routing tables) we simply use Lemma 3′ to route along the flow. This means in the i-th step we stay with probability $1/2$ or we route the packet along the flow to some target of the flow. More concretely, assume that the KRV-scheme uses a flow f between sources $S := \{v \in V \mid \text{bal}_f(v) < 0\}$ and targets $T := \{v \in V \mid \text{bal}_f(v) > 0\}$ in the i-th step. Then we construct two transformation schemes. Let

$$\mu(v) := \begin{cases} -\text{bal}_f(v) & v \in S \\ 0 & \text{otw.} \end{cases} \quad \text{and} \quad \mu'(v) := \begin{cases} \text{bal}_f(v) & v \in T \\ 0 & \text{otw.} \end{cases}$$

We use Lemma 3′ to construct a transformation scheme that routes $\mu \to \mu'$ and one that routes $\mu' \to \mu$. These then allow us to distribute packets in the described way. The guarantees of KRV still hold for this slightly modified scheme, which means that after performing a polylogarithmic number of such steps a packet is at a random location.

The above process and the transformation schemes for the individual iterations can be combined into a single concurrent transformation scheme. The id-sets M_v for this scheme contain bitstrings that encode for every iteration: (a) the id to be used in the transformation scheme for this iteration and (b) a bit that indicates whether to route along the flow or to stay. Note that the CTS is deterministic, i.e., after choosing the id the packet follows a fixed path in the network.

The result by Räcke and Schmid [22] also required a sub-routine for routing a product multicommodity flow. They used a randomized rounding approach on the multicommodity flow solution of the PMCF-instance, and crucially exploited the fact that the number of routing paths going through an edge in such a solution is $\tilde{\mathcal{O}}(C)$. As illustrated in Figure 3, we cannot do this in our scenario as the number of paths going through an edge might be as large as $\tilde{\mathcal{O}}(CW)$. Storing these paths would require large routing tables.

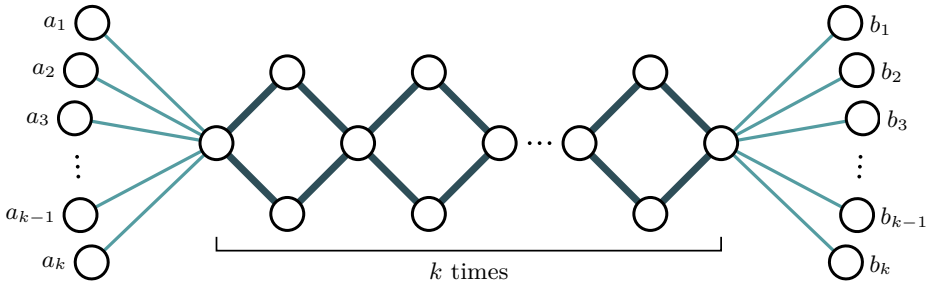

Figure 3 Routing multiple paths over a single edge. Each node a_i sends a packet to b_i. A single path needs k bits of information to encode, there are k paths and $n = \mathcal{O}(k)$ nodes, so on average each node needs to store $k^2/n = \Omega(n)$ bits if an arbitrary set of paths is chosen, which is too much. The same holds for paths chosen uniformly at random.

Routing arbitrary demands

The PMCF-scheme described above routes $\mathbf{1}_u \xrightarrow{w(u)} c$. If we choose $c := w_S$ for some cluster S then this scheme gives us the first part of our goal: we can concurrently route $w_{S_i} \xrightarrow{w_S(S_i)} w_S$ with small congestion. To see this, observe that if we consider the demands in the PMCF-scheme for all commodities $u \in S_i$ combined, this is $\sum_u w_S(u)\mathbf{1}_u = w_S \restriction S_i = \mathrm{out}_{S_i}$. We can go from w_{S_i} to out_{S_i} *within* S_i using Lemma 3′, and then the PMCF-scheme distributes it according to w_S.

Hence, by simply merging commodities $u \in S_i$ into one we obtain our desired CTS.

However, for our oblivious routing scheme we also need to be able to route commodities $w_S \xrightarrow{w_S(S_i)} w_{S_i}$. This turns out to be much more involved. Note that we cannot simply "route in reverse" because a transformation scheme is inherently directed.

We do not directly construct a transformation scheme that routes $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ but we first embed an auxiliary graph into the cluster S (via a transformation scheme). This auxiliary graph is directed and must have small degree for the embedding to be compact.

▶ **Lemma 10′** (general graph embedding). *Let $G' = (S, A, d)$ denote a weighted, directed graph, where the total weight of incoming and outgoing edges of a node v is at most $w_S(v)$, and $\deg_{G'}(v) \in \tilde{\mathcal{O}}(\deg(v))$. Then there is a compact CTS that routes $\mathbf{1}_u \xrightarrow{d(u,v)} \mathbf{1}_v$ for each $(u, v) \in A$ with congestion $\tilde{\mathcal{O}}(C)$.*

This lemma is the main technical contribution of our work. A rough outline of the approach is as follows. The first observation is that one could combine the result for the PMCF-routing with Valiant's trick [28, 27] of routing to random intermediate destinations. Suppose that we want to route from x to y. Then we first apply the PMCF-scheme of Lemma 6′; this brings us to a node z chosen according to w_S. At z we choose a path id id_y that brings us to y, i.e., if we apply the transformation scheme starting from node z with id id_y the packet is delivered to y. We choose id_y uniformly at random from all path ids that will deliver the packet to y. This applies Valiant's trick and the standard analysis shows that the congestion of this approach will be $\tilde{\mathcal{O}}(C)$.

However, implementing this approach with small routing tables is problematic. The node z could store a table of path ids which can be used for routing to y but this is clearly not compact.

If all edges have weight 1, we can apply a suitable randomized rounding to the above path generation method. Then the number of paths that go from x to y are just $\tilde{\mathcal{O}}(\deg(x))$. This allows the node x to store the necessary information for every path. In the weighted setting, however, the randomized rounding approach leads to $\tilde{\mathcal{O}}(W \cdot \deg(x))$ many paths. The resulting tables would not be compact.

Instead we proceed as follows. We say a path p is a *class l path* if the smallest capacity edge of p is from class l. (Recall that we assume all capacities to be powers of two, and that a class l edge is one with capacity 2^l.)

A pair (x, y) is from class l if l is the most frequent class that occurs when generating x-y-paths by the above process.

In a first step we change the path generation process to only use class l paths for a class l pair. This only increases the congestion by a factor of N_{class} (the number of classes). For a randomized rounding approach to guarantee a good congestion we need to spread the traffic between a class l pair (x, y) over roughly $k := d(x, y)/2^l$ many class l paths.

For this we split the packet into k different parts, each with a different path. However, we cannot store information for each such path in x directly, as k may be large. Instead, we identify k many other nodes, each of which we use to store the information for just a single path. Of course, we cannot simply pick any nodes in the cluster — they have to be reachable from x with low congestion.

As it turns out, the set of k class l paths from x to y already contains an appropriate choice. Each class l path contains a class l edge, and we pick one of its two adjacent nodes as helper node. Now observe that each path transports 2^l flow, so there can only be a small number of paths using that edge, because we have low congestion. That means that we can use $\tilde{\mathcal{O}}(1)$ space in the helper node, for each path that uses it.

Now that we have found k helper nodes that can store our routing information, the packets still have to reach these nodes, to pick up that information. So now we send a single-commodity flow from *all* source nodes x' of class l pairs to their helper nodes, and then back. We set up a TS for both directions of the flow, using Lemma 3.

Note that this does not guarantee that a packet from source node x reaches "its" helper node, but this is not required — it only needs to reach *a* node in which to store its routing information. Similarly, the packet may not get back to x, but end up at a different x'.

We have the same packet distribution as before, meaning every x' has the same number of packets, but possibly different ones. However, each packet has picked up $\tilde{\mathcal{O}}(1)$ of information while passing its helper node.

Suppose that all packets now in x have a target y' s.t. (x, y') is a class $l' \geq l$ pair. Then we can pick a single path for each of these packets, and store the information for that path in the helper node. (Recall that paths are generated by the PMCF-scheme of Lemma 6′, so we only need to store their path ids.)

If that is not the case we split the packet further, by applying the scheme recursively.

Hypercube embedding

The previous lemma tells us that we can embed graphs with low degree. More precisely, we can embed any graph $G' = (S, A, d)$ which fulfills the following properties.

(1) The degree $\deg_{G'}(v)$ at a vertex is polylogarithmic.

(2) The capacity of incoming edges and the capacity of outgoing edges at a vertex is roughly equal to $w_S(v)$.

Now, in order to be able to construct an unmixing CTS, i.e., route $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ for a cluster S, we find some graph with the above properties where an unmixing CTS is easy to implement, and then embed that graph into G. In particular, we want a G' which has one additional property.

(3) There is a suitable numbering of the child clusters of S for which there exists a CTS for G' that routes $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ for each S_i with small congestion and commodity S_i encoded as integer i.

The result by Räcke and Schmidt [22] used a hypercube, where each node v received $w_S(v)$ hypercube ids. For weighted edges this would violate property (1).

Instead, we essentially embed several (disconnected) hypercubes, one for each class l. A node v then receives roughly $w_S^{(l)}(v)$ hypercube ids, at most one for each class l edge adjacent to it. The existence of a good CTS scheme for G' then follows from classical results about online routing on the hypercube [28].

A Detailed Analysis

In this section we provide the details for constructing a mixing and an unmixing CTS for every cluster. This will then give the oblivious routing scheme.

Most of our lemmata related to the PMCF work for arbitrary weights c where the corresponding PMCF can be solved with congestion $C \in \mathcal{O}(\text{poly}(nW))$. We prove those without making further assumptions.

Note also that we can restrict the transformation schemes to route within a cluster: If a lemma is proven for arbitrary weights c, then it also works for weights w_S within the subgraph $G[S]$.

A.1 Constructing a mixing CTS

Single-commodity flows

To get started, we show how to use a single-commodity flow to construct a transformation scheme. The key idea is that we decompose the flow into paths with unique identifiers and store intervals for each edge, to encode the outgoing paths.

▶ **Lemma 3** (Flow routing). *Let f denote a flow with $\mathrm{cong}(f) \in \mathcal{O}(\mathrm{poly}(nW))$, and μ, μ' integral distributions with $\mu' - \mu = \mathrm{bal}_f$. Then there exists a deterministic TS that routes $\mu \xrightarrow{\mu(V)} \mu'$ with congestion $\mathcal{O}(\mathrm{cong}(f))$.*

The routing table of node v has size $\mathcal{O}(\deg(v)\log(nW))$, and packet headers have length $\mathcal{O}(\log(nW))$. At a node v there are $N_v := \mu(v)$ valid path ids.

Proof. First, we transform f to be integral and acyclic.

Let $F := \lceil \mathrm{cong}(f) \rceil$. We consider the single-commodity flow problem where we add a source s, a sink t and edges (s, v), (v, t) for $v \in V$ with respective capacities $\mu(v)$ and $\mu'(v)$. We retain the other edges, scaling their capacities by F. All capacities are integral and f is a solution with flow value $\mu(V)$, so there is also an integral, acyclic solution f', which by construction has $\mu' - \mu = \mathrm{bal}_{f'}$ and $\mathrm{cong}(f') \leq F$.

For each source $v \in V$ (i.e., a node that has $k := -\mathrm{bal}_{f'}(v) > 0$) we put k tokens into v. These have labels $a+1, a+2, ..., a+k$ where a is chosen s.t. the labels are disjoint for all nodes. We store a and k in v, which takes $\mathcal{O}(\log(nW))$ space.

Now we repeatedly move those tokens according to f', iteratively constructing the TS in the process. Each token represents a unit of flow.

As f' is acyclic, we iterate over the nodes based on the topological ordering given by f'. Let u denote the current node. We assume the invariant that no previous node contains any tokens, which is true in the beginning and will hold inductively for all other iterations.

Therefore, u has tokens precisely equal to the flow over incoming edges of u (plus $-\mathrm{bal}_{f'}(u)$ if u is a source), which, due to flow conservation, is the same as the flow over outgoing edges (plus $\mathrm{bal}_{f'}(u)$ if u is a sink). We distribute the tokens by sorting them and assign each outgoing edge (u, v) an amount of consecutive tokens, according to its flow $f'(u, v)$. These tokens are sent over that edge. Exactly $\max\{\mathrm{bal}_{f'}(v), 0\}$ tokens remain, which we remove from the graph. Hence we deleted all tokens from u and added tokens only to its successors, so our invariant still holds.

After the last iteration, all nodes are empty, so each token has been routed. To construct a TS, we encode the path of all tokens, by storing an *interval* $I(u, v)$ of ids for each edge (u, v), which contains the tokens which were routed over that edge. Note that the interval may be larger than the number of tokens that use e; all tokens that traverse u and are inside $I(u, v)$ use edge $e = (u, v)$, but the interval may contain tokens that do not traverse u. In total we just need to store two ids of length $\mathcal{O}(\log(nW))$ per incident edge. (Recall that the maximum load over any edge is at most $FW \in \mathcal{O}(\mathrm{poly}(nW))$.)

As we send exactly $|f'(e)|$ tokens over an edge e we get the same congestion as f'.

We want to construct a deterministic TS, so the input label at a node v contains a path id $l \in \{1, ..., \mu(v)\}$. As v stores the offset a from above, we can map the path id to $a + l$, one of the tokens starting at v. Afterwards, the routing algorithm simply needs to check which interval contains the token, to simulate their movement. This is deterministic. ◀

We use Lemma 3 typically to route between distributions which are 'close' to our weights c. As we can solve the PMCF with low congestion, this will have low congestion as well. The following lemma encapsulates that argument.

▶ **Lemma 4.** *Let $\mu_{\text{in}}, \mu_{\text{out}}$ denote distributions with $\mu_{\text{in}}, \mu_{\text{out}} \leq c$ and $\mu_{\text{in}}(V) = \mu_{\text{out}}(V)$. Then there is a flow f with $\text{bal}_f = \mu_{\text{out}} - \mu_{\text{in}}$ and $\text{cong}(f) \leq 2C$.*

Proof (omitted). The proof simply uses the PMCF together with Valiant's trick. It can be found in the full version of this paper. ◀

Routing the PMCF

Our first goal is to create a transformation scheme for the PMCF, for which we use the technique of cut-matching games introduced in [16]. We will not discuss it in detail, but instead encapsulate the properties of interest and refer to the original proofs. We need modify the technique slightly [3] , so for those parts we briefly show how the proofs can be adapted.

Consider the following game. We are given a finite set of nodes V', with $|V'|$ even. There are $N \in \mathcal{O}(\log^2 |V'|)$ rounds and two players. In round k,

- Player 1 (the"cut player") chooses a partition $A_1 \dot\cup A_2 = V'$ with $|A_1| = |A_2|$,
- Player 2 (the"matching player") chooses a bijection $M : V' \to V'$ *respecting the partition*, i.e., it maps A_1 to A_2 and vice versa, and
- Player 2 chooses a partition B of V'.

At the end of the game, we define a random walk on V' consisting of N steps. In step k, a packet

- moves from node v to either v or $M(v)$ with probability $\frac{1}{2}$, and then
- moves from the resulting node v' to a node in $B_{v'}$ uniformly at random, where $v' \in B_{v'} \in B$ is the group of v' in the partition B.

The game is won by Player 1 if this random walk is *mixing*, i.e., for any $u, v \in V'$ it moves from u to v with probability between $1/|V'| \pm \varepsilon$, where $\varepsilon = 1/|V'|^2$.

▶ **Lemma 5** (KRV)**.** *Player 1 has a winning strategy.*

Proof (omitted). See [16, Section 3.1]. The proofs have to be changed slightly to work here, a precise explanation can be found in the full version of this paper. ◀

These random walks can be made deterministic, by storing whether to switch sides at each step, provided that we can send packets along our chosen bijection M. Additionally, while we need a lot of nodes in V' to match the weights c, a single node v can simulate many in V' with only little bookkeeping. Here we use that "mixing" nodes of V' at each step is not problematic, a notion made precise by choosing the appropriate partition B. The bijections M will be stored implicitly using single-commodity flows.

In total we get short descriptions of the possible paths taken by the random walk, enabling us to circumvent one of the key problems arising in weighted graphs — the inability to store paths directly within the graph due to too many paths going over a single edge.

▶ **Lemma 6** (PMCF transformation scheme)**.** *There exists a deterministic CTS that routes $\mathbf{1}_v \xrightarrow{c(v)} c$ for each $v \in V$ with approximation $1 + \mathcal{O}(n^{-1})$ and congestion $\mathcal{O}(C \log^2 n)$.*

The routing table of node v has size $\mathcal{O}(\deg(v) \log^3(nW))$, while path ids and packet headers have length $\mathcal{O}(\log^3(nW))$.

[3] In particular, we use a bijection instead of a perfect matching, allow the matching player to choose subsets which will be shuffled randomly, and require a stronger bound on the error.

Proof. We want to play the game described above Lemma 5, so we define a set of"virtual" nodes $V' := \{1, ..., 2nc(V)\}$ [4] and choose an embedding $\varphi : V' \to V$ which assigns each node virtual nodes according to its weight, i.e. $|\varphi^{-1}(v)| = 2nc(v)$.

In each turn we have $A_1 \cup A_2 = V', |A_1| = |A_2|$ and can choose any bijection M respecting that partition. We want to simulate the random walk, so we also need a way to send packets according to M. In other words, we need a CTS that routes $\mathbf{1}_{\varphi(v')} \to \mathbf{1}_{M(\varphi(v'))}$ for each $v' \in V'$. It is difficult to construct such a CTS *given* a specific M, so instead we build the transformation scheme first, and then define M accordingly.

We construct two deterministic transformation schemes TS_1 and TS_2, routing from A_1 to A_2 and vice versa. Let us first consider TS_1.

A node v sends out a packet for each virtual node in A_1 assigned to it, so $\mu_1(v) := |\varphi^{-1}(v) \cap A_1|$ in total. Analogously, it receives $\mu_2(v) := |\varphi^{-1}(v) \cap A_2|$ packets. Hence we want to route $\mu_1 \xrightarrow{nc(V)} \mu_2$.

We have $\mu_1, \mu_2 \leq c$ and $\mu_1(V) = \mu_2(V) = nc(V)$, so Lemma 4 yields a flow f with $\mathrm{bal}_f = \mu_2 - \mu_1$ and $\mathrm{cong}(f) \leq 2nc(V)$. (We scale μ_1, μ_2 by $1/n$ and the resulting flow by n.)

Using f, we apply Lemma 3 to get a deterministic transformation scheme TS_1 that routes $\mu_1 \xrightarrow{nc(V)} \mu_2$ with congestion $\mathcal{O}(nC)$.

At each node v there are now $\mu_1(v)$ path ids to route a packet using TS_1. The transformation scheme is deterministic, so each path id corresponds to a single target node. Consider giving $\mu_1(v)$ packets to each node v, one for each path id, and routing them accordingly. Then, v will receive $\mu_2(v)$ packets. By mapping the outgoing packets to $\varphi^{-1}(v) \cap A_1$ and the incoming packets to $\varphi^{-1}(v) \cap A_2$ in some fashion, we get a bijection from A_1 to A_2.

We construct TS_2 in the same manner, and combine the two mappings to get the desired bijection M from V' to V'.

It remains to be shown that we can indeed route this bijection efficiently, i.e., without encoding any arbitrary mappings between virtual nodes and path ids.

Instead, we will simply choose a *random* path id for either TS_1 or TS_2, weighted such that each path id has the same probability. This corresponds to moving to a random virtual node assigned to v in each iteration, i.e. choosing our partition as $B := \{\varphi^{-1}(v) : v \in V\}$ in each round.

To summarize, we route the random walk as follows. In each iteration $k = 1, ..., N$ we flip a fair coin to decide whether we move from node v according to M or not. If yes, we pick a number i u.a.r. in $\{1, ..., 2nc(v)\}$. The first $\mu_1(v)$ numbers stand for path ids of TS_1, the others for path ids of TS_2. Then we route using the given transformation scheme and path id.

As we want our transformation scheme to be deterministic, these random choices will not be made while routing the packet, but encoded in the path id. There is a small technical issue in that the set $\{1, ..., 2nc(v)\}$ from which we sample i depends on v, but needs to be encoded in a path id chosen u.a.r. from some *fixed* range of integers. Instead, we will sample $i' \in \{1, ..., 2n^2c(V)N\}$ u.a.r and set $i := i' \pmod{2nc(v)}$. (Recall that N is the number of rounds.) So i is not quite uniform, but the probabilities differ by at most a factor of $1 + 1/nN$ in each round, and $1 + 1/n$ in total.

Thus we can store all random choices for the $\mathcal{O}(\log^2 nc(V)) = \mathcal{O}(\log^2(nW))$ iterations using $\mathcal{O}(\log^3(nW))$ bits. These are the path ids of our transformation scheme. As there is no randomness apart from the choices encoded in the path id, the transformation scheme is deterministic. The packet headers need to include the headers from Lemma 3, as well as our path ids; the length of the latter dominates.

[4] We would like to have $V' = \{1, ..., c(V)\}$, but we need to make sure that $|V'|$ is even and at least n.

Recall that we want to have a CDS that routes $\mathbf{1}_v \xrightarrow{c(v)} c$ for each $v \in V$. Hence, in aggregate the input distribution is c.

Let us now analyze the congestion. TS_1 routes $\mu_1 \xrightarrow{nc(V)} \mu_2$ and TS_2 does $\mu_2 \xrightarrow{nc(V)} \mu_1$, both with congestion $\mathcal{O}(nC)$. If we add them and scale the demand by $1/n$ we route $c \xrightarrow{c(V)} c$ with congestion $\mathcal{O}(C)$. So the distribution of packets does not change in an iteration, except for the factor of $1 + 1/nN$ above, and the total congestion is $\mathcal{O}(C \log^2(nW))$.

Due to Lemma 5, the random walk moves to any virtual node with probability between $1/2nc(V) \pm 1/|V'|^2$. We have $|V'|^2 \geq 2n^2 c(V)$, so scaling by the total amount of flow $c(V)$ yields a value in $1/2n \pm 1/2n^2$. A node $v \in V$ has $2nc(v)$ virtual nodes, so it receives between $c(v)(1 \pm 1/n)$ packets in the random walk, or between $c(v)(1 \pm 2/n)$ in the actual CTS. Hence the output distribution is c, with an approximation of $1 + \mathcal{O}(n^{-1})$. ◀

We remark that this CTS has input distribution $\mathbf{1}_v$ for commodity $v \in V$, which means that the source node of a packet already encodes its commodity.

Mixing CTS

To close out section we prove that we can implement the mixing step with the tools we have. To start, we need a small helper lemma.

▶ **Lemma 7** (Routing distributions similar to c)**.** *Let $\mu_{\text{in}}, \mu_{\text{out}}$ denote integral distributions with $\mu_{\text{in}}, \mu_{\text{out}} \leq c$ and set $M := \min\{\mu_{\text{in}}(V), \mu_{\text{out}}(V)\}$. Then there exists a deterministic TS that routes $\mu_{\text{in}}(V) \xrightarrow{M} \mu_{\text{out}}(V)$ with congestion $\mathcal{O}(C)$. The routing table of node v has size $\mathcal{O}(\deg(v) \log(nW))$, while path ids and packet headers have length $\mathcal{O}(\log(nW))$.*

Proof (omitted). The proof can be found in the full version of this paper. ◀

Now we fix a cluster S with children $S_1, ..., S_r$. As we will later change the numbering of children, it is important that the following lemma works for an arbitrary one.

▶ **Lemma 8** (Mixing CTS)**.** *There exists a CTS that routes $w_{S_i} \xrightarrow{w_S(S_i)} w_S$ for each $i = 1, ..., r$ with congestion $\mathcal{O}(C \log^2 n)$ and approximation $1 + \mathcal{O}(n^{-1})$. The routing table of node v has size $\mathcal{O}(\deg(v) \log^3(nW))$, while path ids and packet headers have length $\mathcal{O}(\log^3(nW))$.*

Proof. For each S_i we route $w_{S_i} \xrightarrow{w_S(S_i)} \text{out}_{S_i}$ *within* S_i using Lemma 7 for weights $c := w_{S_i}$. This has congestion $\mathcal{O}(C)$, as $w_S(S_i) = \text{out}(S_i)$. It uses space only within S_i, so $\mathcal{O}(\deg(v) \log(nW))$ per node $v \in S$.

In total, the packets are now in distribution $\sum_i \text{out}_{S_i} = w_S$ and we apply Lemma 6 with $c := w_S$. (Here we do not use that Lemma 6 gives a deterministic CTS.) As all source nodes route to w_S concurrently, we route $\text{out}_{S_i} \xrightarrow{w_S(S_i)} w_S$ for each $i = 1, ..., r$ (with approximation $1 + \mathcal{O}(n^{-1})$). This has congestion $\mathcal{O}(C \log^2 n)$.

For the bounds on space, the costs of the latter step dominate. ◀

As for Lemma 6, the source node of a packet already determines the commodity, so there is no need to specify an encoding for it.

A.2 Constructing an Unmixing CTS

General Graph Embedding

Up until now, we have not used that we have only edges of distinct classes. The next two lemmas concern randomized rounding, which we use to select a small number of paths from a flow without increasing congestion. This uses a probabilistic argument to prove existence, but the choice of paths is fixed and not subject to randomness.

Consider some flow f sending k packets from a source node u to a node v with congestion 1, where the flow involves only edges of weight 1. It is obvious that taking a single path with weight k from that flow uniformly at random increases the congestion to k, while taking k paths with weight one should intuitively work quite well, giving a congestion $1 + \mathcal{O}(\log k)$. This intuition is correct, which we now prove formally.

We call a multi-set of u-v-paths a *path system*. The *class of a path* is the minimum class of its edges, and the *class of a path system* P is the minimum class amongst its paths. To send a packet using a path system P we choose a path uniformly at random. Therefore, if we have multiple path systems $P = \{P_1, ..., P_k\}$ with demands $d = \{d_1, ..., d_k\}$, then their total congestion is $\text{cong}(P, d) := \text{cong}(\{d_i p/|P_i| : i \in \{1, ..., k\}, p \in P_i\})$.

▶ **Lemma 9** (Randomized rounding). *Let $P = \{P_1, ..., P_k\}$ denote a set of path systems with demands d. Then there exists a set $P' = \{P'_1, ..., P'_k\}$, with $P'_i \subseteq P_i$ and $|P'_i| \leq \lceil 2^{-l} d_i \rceil$ for each P_i of class l. The congestion is $\text{cong}(P', d) \in \mathcal{O}(\text{cong}(P, d) + \log n)$.*

Proof (omitted). The proof can be found in the full version of this paper. ◀

Having the tool of randomized rounding at our disposal, we now turn to the most involved lemma in our construction. If we want to route small demands we can already do so using Lemmata 6 (to get a path system) and 9 (to pick a small number of paths to store). However, routing a demand of size, say, W from node u to v, we would have to pick $2^{-l}W$ paths from a path system $P_{u,v}$ connecting u and v, to ensure low congestion. Here, l is the class of $P_{u,v}$.

Hence, if l is small we would need to route a large number of paths. Instead, we find a cut consisting only of small (i.e., class l) edges separating each path in $P_{u,v}$. [5] These can be used to store routing information.

So we take all pairs (u_i, v_i) in the same situation, that is, connected by a class l path system, and take the union of all the cuts consisting of class l edges. Then we route a single-commodity flow from the nodes u_i to this cut. Of course, the packets from u may have ended up at an edge belonging to some other u_i, so it may not be possible to route to v directly. Instead we send the packets back through the single-commodity flow.

Again, the packets from u may now reside in a different node u'. However, on the way they passed through a class l edge, which we can use for storing the path from u' to v. (To be precise, we use one of the adjacent nodes for storage.) But now we have a new problem – while both $P_{u,v}$ and $P_{u',v'}$ are class l path systems, $P_{u',v}$ need not be. If it has class at least l, all is well and we can route the packet with a single path. Though if it has a class $l' < l$ we have to route using multiple paths again.

The fact that the class keeps decreasing allows us to solve this problem recursively. At each class we split the packet into smaller ones and find an edge to store the routing information for each of them. This stops when the packet is small enough to route directly, at the latest once it has reached size 1.

When we refer to storing the routing information for a node u in some previous node v on the path of a packet, we are using shorthand for a slightly elaborate transformation scheme, which we will refer to as *anticipative routing*. When the packet arrives at node v, the node checks the packet header and adds the stored routing information to it, before sending the packet on its way normally. Then, once the packet has reached the node u the routing information is extracted from the packet header and used.

[5] Note that this is not a cut of the *graph*, which might still be connected, but of the *path system*.

▶ **Lemma 10** (General graph embedding). *Let $G' = (V, A, d)$ denote a weighted, directed graph, where the total weight of incoming and outgoing arcs of a node v is at most $c(v)$, and $\deg_{G'}(v) \in \mathcal{O}(\deg(v) \log^2 n)$. Then there is a CTS that routes $\mathbf{1}_v \xrightarrow{d(u,v)} \mathbf{1}_v$ for each $(u, v) \in A$ with congestion $\mathcal{O}(C \log^2 n \log^2 W)$.*

The routing table of node v has size $\mathcal{O}(\deg(v) C \log^2 n \log W \log^3(nW))$, while packet headers have length $\mathcal{O}(\log^3(nW))$. Commodity $(u, v) \in A$ is encoded as $l \in \{1, ..., \deg_{G'}(u)\}$.

Proof. As mentioned above, the problematic demands are those which need multiple paths to route with low congestion. We will refer to those demands as *large*. More precisely, we call an arc $(u, v) \in A$ *l-large* if $d(u, v) > 2^l$ and l is the class of $P_{u,v}$ (defined below).

The proof will proceed in three parts.

(a) First, we construct path systems $P = \{P_{u,v} : u, v \in V\}$, s.t. all paths in $P_{u,v}$ have the same class and can be routed by storing a $\mathcal{O}(\log^3(nW))$ path id. For any demands d' where both the total incoming and outgoing demand of a node v are at most $c(v)$, we have $\text{cong}(P, d') \in \mathcal{O}(C \log^2 n \log W)$.

(b) Then we show that we can partially route arcs $a \in A$ which are l-large, replacing them with $2^{-l} d(u, v)$ arcs of weight 2^l. This does not change either the total outgoing or incoming demand of any node.

(c) Finally, we construct the CTS and derive the resulting bounds.

Part (a). We use Lemma 6 to construct a *deterministic* concurrent transformation scheme TS_1 routing the PMCF. Hence we can have $P'_{u,v}$ denote the path system containing the paths from u to v, one for each path id. Then we employ Valiant's trick and define $P^*_{u,v}$ as $\bigcup_{w \in V} P'_{u,w} \circ P'_{w,v}$, where $P \circ P'$ is a concatenation of path systems P, P' given by $P \circ P' := \{p \circ p' : p \in P, p' \in P'\}$. That means that we can split a path in $P^*_{u,v}$ into its first and second part.

Now consider some demands d', where the incoming or outgoing demand of any node v is at most $c(v)$. As $\bigcup_{w \in V} P'_{u,w}$ are all outgoing paths of u, sampling one u.a.r. is equivalent to sending a packet with TS_1 from u. So the first parts create the same congestion as TS_1, given that $\sum_v d(u, v) \leq c(v)$. To be precise, the congestion increases by a factor of $1 + \mathcal{O}(n^{-1})$, the approximation guaranteed by Lemma 6. This is only a constant factor, so we are going to disregard it.

The intermediate node w follows distribution c. The second parts, i.e., the paths from $P'_{w,v}$ then have weight $\sum_u c(w) d(u, v) \leq c(w) c(v)$. Routing a packet from w using TS_1 chooses a path from $P'_{w,v}$ with weight $\bar{c}(v)$, so we also bound the congestion based on TS_1.

In total we get $\text{cong}(P^*, d') \leq 2 \,\text{cong}(TS_1, c) \in \mathcal{O}(C \log^2 n)$. Finally, we want to modify $P^*_{u,v}$ so that it only contains paths of one class. We simply pick a class l with the maximum number of paths in $P^*_{u,v}$, and set $P_{u,v} := \{p \in P^*_{u,v} : p \text{ has class } l\}$. As there are N_{class} classes, we have $|P^*_{u,v}| \leq |P_{u,v}| N_{\text{class}}$ and the congestion increases by $\mathcal{O}(\log W)$.

Each path in $P_{u,v}$ is the concatenation of two paths from TS_1, so we can store two path ids of TS_1 to route it.

Part (b). We choose the highest class l where the set A' of l-large arcs is non-empty. Additionally, we introduce $\text{str} : A \to V$, which is the node that will be used to store the routing information for an arc. Initially, $\text{str}(u, v) = u$.

For any arc $a \in A'$ we define $d'(a)$ as the largest multiple of 2^l s.t. $d'(a) \leq d(a)$, and then set $d := d - d'$. So when routing a, a coin is flipped. With weight $d(a)$ we route using a (how precisely is yet to be determined), with weight $d'(a)$ we do the following procedure.

For all $(u, v) \in A'$ the path system $P_{u,v}$ has class l. Using Lemma 9 with demands d', we find a set of $d'(u, v)2^{-l}$ class l paths from u to v for $(u, v) \in A$, with congestion $\mathcal{O}(C \log^2 n \log W)$. We let M denote the set of prefixes of these paths, up to (and including) their first class l edge. By treating M them as a flow f, we can construct a transformation scheme TS, using Lemma 3, which has the same congestion.

Going back to the arc a we want to route, we send a packet using TS, with path id chosen uniformly at random. The necessary information for this is stored in $\text{str}(a)$. There are $N := d'(a)2^{-l}$ paths in M for a (and thus path ids of TS). If we put that number of tokens into the source of a and apply TS (one path id per token), they end up at nodes $z_1, ..., z_N$. A node z_i may receive tokens from other demands $a' \in A'$, but at most $\mathcal{O}(\deg(z_i)C \log^2 n \log W)$ in total, as each path ending in z_i in M induces a load of 2^l on a class l edge adjacent to z_i, i.e., a congestion of 1.

We also construct a transformation scheme based on the reverse flow $-f$, to send the tokens back. This does *not* use a random path id, instead a node z_i stores a mapping from incoming to outgoing path ids (any mapping is fine). We remark that the tokens of a may not end up where they started, as routing through a single-commodity flow mixes packets arbitrarily.

To summarize, an arc $a =: (u, v)$ has sent out N tokens, each of which corresponds to 2^l flow from $d'(a)$. Each token traversed an intermediate node z_i to end up at a node u'. Node z_i was passed by a low number of tokens in total. So now we add a new arc $a' := (u', v)$ to A, with demand $d(a') := 2^l$. Crucially, the routing information for a' is stored in z_i, i.e., $\text{str}(a') := z_i$.

As a technical detail we note that we allow for parallel arcs in G'. It is important that we do not merge multiple small demands into a larger one, as we have already ensured sufficient storage space for each, which would be lost.

The tokens are routed through f and then $-f$, so the number of tokens starting and ending at u is the same. This implies that both the total outgoing and incoming demand of any node remain unchanged.

As mentioned above, this procedure uses anticipative routing. For demand a we send N packets from u, each of which follows a deterministic path. So the intermediate node z_i assigns the packet the specific path id sending it to u' as well as the (yet to be determined) information on how to proceed from there. At u' the node does not have to look up the packet header in its routing table, but merely execute the information contained within.

Part (c). First, we apply (b) at most N_{class} times to eliminate all large arcs. Note that while (b) introduces new arcs, these have demand 2^l, where l is maximum class s.t. l-large arcs exist. So the new demands can only be l'-large for an $l' < l$.

Now we route the remaining arcs. Those are not large, so we can use Lemma 9 to pick a single path from $P_{u,v}$ for each $(u, v) \in A$. Based on our construction in (a), each path in $P_{u,v}$ can be routed using a $\mathcal{O}(\log^3(nW))$ path id. This will be stored in $\text{str}(u, v)$.

For the initial arcs, we store their path ids within their respective source nodes together with their (encoded) commodity.

Finally, we analyze the congestion and space requirements.

Each use of (b) creates congestion of $\mathcal{O}(C \log^2 n \log W)$, due to embedding two flows. Routing the non-large arcs at the end creates the same congestion (though only once). So in total we have a congestion of $\mathcal{O}(C \log^2 n \log^2 W)$.

In total, each node v is used at most $\deg_{G'}(v) \in \mathcal{O}(\deg(v) \log^2 n)$ times for storage due to our initial demands, and then at most $\cdot\mathcal{O}(C \log^2 n \log W)$ times for each adjacent class l edge when executing (b) for class l. Storing routing information for a large arc needs $\mathcal{O}(\log(nW))$

additional space to store the number of tokens and the range of path ids for them. This is dominated by the $\mathcal{O}(\log^3(nW))$ sized path id we need for both large and non-large arcs. (Recall that a large demand is first split into a fractional part and a multiple of 2^l.)

To embed the flows in (b) using Lemma 3, we need a total of $\mathcal{O}(\deg(v)\log(nW)\log W)$ space per node v for the routing tables, and transformation scheme in (a) from Lemma 6 uses $\mathcal{O}(\deg(v)\log^3(nW)))$ space. Summing everything up, we get $\mathcal{O}(\deg(v)C\log^2 n\log^2 W\log^3(nW))$.

Regarding packet headers, we need packet headers of Lemmata 3 and 6, as well as some additional space for our anticipative routing (at most $\mathcal{O}(\log^3(nW)))$. In total we get $\mathcal{O}(\log^3(nW))$. ◀

We want to remark on a slight technicality in the previous proof. Usually, scaling the routed distributions by some constant factor will scale the congestion by the same and nothing of importance has changed. However, the proof argues that there is a bound on the space used for each node, based on the congestion. Scaling the routed distribution to decrease congestion does actually affect this bound, so we could try scaling the congestion even lower. Though, as it turns out it is not possible to get a congestion below $\mathcal{O}(C\log^2 n\log W)$ as that is the minimum when fixing a single path provided by part (a). Using a fractional path would indeed have lower congestion, but not take up less space.

Hypercube embedding

Similar to Räcke and Schmid [22], we embed a hypercube. However, as mentioned earlier, we use a hypercube for each class l of edges and each hypercube id we assign has weight 2^l, i.e., a node $v \in S$ gets roughly $\mathrm{maj}_S^{(l)}(v)/2^l$ hypercube ids. The construction proceeds in a similar manner as the one of Räcke and Schmid up until the embedding of the hypercube edges, where we use Lemma 10 instead of simple randomized rounding.

The details can be found in the full version of this paper.

▶ **Lemma 11** (Hypercube embedding). *Let S be an arbitrary cluster with children $S_1, ..., S_r$. There exists a compact CTS that routes $\mathrm{maj}_S^{(l)} \xrightarrow{w_S(S_i)} \mathrm{out}_{S_i}^{(l)}$ for each S_i of class l with approximation 2 and congestion $\mathcal{O}(C\log^3 n\log^3 W)$.*

The routing table of node v has size $\mathcal{O}(\deg(v)C\log^2 n\log W\log^3(nW))$, while packet headers have length $\mathcal{O}(\log^3(nW))$. There exists a numbering of $S_1, ..., S_r$ s.t. commodity S_i is encoded as integer i.

Unmixing CTS

Given the hypercube embedding from the last lemma, we can now construct the unmixing CTS. At the beginning we need to ensure that we move to the distribution for the correct class, then we move through the (class specific) hypercube, and finally we go to the target distribution.

▶ **Lemma 12** (Unmixing CTS). *There exists a CTS that routes $w_S \xrightarrow{w_S(S_i)} w_{S_i}$ for each $i = 1, ..., r$ with congestion $\mathcal{O}(C\log^3 n\log^3 W)$. The routing table of node v has size $\mathcal{O}(\deg(v)C\log^2 n\log W\log^3(nW))$, while packet headers have length $\mathcal{O}(\log^3(nW))$. There exists a numbering of $S_1, ..., S_r$ s.t. commodity S_i is encoded as integer i.*

Proof. The numbering of child clusters and our path ids are the same as for Lemma 11. Therefore we can determine the class l of S_i based on its index, as shown in the proof of that lemma.

For a child S_i with class l we want to route $w_S \to \mathrm{maj}_S^{(l)} \to \mathrm{out}_{S_i}^{(l)} \to \mathrm{out}_{S_i}$.

(1) For each class l let $M \subseteq S$ denote the union of class l child clusters. We route $w_S \xrightarrow{w_S(M)} \operatorname{maj}_S^{(l)}$ using Lemma 7 with congestion $C \cdot w_S(M)/\operatorname{maj}_S^{(l)}(M)$. This is at most CN_{class}, as $\operatorname{maj}_S^{(l)}(S_i) = \operatorname{out}_{S_i}^{(l)}(S_i) \geq w_S(S_i)/N_{\text{class}}$ for each child S_i with class l.

(2) We use Lemma 11 once, to route $\operatorname{maj}_S^{(l)} \xrightarrow{w_S(S_i)} \operatorname{out}_{S_i}^{(l)}$, with congestion $\mathcal{O}(C \log^3 n \log^3 W)$.

(3) For each S_i we route $\operatorname{out}_{S_i}^{(l)} \xrightarrow{w_S(S_i)} \operatorname{out}_{S_i}$ *within* S_i using Lemma 7. Here we have congestion $C \cdot w_S(S_i)/\operatorname{out}_{S_i}^{(l)}(S_i) \leq CN_{\text{class}}$.

Note that (1) has to be implemented on the whole cluster for each class, so its total congestion is $\mathcal{O}(C \log^2 W)$ (but still lower than step (2)). For the bounds on size of routing tables and length of packet headers, the costs of step (2) dominate. ◀

A.3 Combining the Results

Lemma 11 can be used directly as a drop-in replacement in the original result in [22].

The key idea is routing between two nodes u and v using the decomposition tree, spreading out a packet according to distribution w_S in each cluster. This ensures that routing within a cluster can be done with low congestion. Moving through the tree, the congestion is determined by the bottlenecks out_S. However, the optimal algorithm has to send the packets through these bottlenecks as well, so we remain competitive.

▶ **Theorem 13.** *There exists a compact oblivious routing scheme with competitive ratio* $\mathcal{O}(\log^6 n \log^3 W)$*, using a routing table of length* $\mathcal{O}(\deg(v) \log^5 n \log W \log^3(nW))$ *for a node* $v \in V$*, packet headers of length* $\mathcal{O}(\log^3(nW))$*, and node labels of length at most* $\mathcal{O}(\operatorname{height}(T) \log \deg(T))$*.*

Proof (omitted). The proof can be found in the full version of this paper. ◀

▶ **Corollary 14.** *Assume* $W \in \mathcal{O}(\operatorname{poly}(n))$*. Then there exists a compact oblivious routing scheme with competitive ratio* $\mathcal{O}(\log^9 n)$*, using a routing table of length* $\mathcal{O}(\deg(v) \log^9 n)$ *for a node* $v \in V$*, packet headers of length* $\mathcal{O}(\log^3 n)$ *and node labels of length* $\mathcal{O}(\log^2 n)$*.*

Approximation Algorithms for Clustering with Dynamic Points

Abstract

In many classic clustering problems, we seek to sketch a massive data set of n points (a.k.a *clients*) in a metric space, by segmenting them into k categories or clusters, each cluster represented concisely by a single point in the metric space (a.k.a. the cluster's *center* or its *facility*). The goal is to find such a sketch that minimizes some objective that depends on the distances between the clients and their respective facilities (the objective is a.k.a. the *service cost*). Two notable examples are the k-center/k-supplier problem where the objective is to minimize the maximum distance from any client to its facility, and the k-median problem where the objective is to minimize the sum over all clients of the distance from the client to its facility.

In practical applications of clustering, the data set may evolve over time, reflecting an evolution of the underlying clustering model. Thus, in such applications, a good clustering must simultaneously represent the temporal data set well, but also not change too drastically between time steps. In this paper, we initiate the study of a dynamic version of clustering problems that aims to capture these considerations. In this version there are T time steps, and in each time step $t \in \{1, 2, \ldots, T\}$, the set of clients needed to be clustered may change, and we can move the k facilities between time steps. The general goal is to minimize certain combinations of the service cost and the facility movement cost, or minimize one subject to some constraints on the other. More specifically, we study two concrete problems in this framework: the Dynamic Ordered k-Median and the Dynamic k-Supplier problem. Our technical contributions are as follows:

- We consider the Dynamic Ordered k-Median problem, where the objective is to minimize the weighted sum of ordered distances over all time steps, plus the total cost of moving the facilities between time steps. We present one constant-factor approximation algorithm for $T = 2$ and another approximation algorithm for fixed $T \geq 3$.
- We consider the Dynamic k-Supplier problem, where the objective is to minimize the maximum distance from any client to its facility, subject to the constraint that between time steps the maximum distance moved by any facility is no more than a given threshold. When the number of time steps T is 2, we present a simple constant factor approximation algorithm and a bi-criteria constant factor approximation algorithm for the outlier version, where some of the clients can be discarded. We also show that it is NP-hard to approximate the problem with any factor for $T \geq 3$.

1 Introduction

Clustering a data set of points in a metric space is a fundamental abstraction of many practical problems of interest and has been subject to extensive study as a fundamental problem of both machine learning and combinatorial optimization. In particular, cluster analysis is one of the main methods of unsupervised learning, and clustering often models facility location problems.[1] More specifically, some of the most well-studied clustering problems involve the following generic setting. We are given a set C of points in a metric space, and our goal is to compute a set of k centers that optimizes a certain objective function which involves the distances between the points in C and the computed centers. Two prominent examples are the k-median problem and the k-center problem. They are formally defined as follows. Let S denote the computed set of k cluster centers, let $d(j,S) = \min_{i\in S} d(i,j)$ be the minimum distance from a point $j \in C$ to S, and let $D = (d(j,S))_{j\in C}$ be called the *service cost vector*. The k-median problem aims to minimize the L_1 objective $\|D\|_1 = \sum_{j\in C} d(j,S)$ over the choices of S, and the k-center aims to minimize the L_∞ objective $\|D\|_\infty = \max_{j\in C} d(j,S)$. In general metric spaces and when k is not a fixed constant, both problems are APX-hard and exhibit constant factor approximation algorithms [4, 6, 12, 23, 30]. An important generalization is the *ordered k-median* problem. Here, in addition to C and k, we are given also a non-increasing weight vector $w \in \mathbb{R}^{|C|}_{\geq 0}$. Letting $D^\downarrow$ denote the sorted version of D in non-increasing order, the objective of ordered k-median is to minimize $w \cdot D^\downarrow$. This problem generalizes both k-center and k-median and has attracted significant attention recently and several constant factor approximation algorithms have been developed [3, 7, 9, 10].

In this paper, we study several dynamic versions of the classical clustering problems, in which the points that need to be clustered may change for each time step, and we are allowed to move the cluster centers in each time step, either subject to a constraint on the distance moved, or by incurring a cost proportional to that distance. These versions are motivated in general by practical applications of clustering, where the data set evolves over time, reflecting an evolution of the underlying clustering model. Consider, for instance, a data set representing the active users of a web service, and a clustering representing some meaningful segmentation of the user base. The segmentation should be allowed to change over time, but if it is changed drastically between time steps, then it is probably meaningless. For a more concrete example, consider the following application scenario. There is a giant construction company with several construction teams working in a city. The company has k movable wireless base stations for their private radio communication, and each construction team also has a terminal device. The teams need to put their devices at a certain energy level, in order to maintain the communication channel between the device and the nearest base station. Some construction team may finish some project and move to another place at

[1] In the facility location literature, points are called clients and centers are called facilities, and we will use these terms interchangeably.

some time. Note that the wireless base stations are also movable at a certain expense. Our high level objective is to have all teams covered by the base stations at all times, meanwhile minimizing the energy cost of all teams plus the cost of moving these base stations.

We study two problems of this flavor. The first problem, a dynamic version of the *ordered k-median* problem, is a very general model that captures a wide range of dynamic clustering problems where the objective is to minimize the sum of service cost and movement cost. In particular, it generalizes dynamic versions of k-center and k-median. The problem is defined as follows. We are given a metric space and there are T time steps. In each time step t, there is a set C_t of clients that we need to serve. In each time step, we can also choose the locations for k movable facilities to serve the clients (each client is served by its closest facility). Our goal is to minimize the total ordered service distance (i.e., the ordered k-median objective), summed over all times steps, plus the total distances traveled by the k movable facilities. We define the problem formally as follows.

▶ **Definition 1** (Dynamic Ordered k-Median). *We are given a metric space (X, d). An instance of Dynamic Ordered k-Median is specified by $(\{C_t\}_{t=1}^T, \{F_t\}_{t=1}^T, \{w_t \in \mathbb{R}_{\geq 0}^{|C_t|}\}_{t=1}^T, \gamma > 0, k \in \mathbb{N}_+)$, where $T \geq 2$ is a constant integer, $C_t \subset X$ is the set of clients for time t, $F_t \subset X$ is the set of candidate locations where we can place facilities. For a vector v, denote by $v^{\downarrow}$ the vector derived from v by sorting its entries in non-increasing order. Also denote by $m(X, Y) = \min_{M_0 \in M(X,Y)} \sum_{(i,i') \in M_0} d(i, i')$ the total weight of minimum-weight perfect matching between two equal-sized multi-sets X, Y. We are required to compute a sequence of multi-sets of facilities $\{A_t\}_{t=1}^T$ with $A_t \subset F_t, |A_t| = k$, so that the following sum of ordered service cost and movement cost is minimized:*

$$\sum_{t=1}^{T} w_t \cdot (d(j, A_t))_{j \in C_t}^{\downarrow} + \gamma \cdot \sum_{t=1}^{T-1} m(A_t, A_{t+1}). \tag{1}$$

It is also natural to formulate dynamic clustering problems where the objective is to minimize just the service cost, subject to a constraint on the movement cost. This turns out to be technically very different from Dynamic Ordered k-Median. Our second problem, which we call Dynamic k-Supplier, is such a concrete problem, motivated by the above-mentioned construction company application. In this problem the service cost is the k-supplier objective, i.e. the maximum client service distance over all time steps, and the constraints are that any facility cannot be moved further than a fixed value $B > 0$ between any two consecutive time steps. More formally:

▶ **Definition 2** (Dynamic k-Supplier). *We are given a metric space (X, d). An instance of Dynamic k-Supplier is specified by $(\{C_t\}_{t=1}^T, \{F_t\}_{t=1}^T, B > 0, k \in \mathbb{N}_+)$, where $T \geq 2$ is the number of time steps, $C_t \subset X$ is the set of clients for time t, $F_t \subset X$ is the set of candidate locations where we can place facilities. We are required to compute a sequence of multi-sets of facilities $\{A_t\}_{t=1}^T$, with $A_t \subset F_t$, $|A_t| = k$, minimizing the maximum service cost of any client $\max_t \max_{j \in C_t} d(j, A_t)$, subject to the constraint that there must exist a one-to-one matching between A_t and A_{t+1} for any t, such that the distance between each matched pair is at most B.*

In the outlier version, we are additionally given the outlier constraints $\{l_t \in \mathbb{N}\}_{t=1}^T$. We are asked to identify a sequence of multi-sets of facilities $\{A_t\}_{t=1}^T$, as well as a sequence of subsets of served clients $\{S_t \subset C_t\}_{t=1}^T$. The goal is to minimize the maximum service cost of any served client $\max_t \max_{j \in S_t} d(j, A_t)$, with the constraints that $A_t \subset F_t, |A_t| = k, |S_t| \geq l_t$, and there must exist a one-to-one matching between A_t and A_{t+1} for any t, such that the distance between each matched pair is at most B.

Note. The solutions for both Dynamic Ordered k-Median and Dynamic k-Supplier may be multi-sets, since we allow multiple centers to travel to the same location.

1.1 Our Results

We first study Dynamic Ordered k-Median. We assume the number of time steps T is a constant and all entries of the weight vector are larger than some small constant $\epsilon > 0$. We present a polynomial-time approximation on general metrics. Moreover, if $T = 2$ we present a constant-factor approximation algorithm without the assumption on the entries of the weight vectors.

▶ **Theorem 3.** 1. *If $T = 2$, for any constant $\delta > 0$ there exists a polynomial-time $(48 + 20\sqrt{3} + \delta)$-approximation for Dynamic Ordered k-Median.*
2. *If $T \geq 3$ is a constant and all entries in $\{w_t\}_{t=1}^{T}$ are at least $\epsilon > 0$, for any constant $\delta > 0$ there exists a polynomial-time $(48 + 20\sqrt{3} + \delta + 6\gamma/\epsilon)$-approximation algorithm for Dynamic Ordered k-Median.*

Our techniques. The key idea in our algorithm is to design a surrogate relaxed LP as in [7] and embed the fractional LP solution in a network flow instance. We then proceed to round the fractional flow to an integral flow, thus obtaining the integral solution. The network is constructed based on a filtering process introduced by Charikar and Li [12]. We also adapt the oblivious clustering arguments by Byrka et al. [7], but with a slight increase in approximation factors due to the structure of our network flow.

Our approach can also give a constant approximation to the facility-weighted minimum total movement mobile facility location problem (facility-weighted TM-MFL), with a simpler analysis than the previously known local-search based algorithm [1], which achieves an approximation factor of $3 + O(\sqrt{\log \log p / \log p})$ for a p-Swap algorithm. The following result is also an improvement over the previously proven factor 499 in [1] when $p = 1$. For more details, we direct the interested readers to the full version of the paper and [1].

▶ **Theorem 4.** *There exists a polynomial-time 10-approximation algorithm for facility-weighted minimum total movement mobile facility location problem.*

As a second result, we consider Dynamic k-Supplier and its outlier version. We show that if $T \geq 3$, it is not possible to obtain efficient approximation algorithms for Dynamic k-Supplier with *any* approximation factor, unless P = NP, via a simple reduction from perfect 3D matching [27]. However, for the case of $T = 2$, we present a flow-based 3-approximation, which is the best possible factor since vanilla k-supplier is NP-hard to approximate within a factor of $(3 - \epsilon)$ for any constant $\epsilon > 0$ [24].

▶ **Theorem 5.**
1. *There exists a 3-approximation for Dynamic k-Supplier when $T = 2$.*
2. *There is no polynomial time algorithm for solving Dynamic k-Supplier with any approximation factor if $T \geq 3$, unless $P = NP$.*

We also study the outlier version of the problem for $T = 2$. In the outlier version, we can exclude a certain fraction of the clients as outliers in each time step. We obtain a bi-criteria approximation for the problem.

▶ **Theorem 6.** *For any constant $\epsilon > 0$, there exists a bi-criteria 3-approximation algorithm for Dynamic k-Supplier with outliers when $T = 2$, that outputs a solution which covers at least $(1 - \epsilon)l_t$ clients within radius $3R^*$ at time t, where $t = 1, 2$ and R^* is the optimal radius.*

Our techniques. We first guess a constant-size portion of facilities in the optimal solution, remove these facilities and solve the LP relaxation of the remaining problem. This guessing step is standard as in multi-objective optimizations in [20]. From the LP solution, we form clusters as in Harris et al. [22], cast the outlier constraints as budget constraints over the LP solution, and finally round the fractional LP solution to an integral solution using the budgeted optimization methods by Grandoni et al. [20]. Note that since our outlier constraints translate naturally to budget lower bounds, and our optimization goal is minimization, we are only able to achieve bi-criteria approximations instead of pure approximations. For more details, please refer to the full version of this paper.

1.2 Other Related Work

The ordered k-median problem generalizes a number of classic clustering problems like k-center, k-median, k-facility l-centrum, and has been studied extensively in the literature. There are numerous approximation algorithms known for its special cases. We survey here only the results most relevant to our work (ignoring, for instance, results regarding restricted metric spaces or fixed k). Constant approximations for k-median can be obtained via local search, Lagrangian relaxations and the primal-dual schema, or LP-rounding [4, 6, 25, 26]. Constant approximations for k-center are obtained via greedy algorithms [23]. Aouad and Segev [3] employ the idea of surrogate models and give the first $O(\log n)$-approximation for ordered k-median. Later, Byrka et al. [7], Chakrabarty and Swamy [9] both successfully design constant-factor approximations for k-facility l-centrum and ordered k-median. Chakrabarty and Swamy [10] subsequently improve the approximation factor for ordered k-median to $(5+\epsilon)$, using deterministic rounding in a unified framework.

The outlier setting of clustering problems, specifically for center-type clustering problems, was introduced by Charikar et al. [11] and later further studied by Chakrabarty et al. [8]. Many other variants of different clustering constraints are also extensively studied, including matroid and knapsack center with outliers [13], and fair center-type problems with outliers [22].

Our problems are closely related to the mobile facility location problems (MFL), introduced by Demaine et al. [16]. In these problems, a static set of clients has to be served by a set of facilities that are given initial locations and can be moved to improve the service cost at the expense of incurring a facility movement cost. For the minimum total movement MFL problem (TM-MFL), Friggstad and Salavatipour [18] give an 8-approximation using LP-rounding, where all facilities have unit weights. Ahmadian et al. [1] give a local search algorithm for TM-MFL with weighted facilities using p-swaps with an approximation ratio of $3+O(\sqrt{\log\log p/\log p})$, and specifically show that the approximation ratio is at most 499 for $p=1$.

The dynamic formulations of our problems are closely related to the facility location problem with evolving metrics, proposed by Eisenstat et al. [17]. In this problem, there are also T time steps, while the facilities and clients are fixed, and the underlying metric is changing. The total cost is the sum of facility-opening cost, client-serving cost and additional switching costs for each client. The switching cost is paid whenever a client switches facility between adjacent time steps. In comparison, our problem Dynamic k-Supplier considers the cost of moving facilities instead of opening costs, and allows the number of clients to change over time. Eisenstat et al. [17] consider the problem when the open facility set A is fixed, and give a $O(\log(nT))$-approximation, where n is the number of clients. They also show a hardness result on $o(\log T)$-approximations. An et al. [2] consider the case when the open facilities are allowed to evolve as well, and give a 14-approximation.

Our problem is also related to stochastic k-server [15] and the page migration problem [5, 32]. Dehghani et al. [15] first study the *stochastic k-server* problem. In this problem, we also have T time steps, and the distributions $\{P_t\}_{t\in[T]}$ are given *in advance*. The t-th client is drawn from P_t, and we can use k movable servers. One variant they consider is that, after a client shows up, its closest server goes to the client's location and comes back, and the optimization objective is the total distance travelled by all servers. They provide an $O(\log n)$-approximation for general metrics, where n is the size of the distribution support. In expectation, their objective is the same as in Dynamic Ordered k-Median, if we consider non-ordered weighted clients and total weights sum up to 1 for each time slot. However, we note that our result does not imply a constant approximation for their problem. The difficulty is that if one maps the stochastic k-server problem to our problem, the corresponding weight coefficient γ is not necessarily a constant and our approximation ratio is proportional to γ. Obtaining a constant factor approximation algorithm for stochastic k-server is still an interesting open problem.

2 A Constant Approximation for Dynamic Ordered k-Median

We devise an LP-based algorithm, which generalizes the oblivious-clustering argument by Byrka et al. [7]. At the center of our algorithm, a network flow method is used, where an integral flow is used to represent our solution.

2.1 Flow-based Rounding of LP Solution

We first formulate the LP relaxation. By adding a superscript to every variable to indicate the time step, we denote $x_{ij}^{(t)} \in [0,1]$ the partial assignment of client j to facility i and $y_i^{(t)} \in [0,1]$ the extent of opening facility location i at time step t. Moreover, denote $z_{ii'}^{(t)}$ the fractional movement from facility i to facility i', between neighboring time steps t and $t+1$.

The following surrogate LP is designed using the cost reduction trick by Byrka et al. [7]. When the reduced cost functions are exactly guessed, the LP relaxation has an objective value at most the total cost of the optimal solution, denoted by OPT. Call $d' : X \times X \to R_{\geq 0}$ a reduced cost function (not necessarily a metric) of distance function d, if for any $x, y \in X$, $d'(x,y) \geq 0$, $d'(x,y) = d'(y,x)$, and $d(x_1,y_1) \leq d(x_2,y_2) \Rightarrow d'(x_1,y_1) \leq d'(x_2,y_2)$. For a sequence of reduced cost functions $\mathfrak{D} = \{d^t\}_{t=1}^T$ of d, the modified LP relaxation is defined as follows.

$$\text{minimize}: \sum_{t=1}^{T}\sum_{j\in C_t}\sum_{i\in F_t} d^t(i,j)x_{ij}^{(t)} + \gamma\sum_{t=1}^{T-1}\sum_{i\in F_t}\sum_{i'\in F_{t+1}} d(i,i')z_{ii'}^{(t)} \qquad \mathsf{LP}(\mathfrak{D})$$

$$\text{subject to}: \sum_{i\in F_t} x_{ij}^{(t)} = 1, \quad \forall j \in C_t, t \in [T] \tag{2}$$

$$\sum_{i\in F_t} y_i^{(t)} = k, \quad \forall t \in [T] \tag{3}$$

$$0 \leq x_{ij}^{(t)} \leq y_i^{(t)}, \quad \forall i \in F_t, j \in C_t, t \in [T] \tag{4}$$

$$\sum_{i'\in F_{t+1}} z_{ii'}^{(t)} = y_i^{(t)}, \quad \forall i \in F_t, t \in [T-1] \tag{5}$$

$$\sum_{i\in F_t} z_{ii'}^{(t)} = y_{i'}^{(t+1)}, \quad \forall i' \in F_{t+1}, t \in [T-1] \tag{6}$$

Suppose we have solved the corresponding surrogate $\mathsf{LP}(\mathfrak{D})$. In the optimal solution (x, y, z), we assume that whenever $x_{ij}^{(t)} > 0$, we have $x_{ij}^{(t)} = y_i^{(t)}$, via the standard duplication technique of facility locations (for example, see [12]). Denote $\mathsf{Ball}^o(j, R) = \{x \in X : d(x, j) < R\}$ the open ball centered at j with radius R, and $E_j^{(t)} = \{i \in F_t : x_{ij}^{(t)} > 0\}$ the relevant facilities for client j. For any specific time step t, denote $d_{\mathsf{av}}^{(t)}(j) = \sum_{i \in F_t} d(i, j) x_{ij}^{(t)}$ the average *unweighted* service cost of client j and $y^{(t)}(S) = \sum_{i \in S} y^{(t)}(i)$ the amount of fractional facilities in $S \subset F_t$. We perform a filtering-and-matching algorithm (see the full version of this paper) to obtain a subset $C_t' \subset C_t$ for each t, a bundle $\mathcal{U}_j^{(t)} \subset F_t$ for each $j \in C_t'$, as well as P_t a partition of C_t', where

1. C_t' is a subset of "well-separated" clients of C_t, such that for any client in $C_t \backslash C_t'$, there exists another relatively close client in C_t'. To be more precise, for any $j \neq j'$ in C_t', $d(j, j') \geq 4 \max\{d_{\mathsf{av}}^{(t)}(j), d_{\mathsf{av}}^{(t)}(j')\}$, and for any $j'' \in C_t \backslash C_t'$, there exists $j''' \in C_t'$ such that $d_{\mathsf{av}}^{(t)}(j''') \leq d_{\mathsf{av}}^{(t)}(j''), d(j'', j''') \leq 4 \max\{d_{\mathsf{av}}^{(t)}(j''), d_{\mathsf{av}}^{(t)}(j''')\}$;
2. $\mathcal{U}_j^{(t)}$ is a subset of fractionally open facility locations that are relatively close to client j;
3. P_t is a judiciously created partition of C_t', where every subset contains either a pair of clients, or a single client. Each pair $\{j, j'\}$ in P_t is chosen such that either j or j' is the closest neighbor of the other, and we guarantee to open a facility location in $\mathcal{U}_j^{(t)}$ or $\mathcal{U}_{j'}^{(t)}$.

The filtering-and-matching algorithm is fairly standard in several LP-based methods for median-type problems (see e.g. [7, 10, 12]). It is worth noting that, while we define the objective value of $\mathsf{LP}(\mathfrak{D})$ using reduced cost functions $\mathfrak{D}$ with respect to the weights, the filtering algorithm is completely oblivious of the weights and only uses the underlying metric d.

Network construction. We construct an instance of network flow $\mathcal{N}$, and embed the LP solution as a fractional flow $\tilde{f}$. The network $\mathcal{N}$ consists of a source s, a sink t and $6T$ intermediate layers $L_1, L_2, \ldots, L_{6T}$ arranged in a linear fashion.

For each time step $t \in [T]$, we create two nodes for every pair $p \in P_t$, every bundle $\mathcal{U}_j^{(t)}$ and every candidate facility location $i \in F_t$. All these nodes are contained in the layers $L_{6t-5}, \ldots, L_{6t}$. To distinguish between the two mirror nodes, we use $\mathscr{L}(\cdot)$ and $\mathscr{R}(\cdot)$ to represent the nodes in $\{L_{6t-5}, L_{6t-4}, L_{6t-3}\}$ and the nodes in $\{L_{6t-2}, L_{6t-1}, L_{6t}\}$, respectively. The network is constructed as follows. An example figure is shown in Figure 1.

1. For all $t \in [T]$, add $\mathscr{L}(i)$ to L_{6t-5} and $\mathscr{R}(i)$ to L_{6t} for each $i \in F_t$.
2. For all $t \in [T]$, add $\mathscr{L}(\mathcal{U}_j^{(t)})$ to L_{6t-4} and $\mathscr{R}(\mathcal{U}_j^{(t)})$ to L_{6t-1} for each $\mathcal{U}_j^{(t)}$.
3. For all $t \in [T]$, add $\mathscr{L}(p)$ to L_{6t-3} and $\mathscr{R}(p)$ to L_{6t-2} for each $p \in P_t$.
4. For all $t \in [T], j \in C_t', p \in P_t$ such that $j \in p$, connect $(\mathscr{L}(\mathcal{U}_j^{(t)}), \mathscr{L}(p)), (\mathscr{R}(p), \mathscr{R}(\mathcal{U}_j^{(t)}))$ *in neighboring layers* with an edge of capacity $\left[\lfloor y^{(t)}(\mathcal{U}_j^{(t)}) \rfloor, \lceil y^{(t)}(\mathcal{U}_j^{(t)}) \rceil\right]$. Let their initial fractional flow values be $\tilde{f}(\mathscr{L}(\mathcal{U}_j^{(t)}), \mathscr{L}(p)) = \tilde{f}(\mathscr{R}(p), \mathscr{R}(\mathcal{U}_j^{(t)})) = y^{(t)}(\mathcal{U}_j^{(t)})$. The capacity is either $[0, 1]$ or $\{1\}$.
5. For all $t \in [T], p \in P_t$, connect $(\mathscr{L}(p), \mathscr{R}(p))$ with an edge of capacity $\left[\lfloor y^{(t)}(p) \rfloor, \lceil y^{(t)}(p) \rceil\right]$, and define $\tilde{f}(\mathscr{L}(p), \mathscr{R}(p)) = y^{(t)}(p) = \sum_{j \in p} y^{(t)}(\mathcal{U}_j^{(t)})$. If p is a normal pair, the capacity is either $[1, 2]$ or $\{1\}$ or $\{2\}$; if p is a singleton pair, the capacity is either $[0, 1]$ or $\{1\}$.
6. For all $t \in [T], j \in C_t'$ and $i \in \mathcal{U}_j^{(t)}$, connect $(\mathscr{L}(i), \mathscr{L}(\mathcal{U}_j^{(t)})), (\mathscr{R}(\mathcal{U}_j^{(t)}), \mathscr{R}(i))$ *in neighboring layers* with an edge of unit capacity. Let the initial fractional flows be $\tilde{f}(\mathscr{L}(i), \mathscr{L}(\mathcal{U}_j^{(t)})) = \tilde{f}(\mathscr{R}(\mathcal{U}_j^{(t)}), \mathscr{R}(i)) = y_i^{(t)}$.

7. For all $t \in [T]$ but $i \in F_t - \bigcup_{j \in C'_t} \mathcal{U}_j^{(t)}$, connect $(\mathscr{L}(i), \mathscr{R}(i))$ with an edge of unit capacity (*across intermediate layers* $L_{6t-4}, \ldots, L_{6t-1}$). Let its initial fractional flow be $\tilde{f}(\mathscr{L}(i), \mathscr{R}(i)) = y_i^{(t)}$.
8. For all $z_{ii'}^{(t)}, i \in F_t, i' \in F_{t+1}$, connect $(\mathscr{R}(i), \mathscr{L}(i'))$ with an edge of unit capacity. Let its initial fractional flow be $\tilde{f}(\mathscr{R}(i), \mathscr{L}(i')) = z_{ii'}^{(t)}$.

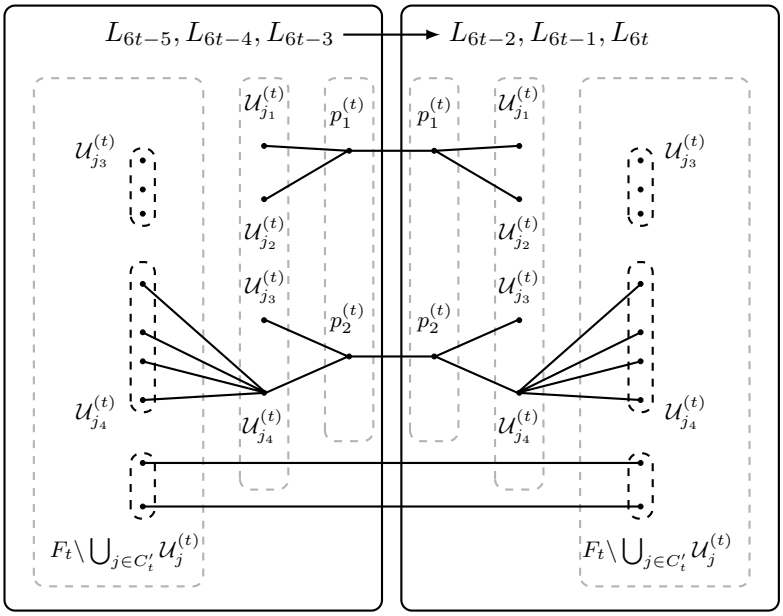

Figure 1 Some intermediate layers of $\mathcal{N}$ representing a single time step t.

Notice $\tilde{f}$ is naturally a flow with value k. Since the flow polytope is defined by a totally unimodular matrix, and our capacity constraints are all integers, it is a well-known result (see e.g. [19]) that we can efficiently and stochastically round $\tilde{f}$ to an integral flow $\bar{f}$, such that $\bar{f}$ is guaranteed to have value k, and $\mathbb{E}[\bar{f}] = \tilde{f}$. Next, given the integral flow $\bar{f}$, we deterministically construct the facilities to open $\{A_t\}_{t \in [T]}$ as follows.

- If $T = 2$, there are 12 layers $L_1, L_2, \ldots, L_{12}$ in the network. For each link $e = (\mathscr{R}(i_1), \mathscr{L}(i_2))$ between L_6 and L_7 such that $\bar{f}(e) = 1$, we add the original facility corresponding to i_1 to A_1, and the original facility of i_2 to A_2.
- If $T \geq 3$, the integral flow $\bar{f}$ may enter L_{6t-5} and exit from L_{6t} at sets of different facility locations. For illustration, denote $A_{t,1}$ the set in L_{6t-5} and $A_{t,2}$ the set in L_{6t}. Notice it may happens that $|A_{t,1} \bigcup A_{t,2}| > k$ and we cannot open them both, so we design an algorithm to find $A_t \subseteq A_{t,1} \bigcup A_{t,2}$ and $|A_t| = k$, and open the facilities in A_t for time t. The algorithm looks at each pair $(j_1, j_2) = p \in P_t$, and consider the 1 or 2 units of flow $\bar{f}$ on the link $(\mathscr{L}(p), \mathscr{R}(p))$. For a facility i, if there is one unit of flow through $\mathscr{L}(i)$ or $\mathscr{R}(i)$, we call the facility i *activated*. But if $\mathscr{L}(i_1)$ and $\mathscr{R}(i_2)$ are activated and $i_1, i_2 \in \mathcal{U}_{j_1}, i_1 \neq i_2$, we only open one of them. The same is true when $i_1 \in \mathcal{U}_{j_1}, i_2 \in \mathcal{U}_{j_2}, i_1 \neq i_2$.
  For each unit flow, our algorithm either always choose i_1 to open where $\mathscr{L}(i_1)$ is activated, or always choose the facility in $\mathcal{U}_{j_2}$ if j_1 is not the closest neighbor of j_2. As a result, we give the following lemma estimating the movement cost, and the detailed algorithm can be found in the full version of this paper.

▶ **Lemma 7.** *Let $d(A, A')$ denote the cost of minimum weight matching between A, A'. If $T = 2$, the expected movement cost of solution $\{A_1, A_2\}$ satisfies*

$$\mathbb{E}[d(A_1, A_2)] = \sum_{i \in F_1} \sum_{i' \in F_2} d(i, i') z^{(1)}_{ii'}.$$

If $T \geq 3$, the expected movement cost of solution $\{A_t\}_{t=1}^T$ after rerouting satisfies

$$\mathbb{E}\left[\sum_{t \in [T-1]} d(A_t, A_{t+1})\right] \leq \sum_{t \in [T-1]} \sum_{i \in F_t} \sum_{i' \in F_{t+1}} d(i, i') z^{(t)}_{ii'} + 6 \sum_{t=1}^{T} \sum_{j \in C_t} d^{(t)}_{\mathsf{av}}(j).$$

2.2 From Rectangular to General Cases

We first provide a lemma to bound the stochastic k-facility l-centrum cost of A_t for any fixed time t. Consequently, the ordered cost can be nicely bounded as well. The proof of the following lemma can be found in the full version of this paper.

▶ **Lemma 8** (adapted from [7]). *Fix $t \in [T]$ and let $m \in \mathbb{N}_+, h > 0$. Define $\mathsf{rect}(a, b)$ the rectangular vector of length b, where the first a elements are 1s and the rest are 0s. For A_t as the (random) set of activated locations returned by our algorithm, and $d(C_t, A_t) = (d(j, A_t))_{j \in C_t}$ as the service cost vector, we have*

$$\mathbb{E}_{A_t}[\mathsf{rect}(m, |C_t|) \cdot d(C_t, A_t)^{\downarrow}] \leq (24 + 10\sqrt{3}) m \cdot h + (24 + 10\sqrt{3}) \sum_{j \in C_t} d^{-h^{(t)}}_{\mathsf{av}}(j),$$

where $d^{-h}(j, j') = 0$ if $d(j, j') < h$ and $d^{-h}(j, j') = d(j, j')$ otherwise. Similar to $d_{\mathsf{av}}(j)$, the average clipped service cost $d^{-h^{(t)}}_{\mathsf{av}}(j)$ is defined as $d^{-h^{(t)}}_{\mathsf{av}}(j) = \sum_{i \in F_t} d^{-h}(i, j) x^{(t)}_{ij}$.

Finally we turn to the generally-weighted case, where the weight vectors $w_t, t \in [T]$ are not necessarily rectangular ones like $\mathsf{rect}(m, |C_t|)$. The guessing of underlying reduced cost functions $\mathfrak{D}$ is exactly the same as in Byrka et al. [7], thus omitted here. We solve $\mathsf{LP}(\mathfrak{D})$ using these induced reduced cost functions and proceed accordingly. The following lemma is similar to that of Lemma 5.1 in Byrka et al. [7], and the proof can be found in the full version of this paper.

▶ **Lemma 9.** *When $T = 2$, the procedure described above is a $(48 + 20\sqrt{3})$-approximation for Dynamic Ordered k-Median.*

If $T \geq 3$ is a constant and the smallest entry in $\{w_t\}_{t=1}^T$ is at least some constant $\epsilon > 0$, the above-described procedure is a $(48 + 20\sqrt{3} + 6\gamma/\epsilon)$-approximation for Dynamic Ordered k-Median.

In both cases, the procedure makes $O\left(\prod_{t=1}^T (|F_t| \cdot |C_t|)^{N_t}\right)$ calls to its subroutines, where N_t is the number of distinct entries in the weight vector w_t, $t \in [T]$.

Fix some positive parameter $\delta > 0$ and recall the distance bucketing trick by Aouad and Segev [3]. When T is a constant, it is possible to guess the largest service distance for each time step by paying a polynomial factor in the running time. Then we make logarithmically many buckets for each time step to hold the service cost values of clients. For each bucket, its average weight is also guessed up to a small multiplicative error $(1 + \delta)$. Since there are at most $O\left(\log_{1+\delta}\left(\frac{n}{\delta}\right)\right) = O\left(\frac{1}{\delta}\log\left(\frac{n}{\delta}\right)\right)$ buckets for each time step, where $n = |F| + |C|$, guessing a non-increasing sequence of the average weights only causes another polynomial factor $\exp\left(O\left(\frac{1}{\delta}\log\left(\frac{n}{\delta}\right)\right)\right) = n^{O(1/\delta)}$. Finally, because T is a constant, the overall number of guesses is still bounded by a polynomial. For more details, see [3, 7].

▶ **Theorem 10.** *When $T = 2$, for any $\delta > 0$ there exists a $(48+20\sqrt{3})(1+\delta)$-approximation algorithm for Dynamic Ordered k-Median, with running time $(|F_1| + |C_1|)^{O(1/\delta)} \cdot (|F_2| + |C_2|)^{O(1/\delta)}$.*

When $T \geq 3$ is a constant, and the smallest entry in $\{w_t\}_{t=1}^T$ is at least some constant $\epsilon > 0$, for any $\delta > 0$ there exists a $\left(48 + 20\sqrt{3} + 6\gamma/\epsilon\right)(1+\delta)$-approximation algorithm for Dynamic Ordered k-Median, with running time $\prod_{t\in[T]} (|F_t| + |C_t|)^{O(1/\delta)}$.

Proof. This is almost a direct consequence of Theorem 5.2 in [7], with the constant factor replaced by our $\mu = 24+10\sqrt{3}$. Notice that we need to slightly modify the way of constructing rounded weights $\{w_t^*\}_{t=1}^T$ in the following way,

$$\forall t \in [T], r \in [|C_t|], w_{tr}^* = \begin{cases} w_{t1} & r = 1, \\ \min\left\{(1+\delta)^{\lceil \log_{1+\delta} w_{tr} \rceil}, w_{t1}\right\} & w_{tr} \geq \epsilon w_{t1}/|C_t|, r \neq 1, \\ \epsilon w_{t1}/|C_t| & w_{tr} < \epsilon w_{t1}/|C_t|, \end{cases}$$

so that the perturbed weight vectors are rounded larger, but at most $(1+\delta)$ times larger in terms of the overall objective, and there are $O(\log_{1+\delta}(|C_t|/\delta))$ different values in w_t^*.

Plugging in the approximations of individual time steps does not affect the analysis of movement costs in the proof of Lemma 9, hence the approximation factor follows. We omit the technical details here due to space limit. They can be be found in Appendix D of [7]. ◀

3 Approximating Dynamic k-Supplier

We present a flow-based algorithm that gives a 3-approximation for Dynamic k-Supplier when $T = 2$, and show it is NP-hard to obtain polynomial-time approximation algorithms for Dynamic k-Supplier with any approximation factor when $T \geq 3$. We also briefly introduce our bi-criteria approximation algorithm for Dynamic k-Supplier with outliers and $T = 2$, while the detailed algorithm and analysis can be found in the full version of this paper.

3.1 A 3-Approximation for Dynamic k-Supplier, $T = 2$

In contrast to the NP-hardness of approximating Dynamic k-Supplier for $T \geq 3$, we consider Dynamic k-Supplier when $T = 2$ on general metrics and present a simple flow-based constant approximation. Suppose we are given the client sets C_1, C_2 and F_1, F_2 as candidate facility locations and the movement constraint is $B > 0$.

First, since the optimal radius R^* is obviously the distance between some client and some facility location, we assume we have successfully guessed the optimal radius R^* (using binary search). Next, we construct the following network flow instance $\mathcal{G}(\mathcal{V}, \mathcal{E})$. $\mathcal{V}$ consists of 4 layers of vertices (two layers $\mathcal{L}^{11}, \mathcal{L}^{12}$ for $t = 1$, two layers $\mathcal{L}^{21}, \mathcal{L}^{22}$ for $t = 2$), a source s and sink t. We define the layers and links in $\mathcal{G}$ as follows:

- For each $i \in F_1$, add a vertex in $\mathcal{L}^{12}$. For $i' \in F_2$, add a vertex in $\mathcal{L}^{21}$.
- Repeatedly pick an arbitrary client $j \in C_1$ and remove from C_1 every client within distance $2R^*$ from j. Denote these clients a new cluster corresponding to j. Since we have guessed the optimal radius R^*, it is easy to see we can get at most k such clusters. And if there are less than k clusters, we create some extra dummy clusters to obtain exactly k clusters, while dummy clusters do not correspond to any client. For each cluster, add a vertex to $\mathcal{L}^{11}$. Repeat this for C_2 and form $\mathcal{L}^{22}$.
- The four layers are arranged in order as $\mathcal{L}^{11}, \mathcal{L}^{12}, \mathcal{L}^{21}, \mathcal{L}^{22}$. With a slight abuse of notation, for $u \in \mathcal{L}^{11}, v \in \mathcal{L}^{12}$, connect them using a link with unit capacity if $d(u, v) \leq R^*$; for $w \in \mathcal{L}^{21}, z \in \mathcal{L}^{22}$, connect them using a link with unit capacity if $d(w, z) \leq R^*$. For $v \in \mathcal{L}^{12}, w \in \mathcal{L}^{21}$, connect them using a link with *unbounded* capacity if $d(v, w) \leq B$.

- Connect every dummy cluster in $\mathcal{L}^{11}$ with every facility location vertex in $\mathcal{L}^{12}$. Connect every dummy cluster in $\mathcal{L}^{22}$ with every facility location vertex in $\mathcal{L}^{21}$. Every such link has unit capacity.
- Finally, the source $\mathtt{s}$ is connected to every vertex in $\mathcal{L}^{11}$ and the sink $\mathtt{t}$ is connected to every vertex in $\mathcal{L}^{22}$, with every edge having unit capacity.

▶ **Lemma 11.** *$\mathcal{G}(\mathcal{V}, \mathcal{E})$ admits a flow of value k. Moreover, we can obtain a feasible solution of cost at most $3R^*$ from an integral flow of value k in $\mathcal{G}(\mathcal{V}, \mathcal{E})$.*

Proof. As an optimal solution with objective R^*, there exist two multi-sets $A_1 \subset F_1, A_2 \subset F_2$ such that $|A_1| = |A_2| = k$ and there exists a perfect matching between them. For any $i \in F_1, i' \in F_2$, if the pair (i, i') appears m times in the perfect matching, define a flow value $f(i, i') = m$ over link (i, i').

Consider the first time step. For any facility location i and clusters j, j', either $d(i, j)$ or $d(i, j')$ is larger than R^*, otherwise $d(j, j') \leq 2R^*$, contradicting with our construction. Because A_1 also covers all $j \in C_1$ with radius R^*, for every $j \in \mathcal{L}^{11}$, we can always find a different element $i \in A_1$ such that $d(i, j) \leq R^*$, and we add a unit flow as $f(j, i) = 1$. The same process is repeated for $\mathcal{L}_{22}$ and A_2.

The total flow between $\mathcal{L}^{12}$ and $\mathcal{L}^{21}$ is now obviously k, since the perfect matching between A_1 and A_2 has size k. After the construction of unit flows for non-dummy clusters, we arbitrarily direct the remaining flows from facility locations to the dummy clusters, one unit each time. Finally, for any cluster with unit flow, define the flow between it and the source/sink to be 1. This completes an integral flow of value k on $\mathcal{G}$.

For the second part, suppose we have an integral flow $\bar{f}$ of value k on $\mathcal{G}$. For any facility location $i \in F_1$, denote $g(i)$ the total flow through i. We place $g(i)$ facilities at location i, and repeat the same procedures for $i' \in F_2$. If $\bar{f}(i, i') = m$ for $i \in F_1, i' \in F_2$, move m facilities from i to i' in the transition between 2 time steps.

For any $j' \in C_1$, if j is the cluster center it belongs to, there exists a facility at most $d(j', i) \leq d(j', j) + d(j, i) \leq 3R^*$ away. ◀

▶ **Theorem 12.** *There exists a 3-approximation for Dynamic k-Supplier when $T = 2$.*

Proof. Consider the network flow instance we construct. It only has integer constraints and the coefficient matrix is totally unimodular. Moreover, there exists a flow of value k due to Lemma 11, hence we can efficiently compute an integral solution $\bar{f}$ of value k, thus obtaining a 3-approximation solution. ◀

3.2 The Hardness of Approximating Dynamic k-Supplier, $T \geq 3$

We show it is NP-hard to design approximation algorithms for Dynamic k-Supplier with any approximation factor when $T \geq 3$. The proof is via reduction from the perfect 3D matching problem, which is known to be NP-Complete [27].

▶ **Theorem 13.** *There is no polynomial time algorithm for solving Dynamic k-Supplier with any approximation factor if $T \geq 3$, unless $P = NP$.*

Proof. We reduce an arbitrary instance of perfect 3D-matching to Dynamic k-Supplier to show the NP-hardness. Recall for an instance of perfect 3D-matching, we are given three finite sets A, B, C with $|A| = |B| = |C|$, and a triplet set $\mathcal{T} \subset A \times B \times C$. Suppose $|A| = n$ and $|\mathcal{T}| = m$, and we are asked to decide whether there exists a subset $\mathcal{S} \subset \mathcal{T}$, such that $|\mathcal{S}| = n$, and each element in A, B, C appears exactly once in some triplet in $\mathcal{S}$. We construct the following graph $G = (V, E)$, where V, E are initially empty.

- For each triplet $g = (a, b, c) \in \mathcal{T}$, add three new vertices a_g, b_g, c_g to V correspondingly. Connect a_g, b_g with an edge of length α. Connect b_g, c_g with an edge of length α.
- Denote V_A all the vertices that correspond to vertices in A. Similarly for V_B and V_C.
- For any two vertices in V_A corresponding to the same element $a \in A$, connect them with an edge of length 1. Repeat the same procedure for V_B, V_C.

Assume we are able to solve Dynamic k-Supplier for $T = 3$ with an approximation factor α. We solve Dynamic k-Supplier for G on its graph metric d_G, with $k = n$ and the movement constraint $B = \alpha$, where the client sets are $\{V_A, V_B, V_C\}$ and facility sets are $\{V_A, V_B, V_C\}$ for the three time steps, respectively.

It is easy to see that the reduced Dynamic k-Supplier instance has covering radius $R^* = 1$ if and only if there exists a perfect 3D-matching, otherwise the covering radius is at least $2\alpha+1$. Since our approximation factor is α, this concludes the NP-hardness of approximation algorithms with any factor for Dynamic k-Supplier when $T \geq 3$. ◀

3.3 A Bi-criteria Approximation for Dynamic k-Supplier with Outliers

Lastly, we present our bi-criteria approximation algorithm that solves Dynamic k-Supplier, when $T = 2$ and outliers are allowed. As a useful ingredient, let us first briefly review the *m-budgeted bipartite matching* problem. The input consists of a bipartite graph $G = (V, E)$, and each edge $e \in E$ is associated with a weight $w(e) \geq 0$ and m types of lengths $f_i(e) \geq 0, i = 1, \ldots, m$. The problem asks for a maximum weight matching M with m budget constraints, where the ith constraint is that the sum of all f_i lengths in M is no more than L_i, i.e. $\sum_{e \in M} f_i(e) \leq L_i$. When the number of constraints m is a constant, a pure $(1 - \epsilon)$-approximation algorithm for any constant $\epsilon > 0$ is devised by Grandoni et al. [20].

Sketch. Due to space limit, we provide a sketch here and defer the details to the full version of this paper. Consider Dynamic k-Supplier with outliers and $T = 2$. In the solution, we place k facilities for time $t = 1$, serving in total at least l_1 clients in C_1, then move each of these facilities for a distance at most B to serve at least l_2 clients in C_2, and the maximum service distance is our minimization goal. Clearly, the optimal solution R^* only has a polynomial number of possible values and can be guessed efficiently, so we assume that R^* is known to us in the following analysis.

For a fixed R^*, denote c_i the number of clients that facility location i can serve within distance R^*. We assign two lengths $f_1(e) = c_i, f_2(e) = c_{i'}$ and weight $w(e) = 1$ for every candidate edge $e = (i, i')$, where $i \in F_1, i' \in F_2$. By duplicating each possible facility location in F_1 and F_2 and only allowing vertices within distance B to be matched, the required solution can be fully represented by a k-cardinality matching M between F_1 and F_2. Let us temporarily assume that any client miraculously contribute only once to the total number of clients served. Then the problem naturally translates to deciding whether there exists a bipartite matching M between F_1 and F_2 (with candidate facility locations duplicated) with weight k, such that the sum of all f_1 lengths in M is at least l_1, and the sum of all f_2 lengths in M is at least l_2.

This new problem is very similar to 2-*budgeted bipartite matching*, but there are still some major differences. In the approximation algorithm in [20], every integral matching M is obtained by first finding a *feasible* fractional matching M', which has at most $2m$ edges being fractional, and then dropping these fractionally-matched edges completely. Back to our problem where $m = 2$. If we obtain such a fractional solution M' which satisfies the constraints and only has at most 4 fractional edges, we would like to find an integral

matching M in a way that uses more "budget" instead of using less, so as to cover at least as many clients as M' does and not violate any budget constraint (in other words, outlier constraints), and we have to drop these fractional edges again from M'.

Contrary to 2-*budgeted bipartite matching*, we want to control the portion of budget dropped in this case. We achieve this by guessing a constant number of edges, which has either the top-θ f_1 lengths or top-θ f_2 lengths in the optimal solution, using a suitably chosen constant $\theta > 0$. We are able to devise a bi-criteria approximation algorithm that violates both budget constraints by any small constant ϵ-portion. The bi-criteria method is developed in line with the multi-criteria approximation schemes in [20].

To fully avoid counting any served client multiple times, whenever we duplicate a facility location, we make sure that only one copy induces non-zero lengths on edges that reside on it. We also use a greedy algorithm to remove some facility locations in F_1, F_2 and form client clusters around the remaining ones. Now, instead of defining c_i as the number of clients that facility location i can serve within distance R^*, we change c_i to the number of clients that are gathered around i. More specifically, for client set C_t and facility location set F_t, we find a subset $F'_t \subset F_t$ and a corresponding sub-partition $\{K_i\}_{i \in F'_t}$ of C_t (i.e., K_is are pair-wise disjoint and their union is a subset of C_t), such that $\forall j \in K_i, d(i,j) \leq 3R^*$ and we define $c_i = |K_i|$ for $i \in F'_t$, $c_i = 0$ for $i \in F_t \backslash F'_t$. Using this method, every client is counted at most once in all c_is, hence its contribution to the total number is always at most 1. The same filtering process can be found in [22]. See the full version of the paper for more details.

4 Future Directions

We list some interesting future directions and open problems.

1. It would be very interesting to remove the dependency of γ (the coefficient of movement cost) and ϵ (the lower bound of the weight) from the approximation factor for Dynamic Ordered k-Median in Theorem 10, or show such dependency is inevitable. We leave it as an important open problem. We note that a constant approximation factor for Dynamic Ordered k-Median without depending on γ would imply a constant approximation for stochastic k-server, for which only a logarithmic-factor approximation algorithm is known [15].
2. Our approximation algorithm for Dynamic Ordered k-Median is based on the technique developed in Byrka et al. [7]. The original ordered k-median problem has subsequently seen improved approximation results in [9, 10]. We did not try hard to optimize the constant factors. Nevertheless, it is an interesting future direction to further improve the constant approximation factors by leveraging the techniques from [9, 10] or other ideas.
3. From Theorem 13, we can see that Dynamic k-Supplier is hard to approximate when $T \geq 3$. However, it makes sense to relax the hard constraint B (we allow the distance a facility can move be at most αB for some constant α).

It is possible to formulate other concrete problems that naturally fit into the dynamic clustering theme and are well motivated by realistic applications, but not yet considered in the paper. For example, one can use the k-median objective for the service cost and the maximum distance of any facility movement as the movement cost. One can also consider combining the cost in more general fashion like in [10], or extending the problems to the fault-tolerant version [21, 28, 31] or the capacitated version [14, 29].

huding@ustc.edu.cn

Abstract

Many real-world problems can be formulated as geometric optimization problems in high dimensions, especially in the fields of machine learning and data mining. Moreover, we often need to take into account of outliers when optimizing the objective functions. However, the presence of outliers could make the problems to be much more challenging than their vanilla versions. In this paper, we study the fundamental minimum enclosing ball (MEB) with outliers problem first; partly inspired by the core-set method from Bădoiu and Clarkson, we propose a sub-linear time bi-criteria approximation algorithm based on two novel techniques, the Uniform-Adaptive Sampling method and Sandwich Lemma. To the best of our knowledge, our result is the first sub-linear time algorithm, which has the sample size (i.e., the number of sampled points) independent of both the number of input points n and dimensionality d, for MEB with outliers in high dimensions. Furthermore, we observe that these two techniques can be generalized to deal with a broader range of geometric optimization problems with outliers in high dimensions, including flat fitting, k-center clustering, and SVM with outliers, and therefore achieve the sub-linear time algorithms for these problems respectively.

1 Introduction

Geometric optimization is a fundamental topic that has been extensively studied in the community of computational geometry [1]. The *minimum enclosing ball (MEB)* problem is one of the most popular geometric optimization problems who has attracted a lot of attentions in past years, where the goal is to compute the smallest ball covering a given set of points in the Euclidean space [11, 50, 32]. Though its formulation is very simple, MEB has a number of applications in real world, such as classification [68, 20, 21], preserving privacy [59, 31], and quantum cryptography [38]. A more general geometric optimization problem is called *flat fitting* that is to compute the smallest slab (centered at a low-dimensional flat) to cover the input data [42, 60, 71]. Another closely related important topic is the *k-center clustering* problem, where the goal is to find $k > 1$ balls to cover the given input data and minimize the maximum radius of the balls [35]; the problem has been widely applied to many areas, such as facility location [18] and data analysis [67]. Moreover, some geometric optimization problems are trying to maximize their size functions. As an example, the well known classification technique *support vector machine (SVM)* [17] is to maximum the margin separating two differently labeled point sets in the space.

Real-world datasets are often noisy and contain outliers. Moreover, outliers could seriously affect the final optimization results. For example, it is easy to see that even one outlier could make the MEB arbitrarily large. In particular, as the rapid development of machine learning, the field of *adversarial machine learning* concerning about the potential vulnerabilities of the algorithms has attracted a great amount of attentions [45, 51, 9, 36]. A small set of outliers could be added by some adversarial attacker to make the decision boundary severely deviate [8, 48]. Furthermore, the presence of outliers often results in a quite challenging combinatorial optimization problem; as an example, if m of the input n data items are outliers ($m < n$), we have to consider an exponentially large number $\binom{n}{m}$ of different possible cases when optimizing the objective function. Therefore, the design of efficient and robust optimization algorithms is urgently needed to meet these challenges.

1.1 Our Contributions

In big data era, the data size could be so large that we cannot even afford to read the whole dataset once. In this paper, we consider to develop sub-linear time algorithms for several geometric optimization problems involving outliers. We study the aforementioned MEB with outliers problem first. Informally speaking, given a set of n points in $\mathbb{R}^d$ and a small parameter $\gamma \in (0, 1)$, the problem is to find the smallest ball covering at least $(1 - \gamma)n$ points from the input. We are aware of several existing sub-linear time bi-criteria approximation algorithms based on uniform sampling for MEB and k-center clustering with outliers [7, 46, 29], where the "bi-criteria" means that the ball (or the union of the k balls) is allowed to exclude a little more points than the pre-specified number of outliers. Their ideas are based on the theory of VC dimension [69]. But the sample size usually depends on the dimensionality d, which is roughly $O\big(\frac{1}{\delta^2\gamma}kd \cdot polylog(\frac{kd}{\delta\gamma})\big)$, if allowing to discard $(1 + \delta)\gamma n$ outliers with $\delta \in (0, 1)$ ($k = 1$ in the complexity for the MEB with outliers problem). A detailed overview on previous works is shown in Section 1.2.

Since many optimization problems in practice need to consider high-dimensional datasets, especially in the fields of machine learning and data mining, the above sample size from [7, 46, 29] could be very large. Partly inspired by the core-set method from Bădoiu and Clarkson [11] for computing MEB in high dimensions, **we are wondering that whether it is possible to remove the dependency on d in the sample size for MEB with outliers and other related high dimensional geometric optimization problems**. Given a parameter $\epsilon \in (0, 1)$, the method of [11] is a simple greedy algorithm that selects $\frac{2}{\epsilon}$ points (as the core-set) for constructing a $(1 + \epsilon)$-approximate MEB, where the resulting radius is at most $1 + \epsilon$ times the optimal one. A highlight of their method is that the core-set size $\frac{2}{\epsilon}$ is independent of d. However, there are several substantial challenges when applying their method to design sub-linear time algorithm for MEB with outliers. First, we need to implement the "greedy selection" step by a random sampling manner, but it is challenging to guarantee the resulting quality especially when the data is mixed with outliers. Second, the random sampling approach often yields a set of candidates for the ball center (e.g., we may need to repeatedly run the algorithm multiple times for boosting the success probability, and each time generates a candidate solution), and thus it is necessary to design an efficient strategy to determine which candidate is the best one in sub-linear time.

To tackle these challenges, we propose two key techniques, the novel "**Uniform-Adaptive Sampling**" method and "**Sandwich Lemma**". Roughly speaking, the Uniform-Adaptive Sampling method can help us to bound the error induced in each "randomized greedy selection" step; the Sandwich Lemma enables us to estimate the objective value of each candidate and select the best one in sub-linear time. To the best of our knowledge, our result

is the first sub-linear time approximation algorithm for the MEB with outliers problem with sample size being independent of the number of points n and the dimensionality d, which significantly improves the time complexities of existing algorithms.

Moreover, we observe that our proposed techniques can be used to solve a broader range of geometric optimization problems. We define a general optimization problem called **minimum enclosing "x" (MEX) with Outliers**, where the "x" stands for a specified kind of shape (e.g., the shape is a ball for MEB with outliers). We prove that it is able to generalize the Uniform-Adaptive Sampling method and Sandwich Lemma to adapt the shape "x", as long as it satisfies several properties. In particular we focus on the MEX with outlier problems including flat fitting, k-center clustering, and SVM with outliers; a common characteristic of these problems is that each of them has an iterative algorithm based on greedy selection for its vanilla version (without outliers) that is similar to the MEB algorithm of [11]. Though these problems have been widely studied before, the research in terms of their sub-linear time algorithms is still quite limited.

1.2 Related Work

Sub-linear time algorithms. The research on sub-linear time algorithms design has a long history [63, 25]. For example, a number of sub-linear time clustering algorithms have been studied in [47, 56, 57, 24]. Another important application of sub-linear time algorithms is property testing on graphs or probability distributions [34].

As mentioned before, the uniform sampling idea can be used to design sub-linear time algorithms for the problems of MEB and k-center clustering with outliers [7, 46, 29], but the sample size depends on the dimensionality d that could be very large in practice. Note that Alon et al. [7] presented another sub-linear time algorithm, which has the sample size independent of d, to test whether an input point set can be covered by a ball with a given radius; however, it is difficult to apply their method to solve the MEB with outliers problem as the algorithm relies on some nice properties of minimum enclosing ball, but these properties are not easy to be utilized when inliers and outliers are mixed. In [26], we proposed a notion of stability for MEB and developed the sub-linear time MEB algorithms for stable instance. Clarkson et al. [21] developed an elegant perceptron framework for solving several optimization problems arising in machine learning, such as MEB. For a set of n points in $\mathbb{R}^d$, their framework can solve the MEB problem in $\tilde{O}(\frac{n}{\epsilon^2} + \frac{d}{\epsilon})$ [1] time. Based on a stochastic primal-dual approach, Hazan et al. [44] provided an algorithm for solving the SVM problem in sub-linear time.

MEB and k-center clustering with outliers. *Core-set* is a popular technique to reduce the time complexities for many optimization problems [2, 61]. The core-set idea has also been used to compute approximate MEB in high dimensional space [20, 13, 50, 60, 49]. Bădoiu and Clarkson [11] showed that it is possible to find a core-set of size $\lceil 2/\epsilon \rceil$ that yields a $(1+\epsilon)$-approximate MEB. There are also several exact and approximation algorithms for MEB that do not rely on core-sets [32, 64, 6]. Streaming algorithms for computing MEB were also studied before [4, 16].

Bădoiu et al. [13] extended their core-set idea to the problems of MEB and k-center clustering with outliers, and achieved linear time bi-criteria approximation algorithms (if k is assumed to be a constant). Several algorithms for the low dimensional MEB with

[1] The asymptotic notation $\tilde{O}(f) = O\big(f \cdot polylog(\frac{nd}{\epsilon})\big)$.

outliers problem have been also developed [5, 30, 39, 54]. A 3-approximation algorithm for k-center clustering with outliers in arbitrary metrics was proposed by Charikar et al. [18]; Chakrabarty et al. [15] proposed a 2-approximation algorithm for k-center clustering with outliers. These algorithms often have high time complexities (e.g., $\Omega(n^2d)$). Recently, Ding et al. [29] provided a linear time greedy algorithm for k-center clustering with outliers based on the idea of the Gonzalez's algorithm [35]. Furthermore, there exist a number of works on streaming and distributed algorithms, such as [19, 55, 72, 53, 37, 14, 52].

Flat fitting with outliers. Given an integer $j \geq 0$ and a set of points in $\mathbb{R}^d$, the flat fitting problem is to find a j-dimensional flat having the smallest maximum distance to the input points [41]; obviously, the MEB problem is a special case with $j = 0$. In high dimensions, Har-Peled and Varadarajan [42] provided a linear time algorithm if j is assumed to be fixed; their running time was further reduced by Panigrahy [60] based on a core-set approach. There also exist several methods considering flat fitting with outliers but only for low-dimensional case [43, 3].

SVM with outliers. Given two point sets P_1 and P_2 in $\mathbb{R}^d$, the problem of *Support Vector Machine (SVM)* is to find the largest margin to separate P_1 and P_2 (if they are separable) [17]. SVM can be formulated as a quadratic programming problem, and a number of efficient techniques have been developed in the past, such as the soft margin SVM [22, 62], ν-SVM [65, 23], and Core-SVM [68, 20]. There also exist a number of works on designing robust algorithms of SVM with outliers [70, 40, 66, 28].

2 Definitions and Preliminaries

In this paper, we let $|A|$ denote the number of points of a given point set A in $\mathbb{R}^d$, and $||x - y||$ denote the Euclidean distance between two points x and y in $\mathbb{R}^d$. We use $\mathbb{B}(c, r)$ to denote the ball centered at a point c with radius $r > 0$. Below, we give several definitions used throughout this paper.

▶ **Definition 1** (Minimum Enclosing Ball (MEB)). *Given a set P of n points in $\mathbb{R}^d$, the MEB problem is to find a ball with minimum radius to cover all the points in P. The resulting ball and its radius are denoted by $MEB(P)$ and $Rad(P)$, respectively.*

A ball $\mathbb{B}(c, r)$ is called a λ-approximation of $MEB(P)$ for some $\lambda \geq 1$, if the ball covers all points in P and has radius $r \leq \lambda Rad(P)$.

▶ **Definition 2** (MEB with Outliers). *Given a set P of n points in $\mathbb{R}^d$ and a small parameter $\gamma \in (0, 1)$, the MEB with outliers problem is to find the smallest ball that covers $(1 - \gamma)n$ points. Namely, the task is to find a subset of P with size $(1 - \gamma)n$ such that the resulting MEB is the smallest among all possible choices of the subset. The obtained ball is denoted by $MEB(P, \gamma)$.*

For convenience, we use P_{opt} to denote the optimal subset of P with respect to $MEB(P, \gamma)$. That is, $P_{\text{opt}} = \arg_Q \min \left\{ Rad(Q) \mid Q \subset P, |Q| = (1 - \gamma)n \right\}$. From Definition 2, we can see that the main issue is to determine the subset of P. Actually, solving such combinatorial problems involving outliers are often challenging. In Section A.1, we present an example to show that it is impossible to achieve an approximation factor less than 2 for MEB with outliers, if the time complexity is required to be independent of n. Therefore, we consider finding the bi-criteria approximation. Actually, it is also a common way for solving other

optimization problems with outliers. For example, Mount et al. [58] and Meyerson et al. [56] studied the bi-criteria approximation algorithms respectively for the problems of linear regression and k-median clustering with outliers before.

▶ **Definition 3** (Bi-criteria Approximation). *Given an instance (P, γ) for MEB with outliers and two small parameters $0 < \epsilon, \delta < 1$, a $(1+\epsilon, 1+\delta)$-approximation of (P, γ) is a ball that covers at least $\big(1-(1+\delta)\gamma\big)n$ points and has radius at most $(1+\epsilon)Rad(P_{opt})$.*

When both ϵ and δ are small, the bi-criteria approximation is very close to the optimal solution with only slight changes on the number of covered points and the radius.

We also extend Definition 2 to the problem called **minimum enclosing "x" (MEX) with Outliers**, where the "x" could be any specified shape. To keep the structure of our paper more compact, we state the formal definition of MEX with outliers and the corresponding results in Section 5.

2.1 A More Careful Analysis for Core-set Construction in [11]

Before presenting our main results, we first revisit the core-set construction algorithm for MEB of Bădoiu and Clarkson [11], since their method will be used in our algorithms for MEB with outliers.

Let $0 < \epsilon < 1$. The algorithm in [11] yields an MEB core-set of size $2/\epsilon$ (for convenience, we always assume that $2/\epsilon$ is an integer). However, there is a small issue in their paper. The analysis assumes that the exact MEB of the core-set is computed in each iteration, but in fact one may only compute an approximate MEB. Thus, an immediate question is whether the quality is still guaranteed with such a change. Kumar et al. [50] fixed this issue, and showed that computing a $(1+O(\epsilon^2))$-approximate MEB for the core-set in each iteration still guarantees a core-set with size $O(1/\epsilon)$, where the hidden constant is larger than 80. Clarkson [20] systematically studied the *Frank-Wolfe* algorithm [33], and showed that the greedy core-set construction algorithm of MEB, as a special case of the Frank-Wolfe algorithm, yields a core-set with size slightly larger than $4/\epsilon$. Note that there exist several other methods yielding even lower core-set size [12, 49], but their construction algorithms are more complicated and thus not applicable to our problems. Increasing the core-set size from $2/\epsilon$ to α/ϵ (for some $\alpha > 2$) is neglectable in asymptotic analysis. But in Section 4, we will show that it could cause serious issue if outliers exist. Hence, a core-set of size $2/\epsilon$ is still desirable. **For this purpose, we provide a new analysis which is also interesting in its own right.**

For the sake of completeness, we first briefly introduce the idea of the core-set construction algorithm in [11]. Given a point set $P \subset \mathbb{R}^d$, the algorithm is a simple iterative procedure. Initially, it selects an arbitrary point from P and places it into an initially empty set T. In each of the following $2/\epsilon$ iterations, the algorithm updates the center of $MEB(T)$ and adds to T the farthest point from the current center of $MEB(T)$. Finally, the center of $MEB(T)$ induces a $(1+\epsilon)$-approximation for $MEB(P)$. The selected set of $2/\epsilon$ points (i.e., T) is called the core-set of MEB. To ensure the expected improvement in each iteration, [11] showed that the following two inequalities hold if the algorithm always selects the farthest point to the current center of $MEB(T)$:

$$r_{i+1} \geq (1+\epsilon)Rad(P) - L_i; \qquad r_{i+1} \geq \sqrt{r_i^2 + L_i^2}, \tag{1}$$

where r_i and r_{i+1} are the radii of $MEB(T)$ in the i-th and $(i+1)$-th iterations, respectively, and L_i is the shifting distance of the center of $MEB(T)$ from the i-th to $(i+1)$-th iteration.

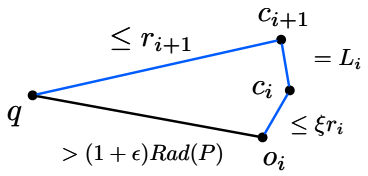

Figure 1 An illustration of (2).

As mentioned earlier, we often compute only an approximate $MEB(T)$ in each iteration. In the i-th iteration, we let c_i and o_i denote the centers of the exact and the approximate $MEB(T)$, respectively. Suppose that $||c_i - o_i|| \leq \xi r_i$, where $\xi \in (0, \frac{\epsilon}{1+\epsilon})$ (we will see why this bound is needed later). Using another algorithm proposed in [11], one can obtain the point o_i in $O(\frac{1}{\xi^2}|T|d)$ time. Note that we only compute o_i rather than c_i in each iteration. Hence we can only select the farthest point (say q) to o_i. If $||q - o_i|| \leq (1+\epsilon)Rad(P)$, we are done and a $(1+\epsilon)$-approximation of MEB is already obtained. Otherwise, we have

$$(1+\epsilon)Rad(P) < ||q - o_i|| \leq ||q - c_{i+1}|| + ||c_{i+1} - c_i|| + ||c_i - o_i|| \leq r_{i+1} + L_i + \xi r_i \quad (2)$$

by the triangle inequality (see Figure 1). In other words, we should replace the first inequality of (1) by $r_{i+1} > (1+\epsilon)Rad(P) - L_i - \xi r_i$. Also, the second inequality of (1) still holds since it depends only on the property of the exact MEB (see Lemma 2.1 in [11]). Thus, we have

$$r_{i+1} \geq \max\left\{\sqrt{r_i^2 + L_i^2}, (1+\epsilon)Rad(P) - L_i - \xi r_i\right\}. \quad (3)$$

This leads to the following theorem whose proof can be found in Section A.2.

▶ **Theorem 4.** *In the core-set construction algorithm of [11], if one computes an approximate MEB for T in each iteration and the resulting center o_i has the distance to c_i less than $\xi r_i = s\frac{\epsilon}{1+\epsilon}r_i$ for some $s \in (0,1)$, the final core-set size is bounded by $z = \frac{2}{(1-s)\epsilon}$. Also, the bound could be arbitrarily close to $2/\epsilon$ when s is small enough.*

▶ Remark 5. We want to emphasize a simple observation on the above core-set construction procedure, which will be used in our algorithms and analysis later on. The algorithm always selects the farthest point to o_i in each iteration. However, this is actually not necessary. As long as the selected point has distance at least $(1+\epsilon)Rad(P)$, the inequality (2) always holds and the following analysis is still true. If no such a point exists (i.e., $P \setminus \mathbb{B}\big(o_i, (1+\epsilon)Rad(P)\big) = \emptyset$), a $(1+\epsilon)$-approximate MEB (i.e., $\mathbb{B}\big(o_i, (1+\epsilon)Rad(P)\big)$) has already been obtained.

3 Two Key Lemmas for Handling Outliers

In this section, we introduce two important techniques, Lemma 6 and 7, for solving the problem of MEB with outliers in sub-linear time; the proofs are placed in Section 3.1 and 3.2, respectively. The algorithms are presented in Section 4. Moreover, these techniques can be generalized to solve a broader range of optimization problems, and we show the details in Section 5.

To shed some light on our ideas, consider using the core-set construction method in Section 2.1 to compute a bi-criteria $(1+\epsilon, 1+\delta)$-approximation for an instance (P, γ) of MEB with outliers. Let o_i be the obtained ball center in the current iteration, and Q be the set of $(1+\delta)\gamma n$ farthest points to o_i from P. A key step for updating o_i is finding a point in the set $P_{opt} \cap Q$ (the formal analysis is given in Section 4). Actually, this can be done

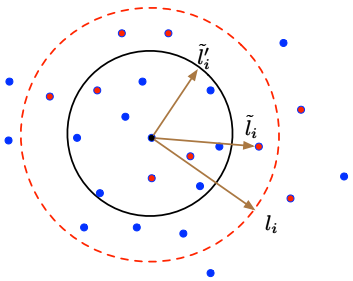

Figure 2 The red points are the sampled n'' points in Lemma 7, and the $\big((1+\delta)^2\gamma n''+1\big)$-th farthest point is in the ring bounded by the spheres $\mathbb{B}(o_i,\tilde{l}'_i)$ and $\mathbb{B}(o_i,l_i)$.

by performing a random sampling from Q. However, it requires to compute the set Q in advance, which takes an $\Omega(nd)$ time complexity. To keep the running time to be sub-linear, we need to find a point from $P_{opt}\cap Q$ by a more sophisticated way.

Since P_{opt} is mixed with outliers in the set Q, simple uniform sampling cannot realize our goal. To remedy this issue, we propose a "two level" sampling procedure which is called "**Uniform-Adaptive Sampling**" (see Lemma 6). Roughly speaking, we take a random sample A of size n' first (i.e., the uniform sampling step), and then randomly select a point from Q', the set of the farthest $\frac{3}{2}(1+\delta)\gamma n'$ points from A to o_i (i.e., the adaptive sampling step). According to Lemma 6, with probability at least $(1-\eta_1)\frac{\delta}{3(1+\delta)}$, the selected point belongs to $P_{opt}\cap Q$; more importantly, the sample size n' is independent of n and d. The key to prove Lemma 6 is to show that the size of the intersection $Q'\cap\big(P_{opt}\cap Q\big)$ is large enough. By setting an appropriate value for n', we can prove a lower bound of $|Q'\cap\big(P_{opt}\cap Q\big)|$.

▶ **Lemma 6** (Uniform-Adaptive Sampling). *Let $\eta_1\in(0,1)$. If we sample $n'=O(\frac{1}{\delta\gamma}\log\frac{1}{\eta_1})$ points independently and uniformly at random from P and let Q' be the set of farthest $\frac{3}{2}(1+\delta)\gamma n'$ points to o_i from the sample, then, with probability at least $1-\eta_1$, the following holds*

$$\frac{\Big|Q'\cap\big(P_{opt}\cap Q\big)\Big|}{|Q'|}\geq\frac{\delta}{3(1+\delta)}. \tag{4}$$

The Uniform-Adaptive Sampling procedure will result in a "side-effect". To boost the overall success probability, we have to repeatedly run the algorithm multiple times and each time the algorithm will generate a candidate solution (i.e., the ball center). Consequently we have to select the best one as our final solution. With a slight abuse of notation, we still use o_i to denote a candidate ball center; to achieve a $(1+\epsilon,1+\delta)$-approximation, its radius should be the $\big((1+\delta)\gamma n+1\big)$-th largest distance from P to o_i, which is denoted as l_i. A straightforward way is to compute the value "l_i" in linear time for each candidate and return the one having the smallest l_i. In this section, we propose the "**Sandwich Lemma**" to estimate l_i in sub-linear time (see Lemma 7). Let B be the set of n'' sampled points from P in Lemma 7, and $\tilde{l}_i$ be the $\big((1+\delta)^2\gamma n''+1\big)$-th largest distance from B to o_i. The key idea is to prove that the ball $\mathbb{B}(o_i,\tilde{l}_i)$ is "sandwiched" by two balls $\mathbb{B}(o_i,\tilde{l}'_i)$ and $\mathbb{B}(o_i,l_i)$, where $\tilde{l}'_i$ is a carefully designed value satisfying (i) $\tilde{l}'_i\leq\tilde{l}_i\leq l_i$ and (ii) $\Big|P\setminus\mathbb{B}(o_i,\tilde{l}'_i)\Big|\leq(1+O(\delta))\gamma n$. See Figure 2 for an illustration. These two conditions of $\tilde{l}'_i$ can imply the inequalities (5) and (6) of Lemma 7. Further, the inequalities (5) and (6) jointly imply that $\tilde{l}_i$ is a qualified estimation of l_i: if $\mathbb{B}(o_i,l_i)$ is a $(1+\epsilon,1+\delta)$-approximation, the ball $\mathbb{B}(o_i,\tilde{l}_i)$ should be a $(1+\epsilon,1+O(\delta))$-approximation. Similar to Lemma 6, the sample size n'' is also independent of n and d.

▶ **Lemma 7** (Sandwich Lemma). *Let $\eta_2 \in (0,1)$ and assume $\delta < 1/3$. If we sample $n'' = O\big(\frac{1}{\delta^2\gamma}\log\frac{1}{\eta_2}\big)$ points independently and uniformly at random from P and let $\tilde{l}_i$ be the $\big((1+\delta)^2\gamma n''+1\big)$-th largest distance from the sample to o_i, then, with probability $1-\eta_2$, the following holds*

$$\tilde{l}_i \leq l_i; \tag{5}$$

$$\Big|P \setminus \mathbb{B}(o_i, \tilde{l}_i)\Big| \leq (1+O(\delta))\gamma n. \tag{6}$$

3.1 Proof of Lemma 6

Let A denote the set of sampled n' points from P. First, we know $|Q| = (1+\delta)\gamma n$ and $|P_{opt} \cap Q| \geq \delta\gamma n$ (since there are at most γn outliers in Q). For ease of presentation, let $\lambda = \frac{|P_{opt}\cap Q|}{n} \geq \delta\gamma$. Let $\{x_i \mid 1 \leq i \leq n'\}$ be n' independent random variables with $x_i = 1$ if the i-th sampled point of A belongs to $P_{opt} \cap Q$, and $x_i = 0$ otherwise. Thus, $E[x_i] = \lambda$ for each i. Let σ be a small parameter in $(0,1)$. By using the Chernoff bound, we have $\mathbf{Pr}\Big(\sum_{i=1}^{n'} x_i \notin (1\pm\sigma)\lambda n'\Big) \leq e^{-O(\sigma^2\lambda n')}$. That is,

$$\mathbf{Pr}\Big(|A \cap \big(P_{opt}\cap Q\big)| \in (1\pm\sigma)\lambda n'\Big) \geq 1 - e^{-O(\sigma^2\lambda n')}. \tag{7}$$

Similarly, we have

$$\mathbf{Pr}\Big(|A\cap Q| \in (1\pm\sigma)(1+\delta)\gamma n'\Big) \geq 1 - e^{-O(\sigma^2(1+\delta)\gamma n')}. \tag{8}$$

Note that $n' = O(\frac{1}{\delta\gamma}\log\frac{1}{\eta_1})$. By setting $\sigma < 1/2$ in (7) and (8), we have

$$\Big|A \cap \big(P_{opt}\cap Q\big)\Big| > \frac{1}{2}\delta\gamma n' \quad \text{and} \quad \Big|A\cap Q\Big| < \frac{3}{2}(1+\delta)\gamma n' \tag{9}$$

with probability $1-\eta_1$. Note that Q contains all the farthest $(1+\delta)\gamma n$ points to o_i. Denote by l_i the $\big((1+\delta)\gamma n+1\big)$-th largest distance from P to o_i. Thus

$$A\cap Q = \{p \in A \mid ||p-o_i|| > l_i\}. \tag{10}$$

Also, since Q' is the set of the farthest $\frac{3}{2}(1+\delta)\gamma n'$ points to o_i from A, there exists some $l_i' > 0$ such that

$$Q' = \{p \in A \mid ||p-o_i|| > l_i'\}. \tag{11}$$

(10) and (11) imply that either $(A\cap Q) \subseteq Q'$ or $Q' \subseteq (A\cap Q)$. Since $\Big|A\cap Q\Big| < \frac{3}{2}(1+\delta)\gamma n'$ and $|Q'| = \frac{3}{2}(1+\delta)\gamma n'$, we know $\Big(A\cap Q\Big) \subseteq Q'$. Therefore,

$$\Big(A\cap\big(P_{opt}\cap Q\big)\Big) = \Big(P_{opt}\cap\big(A\cap Q\big)\Big) \subseteq Q'. \tag{12}$$

Obviously,

$$\Big(A\cap\big(P_{opt}\cap Q\big)\Big) \subseteq \big(P_{opt}\cap Q\big). \tag{13}$$

The above (12) and (13) together imply

$$\Big(A\cap\big(P_{opt}\cap Q\big)\Big) \subseteq \Big(Q'\cap\big(P_{opt}\cap Q\big)\Big). \tag{14}$$

Moreover, since $Q' \subseteq A$, we have

$$\Big(Q'\cap\big(P_{opt}\cap Q\big)\Big) \subseteq \Big(A\cap\big(P_{opt}\cap Q\big)\Big). \tag{15}$$

Consequently, (14) and (15) together imply $Q' \cap \big(P_{opt} \cap Q\big) = A \cap \big(P_{opt} \cap Q\big)$ and hence

$$\frac{\Big|Q' \cap \big(P_{opt} \cap Q\big)\Big|}{|Q'|} = \frac{\Big|A \cap \big(P_{opt} \cap Q\big)\Big|}{|Q'|} \geq \frac{\delta}{3(1+\delta)}, \tag{16}$$

where the final inequality comes from the first inequality of (9) and the fact $|Q'| = \frac{3}{2}(1+\delta)\gamma n'$.

3.2 Proof of Lemma 7

Let B denote the set of sampled n'' points from P. For simplicity, let $t = (1+\delta)\gamma n$. Assume $\tilde{l}'_i > 0$ is the value such that $\Big|P \setminus \mathbb{B}(o_i, \tilde{l}'_i)\Big| = \frac{(1+\delta)^2}{1-\delta}\gamma n$. Recall that l_i is the $\big(t+1\big)$-th largest distance from P to o_i. Since $(1+\delta)\gamma n < \frac{(1+\delta)^2}{1-\delta}\gamma n$, it is easy to know $\tilde{l}'_i \leq l_i$. Below, we aim to prove that the $\big((1+\delta)^2\gamma n'' + 1\big)$-th farthest point from B is in the ring bounded by the spheres $\mathbb{B}(o_i, \tilde{l}'_i)$ and $\mathbb{B}(o_i, l_i)$ (see Figure 2).

Again, using the Chernoff bound (let $\sigma = \delta/2$) and the same idea for proving (9), since $|B| = n'' = O\big(\frac{1}{\delta^2\gamma}\log\frac{1}{\eta_2}\big)$, we have

$$\Big|B \setminus \mathbb{B}(o_i, \tilde{l}'_i)\Big| \geq (1-\delta/2)\frac{(1+\delta)^2}{1-\delta}\gamma n'' > (1-\delta)\frac{(1+\delta)^2}{1-\delta}\gamma n'' = (1+\delta)^2\gamma n''; \tag{17}$$

$$\Big|B \cap Q\Big| \leq (1+\delta/2)\frac{t}{n}n'' < (1+\delta)\frac{t}{n}n'' = (1+\delta)^2\gamma n'', \tag{18}$$

with probability $1-\eta_2$. Suppose that (17) and (18) both hold. Recall that $\tilde{l}_i$ is the $\big((1+\delta)^2\gamma n'' + 1\big)$-th largest distance from the sampled points B to o_i, so $\Big|B \setminus \mathbb{B}(o_i, \tilde{l}_i)\Big| = (1+\delta)^2\gamma n''$, and thus $\tilde{l}_i \geq \tilde{l}'_i$ by (17).

The inequality (18) implies that the $\big((1+\delta)^2\gamma n'' + 1\big)$-th farthest point (say q_x) from B to o_i is not in Q. Then, we claim that $\mathbb{B}(o_i, \tilde{l}_i) \cap Q = \emptyset$. Otherwise, let $q_y \in \mathbb{B}(o_i, \tilde{l}_i) \cap Q$. Then we have

$$||q_y - o_i|| \leq \tilde{l}_i = ||q_x - o_i||. \tag{19}$$

Note that Q is the set of farthest t points to o_i of P. So $q_x \notin Q$ implies

$$||q_x - o_i|| < \min_{q \in Q} ||q - o_i|| \leq ||q_y - o_i|| \tag{20}$$

which is in contradiction to (19). Therefore, $\mathbb{B}(o_i, \tilde{l}_i) \cap Q = \emptyset$. Further, since $\mathbb{B}(o_i, l_i)$ excludes exactly the farthest t points (i.e., Q), $\mathbb{B}(o_i, \tilde{l}_i) \cap Q = \emptyset$ implies $\tilde{l}_i \leq l_i$.

Overall, we have $\tilde{l}_i \in [\tilde{l}'_i, l_i]$, i.e., the $\big((1+\delta)^2\gamma n'' + 1\big)$-th farthest point from B locates in the ring bounded by the spheres $\mathbb{B}(o_i, \tilde{l}'_i)$ and $\mathbb{B}(o_i, l_i)$ as shown in Figure 2. Also, $\tilde{l}_i \geq \tilde{l}'_i$ implies

$$\Big|P \setminus \mathbb{B}(o_i, \tilde{l}_i)\Big| \leq \Big|P \setminus \mathbb{B}(o_i, \tilde{l}'_i)\Big| = \frac{(1+\delta)^2}{1-\delta}\gamma n = (1+O(\delta))\gamma n, \tag{21}$$

where the last equality comes from the assumption $\delta < 1/3$. So (5) and (6) are true in Lemma 7.

4 Sub-linear Time Algorithm of MEB with Outliers

Recall the remark following Theorem 4. As long as the selected point has a distance to the center of $MEB(T)$ larger than $(1+\epsilon)$ times the optimal radius, the expected improvement will always be guaranteed. Following this observation, we investigate the following approach.

Suppose we run the core-set construction procedure decribed in Theorem 4 (we should replace P by P_{opt} in our following analysis). In the i-th step, we add an arbitrary point from $P_{\text{opt}} \setminus \mathbb{B}(o_i, (1+\epsilon)Rad(P_{opt}))$ to T. We know that a $(1+\epsilon)$-approximation is obtained after at most $\frac{2}{(1-s)\epsilon}$ steps, that is, $P_{opt} \subset \mathbb{B}\big(o_i, (1+\epsilon)Rad(P_{opt})\big)$ for some $i \leq \frac{2}{(1-s)\epsilon}$.

However, we need to solve two key issues in order to implement the above approach: **(i)** how to determine the value of $Rad(P_{opt})$ and **(ii)** how to correctly select a point from $P_{\text{opt}} \setminus \mathbb{B}(o_i, (1+\epsilon)Rad(P_{opt}))$. Actually, we can implicitly avoid the first issue via replacing $(1+\epsilon)Rad(P_{opt})$ by the t-th largest distance from the points of P to o_i, where we set $t = (1+\delta)\gamma n$ for achieving a $(1+\epsilon, 1+\delta)$-approximation in the following analysis. For the second issue, we randomly select one point from the farthest t points of P to o_i, and show that it belongs to $P_{\text{opt}} \setminus \mathbb{B}(o_i, (1+\epsilon)Rad(P_{opt}))$ with a certain probability.

Based on the above idea, we present a sub-linear time $(1+\epsilon, 1+\delta)$-approximation algorithm in this section. To better understand the algorithm, we show a linear time algorithm first (Algorithm 1 in Sections 4.1). Note that Bădoiu et al. [13] also achieved a $(1+\epsilon, 1+\delta)$-approximation algorithm but with a higher complexity. **Please see more details in our analysis on the running time at the end of Sections 4.1**. More importantly, we improve the running time of Algorithm 1 to be sub-linear. For this purpose, we need to avoid computing the farthest t points to o_i, since this operation will take linear time. Also, Algorithm 1 generates a set of candidates for the solution and we need to select the best one. This process also costs linear time. By using the techniques proposed in Section 3, we can remedy these issues and develop a sub-linear time algorithm that has the sample complexity independent of n and d, in Section 4.2.

4.1 A Linear Time Algorithm

Algorithm 1 $(1+\epsilon, 1+\delta)$-approximation Algorithm for MEB with Outliers.

Input: A point set P with n points in $\mathbb{R}^d$, the fraction of outliers $\gamma \in (0,1)$, and the parameters $0 < \epsilon, \delta < 1$, $z \in \mathbb{Z}^+$.

1: Let $t = (1+\delta)\gamma n$.
2: Initially, randomly select a point $p \in P$ and let $T = \{p\}$.
3: $i = 1$; repeat the following steps until $i > z$:
   (1) Compute the approximate MEB center o_i of T.
   (2) Let Q be the set of farthest t points from P to o_i; denote by l_i the $(t+1)$-th largest distance from P to o_i.
   (3) Randomly select a point $q \in Q$, and add it to T.
   (4) $i = i + 1$.
4: Output the ball $\mathbb{B}(o_{\hat{i}}, l_{\hat{i}})$ where $\hat{i} = \arg_i \min\{l_i \mid 1 \leq i \leq z\}$.

In this section, we present our linear time $(1+\epsilon, 1+\delta)$-approximation algorithm for MEB with outliers (see Algorithm 1). For convenience, denote by c_i and r_i the exact center and radius of $MEB(T)$ respectively in the i-th round of Step 3 of Algorithm 1. In Step 3(1), we compute the approximate center o_i with a distance to c_i of less than $\xi Rad(T) = s\frac{\epsilon}{1+\epsilon}Rad(T)$, where $s \in (0,1)$ as described in Theorem 4 (we will determine the value of s in our following analysis on the running time). The following theorem shows the success probability of Algorithm 1.

▶ **Theorem 8.** *If the input parameter $z = \frac{2}{(1-s)\epsilon}$ (we assume it is an integer for convenience), then with probability $(1-\gamma)(\frac{\delta}{1+\delta})^z$, Algorithm 1 outputs a $(1+\epsilon, 1+\delta)$-approximation for the MEB with outliers problem.*

Before proving Theorem 8, we present the following two lemmas first.

▶ **Lemma 9.** *With probability* $(1-\gamma)(\frac{\delta}{1+\delta})^z$*, after running* z *rounds in Step 3, the set* $T \subset P_{opt}$ *in Algorithm 1.*

Proof. Initially, because $|P_{opt}|/|P| = 1-\gamma$, the first selected point in Step 2 belongs to P_{opt} with probability $1-\gamma$. In each of the z rounds in Step 3, the selected point belongs to P_{opt} with probability $\frac{\delta}{1+\delta}$, since

$$\frac{|P_{opt} \cap Q|}{|Q|} = 1 - \frac{|Q \setminus P_{opt}|}{|Q|} \geq 1 - \frac{|P \setminus P_{opt}|}{|Q|} = 1 - \frac{\gamma n}{(1+\delta)\gamma n} = \frac{\delta}{1+\delta}. \tag{22}$$

Therefore, $T \subset P_{opt}$ with probability $(1-\gamma)(\frac{\delta}{1+\delta})^z$. ◀

▶ **Lemma 10.** *In the* i*-th round of Step 3 for* $1 \leq i \leq z$*, at least one of the following two events happens: (1)* o_i *is the ball center of a* $(1+\epsilon, 1+\delta)$*-approximation; (2)* $r_{i+1} > (1+\epsilon)Rad(P_{opt}) - ||c_i - c_{i+1}|| - \xi r_i$*.*

Proof. If $l_i \leq (1+\epsilon)Rad(P_{opt})$, then we are done. That is, the ball $\mathbb{B}(o_i, l_i)$ covers $(1-(1+\delta)\gamma)n$ points with radius $l_i \leq (1+\epsilon)Rad(P_{opt})$ (the first event happens). Otherwise, $l_i > (1+\epsilon)Rad(P_{opt})$ and we consider the second event. Let q be the point added to T in the i-th round. Using the triangle inequality, we have

$$||o_i - q|| \leq ||o_i - c_i|| + ||c_i - c_{i+1}|| + |c_{i+1} - q|| \leq \xi r_i + ||c_i - c_{i+1}|| + r_{i+1}. \tag{23}$$

Since $l_i > (1+\epsilon)Rad(P_{opt})$ and q lies outside of $\mathbb{B}(o_i, l_i)$, i.e, $||o_i - q|| \geq l_i > (1+\epsilon)Rad(P_{opt})$, (23) implies that the second event happens and the proof is completed. ◀

Proof of Theorem 8. Suppose that the first event of Lemma 10 never happens. As a consequence, we obtain a series of inequalities for each pair of radii r_{i+1} and r_i, i.e., $r_{i+1} > (1+\epsilon)Rad(P_{opt}) - ||c_i - c_{i+1}|| - \xi r_i$. Assume that $T \subset P_{opt}$ in Lemma 9, i.e., each time the algorithm correctly adds a point from P_{opt} to T. Using the almost identical idea for proving Theorem 4 in Section 2.1, we know that a $(1+\epsilon)$-approximate MEB of P_{opt} is obtained after at most z rounds. The success probability directly comes from Lemma 9. Overall, we obtain Theorem 8. ◀

Moreover, Theorem 8 implies the following corollary.

▶ **Corollary 11.** *If one repeatedly runs Algorithm 1* $O(\frac{1}{1-\gamma}(1+\frac{1}{\delta})^z)$ *times, with constant probability, the algorithm outputs a* $(1+\epsilon, 1+\delta)$*-approximation for the problem of MEB with outliers.*

Running time. In Theorem 8, we set $z = \frac{2}{(1-s)\epsilon}$ and $s \in (0,1)$. To keep z small, according to Theorem 4, we set $s = \frac{\epsilon}{2+\epsilon}$ so that $z = \frac{2}{\epsilon} + 1$ (only larger than the lower bound $\frac{2}{\epsilon}$ by 1). For each round of Step 3, we need to compute an approximate center o_i that has a distance to the exact one less than $\xi r_i = s\frac{\epsilon}{1+\epsilon} r_i = O(\epsilon^2) r_i$. Using the algorithm proposed in [11], this can be done in $O(\frac{1}{\xi^2}|T|d) = O(\frac{1}{\epsilon^5}d)$ time. Also, the set Q can be obtained in linear time by the algorithm in [10]. In total, the time complexity for obtaining a $(1+\epsilon, 1+\delta)$-approximation in Corollary 11 is

$$O(\frac{C}{\epsilon}(n + \frac{1}{\epsilon^5})d), \tag{24}$$

where $C = O(\frac{1}{1-\gamma}(1+\frac{1}{\delta})^{\frac{2}{\epsilon}+1})$. As mentioned before, Bădoiu et al. [13] also achieved a linear time bi-criteria approximation. However, the hidden constant of their running time is exponential in $\Theta(\frac{1}{\epsilon\mu})$ (where μ is defined in [13], and should be $\delta\gamma$ to ensure a $(1+\epsilon, 1+\delta)$-approximation) that is much larger than $\frac{2}{\epsilon} + 1$.

4.2 Improvement on Running Time

In this section, we show that the running time of Algorithm 1 can be further improved to be independent of the number of points n. First, we observe that it is not necessary to compute the set Q of the farthest t points in Step 3(2) of the algorithm. Actually, as long as the selected point q is part of $P_{opt} \cap Q$ in Step 3(3), a $(1+\epsilon, 1+\delta)$-approximation is still guaranteed. The Uniform-Adaptive Sampling procedure proposed in Section 3 can help us to obtain a point $q \in P_{opt} \cap Q$ without computing the set Q. Moreover, in Lemma 7, we show that the radius of each candidate solution can be estimated via random sampling. Overall, we achieve a sub-linear time algorithm (Algorithm 2). Following the analysis in Section 4.1, we set $s = \frac{\epsilon}{2+\epsilon}$ so that $z = \frac{2}{(1-s)\epsilon} = \frac{2}{\epsilon} + 1$. We present the results in Theorem 12 and Corollary 13. Comparing with Theorem 8, we have an extra $(1-\eta_1)(1-\eta_2)$ in the success probability in Theorem 12, due to the probabilities from Lemmas 6 and 7.

Algorithm 2 Sub-linear Time $(1+\epsilon, 1+O(\delta))$-approximation Algorithm for MEB with Outliers.

Input: A point set P with n points in $\mathbb{R}^d$, the fraction of outliers $\gamma \in (0,1)$, and the parameters $\epsilon, \eta_1, \eta_2 \in (0,1)$, $\delta \in (0, 1/3)$, and $z \in \mathbb{Z}^+$.

1: Let $n' = O(\frac{1}{\delta\gamma} \log \frac{1}{\eta_1})$, $n'' = O\big(\frac{1}{\delta^2\gamma} \log \frac{1}{\eta_2}\big)$, $t' = \frac{3}{2}(1+\delta)\gamma n'$, and $t'' = (1+\delta)^2\gamma n''$.

2: Initially, randomly select a point $p \in P$ and let $T = \{p\}$.

3: $i = 1$; repeat the following steps until $j = z$:

- **(1)** Compute the approximate MEB center o_i of T.
- **(2)** Sample n' points uniformly at random from P, and let Q' be the set of farthest t' points to o_i from the sample.
- **(3)** Randomly select a point $q \in Q'$, and add it to T.
- **(4)** Sample n'' points uniformly at random from P, and let $\tilde{l}_i$ be the $(t''+1)$-th largest distance from the sampled points to o_i.
- **(5)** $i = i + 1$.

4: Output the ball $\mathbb{B}(o_{\hat{i}}, \tilde{l}_{\hat{i}})$ where $\hat{i} = \arg_i \min\{\tilde{l}_i \mid 1 \le i \le z\}$.

▶ **Theorem 12.** *If the input parameter $z = \frac{2}{\epsilon} + 1$, then with probability $(1-\gamma)\big((1-\eta_1)(1-\eta_2)\frac{\delta}{3(1+\delta)}\big)^z$, Algorithm 2 outputs a $(1+\epsilon, 1+O(\delta))$-approximation for the problem of MEB with outliers.*

To boost the success probability in Theorem 12, we need to repeatedly run Algorithm 2 and output the best candidate. However, we need to be careful on setting the parameters. The success probability in Theorem 12 consists of two parts, $\mathcal{P}_1 = (1-\gamma)\big((1-\eta_1)\frac{\delta}{3(1+\delta)}\big)^z$ and $\mathcal{P}_2 = (1-\eta_2)^z$, where $\mathcal{P}_1$ indicates the probability that $\{o_1, \cdots, o_z\}$ contains a qualified candidate, and $\mathcal{P}_2$ indicates the success probability of Lemma 7 over all the z rounds. Therefore, if we run Algorithm 2 $N = O(\frac{1}{\mathcal{P}_1})$ times, with constant probability (by taking the union bound), the set of all the generated candidates contains at least one that yields a $(1+\epsilon, 1+O(\delta))$-approximation; moreover, to guarantee that we can correctly estimate the resulting radii of all the candidates via the Sandwich Lemma with constant probability, we need to set $\eta_2 = O(\frac{1}{zN})$ (because there are $O(zN)$ candidates).

▶ **Corollary 13.** *If one repeatedly runs Algorithm 2 $N = O\Big(\frac{1}{1-\gamma}\big(\frac{1}{1-\eta_1}(3+\frac{3}{\delta})\big)^z\Big)$ times with setting $\eta_2 = O(\frac{1}{zN})$, with constant probability, the algorithm outputs a $(1+\epsilon, 1+O(\delta))$-approximation for the problem of MEB with outliers.*

The calculation of running time is similar to (24) in Section 4.1. We just replace n by $\max\{n', n''\} = O\big(\frac{1}{\delta^2\gamma}\log\frac{1}{\eta_2}\big) = O\big(\frac{1}{\delta^2\gamma}\log(zN)\big) = \tilde{O}\big(\frac{1}{\delta^2\gamma\epsilon}\big)$ [2], and change the value of C to be $O\Big(\frac{1}{1-\gamma}\big(\frac{1}{1-\eta_1}(3+\frac{3}{\delta})\big)^{\frac{2}{\epsilon}+1}\Big)$. So the total running time is independent of n. Also, to covert the result from $(1+\epsilon, 1+O(\delta))$-approximation to $(1+\epsilon, 1+\delta)$-approximation, we just need to reduce the value of δ in the input of Algorithm 2 appropriately.

5 The Extension: MEX with Outliers

In this section, we extend Definition 2 and define a more general problem called **minimum enclosing "x" (MEX) with Outliers**. We observe that the ideas of Lemma 6 and 7 can be further extended to deal with MEX with outliers problems, as long as the shape "x" satisfies several properties. **To describe a shape "x", we need to clarify three basic concepts: center, size, and distance function.**

Let $\mathcal{X}$ be the set of specified shapes in $\mathbb{R}^d$. In this paper, we require that each shape $x \in \mathcal{X}$ is uniquely determined by the following two components: "$c(x)$", the **center** of x, and "$s(x) \geq 0$", the **size** of x. For any two shapes $x_1, x_2 \in \mathcal{X}$, $x_1 = x_2$ if and only if $c(x_1) = c(x_2)$ and $s(x_1) = s(x_2)$. Moreover, given a center o_0 and a value $l_0 \geq 0$, we use $x(o_0, l_0)$ to denote the shape x with $c(x) = o_0$ and $s(x) = l_0$. For different shapes, we have different definitions for the center and size. For example, if x is a ball, $c(x)$ and $s(x)$ should be the ball center and the radius respectively; given $o_0 \in \mathbb{R}^d$ and $l_0 \geq 0$, $x(o_0, l_0)$ should be the ball $\mathbb{B}(o_0, l_0)$. As a more complicated example, consider the k-center clustering with outliers problem, which is to find k balls to cover the input point set excluding a certain number of outliers and minimize the maximum radius (*w.l.o.g.,* we can assume that the k balls have the same radius). For this problem, the shape "x" is a union of k balls in $\mathbb{R}^d$; the center $c(x)$ is the set of the k ball centers and the size $s(x)$ is the radius.

For any point $p \in \mathbb{R}^d$ and any shape $x \in \mathcal{X}$, we also need to define a **distance function** $f(c(x), p)$ between the center $c(x)$ and p. For example, if x is a ball, $f(c(x), p)$ is simply equal to $||p - c(x)||$; if x is a union of k balls with the center $c(x) = \{c_1, c_2, \cdots, c_k\}$, the distance should be $\min_{1\leq j\leq k} ||p - c_j||$. Note that the distance function is only for ranking the points to $c(x)$, and not necessary to be non-negative (e.g., we define a distance function $f(c(x), p) \leq 0$ for SVM). By using this distance function, we can define the set "Q" and the value "l_i" when generalizing Lemma 6 and 7 below. To guarantee their correctnesses, we also require $\mathcal{X}$ to satisfy the following three properties.

▶ **Property 1.** *For any two shapes $x_1 \neq x_2 \in \mathcal{X}$, if $c(x_1) = c(x_2)$, then*

$$s(x_1) \leq s(x_2) \Longleftrightarrow x_1 \text{ is covered by } x_2, \tag{25}$$

where "x_1 is covered by x_2" means "for any point $p \in \mathbb{R}^d$, $p \in x_1 \Rightarrow p \in x_2$".

▶ **Property 2.** *Given any shape $x \in \mathcal{X}$ and any point $p_0 \in x$, the set*

$$\{p \mid p \in \mathbb{R}^d \text{ and } f(c(x), p) \leq f(c(x), p_0)\} \subseteq x. \tag{26}$$

▶ **Property 3.** *Given any shape center o_0 and any point $p_0 \in \mathbb{R}^d$, they together determine a value $r_0 = \min\{r \mid r \geq 0, p_0 \in x(o_0, r)\}$; that is, $p_0 \in x(o_0, r_0)$ and $p_0 \notin x(o_0, r)$ for any $r < r_0$. (**Note:** usually the value r_0 is just the distance from p_0 to the shape center o_0; but for some cases, such as the SVM problem, the shape size and distance function have different meanings).*

[2] The asymptotic notation $\tilde{O}(f) = O\big(f \cdot polylog(\frac{1}{\eta_1\delta(1-\gamma)})\big)$.

Intuitively, Property 1 shows that $s(x)$ defines an order of the shapes sharing the same center $c(x)$. Property 2 shows that the distance function f defines an order of the points to a given shape center $c(x)$. Property 3 shows that a center o_0 and a point p_0 can define a shape just "touching" p_0. We can take $\mathcal{X} = \{\text{all } d\text{-dimensional balls}\}$ as an example. For any two concentric balls, the smaller one is always covered by the larger one (Property 1); if a point p_0 is inside a ball x, any point p having the distance $||p - c(x)|| \leq ||p_0 - c(x)||$ should be inside x too (Property 2); also, given a ball center o_0 and a point p_0, $p_0 \in \mathbb{B}(o_0, ||p_0 - o_0||)$ and $p_0 \notin \mathbb{B}(o_0, r)$ for any $r < ||p_0 - o_0||$ (Property 3).

Now, we introduce the formal definitions of the MEX with outliers problem and its bi-criteria approximation.

▶ **Definition 14** (MEX with Outliers)**.** *Suppose the shape set $\mathcal{X}$ satisfies Property 1, 2, and 3. Given a set P of n points in $\mathbb{R}^d$ and a small parameter $\gamma \in (0, 1)$, the MEX with outliers problem is to find the smallest shape $x \in \mathcal{X}$ that covers $(1-\gamma)n$ points. Namely, the task is to find a subset of P with size $(1-\gamma)n$ such that its minimum enclosing shape of $\mathcal{X}$ is the smallest among all possible choices of the subset. The obtained solution is denoted by $MEX(P, \gamma)$.*

▶ **Definition 15** (Bi-criteria Approximation)**.** *Given an instance (P, γ) for MEX with outliers and two small parameters $0 < \epsilon, \delta < 1$, a $(1+\epsilon, 1+\delta)$-approximation of (P, γ) is a solution $x \in \mathcal{X}$ that covers at least $\big(1-(1+\delta)\gamma\big)n$ points and has the size at most $(1+\epsilon)s(x_{opt})$, where x_{opt} is the optimal solution.*

It is easy to see that Definition 2 of MEB with outliers actually is a special case of Definition 14. Similar to MEB with outliers, we still use P_{opt}, where $P_{opt} \subset P$ and $|P_{opt}| = (1-\gamma)n$, to denote the subset covered by the optimal solution of MEX with outliers.

Now, we provide the generalized versions of Lemma 6 and 7. Similar to the core-set construction method in Section 2.1, we assume that there exists an iterative algorithm Γ to compute MEX (without outliers); actually, this is an important prerequisite to design the sub-linear time algorithms under our framework (we will discuss the iterative algorithms for the MEX with outliers problems considered in our paper, including flat fitting, k-center clustering, and SVM, in the appendix). In the i-th iteration of Γ, it maintains a shape center o_i. Also, let Q be the set of $(1+\delta)\gamma n$ farthest points from P to o_i with respect to the distance function f. First, we need to define the value "l_i" by Q in the following claim.

▷ Claim 16. There exists a value $l_i \geq 0$ satisfying $P \setminus x(o_i, l_i) = Q$.

Proof. The points of P can be ranked based on their distances to o_i. Without loss of generality, let $P = \{p_1, p_2, \cdots, p_n\}$ with $f(o_i, p_1) > f(o_i, p_2) > \cdots > f(o_i, p_n)$ (for convenience, we assume that any two distances are not equal; if there is a tie, we can arbitrarily decide their order to o_i). Therefore, the set $Q = \{p_j \mid 1 \leq j \leq (1+\delta)\gamma n\}$. Moreover, from Property 3, we know that each point $p_j \in P$ corresponds to a value r_j that $p_j \in x(o_i, r_j)$ and $p_j \notin x(o_i, r)$ for any $r < r_j$. Denote by x_j the shape $x(o_i, r_j)$. We select the point p_{j_0} with $j_0 = (1+\delta)\gamma n + 1$. From Property 2, we know that $p_j \in x_{j_0}$ for any $j \geq j_0$, i.e., **(a)** $P \setminus Q \subseteq x_{j_0}$. We also need to prove that $p_j \notin x_{j_0}$ for any $j < j_0$. Assume there exists some $p_{j_1} \in x_{j_0}$ with $j_1 < j_0$. Then we have $r_{j_1} < r_{j_0}$ and thus $p_{j_0} \notin x_{j_1}$ (by Property 3). By Property 2, $p_{j_0} \notin x_{j_1}$ implies $f(o_i, p_{j_0}) > f(o_i, p_{j_1})$, which is in contradiction to the fact $f(o_i, p_{j_0}) < f(o_i, p_{j_1})$. So we have **(b)** $Q \cap x_{j_0} = \emptyset$.

From the above **(a)** and **(b)**, we know $P \setminus x_{j_0} = Q$. Therefore, we can set the value $l_i = r_{j_0}$ and then $P \setminus x(o_i, l_i) = Q$. ◁

▶ **Lemma 17** (Generalized Uniform-Adaptive Sampling). *Let $\eta_1 \in (0,1)$. If we sample $n' = O(\frac{1}{\delta\gamma}\log\frac{1}{\eta_1})$ points independently and uniformly at random from P and let Q' be the set of farthest $\frac{3}{2}(1+\delta)\gamma n'$ points to o_i from the sample, then, with probability at least $1-\eta_1$, the following holds*

$$\frac{\left|Q' \cap \left(P_{opt} \cap Q\right)\right|}{|Q'|} \geq \frac{\delta}{3(1+\delta)}. \tag{27}$$

Proof. Let A denote the set of sampled n' points from P. Similar to (9), we have

$$\left|A \cap \left(P_{opt} \cap Q\right)\right| > \frac{1}{2}\delta\gamma n' \quad \text{and} \quad \left|A \cap Q\right| < \frac{3}{2}(1+\delta)\gamma n' \tag{28}$$

with probability $1-\eta_1$. Similar to (10), we have

$$A \cap Q = \{p \in A \mid f(o_i, p) > f(o_i, p_{j_0})\}, \tag{29}$$

where p_{j_0} is the point selected in the proof of Claim 16. By using the same manner of Claim 16, we also can select a point $p_{j_0'} \in A$ with

$$Q' = \{p \in A \mid f(o_i, p) > f(o_i, p_{j_0'})\}. \tag{30}$$

Then, we can prove

$$\left(A \cap \left(P_{opt} \cap Q\right)\right) = \left(Q' \cap \left(P_{opt} \cap Q\right)\right). \tag{31}$$

by using the same idea of (14). Hence,

$$\frac{\left|Q' \cap \left(P_{opt} \cap Q\right)\right|}{|Q'|} = \frac{\left|A \cap \left(P_{opt} \cap Q\right)\right|}{|Q'|} \geq \frac{\delta}{3(1+\delta)}, \tag{32}$$

where the final inequality comes from the first inequality of (28) and the fact $|Q'| = \frac{3}{2}(1+\delta)\gamma n'$. ◀

▶ **Lemma 18** (Generalized Sandwich Lemma). *Let $\eta_2 \in (0,1)$ and assume $\delta < 1/3$. l_i is the value from Claim 16. We sample $n'' = O\left(\frac{1}{\delta^2\gamma}\log\frac{1}{\eta_2}\right)$ points independently and uniformly at random from P and let q be the $\left((1+\delta)^2\gamma n'' + 1\right)$-th farthest one from the sampled points to o_i. If $\tilde{l}_i = \min\{r \mid r \geq 0, q \in x(o_i, r)\}$ (similar to the way defining "r_0" in Property 3), then, with probability $1-\eta_2$, the following holds*

$$\tilde{l}_i \leq l_i; \tag{33}$$

$$\left|P \setminus x(o_i, \tilde{l}_i)\right| \leq (1+O(\delta))\gamma n. \tag{34}$$

Proof. Let B denote the set of sampled n'' points from P. By using the same manner of Claim 16, we know that there exists a value $\tilde{l}_i' > 0$ satisfying $\left|P \setminus x(o_i, \tilde{l}_i')\right| = \frac{(1+\delta)^2}{1-\delta}\gamma n$. Similar to the proof of Lemma 7, we can prove that $\tilde{l}_i \in [\tilde{l}_i', l_i]$. Due to Property 1, we know that $x(o_i, \tilde{l}_i)$ is "sandwiched" by the two shapes $x(o_i, \tilde{l}_i')$ and $x(o_i, l_i)$. Further, since $x(o_i, \tilde{l}_i')$ is covered by $x(o_i, \tilde{l}_i)$, we have

$$\left|P \setminus x(o_i, \tilde{l}_i)\right| \leq \left|P \setminus x(o_i, \tilde{l}_i')\right| = \frac{(1+\delta)^2}{1-\delta}\gamma n = (1+O(\delta))\gamma n, \tag{35}$$

where the last equality comes from the assumption $\delta < 1/3$. So (33) and (34) are true. ◀

Due to the space limit, we place other parts to the full version of our paper [27]. We propose the sub-linear time bi-criteria approximation algorithms for three different MEX with outlier problems: k-center clustering, flat fitting, and SVM with outliers. All of these problems have important applications in real world, and our results significantly reduce their time complexities comparing with existing approaches.

A Appendix

A.1 The Lower Bound of Sample Size for MEB with Outliers

Actually, it is easy to obtain a sub-linear time randomized 2-approximation algorithm for MEB with outliers (if only returning the center): one can randomly select one point $p \in P$, and it belongs P_{opt} with probability $1-\gamma$; thus, with probability $1-\gamma$, the point p yields a 2-approximation by using the triangle inequality. Below, we consider an example and show that it is impossible to achieve a single-criterion λ-approximation for any $\lambda < 2$, if the time complexity is required to be independent of n.

Let q_a, q_b, and q_c be three colinear points in $\mathbb{R}^d$, where $||q_a - q_b|| = x$ and $||q_b - q_c|| = y$ (see Figure 3). Let $\gamma \in (0,1)$ and the point set $P = P_a \cup P_b \cup P_c$, where P_a contains a single point located at q_a, P_b contains $(1-\gamma)n - 1$ points overlapping at q_b, and P_c contains γn points overlapping at q_c. Consider the instance (P, γ) for the problem of MEB with outliers. Suppose $x \ll y$. Consequently, the optimal subset P_{opt} should be $P_a \cup P_b$ and the optimal radius is $x/2$.

Figure 3 $||q_a - q_b|| = x$ and $||q_b - q_c|| = y$.

If we take a random sample S of size $m = o(n)$ from P, with high probability, $P_a \cap S = \emptyset$ (even if we repeat our sampling a constant number of times, the single point P_a will still be missing with high probability). Therefore, S only contains the points from P_b and P_c. If we run an existing algorithm on S, the resulting ball center, say o, should always be inside the convex hull of S, i.e., the segment $\overline{q_b q_c}$. Let $\mathbb{B}(o, r)$ be the ball covering $(1-\gamma)n$ points of P. We consider two cases: (1) $q_a \in \mathbb{B}(o, r)$ and (2) $q_a \notin \mathbb{B}(o, r)$. For case (1), since $o \in \overline{q_b q_c}$, it is easy to know that the radius $r \geq ||q_a - q_b|| = x$ and therefore the approximation ratio is at least 2. For case (2), since $|P_b| = (1-\gamma)n - 1$, $\mathbb{B}(o, r)$ must cover some point from P_c and therefore $r = y/2$; because $x \ll y$, the approximation ratio is also larger than 2.

A.2 Proof of Theorem 4

Similar to the analysis in [11], we let $\lambda_i = \frac{r_i}{(1+\epsilon)Rad(P)}$. Because r_i is the radius of $MEB(T)$ and $T \subset P$, we know $r_i \leq Rad(P)$ and then $\lambda_i \leq 1/(1+\epsilon)$. By simple calculation, we know that when $L_i = \frac{\big((1+\epsilon)Rad(P) - \xi r_i\big)^2 - r_i^2}{2\big((1+\epsilon)Rad(P) - \xi r_i\big)}$ the lower bound of r_{i+1} in (3) achieves the minimum value. Plugging this value of L_i into (3), we have

$$\lambda_{i+1}^2 \geq \lambda_i^2 + \frac{\big((1-\xi\lambda_i)^2 - \lambda_i^2\big)^2}{4(1-\xi\lambda_i)^2}. \tag{36}$$

To simplify inequality (36), we consider the function $g(x) = \frac{(1-x)^2 - \lambda_i^2}{1-x}$, where $0 < x < \xi$. Its derivative $g'(x) = -1 - \frac{\lambda_i^2}{(1-x)^2}$ is always negative, thus we have

$$g(x) \geq g(\xi) = \frac{(1-\xi)^2 - \lambda_i^2}{1-\xi}. \tag{37}$$

Because $\xi < \frac{\epsilon}{1+\epsilon}$ and $\lambda_i \leq 1/(1+\epsilon)$, we know that the right-hand side of (37) is always non-negative. Using (37), the inequality (36) can be simplified to

$$\begin{aligned} \lambda_{i+1}^2 &\geq \lambda_i^2 + \frac{1}{4}\big(g(\xi)\big)^2 \\ &= \lambda_i^2 + \frac{\big((1-\xi)^2 - \lambda_i^2\big)^2}{4(1-\xi)^2}. \end{aligned} \tag{38}$$

(38) can be further rewritten as

$$\begin{aligned} \Big(\frac{\lambda_{i+1}}{1-\xi}\Big)^2 &\geq \frac{1}{4}\Big(1 + (\frac{\lambda_i}{1-\xi})^2\Big)^2 \\ \Longrightarrow \frac{\lambda_{i+1}}{1-\xi} &\geq \frac{1}{2}\Big(1 + (\frac{\lambda_i}{1-\xi})^2\Big). \end{aligned} \tag{39}$$

Now, we can apply a similar transformation of λ_i which was used in [11]. Let $\gamma_i = \frac{1}{1 - \frac{\lambda_i}{1-\xi}}$.

We know $\gamma_i > 1$ (note $0 \leq \lambda_i \leq \frac{1}{1+\epsilon}$ and $\xi < \frac{\epsilon}{1+\epsilon}$). Then, (39) implies that

$$\begin{aligned} \gamma_{i+1} &\geq \frac{\gamma_i}{1-\frac{1}{2\gamma_i}} \\ &= \gamma_i\big(1+\frac{1}{2\gamma_i}+(\frac{1}{2\gamma_i})^2+\cdots\big) \\ &> \gamma_i+\frac{1}{2}, \end{aligned} \tag{40}$$

where the equation comes from the fact that $\gamma_i > 1$ and thus $\frac{1}{2\gamma_i} \in (0, \frac{1}{2})$. Note that $\lambda_0 = 0$ and thus $\gamma_0 = 1$. As a consequence, we have $\gamma_i > 1 + \frac{i}{2}$. In addition, since $\lambda_i \leq \frac{1}{1+\epsilon}$, that is, $\gamma_i \leq \frac{1}{1-\frac{1}{(1+\epsilon)(1-\xi)}}$, we have

$$i < \frac{2}{\epsilon-\xi-\epsilon\xi} = \frac{2}{(1-\frac{1+\epsilon}{\epsilon}\xi)\epsilon}. \tag{41}$$

Consequently, we obtain the theorem.

Abstract

For a text $T[1,n]$, a Longest Common Extension (LCE) query $\mathrm{lce}_T(i,j)$ asks for the length of the longest common prefix of the suffixes $T[i,n]$ and $T[j,n]$ identified by their starting positions $1 \le i,j \le n$. A classic problem in stringology asks to preprocess a static text $T[1,n]$ over an alphabet of size σ so that LCE queries can be efficiently answered on-line. Since its introduction in the 1980's, this problem has found numerous applications: in suffix sorting, edit distance computation, approximate pattern matching, regularities finding, string mining, and many more. Text-book solutions offer $O(n)$ preprocessing time and $O(1)$ query time, but they employ memory-heavy data structures, such as suffix arrays, in practice several times bigger than the text itself.

Very recently, more space efficient solutions using $O(n \log \sigma)$ bits of total space or even only $O(\log n)$ bits of extra space have been proposed: string synchronizing sets [Kempa and Kociumaka, STOC'19, and Birenzwige et al., SODA'20] and in-place fingerprinting [Prezza, SODA'18]. The goal of this article is to present well-engineered implementations of these new solutions and study their practicality on a commonly agreed text corpus. We show that both perform extremely well in practice, with space consumption of only around 10% of the input size for string synchronizing sets (around 20% for highly repetitive texts), and essentially no extra space for fingerprinting. Interestingly, our experiments also show that both solutions become much faster than naive scanning even for finding common prefixes of moderate length, contradicting a common belief that sophisticated data structures for LCE queries are not competitive with naive approaches [Ilie and Tinta, SPIRE'09].

1 Introduction and Related Work

The longest common extension (LCE) problem is formally defined as follows:

Given: A text $T[1,n]$ with n symbols from an alphabet of size σ.

Construct: A data structure that allows subsequent on-line queries of the form

$$\mathrm{lce}_T(i,j) := \max\{\ell \geq 0 \ : \ T[i,i+\ell) = T[j,j+\ell)\}.$$

This is a fundamental problem in stringology, with numerous applications in (sparse) suffix sorting [12,19,24], edit distance computation [35,37], approximate pattern matching [2,22,36], regularities finding [4,5,13], string mining [21], and many more. The problem has a classic solution with $O(1)$-time queries based either on the suffix tree of T combined with lowest common ancestor queries [15,26,37], or using the inverse suffix array of T and the longest common prefix array with a data structure for range minimum queries [18,30]. The latter variant is more space efficient in practice but still several times larger than the text itself.

Recently, two notable methods appeared that also partly address the LCE problem: Prezza's *in-place fingerprinting* data structure [44] using a clever replacement of the original text by well-chosen Karp–Rabin fingerprints [31], and data structures relying on local consistency techniques [33,39,46] to construct so-called *string synchronizing sets* (SSS) [12,32].

Although the LCE problem is also of high practical importance, we are only aware of a few experimental papers on the LCE problem [18,29]. However, these studies are now somewhat dated, and naturally none of them includes the recent theoretical advances on the problem. As a result, practitioners (e.g., in bioinformatics) still use those old (slow and/or memory-heavy) data structures (see, e.g., [43,45,47,50]), thereby limiting themselves to problem sizes much smaller than they could actually handle.

Our Contributions and Outline. The goal of this paper is to engineer and evaluate LCE data structures based on the recent theoretical advances in this field [12,32,44]: in-place fingerprinting and string synchronizing sets. We first describe the theory behind these two approaches in Sect. 3, after having introduced some general background in Sect. 2. Sect. 4 describes further details of the implementations, including a simple but practical data structure for the well-known predecessor/successor queries [49]. Finally, in Sect. 5, we evaluate our implementations on a well-established benchmarking set, showing that

(1) our implementations based on SSS are always among the fastest to answer queries and

(2) in-place fingerprinting is very fast in practice and useful to answer queries that have long results.

Further Related Work. Compressed suffix trees with LCA functionality [20] can also be used for LCE queries, but they are certainly too powerful (and hence too space consuming) for the singular problem considered in this paper; this is confirmed experimentally in Sect. 5.

Time-space tradeoffs for LCE queries were considered by many authors [7,9,10,12,24,48]. Kosolobov [34] showed that the product of extra space (in bits) and LCE query time must be at least $\Omega(n \log n)$ under certain assumptions. Furthermore, there are data structures for LCE queries in compressed [6,8,27,28,42,48] and dynamic texts [1,23,39,42].

2 Preliminaries

2.1 Karp–Rabin Fingerprints

The goal of Karp–Rabin fingerprints [31] is to hash substrings to small integers in order to achieve fast comparisons for equality. To construct Karp–Rabin fingerprints, we choose a random prime number $q = \Theta(n^c)$ for some constant $c > 1$. The Karp–Rabin fingerprint $\phi(x, y)$ of the substring $T[x, y]$ is then defined as

$$\phi(x, y) = \left(\sum_{z=x}^{y} T[z] \cdot \sigma^{y-z} \right) \bmod q \ . \tag{1}$$

Observe that the Karp–Rabin fingerprints of matching substrings are equal, i.e., for every integer $\ell \geq 0$, if $T[x, x + \ell] = T[y, y + \ell]$, then $\phi(x, x + \ell) = \phi(y, y + \ell)$. On the other hand, if two substrings do not match, their fingerprints will be different with high probability. Specifically, if $T[x, x+\ell] \neq T[y, y+\ell]$, then $\mathrm{Prob}[\phi(x, x+\ell) = \phi(y, y+\ell)] = O\big(\frac{\ell \log \sigma}{n^c}\big)$. Thus, by choosing large enough constant $c > 1$, we can control the probability of false positives when comparing fingerprints instead of the underlying substrings.

2.2 Static Successor Data Structures

Let U be a universe of u subsequent integers and let $S[0, n-1]$ be a sequence of n integers from U sorted in ascending order. For any $x \in U$, we call $\mathrm{succ}_S(x) := \min\{y \in S \mid y \geq x\}$ the *successor* of x in S, i.e., the smallest value in S larger than or equal to x. Without loss of generality, we assume that $x > S[0]$ (otherwise, its successor is $S[0]$) and $x \leq S[n-1]$ (otherwise, it has no successor). Furthermore, in the following, we are interested only in the *position* i of the successor such that $S[i] = \mathrm{succ}_S(x)$.

The most straightforward ways to find $\mathrm{succ}_S(x)$ are by doing a linear search in time $O(n)$ or, since S is sorted, by doing a binary search in time $O(\log n)$. Both require $O(\log n)$ bits of extra space for keeping track of the current position or the search interval and pivot, respectively. Alternatively, we can construct a bit vector B_S of size $u' = S[n-1] - S[0] + 1$ bits, in which we set $B_S[x - S[0]] := 1$ if and only if $x \in S$. Enhancing B_S to support constant-time rank queries (see [41, p. 75]) then allows for constant-time successor queries, because $\mathrm{succ}_S(x) = \mathrm{rank}_1(B_S, x - S[0])$. However, this method requires $u' + o(u')$ bits of memory and only works for static sets. Matsuoka et al. [38, Corollary 1] showed how to achieve the same space bounds in a dynamic setting, raising the query time to $O(\log \log u)$.

One can also interpret the numbers from S as binary strings and store them in a trie; some nodes of that trie can then be sampled to speed up the successor search. Such *universe-based sampling* has already been used in the *van Emde Boas tree* [49], which answers successor queries in time $O(\log \log u)$ and requires $O(n \log u)$ bits of memory using hashing. Dementiev et al. [14] described a careful implementation of this idea for 32-bit universes, called *STree*. However, the STree is designed for *dynamic* sequences and contains components to support insertion and deletion into the set, which are not needed in the static case.

3 LCE Data Structures

3.1 In-Place Fingerprinting

Prezza [44] showed how to store the Karp–Rabin fingerprints from Sect. 2.1 succinctly so that the fingerprints *replace* the original text characters, but the original characters can still be recovered.

To facilitate explanation, let us assume a byte-alphabet ($\sigma = 256$) and a computer with word size $w := 64$ bits. We group characters from T into blocks of size $\tau := \Theta(w/\log\sigma)$; in our case, $\tau = 8$. Call the resulting array $B[1, n/\tau]$, with $B[i] := T[(i-1)\tau + 1, i\tau]$ for all $i = 1, \ldots, n/\tau$ (assume for simplicity that τ divides n). Note that τ characters fit into a computer word, and can hence be transferred to/from memory and arithmetically manipulated in constant time. We also choose a random prime q such that $\frac{1}{2}\sigma^\tau \leq q < \sigma^\tau$. We then compute the fingerprints $\phi(1, i\tau)$ for all $i = 1, \ldots, n/\tau$. (The original description actually computes the values $(\phi(1, i\tau) + \bar{s}) \bmod q$, where $0 \leq \bar{s} < q$ is a random seed, which we omit in the following.) Since $D[i] := \lfloor B[i]/q \rfloor \in \{0, 1\}$, all we need to recover the full contents of block $B[i]$ are the two fingerprints $\phi(1, (i-1)\tau)$ and $\phi(1, i\tau)$, and the value $D[i]$. Prezza then shows how to choose q such that w.h.p. the fingerprints $\phi(1, i\tau)$ all have their most significant bit (MSB) set to 0; thus, the array D can be stored instead of those MSBs. (If this doesn't hold, one can recompute the data structure with a different value of q until it holds.) This also allows us to compute the fingerprints for *arbitrary* substrings of T (not necessarily aligned with the block boundaries), also in $O(1)$ time. Prezza shows that with the above choices of q and τ, the fingerprints are collision free with high probability $1 - n^{-\Omega(1)}$.

The advantage of replacing the original text characters with fingerprints is that arbitrarily long substrings of the text can be tested for equality in constant time, using the fingerprints of those substrings. This can be applied for longest common extension queries as follows: To compute $\ell := \mathrm{lce}_T(i, j)$ for any $1 \leq i, j \leq n$, we do an exponential search by comparing $\phi(i, i + 2^k)$ with $\phi(j, j + 2^k)$ for increasing exponents k until the fingerprints mismatch; the actual position of the first mismatch between $T[i, n]$ and $T[j, n]$ is then found by a further binary search on an interval of size $O(\ell)$. The whole process takes $O(\log \ell)$ time, assuming that we have access to a precomputed table of all necessary powers of σ modulo q, which adds another $O(w \log n)$ bits of space (negligible in practice).

3.2 String Synchronizing Sets

The idea behind a *string synchronizing set* (SSS for short) is to designate a (hopefully small) set of positions from T such that this choice of positions is *locally consistent*, meaning that in sufficiently long matching substrings of T, the chosen positions are the same (relative to the beginnings of these substrings). We use the following simplified definition of SSS that is sufficient for our purposes:

▶ **Definition 1.** *For a positive integer $\tau \leq n/2$, the τ-synchronizing set of T is defined as*

$$S = \{i \in [1, n-2\tau+1] : \min\{\phi(j, j+\tau-1) : j \in [i, i+\tau]\} \in \{\phi(i, i+\tau-1), \phi(i+\tau, i+2\tau-1)\}\}.$$

The τ-synchronizing set satisfies the following *consistency property*: for all $i, j \in [1, n-2\tau+1]$, if $T[i, i+2\tau-1] = T[j, j+2\tau-1]$, then $i \in S \iff j \in S$. The original definition [32] also includes a *density property* that is necessary to guarantee a small SSS (of size $O(n/\tau)$) even for highly repetitive parts of T, which we do not consider in this paper, as it would make the data structure and the query procedure significantly more complicated. (Omitting the density property can only make our data structure larger, but it remains correct).

We can use SSS for LCE data structures as follows. We first build a successor data structure on S. Let $n' := |S|$ denote the size of the SSS, and let $s_1 < s_2 < \cdots < s_{n'}$ denote the positions of S in increasing order. Define a new text T' of length n' by setting $T'[i] := T[s_i, s_i + 3\tau - 1]$ for all $1 \leq i \leq n'$. Then, build a data structure for constant-time LCE queries on T', e.g., the RMQ-based solution mentioned in the introduction [18].

In order to answer an $\mathrm{lce}_T(i,j)$ query for arbitrary $1 \leq i,j \leq n$, first compare at most $3\tau+1$ characters from $T[i,i+3\tau]$ and $T[j,j+3\tau]$. If this comparison yields a mismatch, we are done. If not, compute $s_{i'} := \mathrm{succ}_S(i)$, $s_{j'} := \mathrm{succ}_S(j)$, and $\ell' := \mathrm{lce}_{T'}(i',j')$. Then,

$$\mathrm{lce}_T(i,j) = s_{i'+\ell'} - i + \mathrm{lce}_T(s_{i'+\ell'}, s_{j'+\ell'}) \ , \tag{2}$$

and the latter lce_T value can again be computed naively as it is at most 3τ due to $T'[i'+\ell'] \neq T'[j'+\ell']$. Overall, we get $O(\tau)$ query time. (The original description [32] sets $\tau = \Theta(\log_\sigma n)$ and uses the bit-vector approach from Sect. 2.2 for successor queries, as well as word-packing and bit-fiddling techniques, to achieve $O(1)$ query time, still in $O(n \log \sigma)$ bits of space.)

An advantage of this LCE data structure is that it naturally combines fast naive scanning for small LCE values (up to 3τ) with more sophisticated data structures guaranteeing a good worst-case performance. Taken together with the fact that the data structure is easily tunable by adjusting τ, it is an excellent candidate for a practical LCE data structure.

4 Implementation

In this section, we describe our `C++` implementations of the data structures from Sect. 3. The code is optimized for byte-alphabets ($\sigma = 256$) and can handle texts of arbitrary length, with the restriction for the algorithms described in Sect. 4.4 that the synchronizing set S can contain at most $|S| < 2^{32}$ elements.

4.1 A Simple but Fast Static Successor Data Structure

We first describe our implementation of a fast practical data structure for successor queries on a static sorted integer sequence $S[0,n-1]$ of length n over a universe U of size $u = 2^w$. To the best of our knowledge, there is no systematic study of such data structures. Our data structure is a simple index that combines universe-based sampling, binary search, and linear search to find the successor $\mathrm{succ}_S(x)$ for any given $x \in U$.

Let $k < w$ be a trade-off parameter and let c be the number of elements from U that fit into a cache line. We build an index P over S such that we can, in constant time, look up an interval in S of length at most 2^k+1 in which $\mathrm{succ}_S(x)$ is guaranteed to be contained. In this interval, we proceed with a binary search up to the point when the size of the current search interval becomes at most c. In this final small interval, which fully fits into a cache line, we look for $\mathrm{succ}_S(x)$ using linear search. This successor query takes $O(k+c)$ time.

It remains to construct P. Let $\mathrm{hi}_k(x) = \lfloor x/2^k \rfloor$. We define an array I_P of $2^{w-k} = u/2^k$ intervals such that, for every non-negative integer $q < u/2^k$, the entry $I_P[q]$ is defined as

$$[\max\{i \in [0,n-1] \ : \ \mathrm{hi}_k(S[i]) < q\} + 1, \ \max\{j \in [0,n-2] \ : \ \mathrm{hi}_k(S[j]) \leq q\} + 1] \ .$$

If any maximum does not exist, we set the corresponding boundary to 0. As $\mathrm{hi}_k(s) \leq u/2^k$ for each $s \in S$, the right boundary of the last interval is always $n-1$. Informally, we split the universe U into 2^{w-k} intervals of size 2^k, find the corresponding boundaries in S, and store them in I_P with the right boundary shifted forward by one. The successor of x is then guaranteed to be contained in the interval $I_P[\mathrm{hi}_k(x)]$ of S, which is of length at most 2^k+1.

Since, for $1 < q < u/2^k$, the right boundary of $I_P[q-1]$ equals the left boundary of $I_P[q]$, in our final index P, we only store the left boundaries and append $n-1$ (the right boundary of the last interval) at the end. Then, the interval of S in which the successor of x is contained can be expressed as $[P[\mathrm{hi}_k(x)], \ P[\mathrm{hi}_k(x)+1]]$. We can construct P in time $O(n + u/2^k)$ with one scan over S; observe that P takes $(u/2^k+1)\lceil \lg n \rceil$ bits of space.

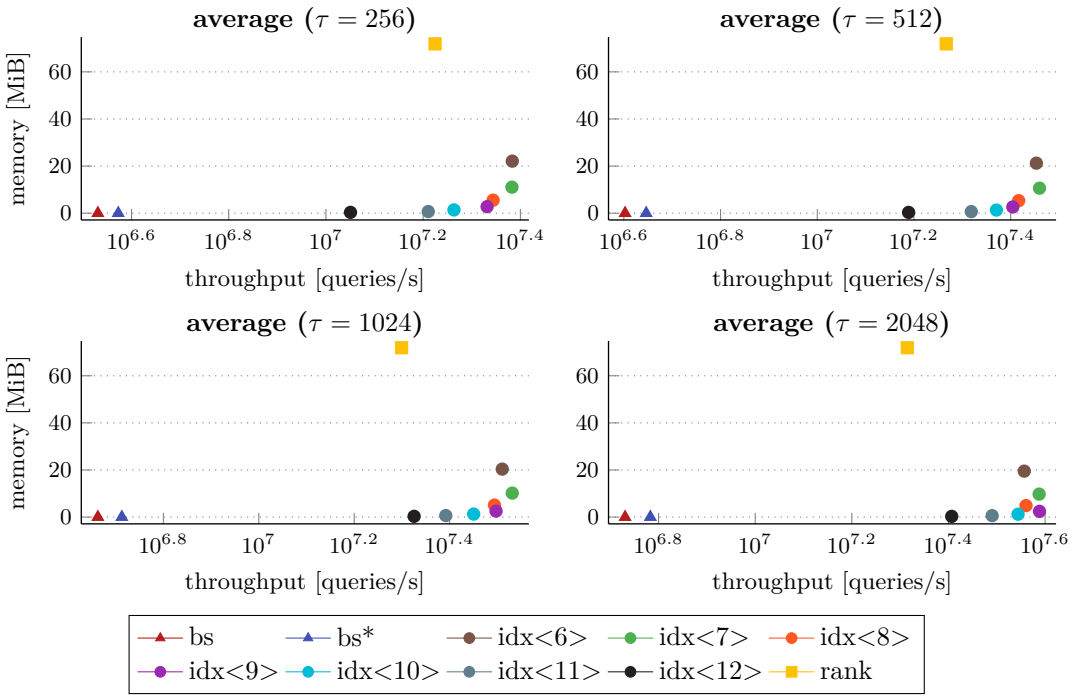

Figure 1 Query throughput versus space usage for static successor data structures built on top of string synchronizing sets with various values of τ, averaged over all texts in the corpus (Tbl. 1).

Note that the space requirement is not optimal in theory and very wasteful if $u \gg n$. However, in our use case of τ-synchronizing sets, the universe is relatively small and gaps between two subsequent integers in S are of length at most τ, making our index practical.

In a preliminary experiment, we looked for the best configuration of the parameter k for our successor data structure. For this experiment, we constructed the string synchronizing sets S for our input texts (see Tbl. 1) and compared the following successor data structures:

1. simple binary search (*bs*),
2. binary search that switches to linear search (*bs**) for intervals of length at most c,
3. the simple data structure from Sect. 2.2, using a bit vector supporting constant-time *rank* queries, and
4. our index P for different parameters k (*idx<k>*).

We measured the memory consumption of the successor data structures and the median query throughput for ten million successor queries over five iterations. The results in Figure 1 indicate that $k := 7$ yields the most beneficial trade-off between query throughput and memory consumption. Therefore, we used this configuration in further experiments. Appendix A shows a detailed breakdown of the results for all input texts.

4.2 Naive LCE Queries

Let us now turn our attention to LCE data structures. An **ultra naive** LCE query algorithm compares characters one by one until a mismatch is detected. This can be sped up significantly by using `uint_128` variables – nowadays supported by most CPUs – to compare blocks of 16 characters at once. Once we have a mismatch, we compare the last block character by character. This algorithm is called **naive**.

4.3 In-Place Fingerprinting

We group 8 consecutive bytes of the input text into a block, reverse the order of the characters in each block by simply swapping the characters (to speed up arithmetic operations when querying the data structure), compute the fingerprint up to the end of the block using Eq. (1), and overwrite the block with this fingerprint. Reversing the order of characters has no significant effect on the construction time, as this construction algorithm is still the fastest on all tested inputs (ignoring the naive approaches that do not require any construction at all), see Sect. 5. We use the smallest prime $q > 2^{63}$, which is $q = 2^{63} + 29$; this worked without any collision detected and with MSB $= 0$ for all stored fingerprints across all tested texts. We also use `uint_128` and the appropriate extended processor instructions for multiplying two 64-bit fingerprints.

Answering LCE queries using the procedure explained in Sect. 2.1 is done block-wise, i.e., in steps by 8, 16, ... characters. Within a block, instead of reconstructing and comparing fingerprints of short substrings, we first translate the fingerprint of the block back to its original contents (characters from T) and scan these characters naively. Because this is faster for LCE values smaller than 256, we also do this at the start of every LCE query. That means that we only start the exponential search after scanning 8 blocks of 8 characters each. We do the same when the final binary search reaches an interval shorter than 256 characters.

4.4 String Synchronizing Sets

While constructing a synchronizing set S, we only need to keep the fingerprints of a window of size 2τ in memory. For reasons of speed, we do so by using a ring buffer of size $2^{\lceil \lg 2\tau \rceil}$: the power of two allows us to compute the positions in the buffer using fast bit operations.

When sorting the suffixes of T', we first use sequential radix sort (`bingmann_msd_CI3_sb`) by Bingmann et al. [11] to reduce the alphabet size of T' (its characters are length-3τ substrings of T). Then, we compute the suffix array using SAIS-LITE [40], because it is the fastest for integer alphabets [3]. According to Sect. 3.2, we now have to compute the LCP array of T'. However, since in the end we are interested only in the LCP values within the original text T, we deviate slightly from Eq. (2) and compute a *sparse* LCP array of T, using the positions from S as indexed positions. For this, we rely on [32, Fact 5.1] that the lexicographic order of suffixes of T' coincides with the order of the corresponding suffixes of T. Apart from eliminating the need to map positions from T' back to T, this also saves us from performing the 3τ naive character comparisons at the end of the query in Eq. (2).

For the actual LCE computation for positions in S, we also build an RMQ data structure on the sparse LCP array; we apply a data structure by Ferrada and Navarro [16] for this purpose. We use a trick to speed up RMQ computations: since we know the length of the interval on which an RMQ is performed, we can make use of the fact that scanning small intervals is faster than an RMQ [29]. In our implementation, we only use the complicated RMQ machinery for intervals larger than 1024; this value yielded the fastest query times. Smaller intervals are simply scanned for the minimum. We implemented two variants of LCE queries:

Prefer-short corresponds to the description in Sect. 3.2: First, scan 3τ characters from T naively; if they are equal, compute the successors, and then apply Eq. (2) (with the modification described in the preceding paragraph). This variant should be used when *small* LCE values are expected, as the procedure is likely to stop already in the initial scan (before computing the successors).

Prefer-long, on the other hand, is optimized for a setting where *large* LCE values are expected. Here, the important observation is that the initial naive scan could reach synchronized positions much earlier than after 3τ comparisons. From that point on, one could immediately resort to LCE computation on T'. We therefore swap the computation of the successors ($s_{i'}$ and $s_{j'}$) and the naive scan. The naive scan then only has to verify that $T[i, s_{i'})$ and $T[j, s_{j'})$ indeed match.

5 Experimental Evaluation

We tested the data structures from Sect. 4: **ultra_naive** and **naive** (Sect. 4.2), **our-rk** (fingerprinting from Sect. 4.3), and **sss**$_\tau$ (string synchronizing sets from Sect. 4.4 with $\tau = 256, 512, 1024, 2048$) in the both variants (*pl* denotes the prefer-long variant). Our implementations are available at `https://github.com/herlez/lce-test`. We also compared our implementations with existing implementations: **prezza-rk** (`https://github.com/nicolaprezza/rk-lce`) and data structures using the compressed suffix trees (CST) **sada** and **sct3** contained in SDSL [25] (`https://github.com/simongog/sdsl-lite`). Other existing implementations were excluded due to their much higher space consumption.

Our experiments were conducted on a computer with two Intel Xeon E5-2640v4 CPUs (each with 10 cores at 2.4 GHz base frequency (3.4 GHz maximum turbo frequency) and cache sizes: 32 KB L1, 256 KB L2, 25.6 MB L3 cache) and 64 GB RAM. All algorithms are sequential and only use a single core, and the results are averages of five runs. The code was compiled with GCC 9.2.0 and compiler flags `-O3`, `-ffast-math`, and `-march=native`.

We ran all algorithms on the input shown in Tbl. 1. The texts were taken from the well-established benchmark suite Pizza&Chili [17]. Data sets from the top half of the table are from the *regular corpus*, whereas those from the bottom half are from the *repetitive corpus*.

Apart from several characteristics of the input texts, like length and alphabet size, Tbl. 1 also shows the sizes of the resulting string synchronizing sets for different values of τ. These numbers confirm our claim from Sect. 3.2 that the additional measures for keeping the SSS small are not necessary in practice, as it can be observed that the growth of SSS size is almost always perfectly proportional to the decrease of the values τ (growth rate only slightly less than 1). The only notable exception is the data set "cere", one of the highly repetitive texts, which contains long runs (of the character `N`). There, for example, when halving τ from 512 to 256, the SSS grows only by a factor of ≈ 1.21 (instead of the expected ≈ 2).

Table 1 Additional information about inputs used in evaluation: name, size n, alphabet size σ, and sizes of the corresponding synchronizing sets $|S_\tau|$ for $\tau = 256$, 512, 1024, and 2048.

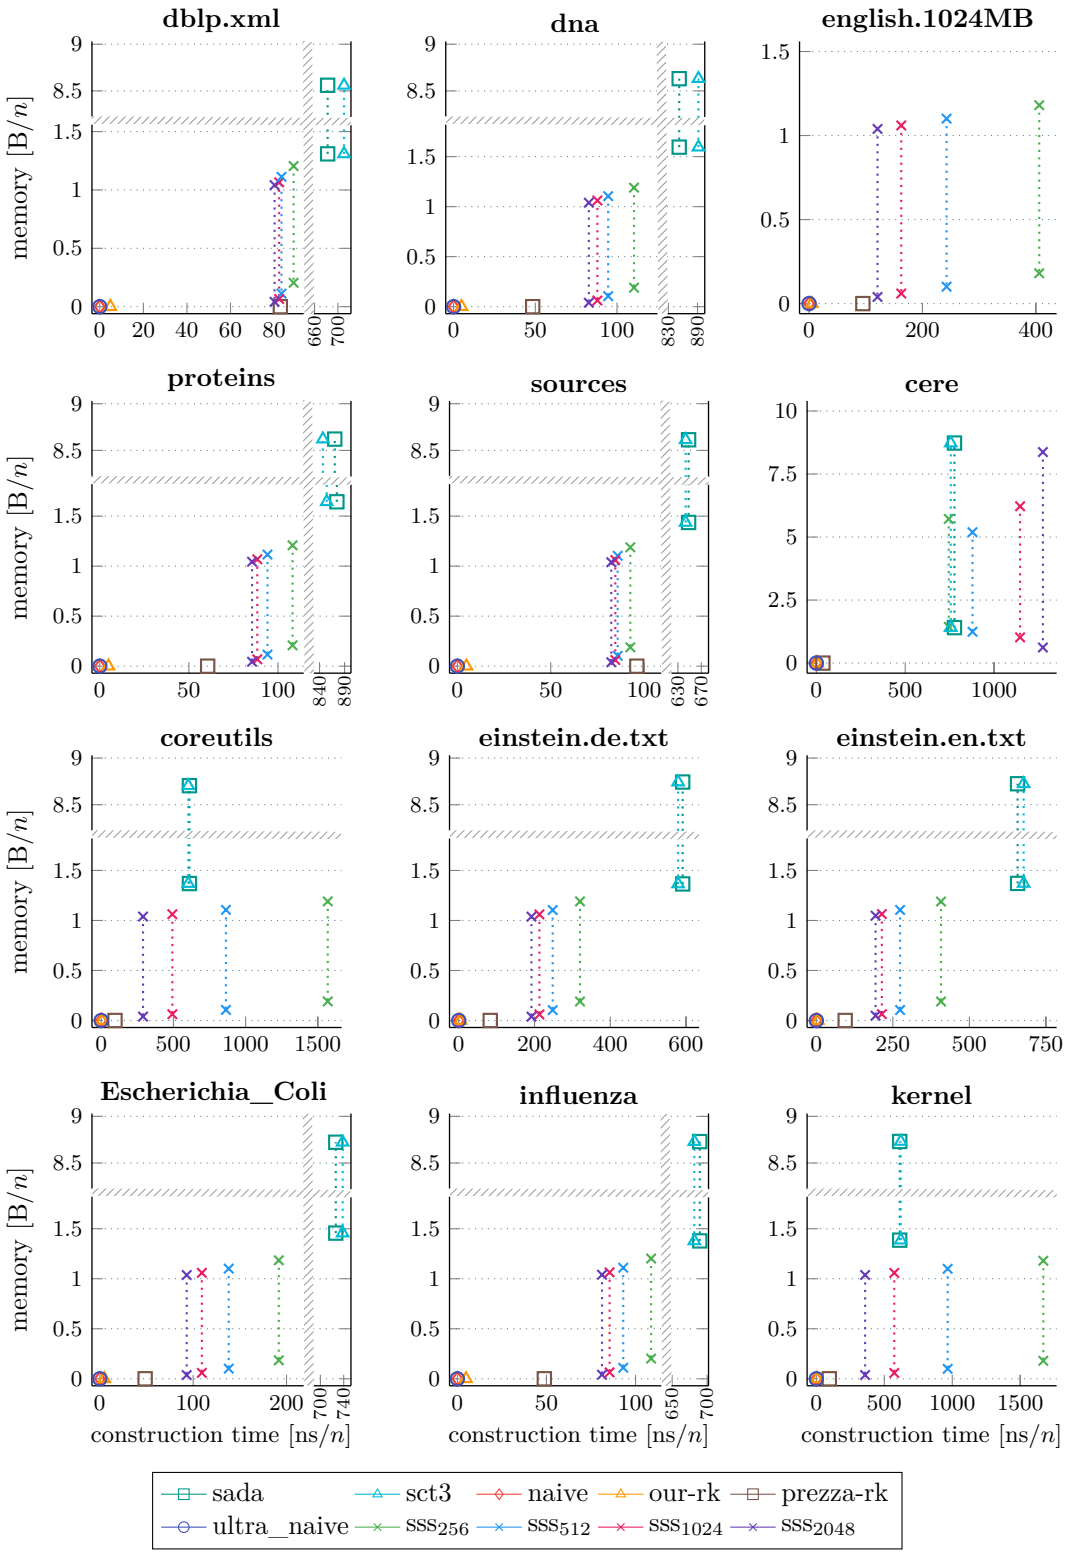

Figure 2 Construction time in nanoseconds and memory consumption in bytes per character of the input for the LCE data structures. The upper mark is the memory peak during construction, and the lower mark is the memory required for the final data structure. (Needs colors for viewing.)

5.1 Construction and Space Usage

Fig. 2 shows the construction times and the space usage of the data structures. For the SSS and CST data structures, that figure shows two numbers: the final size of the data structure (bottom mark) and the memory peak during construction time (top mark). The difference of these two numbers is therefore the additional space at construction time, which results from the intermediate steps using additional data structures (as described in Sect. 4.4 for SSS).

The other data structures need no extra space during construction, as they are either in-place ("prezza-rk" and "our-rk") or do not do any preprocessing at all ("ultra_naive" and "naive"). Also, "our-rk" is significantly faster to build than "prezza-rk" on all inputs; it is 19.76 times faster on "sources". The CST could not be computed for "english.1024MB". Overall, the CST data structures require the most memory. They are also the slowest to construct on all texts but "cere", "coreutils", and "kernel", where SSS is slower for some τ.

The first thing to note is that both time and space requirements grow for SSS with decreasing parameter τ. For space, this is what one would expect immediately, whereas for the running time, this needs further explanation: the times for *sorting* the characters of T', which are substrings of T, depend both on their length 3τ and their number $|S|$. One could now conjecture that, in all cases, roughly the same amount of characters has to be sorted, resulting in construction times mostly independent of τ. However, as our string sorting procedure is *prefix aware* (it only considers the strings up to their distinguishing prefixes), the 3τ-long substrings are usually not inspected in full. This implies that the number of strings can have a higher impact on the running times than their total length, despite the fact that the total length of the strings remains the same (e.g., "english.1024MB"). For other texts (like "dblp.xml"), the construction times are very similar for different values of τ, but are generally faster with growing τ. The notable exception is again the data set "cere", where the order on the time-axis is reversed (but not on the space-axis). This can be explained as follows: we already said before that the growth of the size of the SSS is much less pronounced with decreasing values of τ than for the other data sets. The string sorter is likely to inspect a number of characters proportional to the length of the strings. Therefore, the sorting times for the cere-substrings are influenced more by their total lengths than for the other data sets.

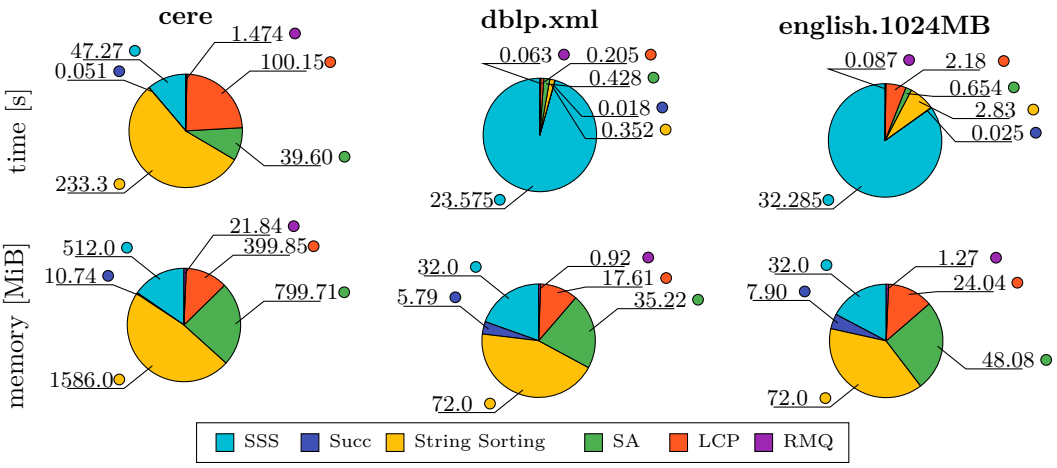

Figure 3 Snapshots of construction time and memory usage during construction for different phases of sss_{512} (same as $\mathrm{sss}^{\mathrm{pl}}_{512}$).

The construction of the SSS structure can be broken down into several steps. Fig. 3 shows examples of how much time is needed for the individual components (building SSS, sorting the length-3τ substrings, building the successor data structure, the suffix array, the LCP array, and the RMQ data structure). Some components differ significantly from text to text: for "cere", the string sorting takes almost half of the total time, whereas for "dblp.xml" (and partly also "english"), the construction of the SSS itself takes almost all of the time. The charts also indicate if and where further engineering efforts can pay off: for example, improving the successor data structure further will most likely neither speed up the final construction times significantly nor improve the space usage. On the contrary, speeding up string sorting or SSS construction (e.g., by parallelization) could result in an overall speedup.

5.2 Query Times

Now, we are interested in query times for different LCE values. To this end, we precomputed queries whose results are in the interval $[2^k, 2^{k+1})$ for all k, allowing us to get a detailed look at query times depending on the LCE value and use the same queries for all data structures.

We now first evaluate the query throughput of the different SSS data structures (with varying values for τ). The results are shown in Fig. 4, grouped by the lengths of the actual LCEs. It can be observed that the initial scanning of characters generally results in a visible drop of the throughput for longer LCEs; smaller values of τ lead to faster query times; the prefer-long variants are indeed faster for longer LCEs, whereas they are slower for shorter ones; and the throughput of all variants does not drop below a threshold for very long LCEs. Indeed, for many data sets, very long LCEs become faster, which can be explained by our method for answering RMQs: for very long LCEs, the corresponding LCP values are likely to be close together in the LCP array, so our query procedure is likely to use the fast scanning for the minimum instead of invoking the heavy $O(1)$-time machinery. Given that the results for $\tau = 512$ and $\tau = 256$ are almost equally fast (in particular for "prefer-long"), we choose the larger of the two values for the following tests, as it results in a smaller data structure.

Fig. 5 shows the query throughput of all data structures (for SSS only with $\tau = 512$). We observe that "ultra_naive" is always slower than "naive" (this comes at no surprise); for short LCEs (roughly up to 2^8), "ultra_naive", "naive", and "sss_{512}" are fastest due to the simple initial scanning; for longer LCEs (greater than 2^{12}), "$\text{sss}^{\text{pl}}_{512}$" becomes the fastest data structure (also faster than "sss_{512}", which becomes faster than the naive approaches for LCEs longer than $\approx 2^{12}$); "our-rk" is slower than Prezza's original implementation "prezza-rk" except for medium sized LCEs around 2^5–2^{10}; and SSS's are much faster than the fingerprinting or naive methods for LCEs longer than $\approx 2^{12}$. The CST data structures "sada" and "sct3" are of similar speed and faster than "ultra_naive" only for long LCEs, around 2^{16} on most inputs. On the repetitive texts "einstein.de.txt" and "einstein.en.txt" both are faster than the fingerprint data structures for medium-size LCEs around $\approx 2^{13}$.

6 Conclusions

We conclude from the experiments that string synchronizing sets (SSS) are the method of choice if their 10–20% overhead on top of the original text size fits into RAM, as they naturally combine the best of two worlds: they answer short LCEs equally fast as naive scanning methods, but are much faster for long LCEs and have a guaranteed worst-case query time. This threshold is much earlier than previously conjectured: even for LCE values larger than $\approx 2^9$, the additional effort for constructing the data structure pays off. If even the little extra space for the SSS is too much and worst case query times have to be guaranteed for long LCEs, then one should use an in-place fingerprinting method.

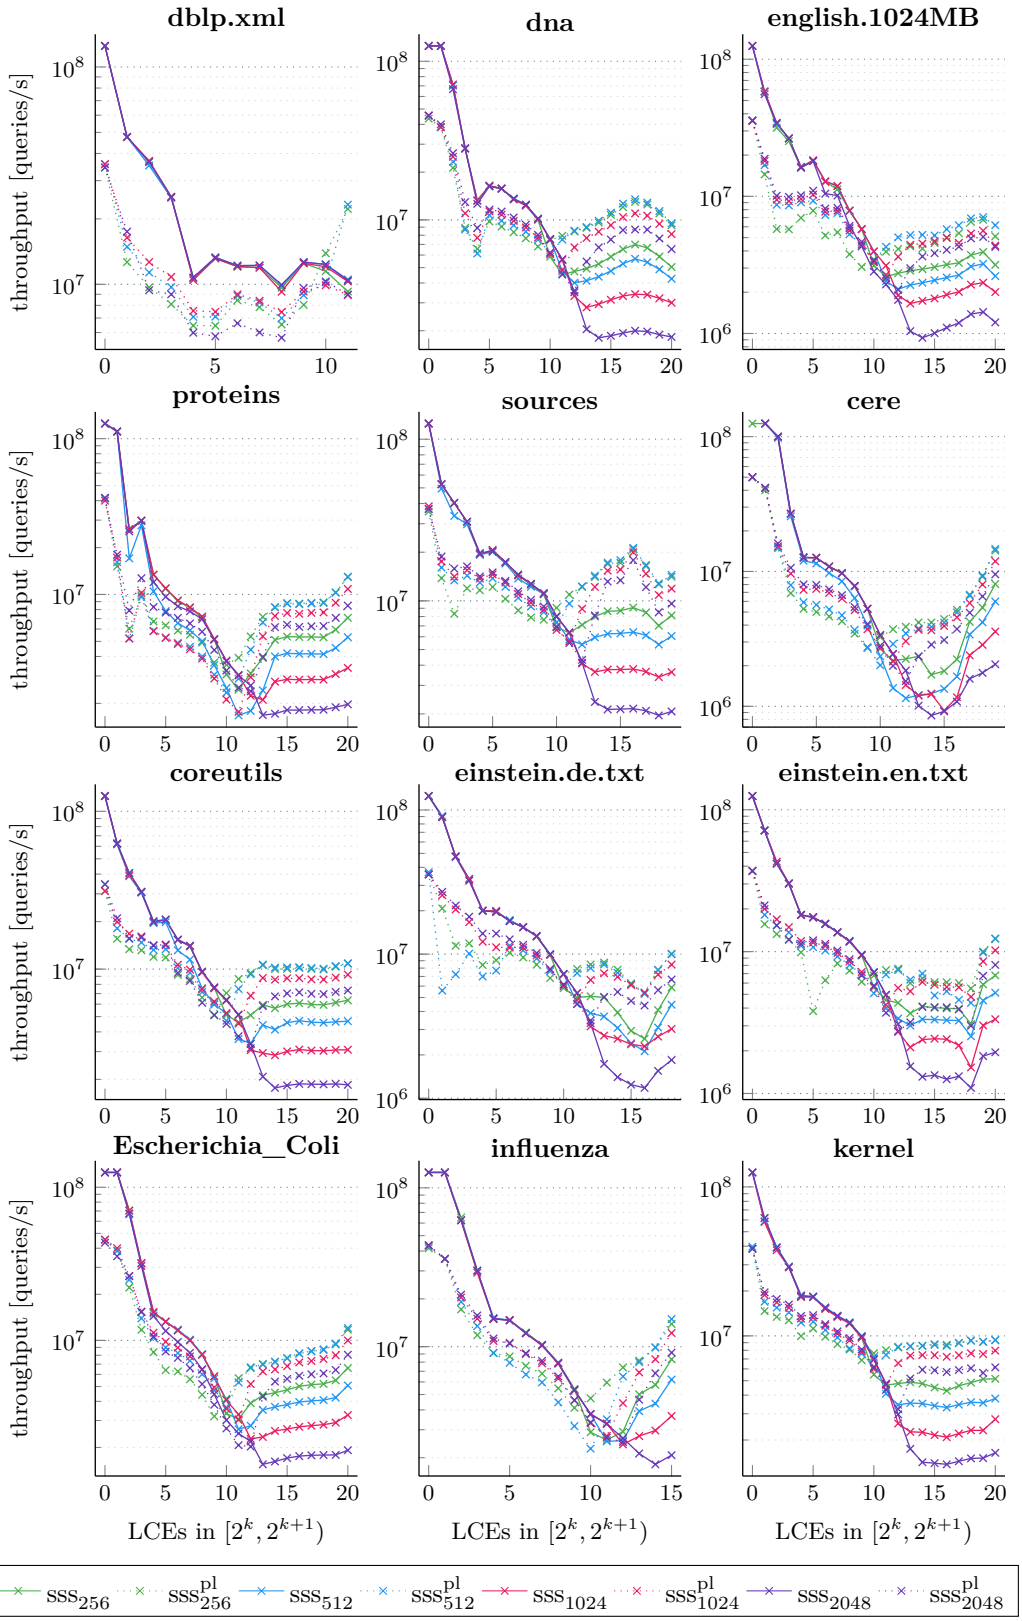

Figure 4 Comparing query throughput of our SSS LCE data structures.

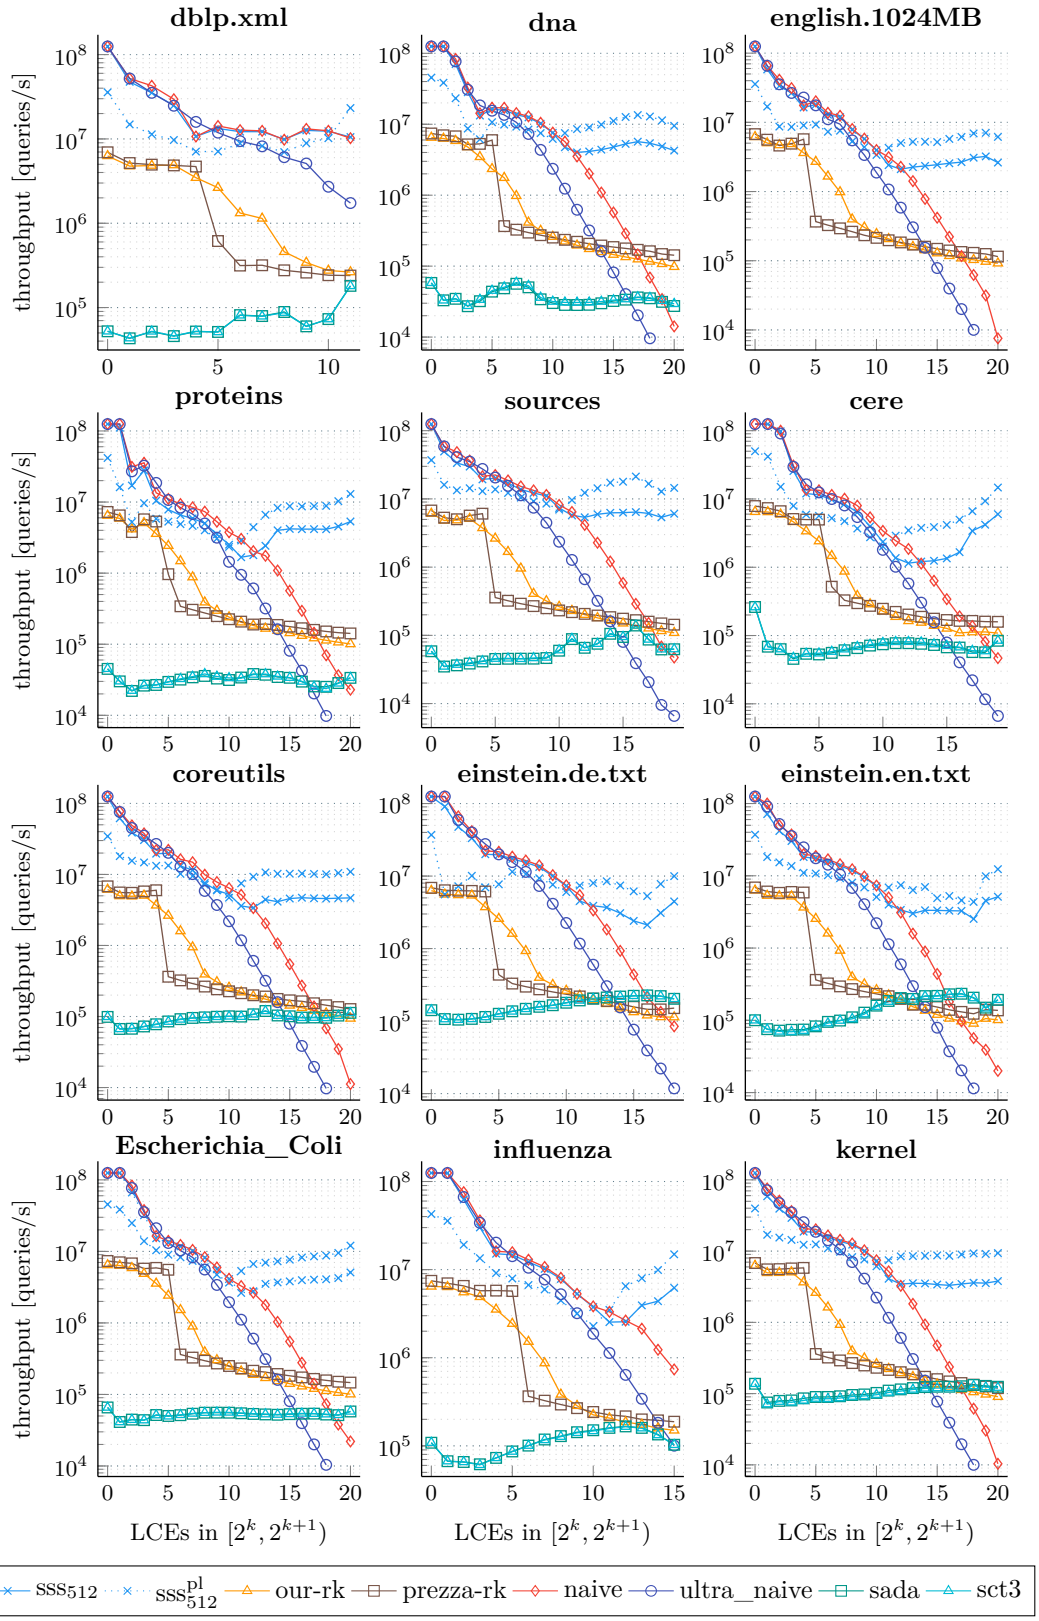

Figure 5 Query throughput of the LCE data structures, only including the fastest SSS ($\tau = 512$).

Abstract

Complex networks are everywhere. They appear for example in the form of biological networks, social networks, or computer networks and have been studied extensively. Efficient algorithms to solve problems on complex networks play a central role in today's society. Algorithmic meta-theorems show that many problems can be solved efficiently. Since logic is a powerful tool to model problems, it has been used to obtain very general meta-theorems. In this work, we consider all problems definable in first-order logic and analyze which properties of complex networks allow them to be solved efficiently.

The mathematical tool to describe complex networks are random graph models. We define a property of random graph models called α-power-law-boundedness. Roughly speaking, a random graph is α-power-law-bounded if it does not admit strong clustering and its degree sequence is bounded by a power-law distribution with exponent at least α (i.e. the fraction of vertices with degree k is roughly $O(k^{-\alpha})$).

We solve the first-order model-checking problem (parameterized by the length of the formula) in almost linear FPT time on random graph models satisfying this property with $\alpha \geq 3$. This means in particular that one can solve every problem expressible in first-order logic in almost linear expected time on these random graph models. This includes for example preferential attachment graphs, Chung–Lu graphs, configuration graphs, and sparse Erdős–Rényi graphs. Our results match known hardness results and generalize previous tractability results on this topic.

1 Introduction

Complex networks, as they occur in society, biology and technology, play a central role in our everyday lives. Even though these networks occur in vastly different contexts, they are structured and evolve according to a common set of underlying principles. Over the last two

decades, with the emergence of the field of network science, there has been an explosion in research to understand these fundamental laws. One well observed property is the *small-world phenomenon*, which means that distances between vertices are very small. This has been verified for the internet and many other networks [1, 56]. Furthermore, many real networks tend to be *clustered*. They contain groups of vertices that are densely connected [67]. If two vertices share a common neighbor, then there is a high chance that there is also an edge between them. A network can be considered clustered if the ratio between the number of triangles and the number of paths with three vertices is non-vanishing. This is formalized by the clustering coefficient, which is high for many networks [72]. A third important property is a *heavy tailed degree distribution*. While most vertices have a low number of connections, there are a few hubs with a high degree. Experiments show that the degrees follow for example a power-law or log-normal distribution. In a power-law distribution, the fraction of vertices with degree k is proportional to $k^{-\alpha}$ (usually with α between 2 and 3). This behavior makes complex networks highly inhomogeneous [65, 58, 10, 15].

One important goal of theoretical computer science has always been to explore what kinds of inputs allow or forbid us to construct efficient algorithms. In this context, *algorithmic meta-theorems* [52] are of particular interest. They are usually theorems stating that problems definable in a certain logic can be solved efficiently on graph classes that satisfy certain properties. Logic is a powerful tool to model problems and therefore has been used to obtain very general meta-theorems. A well-known example is Courcelle's theorem [16], which states that every problem expressible in counting monadic second-order logic can be solved in linear time on graph classes with bounded treewidth. It has been further generalized to graph classes with bounded cliquewidth [17]. To obtain results for larger graph classes one has to consider weaker logics. The languages of relational database systems are based on first-order logic. In this logic, one is allowed to quantify over vertices and to test equality and adjacency of vertices. With k existential quantifiers, one may ask for the existence of a fixed graph with k vertices (k-subgraph isomorphism), a problem relevant to motif-counting [57, 29]. On the other hand, connectivity properties cannot be expressed in first-order logic. We define for every graph class $\mathcal{G}$ the parameterized first-order model-checking problem $p\text{-MC}(\text{FO}, \mathcal{G})$ [45].

$p\text{-MC}(\text{FO}, \mathcal{G})$	
Input:	A graph $G \in \mathcal{G}$ and a first-order sentence φ
Parameter:	The number of symbols in φ, denoted by $\lvert\varphi\rvert$
Problem:	Does φ hold on G (i.e. $G \models \varphi$)?

The aim is to show for a given graph class $\mathcal{G}$ that $p\text{-MC}(\text{FO}, \mathcal{G})$ is *fixed parameter tractable* (FPT), i.e., can be decided in time $f(\lvert\varphi\rvert)n^{O(1)}$ for some function f (see for example [18] for an introduction to fixed parameter tractability). Since input graphs may be large, a linear dependence on n is desirable. If one is successful, then every problem expressible in first-order logic can be solved on $\mathcal{G}$ in linear time.

For the class of all graphs $\mathfrak{G}$, $p\text{-MC}(\text{FO}, \mathfrak{G})$ is AW[$*$]-complete [25] and therefore most likely not fpt. Over time, tractability of $p\text{-MC}(\text{FO}, \mathcal{G})$ has been shown for more and more sparse graph classes $\mathcal{G}$: bounded vertex degree [69], forbidden minors [35], bounded local treewidth [34], and further generalizations [19, 30, 68]. Grohe, Kreutzer and Siebertz prove that $p\text{-MC}(\text{FO}, \mathcal{G})$ can be solved in almost linear FPT time $f(\lvert\varphi\rvert, \varepsilon)n^{1+\varepsilon}$ for all $\varepsilon > 0$ if $\mathcal{G}$ is a nowhere dense graph class [46]. On the other hand if $\mathcal{G}$ is a monotone somewhere dense graph class, $p\text{-MC}(\text{FO}, \mathcal{G})$ is AW[$*$]-hard [46]. Nowhere dense graph classes were introduced by Nešetřil and Ossona de Mendez as those graph classes where for every $r \in \mathbf{N}$ the size of all r-shallow clique minors of all graphs in the graph class is bounded by a function of r

(Section 4.3). A graph class is somewhere dense if it is not nowhere dense. The tractability of the model-checking problem on monotone graph classes is completely characterized with a dichotomy between nowhere dense and somewhere dense graph classes. These very general results come at a cost: Frick and Grohe showed that the dependence of the run time on φ is non-elementary [38]. We want to transfer this rich algorithmic theory to complex networks. But what is the right abstraction to describe complex networks?

Network scientists observed that the chaotic and unordered structure of real networks can by captured using *randomness*. There is a vast body of research using random processes to create graphs that mimic the fundamental properties of complex networks. The most prominent ones are the preferential attachment model [3, 64], Chung–Lu model [12, 13], configuration model [60, 59], Kleinberg model [50, 51], hyperbolic graph model [53], and random intersection graph model [47, 66]. All these are random models. It has been thoroughly analyzed how well they predict various properties of complex networks [43].

When it comes to algorithmic meta-theorems on random graph models "even the most basic questions are wide open," as Grohe puts it [45]. By analyzing which models of complex networks and which values of the model-parameters allow for efficient algorithms, we aim to develop an understanding how the different properties of complex networks control their algorithmic tractability.

In this work we show for a wide range of models, including the well known preferential attachment model, that one can solve the parameterized first-order model-checking problem in almost linear FPT time. This means in particular that one can solve every problem expressible in first-order logic efficiently on these models. Our original goal was to obtain efficient algorithms only for preferential attachment graphs, but we found an abstraction that transfers these results to many other random graph models. Roughly speaking, the following two criteria are sufficient for efficiently solving first-order definable problems on a random graph model:

- The model needs to be unclustered. In particular the expected number of triangles needs to be subpolynomial.
- For every k, the fraction of vertices with degree k is roughly $O(k^{-3})$. In other words, the degree sequence needs to be bounded by a power-law distribution with exponent 3 or higher.

Models satisfying these properties include sparse Erdős–Rényi graphs, preferential attachment graphs as well as certain Chung–Lu and configuration graphs. On the other hand, the Kleinberg model, the hyperbolic random graph model, or the random intersection graph model do not satisfy these properties. Our results generalize previous results [44, 22] and match known hardness results: The model-checking problem has been proven to be hard on power-law distributions with exponent smaller than 3 [28]. We therefore identify the threshold for tractability to be a power-law coefficient of 3. It is also a big open question whether the model-checking problem can also be solved on clustered random graph models, especially since real networks tend to be clustered. Furthermore, significant engineering challenges need to be overcome to make our algorithms applicable in practice.

1.1 Average Case Complexity

Average-case complexity analyzes the typical run time of algorithms on random instances (see [6] for a survey), based on the idea that a worst-case analysis often is too pessimistic as for many problems hard instances occur rarely in the real world. Since models of complex networks are probability distributions over graphs, we analyze the run time of algorithms under average-case complexity. However, there are multiple notions and one needs to be careful which one to choose.

Assume a random graph model is asymptotically almost surely (a.a.s.) nowhere dense, i.e., a random graph from the model with n vertices belongs with probability $1-\delta(n)$ to a nowhere dense graph class, where $\lim_{n\to\infty}\delta(n)=0$ (Section 4.3). Then the first-order model-checking problem can be efficiently solved with a probability converging to one [46]. However, with probability $\delta(n)$ the run time can be arbitrarily high and the rate of convergence of $\delta(n)$ to zero can be arbitrarily slow. These two missing bounds are undesirable from an algorithmic standpoint and the field of average-case complexity has established a theory on how the run time needs to be bounded with respect to the fraction of inputs that lead to this run time.

This is formalized by the well-established notion of *average polynomial run time*, introduced by Levin [54]. An algorithm has average polynomial run time with respect to a random graph model if there is an $\varepsilon>0$ and a polynomial p such that for every n,t the probability that the algorithm runs longer than t steps on an input of size n is at most $p(n)/t^{\varepsilon}$. This means there is a polynomial trade-off between run time and fraction of inputs. This notion has been widely studied [6, 2] and is considered from a complexity theoretic standpoint the right notion of polynomial run time on random inputs. It is closed under invoking polynomial subroutines.

In our work, however, we wish to explicitly distinguish linear time. While Levin's complexity class is a good analogy to the class P, it is not suited to capture algorithms with average linear run time. For this reason, we turn to the expected value of the run time, a stronger notion than average polynomial time. In fact, using Markov's inequality we see that if an algorithm has expected linear run time, all previous measures of average tractability are also bounded. Their relationship is as follows.

$$\text{expected linear} \;\Rightarrow\; \text{expected polynomial} \;\Rightarrow\; \text{average polynomial} \;\Rightarrow\; \text{a.a.s. polynomial}$$

With this in mind we can present our notion of algorithmic tractability. A labeled graph is a graph where every vertex can have (multiple) labels. First-order formulas can have unary predicates for each type of label. These predicates test whether a vertex has a label of a certain type. We define $\mathfrak{G}$ to be the class of all graphs, and $\mathfrak{G}_{lb}$ to be the class of all vertex-labeled graphs. A function $L\colon \mathfrak{G}\to\mathfrak{G}_{lb}$ is an *l-labeling function* for $l\in\mathbf{N}$ if for every $G\in\mathfrak{G}$, $L(G)$ is a labeling of G with up to l classes of labels (see Section 4 for details). Furthermore, a *random graph model* is a sequence $\mathcal{G}=(\mathcal{G}_n)_{n\in\mathbf{N}}$, where $\mathcal{G}_n$ is a probability distribution over unlabeled simple graphs with n vertices.

▶ **Definition 1.** *We say* p-MC$(\mathrm{FO},\mathfrak{G}_{lb})$ *can be decided on a random graph model* $(\mathcal{G}_n)_{n\in\mathbf{N}}$ *in* expected time $f(|\varphi|,n)$ *if there exists a deterministic algorithm* $\mathcal{A}$ *which decides* p-MC$(\mathrm{FO},\mathfrak{G}_{lb})$ *on input* G, φ *in time* $t_{\mathcal{A}}(G,\varphi)$ *and if for all* $n\in\mathbf{N}$, *all first-order sentences* φ *and all* $|\varphi|$*-labeling functions* L, $\mathrm{E}_{G\sim\mathcal{G}_n}\big[t_{\mathcal{A}}(L(G),\varphi)\big]\le f(|\varphi|,n)$. *We say* p-MC$(\mathrm{FO},\mathfrak{G}_{lb})$ *on a random graph model can be decided in* expected FPT time *if it can be decided in expected time* $g(|\varphi|)n^{O(1)}$ *for some function* g.

In particular, this definition implies efficient average run time according to Levin's notion (which is closed under polynomial subroutines). We choose to include labels into our notion of average-case hardness for two reasons: First, it makes our algorithmic results stronger, as the expected run time is small, even in the presence of an adversary that labels the vertices of the graph. Secondly, it matches known hardness results that require adversary labeling.

1.2 Previous Work

There have been efforts to transfer the results for classical graph classes to random graph models by showing that a graph sampled from some random graph model belongs with high probability to a certain algorithmically tractable graph class. For most random graph

models the treewidth is polynomial in the size of the graph [41, 4]. Therefore, people have considered more permissive graph measures than treewidth, such as low degree [44], or bounded expansion [22, 33]. Demaine et al. showed that some Chung–Lu and configuration graphs have bounded expansion and provided empirical evidence that some real-world networks do, too [22]. However, this technique is still limited, as many random graph models (such as the preferential attachment model [22, 27]) are not known to be contained in any of the well-known tractable graph classes.

The previous tractability results presented in this section all use the following technique: Assume we have a formula φ and sample a graph of size n from a random graph model. If the sampled graph belongs to the tractable graph class, an efficient model-checking algorithm for the graph class can solve the instance in FPT time. If the graph does not belong to the graph class, the naive model-checking algorithm can still solve the instance in time $O(n^{|\varphi|})$. Assume we can show that the second case only happens with probability $\delta(n)$ converging to zero faster than any polynomial. Then $\delta(n)O(n^{|\varphi|})$ converges to zero and the expected run time remains bounded by an FPT function.

Let $p(n)$ be a function with $p(n) = O(n^\varepsilon/n)$ for all $\varepsilon > 0$. Grohe showed that one can solve p-MC(FO, $\mathfrak{G}_{lb}$) on Erdős–Rényi graphs $G(n, p(n))$ in expected time $f(|\varphi|, \varepsilon)n^{1+\varepsilon}$ for every $\varepsilon > 0$ [44]. This result was obtained by showing that with high probability the maximum degree of the random graph model is $O(n^\varepsilon)$ for every $\varepsilon > 0$ and then using a model-checking algorithm for low degree graphs. Later Demaine et al. and Farrell et al. showed that certain Chung–Lu and configuration graphs whose degrees follow a power-law distribution with exponent $\alpha > 3$ [22] as well as certain random intersection graphs [33] belong with high probability to a graph class with bounded expansion. While they do not mention it explicitly, the previous argument implies that one can solve p-MC(FO, $\mathfrak{G}_{lb}$) in expected time $f(|\varphi|)n$ on these random graph models.

There further exist some average-case hardness results for the model-checking problem. It has been shown that one cannot decide p-MC(FO, $\mathfrak{G}_{lb}$) on Erdős–Rényi graphs $G(n, 1/2)$ or $G(n, p(n))$ with $p(n) = n^\varepsilon/n$ for some $0 < \varepsilon < 1$, $\varepsilon \in \mathbf{Q}$, in expected FPT time unless AW[$*$] $\subseteq$ FPT/poly [28]. The same holds for Chung–Lu graphs with exponent $2.5 < \alpha < 3$, $\alpha \in \mathbf{Q}$. These hardness results fundamentally require the adversary labeling of Definition 1. It is a big open question whether they can be transferred to model-checking without labels.

Another thing to keep in mind when considering logic and random graphs [70] are *zero-one laws*. They state that in many Erdős–Rényi graphs every first-order formula holds in the limit either with probability zero or one [70, 42, 32]. Not all random graph models satisfy a zero-one law for first-order logic (e.g. the limit probability of the existence of a K_4 in a Chung–Lu graph with weights $w_i = \sqrt{n/i}$ is neither zero nor one).

2 Our Results

We define a property called *α-power-law-boundedness*. This property depends on a parameter α and captures many unclustered random graph models for which the fraction of vertices with expected degree $d \in \mathbf{N}$ is roughly $O(d^{-\alpha})$. Our main contribution is solving the model-checking problem efficiently on all α-power-law-bounded random graph models with $\alpha \geq 3$. This includes preferential attachment graphs, Chung–Lu graphs, Erdős–Rényi graphs, and other random graph models. Note that graphs do not need to have a power-law degree distribution to be α-power-law-bounded. Our results hold for arbitrary labelings of the random graph and are based on a novel decomposition technique for local regions of random graphs. While all previous algorithms work by placing the random graph model with high probability in a sparse graph class, our technique also works for some a.a.s. somewhere dense random graphs (e.g. preferential attachment graphs [27]).

2.1 Power-Law-Boundedness

We start by formalizing our property. Since it generalizes the Chung–Lu model, we define this model first. A Chung–Lu graph with exponent α and vertices $v_1, \dots, v_n$ is defined such that two vertices v_i and v_j are adjacent with probability $\Theta(w_i w_j/n)$ where $w_i = (n/i)^{1/(\alpha-1)}$ [12]. Furthermore all edges are independent, which means that the probability that a set of edges occurs equals the product over the probabilities of each individual edge. In our model the probability of a set of edges can be a certain factor larger than the product of the individual probabilities, which allows edges to be moderately dependent.

▶ **Definition 2.** *Let $\alpha > 2$. We say a random graph model $(\mathcal{G}_n)_{n\in\mathbf{N}}$ is α-power-law-bounded if for every $n \in \mathbf{N}$ there exists an ordering $v_1, \dots, v_n$ of $V(\mathcal{G}_n)$ such that for all $E \subseteq \binom{\{v_1,\dots,v_n\}}{2}$*

$$\Pr\big[E \subseteq E(\mathcal{G}_n)\big] \leq \prod_{v_i v_j \in E} \frac{(n/i)^{1/(\alpha-1)}(n/j)^{1/(\alpha-1)}}{n} \cdot \begin{cases} 2^{O(|E|^2)} & \text{if } \alpha > 3 \\ \log(n)^{O(|E|^2)} & \text{if } \alpha = 3 \\ O(n^\varepsilon)^{|E|^2} \text{ for every } \varepsilon > 0 & \text{if } \alpha < 3. \end{cases}$$

The probability that a set of edges E occurs may be up to a factor $2^{O(|E|^2)}$ or $\log(n)^{O(|E|^2)}$ or $O(n^\varepsilon)^{|E|^2}$ (depending on α) larger than the probability in the corresponding Chung–Lu graph. For conditional probabilities this means the following: The probability bound for an edge under the condition that some set of l edges is already present may be up to a factor $2^{O(l)}$ or $\log(n)^{O(l)}$ or $O(n^\varepsilon)^l$ larger than the unconditional probability. This lets power-law-bounded random graphs capture moderate dependence between edges. The factor undergoes a phase transition at $\alpha = 3$. The smaller factor $2^{O(|E|^2)}$ for $\alpha > 3$ was chosen to guarantee linear FPT run time of our model-checking algorithm (Theorem 4) if $\alpha > 3$. The slightly larger factor of $\log(n)^{O(|E|^2)}$ for $\alpha = 3$ was chosen to capture preferential attachment graphs while still maintaining a quasilinear FPT run time of our algorithm.

The parameter α of an α-power-law-bounded random graph model controls the degree distribution. Note that if a graph class is α-power-law-bounded it is also α'-power-law-bounded for all $2 < \alpha' < \alpha$. It can be easily seen that a vertex v_i has expected degree at most $O(n^\varepsilon)(n/i)^{1/(\alpha-1)}$ for every $\varepsilon > 0$. This means the expected degree sequence of an α-power-law-bounded random graph model is not power-law distributed with exponent smaller than α. The gap is often tight: For example, Chung–Lu graphs with a power-law degree distribution exponent α are α-power-law-bounded and preferential attachment graphs have a power-law degree distribution with exponent 3 and are 3-power-law-bounded. For the interesting case $\alpha = 3$, the inequality in Definition 2 simplifies to

$$\Pr\big[E \subseteq E(\mathcal{G}_n)\big] \leq \log(n)^{O(|E|^2)} \prod_{v_i v_j \in E} \frac{1}{\sqrt{ij}}.$$

2.2 Model Checking

We now present our model-checking algorithm for α-power-law-bounded graphs. We express its run time relative to the term

$$\tilde{d}_\alpha(n) = \begin{cases} O(1) & \alpha > 3 \\ \log(n)^{O(1)} & \alpha = 3 \\ O(n^{3-\alpha}) & \alpha < 3. \end{cases}$$

This term is related to an established property of degree distributions, namely the *second order average degree* [12]. If a random graph with n vertices has expected degrees $w_1, \dots, w_n$ then the second order average degree is defined as $\sum_{i=1}^{n} w_i^2 / \sum_{k=1}^{n} w_k$. In graphs with a power-law degree distribution α we have $w_i = \Theta((n/i)^{1/(\alpha-1)})$. The second order average degree then is $\Theta\big(\sum_{i=1}^{n}(n/i)^{2/(\alpha-1)} / \sum_{k=1}^{n}(n/k)^{1/(\alpha-1)}\big)$. For $\alpha > 3$, this term is constant, for $\alpha = 3$ it is logarithmic, and for $\alpha < 3$ it is polynomial in n [12]. Thus, we can interpret $\tilde{d}_\alpha(n)$ as an estimate of the second order average degree. We prove that the model-checking problem can be solved efficiently if $\tilde{d}_\alpha(n)$ is small.

▶ **Theorem 3.** *There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on every α-power-law-bounded random graph model in expected time $\tilde{d}_\alpha(n)^{f(|\varphi|)}n$.*

The term $\tilde{d}_\alpha(n)$ naturally arises in our proofs and is not a consequence of how we defined the multiplicative factor (i.e., $2^{O(|E|^2)}$, $\log(n)^{O(|E|^2)}$, $O(n^\varepsilon)^{|E|^2}$) in Definition 2. In fact the dependence goes the other way: We defined the factor for each α as large as possible such that it does not dominate the run time of the algorithm. Next we specify exactly those values of α where the previous theorem leads to FPT run times. (In the third case $\varepsilon > 0$ can be chosen arbitrarily small since we require α to be arbitrarily close to 3.)

▶ **Theorem 4.** *Let $(\mathcal{G}_n)_{n\in\mathbf{N}}$ be a random graph model and $\varepsilon > 0$. There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ in expected time*

- $f(|\varphi|)n$ *if $(\mathcal{G}_n)_{n\in\mathbf{N}}$ is α-power-law-bounded for some $\alpha > 3$,*
- $\log(n)^{f(|\varphi|)}n$ *if $(\mathcal{G}_n)_{n\in\mathbf{N}}$ is α-power-law-bounded for $\alpha = 3$,*
- $f(|\varphi|, \varepsilon)n^{1+\varepsilon}$ *for all $\varepsilon > 0$* *if $(\mathcal{G}_n)_{n\in\mathbf{N}}$ is α-power-law-bounded for every $2 < \alpha < 3$.*

This solves the model-checking problem efficiently on a wide range of random graph models. These tractability results are matched by previous intractability results. (Note that the third case of Theorem 4 requires power-law-boundedness for *every* $2 < \alpha < 3$ and thus does not contradict Proposition 5.)

▶ **Proposition 5** ([28] and [26, Lemma 10.3])**.** *For every $2 < \alpha < 3$ there exists an α-power-law-bounded random graph model $(\mathcal{G}_n)_{n\in\mathbf{N}}$ such that one cannot solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on $(\mathcal{G}_n)_{n\in\mathbf{N}}$ in expected* FPT *time unless* AW[$*$] $\subseteq$ FPT/poly*.*

We observe a phase transition in tractability at power-law exponent $\alpha = 3$. Also the run time of our algorithm cannot be linear in n for $\alpha \leq 3$ as a 3-power-law-bounded random graph can have for example $n\log(n)$ edges in expectation. We discuss some of the algorithmic implications of our result for some well-known random graph models in Section 9. More details can be found in Section 10 of [26].

2.3 Structure

Many algorithmic results are based on *structural decompositions*. For example, bidimensionality theory introduced by Demaine et al. [20, 21] is based on the grid minor theorem, which is itself based on a structural decomposition into a clique-sum of almost-embeddable graphs developed by Robertson and Seymour [61]. The model-checking algorithm for graph classes with bounded expansion by Dvořak, Král, and Thomas [30] relies on a structural decomposition of bounded expansion graph classes by Nešetřil and Ossona de Mendez called low tree-depth colorings [63]. Our algorithms are based on a structural decomposition of α-power-law-bounded random graph models.

All algorithms prior to this work rely on showing that a certain graph model is with high probability contained in a certain well-known tractable graph class (for example bounded expansion) and then use the structural decompositions [63] of said graph class. However,

these decompositions were not originally designed with random graphs in mind and therefore may not provide the optimal level of abstraction for random graphs. Our algorithms are based on a specially defined structural decomposition. This direct approach helps us capture random graph models that could otherwise not be captured such as the a.a.s. somewhere dense preferential attachment model. By focusing on α-power-law-bounded random graph models, we obtain structural decompositions for a wide range of models.

We observe that α-power-law-bounded random graphs have mostly an extremely sparse structure with the exception of a part whose size is bounded by the second order average degree. However, this denser part can be separated well from the remaining graph. We show that local regions consist of a core part, bounded in size by the second order average degree, to which trees and graphs of constant size are attached by a constant number of edges. This decomposition is similar to so called *protrusion decompositions*, which have been used by Bodlaender et al. to obtain meta-theorems on kernelization [5]. Our structural decomposition is valid for all graphs that fit into the framework of α-power-law-boundedness, such as preferential attachment graphs or Chung–Lu graphs. We define an approximation of the second order average degree of the degree distribution as $\hat{d}_\alpha(n) = 2$ for $\alpha > 3$, $\hat{d}_\alpha(n) = \log(n)$ for $\alpha = 3$ and $\hat{d}_\alpha(n) = n^{3-\alpha}$ for $\alpha < 3$ (similarly to $\tilde{d}_\alpha(n)$ without O-notation).

▶ **Theorem 6.** *Let $(\mathcal{G}_n)_{n\in\mathbf{N}}$ be an α-power-law-bounded random graph model. There exist constants c, r_0 such that for every $r \geq r_0$ a.a.s. for every r-neighborhood H of $\mathcal{G}_n$ one can partition $V(H)$ into three (possibly empty) sets X, Y, Z with the following properties.*

- *$|X| \leq \hat{d}_\alpha(n)^{cr^2}$.*
- *Every connected component of $H[Y]$ has size at most cr and at most c neighbors in X.*
- *Every connected component of $H[Z]$ is a tree with at most one edge to $H[X \cup Y]$.*

Removing a few vertices makes the local neighborhoods even sparser:

▶ **Corollary 7.** *Let $(\mathcal{G}_n)_{n\in\mathbf{N}}$ be an α-power-law-bounded random graph model. There exist constants c, r_0 such that for every $r \geq r_0$ a.a.s. one can remove $\hat{d}_\alpha(n)^{cr^2}$ vertices from $\mathcal{G}_n$ such that every r-neighborhood has treewidth at most 26.*

Further structural results that may be interesting beyond the purpose of model-checking as well as proofs of the results outlined here can be found in Section 9 of [26]. We now discuss how we use the decomposition of Theorem 6 for our algorithms and why decompositions similar to Corollary 7 are not sufficient for our purposes.

3 Techniques and Outline

A first building block of our algorithm is Gaifman's locality theorem [39]. It implies that in order to solve the first-order model-checking problem on a graph, it is sufficient to solve the problem on all r-neighborhoods of the graph for some small r. We can therefore restrict ourselves to the model-checking problem on the neighborhoods of random graphs. With this in mind, we want to obtain structural decompositions of these neighborhoods.

One important thing to note is that a decomposition according to Corollary 7 is not sufficient. Let us focus on the interesting case $\alpha = 3$ where efficient model-checking is still possible. Corollary 7 then states that the removal of polylogarithmically many vertices yields neighborhoods with treewidth at most 26. While we could easily solve the model-checking problem on graphs with treewidth at most 26 via Courcelle's theorem [16], we cannot solve it on graphs where we need to remove a set X of $\log(n)$ vertices to obtain a treewidth of at most 26. Every vertex not in X may have an arbitrary subset of X as neighborhood. Since

there are $2^{|X|} = n$ possible neighborhoods, we can encode a large complicated structure into this graph by stating that two vertices $i, j \in \mathbf{N}$ are adjacent if and only if there is a vertex whose neighborhood in X represents a binary encoding of the edge ij (omitting some details). Because of this, the model-checking problem on this graph class is as hard as on general graphs. We need the additional requirement that X is only loosely connected to the remaining graph. The decomposition in Theorem 6 fulfills this requirement. Every component of $H \setminus X$ has at most a constant number of neighbors in X.

Let us assume we have decompositions of the neighborhoods of a graph according to Theorem 6 where the sets X are chosen as small as possible. We can now use a variant of the Feferman–Vaught theorem [48] for each r-neighborhood to prune the protrusions and thereby construct a smaller graph that satisfies the same (short) first-order formulas as the original graph, We call this smaller graph the *kernel*. The size of this kernel will be some function of $|X|$. We then use the brute-force model-checking algorithm on the kernel.

For the first steps of the algorithm (decomposition into neighborhoods, kernelization using Feferman–Vaught) one can easily show that they always take FPT time. However, the run time of the last step requires a careful analysis. One can check a formula φ on a graph of size x in time $O(x^{|\varphi|})$ by brute force. Thus, checking the formula on the kernel of all n many r-neighborhoods of a random graph takes expected time at most $n \sum_{x=1}^{n} p_x O(x^{|\varphi|})$, where p_x is the probability that the kernelization procedure on an r-neighborhood of a random graph yields a kernel of size x. In order to guarantee a run time of the form $\log(n)^{f(|\varphi|)} n$ for some function f, p_x should be of order $\log(n)^{f(|\varphi|)} x^{-|\varphi|}$.

Earlier, we discussed that the size of the kernel will be some function of $|X|$ and that we choose X as small as possible. It is therefore sufficient to bound the probability that the set X of the decomposition of a neighborhood exceeds a certain size. Parameterizing the decomposition by two values (denoted by b and μ later on) gives us enough control to guarantee such a bound on p_x. A large part of this work is devoted to proving a good trade-off between the size of the set X of the decomposition and the probability that X is of minimal size. Furthermore, computing the set X is computationally hard, so the whole procedure has to work without knowing the set X, but only its existence.

Our proofs are structured as follows. First, we show in Section 5 that α-power-law-bounded random graph models have the following structure with high probability: They can be partitioned into sets A, B, C, where $A \cup B$ is small, $B \cup C$ is sparse and A and C locally share only few edges. This is done by characterizing this structure by a collection of small forbidden edge-sets and then excluding these edge-sets using the union bound and Definition 2. Then in Section 6 we show that the partition into A, B, C implies the protrusion decomposition of Theorem 6. In Section 7, we partially recover the protrusion decomposition from a given input, and use it to kernelize each r-neighborhood into an equivalent smaller graph. At last, in Section 8, we combine Gaifman's locality theorem with the previous algorithms and probability bounds to obtain our algorithm and bound its run time. Some proofs are quite tedious, but the nature of this problem seems to stop us from using simpler methods.

3.1 Missing Proofs

Many proofs of the results presented in this paper have been omitted. In particular Section 2.3, 5 – 9 sketch only the main ideas behind our results. All missing proofs can be found in the corresponding full version of this paper [26].

4 Notations and Definitions

4.1 Graph Notation

We use common graph theory notation [23]. The *length* of a path equals its number of edges. The *distance* between two vertices u and v ($\mathrm{dist}(u,v)$) equals the length of a shortest path between u and v. For a vertex v let $N_r^G(v)$ be the set of vertices that have distance at most r to v in G. The *radius* of a graph is the minimum among all maximum distances from one vertex to all other vertices. An *r-neighborhood* in G is an induced subgraph of G with radius at most r. The *order* of a graph is $|G| = |V(G)|$. The *size* of a graph is $\|G\| = |V(G) + E(G)|$. The *edge-excess* of a graph G is $|E(G)| - |V(G)|$.

In this work we obtain results for *labeled graphs* [45]. A labeled graph is a tuple $G = (V(G), E(G), P_1(G), \ldots, P_l(G))$ with $P_i(G) \subseteq V(G)$. We call $P_1(G), \ldots, P_l(G)$ the *labels* of G. We say a vertex v is labeled with label $P_i(G)$ if $v \in P_i(G)$. A vertex may have multiple labels. We say the unlabeled simple graph $G' = (V(G), E(G))$ is the *underlying graph* of G and G is a *labeling* of G'. All notations for graphs extend to labeled graphs as expected. The union of two labeled graphs G and H, $(G \cup H)$, is obtained by setting $V(G \cup H) = V(G) \cup V(H)$, $E(G \cup H) = E(G) \cup E(H)$ and for each label $P_i(G \cup H) = P_i(G) \cup P_i(H)$.

For a graph class $\mathcal{G}$, we define $\mathcal{G}_{lb}$ to be the class of all labelings of $\mathcal{G}$. We define $\mathfrak{G}$ to be the class of all simple graphs and $\mathfrak{G}_{lb}$ to be the class of all labeled simple graphs.

4.2 Probabilities and Random Graph Models

We denote probabilities by $\Pr[*]$ and expectation by $\mathrm{E}[*]$. We consider a random graph model to be a sequence of probability distributions. For every $n \in \mathbf{N}$ a random graph model describes a probability distribution on unlabeled simple graphs with n vertices. In order to speak of probability distributions over graphs we fix a sequence of vertices $(v_i)_{i \geq 1}$ and require that a graph with n vertices has the vertex set $\{v_1, \ldots, v_n\}$. A random graph model is a sequence $\mathcal{G} = (\mathcal{G}_n)_{n \in \mathbf{N}}$, where $\mathcal{G}_n$ is a probability distribution over all unlabeled simple graphs G with $V(G) = \{v_1, \ldots, v_n\}$. Even though some random processes naturally lead to graphs with multi-edges or self-loops, we interpret them as simple graphs by removing all self-loops and replacing multiple edges with one single edge. In slight abuse of notation, we also write $\mathcal{G}_n$ for the random variable which is distributed according to $\mathcal{G}_n$. This way, we can lift graph notation to notation for random variables of graphs: For example edge sets and neighborhoods of a random graph $\mathcal{G}_n$ are represented by random variables $E(\mathcal{G}_n)$ and $N_r^{\mathcal{G}_n}(v)$.

4.3 Sparsity

At first, we define nowhere and somewhere density as a property of *graph classes* and then lift the notation to *random graph models*. There are various equivalent definitions and we use the most common definition based on shallow topological minors.

▶ **Definition 8** (Shallow topological minor [63]). *A graph H is an r-shallow topological minor of G if a graph obtained from H by subdividing every edge up to $2r$ times is isomorphic to a subgraph of G. The set of all r-shallow topological minors of a graph G is denoted by $G \widetilde{\nabla} r$. We define the maximum clique size over all shallow topological minors of G as*

$$\omega(G \widetilde{\nabla} r) = \max_{H \in G \widetilde{\nabla} r} \omega(H).$$

▶ **Definition 9** (Nowhere dense [62]). *A graph class $\mathcal{G}$ is nowhere dense if there exists a function f, such that for all $r \in \mathbf{N}$ and all $G \in \mathcal{G}$, $\omega(G \widetilde{\nabla} r) \leq f(r)$.*

▶ **Definition 10** (Somewhere dense [62]). *A graph class $\mathcal{G}$ is somewhere dense if for all functions f there exists an $r \in \mathbf{N}$ and a $G \in \mathcal{G}$, such that $\omega(G \widetilde{\nabla} r) > f(r)$.*

Observe that a graph class is somewhere dense if and only if it is not nowhere dense. We lift these notions to random graph models using the following two definitions.

▶ **Definition 11** (a.a.s. nowhere dense). *A random graph model $\mathcal{G}$ is a.a.s. nowhere dense if there exists a function f such that for all $r \in \mathbf{N}$*

$$\lim_{n\to\infty} \Pr[\omega(\mathcal{G}_n \widetilde{\nabla} r) \leq f(r)] = 1.$$

▶ **Definition 12** (a.a.s. somewhere dense). *A random graph model $\mathcal{G}$ is a.a.s. somewhere dense if for all functions f there is an $r \in N$ such that*

$$\lim_{n\to\infty} \Pr[\omega(\mathcal{G}_n \widetilde{\nabla} r) > f(r)] = 1.$$

While for graph classes the concepts are complementary, a random graph model can both be *neither* a.a.s. somewhere dense *nor* a.a.s. nowhere dense (e.g., if the random graph model is either the empty or the complete graph, both with a probability of 1/2).

4.4 First-Order Logic

We consider only first-order logic over labeled graphs. We interpret a labeled graph $G = (V, E, P_1, \ldots, P_l)$, as a structure with universe V and signature $(E, P_1, \ldots, P_l)$. The binary relation E expresses adjacency between vertices and the unary relations $P_1, \ldots, P_l$ indicate the labels of the vertices. Other structures can be easily converted into labeled graphs. We write $\varphi(x_1, \ldots, x_k)$ to indicate that a formula φ has *free variables* $x_1, \ldots, x_k$. The *quantifier rank* of a formula is the maximum nesting depth of quantifiers in the formula. Two labeled graphs G_1, G_2 with the same signature are *q-equivalent* ($G_1 \equiv_q G_2$) if for every first-order sentence φ with quantifier rank at most q and matching signature holds $G_1 \models \varphi$ if and only if $G_2 \models \varphi$. Furthermore, $|\varphi|$ is the number of symbols in φ. There exists a simple algorithm which decides whether $G \models \varphi$ in time $O(|G|^{|\varphi|})$.

4.5 Model-Checking

With all definitions in place, we can now properly restate the model-checking problem and what it means to solve it efficiently on a random graph model. The model-checking problem on labeled graphs is defined as follows.

p-MC(FO, $\mathfrak{G}_{lb}$)	
Input:	A graph $G \in \mathfrak{G}_{lb}$ and a first-order sentence φ
Parameter:	$\lvert\varphi\rvert$
Problem:	$G \models \varphi$?

Under worst-case complexity, p-MC(FO, $\mathfrak{G}_{lb}$) is AW[$*$]-complete [25] (and PSPACE-complete when unparameterized [71]). We want average case algorithms for p-MC(FO, $\mathfrak{G}_{lb}$) to be efficient for all possible labelings of a random graph model. A function $L : \mathfrak{G} \to \mathfrak{G}_{lb}$ is called a *l-labeling function* for $l \in \mathbf{N}$ if for every $G \in \mathfrak{G}$, $L(G)$ is a labeling of G with up to l labels.

▶ **Definition 1.** *We say* p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ *can be decided on a random graph model* $(\mathcal{G}_n)_{n\in\mathbf{N}}$ *in* expected time $f(|\varphi|, n)$ *if there exists a deterministic algorithm* $\mathcal{A}$ *which decides* p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ *on input* G, φ *in time* $t_{\mathcal{A}}(G, \varphi)$ *and if for all* $n \in \mathbf{N}$, *all first-order sentences* φ *and all* $|\varphi|$*-labeling functions* L, $\mathrm{E}_{G\sim\mathcal{G}_n}\left[t_{\mathcal{A}}(L(G), \varphi)\right] \leq f(|\varphi|, n)$. *We say* p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ *on a random graph model can be decided in* expected FPT time *if it can be decided in expected time* $g(|\varphi|)n^{O(1)}$ *for some function* g.

5 Structure Theorem for Power-Law-Bounded Random Graph Models

The goal of this section is to partition α-power-law-bounded random graph models. We show in Theorem 14 that their vertices can with high probability be partitioned into sets A, B, C with the following properties: The sets A and B are small, the graph $G[B \cup C]$ is locally almost a tree, i.e., has locally only a small edge-excess, and the set B almost separates A from C, i.e., every neighborhood in $G[C]$ has only a small number of edges to A. We call (A, B, C) a b-r-μ-partition. We state the formal definition.

▶ **Definition 13** (b-r-μ-partition)**.** *Let* $b, r, \mu \in \mathbf{N}^+$. *Let* G *be a graph. A tuple* (A, B, C) *is called a* b-r-μ*-partition of* G *if*

1. *the sets* A, B, C *are pairwise disjoint and their union is* $V(G)$,
2. $|A| \leq b$ *and* $|B| \leq b^{\mu}$,
3. *every* $40\mu r$*-neighborhood in* $G[B \cup C]$ *has an edge-excess of at most* μ^2, *and*
4. *for every* $20\mu r$*-neighborhood in* $G[C]$ *there are at most* μ *edges incident to both the neighborhood and to* A.

A graph for which a b-r-μ*-partition exists is called* b-r-μ*-partitionable.*

In summary, B and C are well behaved and the large set C is almost separated from A. Note that the properties of a b-r-μ-partition depend on three parameters b, r, μ. The results of this section imply that our random graphs are asymptotically almost surely b-r-μ-partitionable for $b = \tilde{d}_{\alpha}(n)^{\Omega(1)}$ and constant r, μ. It therefore helps to assume that b is a slowly growing function in n, such as $\log(n)$ and r, μ are constants. Higher values of μ boost the probability of a random graph being b-r-μ-partitionable. The parameter μ is therefore crucial for the design of efficient algorithms. The main result of this section is the following.

▶ **Theorem 14.** *Let* $(\mathcal{G}_n)_{n\in\mathbf{N}}$ *be an* α*-power-law-bounded random graph model and let* $b, r, \mu, n \in \mathbf{N}^+$ *with* $\mu \geq 5$. *The probability that* $\mathcal{G}_n$ *is not* b-r-μ*-partitionable is at most* $\tilde{d}_{\alpha}(n)^{O(\mu^6 r^2)} b^{-\mu^2/10}$.

For proofs of the results in this section, we refer the reader to Section 6 of the full version of this paper [26]. In the following we only sketch the main ideas.

For an α-power-law-bounded random graph model $(\mathcal{G}_n)_{n\in\mathbf{N}}$, we always assume the vertices of $\mathcal{G}_n$ to be $v_1, \ldots, v_n$, ordered as in Definition 2. We will choose $A = \{v_1, \ldots, v_b\}$, $B = \{v_{b+1}, \ldots, v_{b^{\mu}}\}$, $C = \{v_{b^{\mu}+1}, \ldots, v_n\}$ and show that the probability is low that (A, B, C) does not form a b-r-μ-partition. To do so, we first define $\mathcal{H}_n(b, r, \mu)$ to be a set of graphs over the vertex set $\{v_1, \ldots, v_n\}$.

▶ **Definition 15.** *Let* $b, r, \mu, n \in \mathbf{N}^+$. *We define* $\mathcal{H}_n(b, r, \mu)$ *to be the set of*

- *all graphs with vertex set* $V \subseteq \{v_{b+1}, \ldots, v_n\}$ *such that* $|V| \leq 200r\mu^3$, *all vertices have degree at least two, and the graph has an edge-excess of* μ^2, *and*

- *all graphs* $(V_1 \cup V_2, E)$ *such that* $V_1 \subseteq \{v_1, \dots, v_b\}$, $V_2 \subseteq \{v_{b^\mu+1}, \dots, v_n\}$, $|V_1 \cup V_2| \leq 25r\mu^2$, $|E| \leq 25r\mu^2$, $|V_1| \leq \mu$, *all vertices in* V_2 *have degree at least two, and the summed degree of* V_2 *is* $2|V_2| - 2 + \mu$.

We show that if (A, B, C) is not a b-r-μ-partition then the complete edge-set of some graph in $\mathcal{H}_n(b, r, \mu)$ is present in the graph.

▶ **Definition 16.** *Let* G *be a graph and* $\mathcal{H}$ *be a set of graphs over* $V(G)$. *We say* $\mathcal{H} \sqsubseteq G$ *if for some* $H \in \mathcal{H}$, $E(H) \subseteq E(G)$.

▶ **Lemma 17.** *Let* $b, r, \mu, n \in \mathbf{N}^+$. *If a graph* G *with vertex set* $\{v_1, \dots, v_n\}$ *is not* b-r-μ-*partitionable, then* $\mathcal{H}_n(b, r, \mu) \sqsubseteq G$.

For a fixed graph $H \in \mathcal{H}_n(b, r, \mu)$, α-power-law-boundedness (Definition 2) immediately gives us a good bound on the probability $\Pr\big[E(H) \subseteq E(\mathcal{G}_n)\big]$ that its edge-set occurs. Using the union bound over all graphs in $\mathcal{H}_n(b, r, \mu)$ and some tedious calculations (Lemmas 5.6, 5.7, 5.8, 5.9 in [26]) we can bound the probability of the edge-set of any graph from $\mathcal{H}_n(b, r, \mu)$ being present in the random graph model, proving the main result Theorem 14.

At last, we present one more result in which we bound the sum of the expected sizes of all r-neighborhoods in an α-power-law-bounded graph class. This is needed in Section 8 to bound the expected run time of an algorithm that iterates over all r-neighborhoods of a graph.

▶ **Lemma 18.** *Let* $(\mathcal{G}_n)_{n \in \mathbf{N}}$ *be an* α-*power-law-bounded random graph model. Let* $r, \mu, n \in \mathbf{N}^+$ *with* $\mu \geq 5$. *Let* A_b *be the event that* $b \in \mathbf{N}^+$ *is the minimal value such that* $\mathcal{G}_n$ *is* b-r-μ-*partitionable. Then*

$$\mathrm{E}\Big[\sum_{v \in V(\mathcal{G}_n)} \|\mathcal{G}_n[N_r^{\mathcal{G}_n}(v)]\| \;\Big|\; A_b\Big] \Pr[A_b] \leq (r\mu)^{O(r)} \tilde{d}_\alpha(n)^{O(\mu^6 r^2)} b^{-\mu^2/10} n.$$

6 Protrusion Decompositions of Neighborhoods

In this section, we show that local neighborhoods of power-law-bounded graph classes are likely to have the following nice structure: They consist of a (small) core graph to which so called *protrusions* are attached. Protrusions are (possibly large) subgraphs with small treewidth and boundary. The *boundary* of a subgraph is the size of its neighborhood in the remaining graph. Protrusions were introduced by Bodlaender et al. for very general kernelization results in graph classes with bounded genus [5].

Earlier, (Theorem 14) we showed that α-power-law-bounded random graph models are (for certain values of α, b, r, μ) likely to be b-r-μ-partitionable. It is therefore sufficient to show that r-neighborhoods of b-r-μ-partitionable graphs have such a nice protrusion structure.

However, in general it is not easy to find protrusions in a graph [49]. As we later need to be able to find them, we define special protrusion decompositions, called b-r-μ-local-protrusion-partitions in which (most of) the protrusions can be efficiently identified. The main and only result of this section is the following theorem.

▶ **Theorem 19.** *Let* $b, r, \mu \in \mathbf{N}^+$ *and let* G *be a* b-r-μ-*partitionable graph. Let* G^r *be an* r-*neighborhood in* G. *Then* G^r *is* $O(\mu^{17} r^3 b)$-r-$O(\mu)$-*locally-protrusion-partitionable.*

It remains to define what a b-r-μ-local-protrusion-partition of a graph G^r with radius at most r is. The definition has to strike the right balance: It needs to be permissive enough such that neighborhoods of power-law-bounded graph classes are likely to have this structure

and it needs to be restrictive enough to admit efficient algorithms. Informally speaking, a b-r-μ-local-protrusion-partition of a graph G^r is a partition (X, Y, Z) of the vertices of G^r such that X has small size and the connected components of $G^r[Y \cup Z]$ are protrusions. In order to be able to efficiently identify the protrusions, we further require that the components of $G^r[Y]$ have bounded size and the components of $G^r[Z]$ are trees. This is formalized in the following definition.

▶ **Definition 20** (b-r-μ-local-protrusion-partition)**.** *Let $b, r, \mu \in \mathbf{N}^+$. Let G^r be a graph with radius at most r. A tuple (X, Y, Z) is called a b-r-μ-local-protrusion-partition of G^r if*

1. *the sets X, Y, Z are pairwise disjoint and their union is $V(G^r)$,*
2. *$|X| \leq b^\mu$,*
3. *every connected component of $G^r[Y]$ has size at most $r\mu^7$ and at most μ neighbors in X,*
4. *every connected component of $G^r[Z]$ is a tree with at most one edge to $G^r[X \cup Y]$,*
5. *for a subgraph H of $G^r[Y \cup Z]$ we say $N^{G^r}(V(H)) \cap X$ is the boundary of H. The connected components of $G^r[Y]$ may have at most b^μ distinct boundaries, i.e., $|\{N^{G^r}(V(H)) \cap X \mid H \text{ connected component of } G^r[Y \cup Z]\}| \leq b^\mu$.*

A graph for which a b-r-μ-local-protrusion-partition exists is called b-r-μ-locally-protrusion-partitionable.

Property 3 and 4 enforce that the components of $G^r[Y \cup Z]$ are protrusions. Later, we will transform b-r-μ-local-protrusion-partitions into equivalent graphs of bounded size by replacing the protrusions with small graphs. Thus, Property 2 and 5 are there to ensure that the resulting kernelized graph will have size roughly b^μ (without Property 5 we could only guarantee a size of roughly b^{μ^2} which is too large for our purposes).

Proving Theorem 19 involves multiple pages of proofs for which we refer to the full version of this paper [26]. Here, we only sketch the construction of an $O(\mu^{17}r^3b)$-r-$O(\mu)$-local-protrusion-partition. Let a graph G and $b, r, \mu \in \mathbf{N}^+$ be fixed. We further assume G to be b-r-μ-partitionable and we fix a b-r-μ-partition (A, B, C) of G. Let further G^r be an r-neighborhood in G and let $A^r = A \cap V(G^r)$, $B^r = B \cap V(G^r)$, $C^r = C \cap V(G^r)$. We construct an $O(\mu^{17}r^3b)$-r-$O(\mu)$-local-protrusion-partition (X, Y, Z) of G^r by placing all vertices from $A^r \cup B^r$ into X. In order to distribute the vertices C^r to the sets X, Y, and Z, we define so called *ties*.

▶ **Definition 21** (Tie)**.** *Let $W \subseteq B^r \cup C^r$. We say (u_1, u_2, v) is a W-*tie *if $u_1, u_2 \in W$ and v lies on a walk p with the following properties: Every inner vertex of p is contained in C^r and has at least two neighbors in p; u_1 and u_2 are contained only as endpoints of p; and p is contained in a $20\mu r$-neighborhood in $G[B^r \cup C^r]$.*

We use this notion to partition the set C^r. We distinguish vertices connected to A^r, vertices connected to B^r (but not to A^r), those which are connected to neither but lie on a tie, and the rest. We set

- $C^r_A = N(A^r) \cap C^r$,
- $C^r_B = (N(B^r) \setminus N(A^r)) \cap C^r$,
- $C^r_Y = \{v \mid v \in C^r \setminus (C^r_A \cup C^r_B)$ and there exist $u_1, u_2 \in C^r_A \cup C^r_B$ such that (u_1, u_2, v) is a $(C^r_A \cup C^r_B)$-tie $\}$,
- $C^r_Z = C^r \setminus (C^r_A \cup C^r_B \cup C^r_Y)$.

Finally, we define X to be the union of A^r, B^r and all vertices from $C^r_A \cup C^r_B \cup C^r_Y$ which are in a connected component of $G[C^r]$ with more than one edge to B^r. We define Y to be the vertices from $C^r_A \cup C^r_B \cup C^r_Y$ which are in a connected component of $G[C^r]$ with at most one edge to B^r, and we define $Z = C^r_Z$. The fact that (X, Y, Z) is an $O(\mu^{17}r^3b)$-r-$O(\mu)$-local-protrusion-partition is proved in Section 6 of [26].

7 Compressing Neighborhoods

In this section, we kernelize b-r-μ-partitionable graphs. This means we replace the protrusions with subgraphs of bounded size that retain the same boundary. This yields a smaller graph which is q-equivalent to the original graph. The same technique has been used for obtaining small kernels in larger graph classes, e.g., in graphs that exclude a fixed minor [36]. The main result of this section is the following theorem.

▶ **Theorem 22.** *There exists an algorithm that takes $q, r, \mu \in \mathbf{N}^+$ and a connected labeled graph G with radius at most r and at most q labels as input, runs in time at most $f(q,r,\mu)\|G\|$ for some function $f(q,r,\mu)$, and computes a labeled graph $G^* \equiv_q G$. If G is b-r-μ-locally-protrusion-partitionable for some $b \in \mathbf{N}^+$ then $|G^*| \leq f(q,r,\mu)b^\mu$.*

This kernelization procedure and its run time bound is independent in b but the size of the output kernel is not: If b is small, then the output is small. The result is obtained by replacing protrusions with the help of the Feferman–Vaught theorem [48]. However, in order to replace the protrusions, one first has to identify them. The main complication in this section lies in partitioning a graph such that the relevant protrusions can be easily identified. It is crucial that we obtain the size bound $|G^*| \leq f(q,r,\mu)b^\mu$ in Theorem 22. Weaker bounds are easier to obtain but would not be sufficient for our purposes.

We use a variant of the Feferman–Vaught theorem [48] to replace a protrusion by a q-equivalent boundaried graph of minimal size. This size depends only on q and the size of the boundary. The original Feferman–Vaught theorem states that the validity of FO-formulas on the disjoint union or Cartesian product of two graphs is uniquely determined by the value of FO-formulas on the individual graphs. Makowsky adjusted the theorem for algorithmic use [55] in the context of MSO model-checking. The following proposition contains the Feferman–Vaught theorem in a very accessible form. There is also a nice and short proof in [45]. The notation is borrowed from [45], too. At first, we need to define so called q-types.

▶ **Definition 23** ([45]). *Let G be a labeled graph and $\bar{v} = (v_1, \ldots, v_k) \in V(G)^k$, for some nonnegative integer k. The* first-order q-type of $\bar{v}$ in G *is the set $\operatorname{tp}_q^{\mathrm{FO}}(G, \bar{v})$ of all first-order formulas $\psi(x_1, \ldots x_k)$ of rank at most q such that $G \models \psi(v_1, \ldots, v_k)$.*

A q-type could be an infinite set, but one can reduce them to a finite set by syntactically normalizing formulas, so that there are only finitely many normalized formulas of fixed quantifier rank and with a fixed set of free variables. These finitely many formulas can be enumerated. For a tuple $\bar{u} = (u_1, \ldots, u_k)$, we write $\{\bar{u}\}$ for the set $\{u_1, \ldots, u_k\}$. The following is a variant of the Feferman–Vaught theorem [48].

▶ **Proposition 24** ([45, Lemma 2.3]). *Let G, H be labeled graphs and $\bar{u} \in V(G)^k$, such that $V(G) \cap V(H) = \{\bar{u}\}$. Then for all $q \geq 0$, $\operatorname{tp}_q^{\mathrm{FO}}(G \cup H, \bar{u})$ is determined by $\operatorname{tp}_q^{\mathrm{FO}}(G, \bar{u})$ and $\operatorname{tp}_q^{\mathrm{FO}}(H, \bar{u})$.*

We use this proposition to define a q-type preserving protrusion replacement procedure. Assume we identify a protrusion H of a graph with boundary $\bar{u}$. Using Courcelle's theorem [17], we can compute $\operatorname{tp}_q^{\mathrm{FO}}(H, \bar{u})$ by checking all representing formulas. By then enumerating all graphs in ascending order by their size we can find a small graph H' with $\operatorname{tp}_q^{\mathrm{FO}}(H', \bar{u}) = \operatorname{tp}_q^{\mathrm{FO}}(H', \bar{u})$. Proposition 24 now states that we can replace H with H' to obtain a smaller q-equivalent graph. We repeat this for every protrusion we identify. In the full version of this paper [26], this procedure and the proof of Theorem 22 is presented in detail (Section 7).

8 Model-Checking

In this section, we finally obtain the main result of this paper, namely that for certain values of α one can perform model-checking on α-power-law-bounded random graph models in efficient expected time.

An important tool in this section is Gaifman's locality theorem [39]. It states that first-order formulas can express only local properties of graphs. It is a well established tool for the design of model-checking algorithms (e.g. [44, 45, 37]). We use it to reduce the model-checking problem on a graph to the model-checking problem on neighborhoods of said graph [26, Lemma 8.2]. This technique is described well by Grohe [45, section 5].

To illustrate our approach, consider the following thought experiment: Let X be a non-negative random variable with $\Pr[X = b] = \Theta(b^{-10})$ for all $b \in \mathbf{N}$. Assume an algorithm that gets an integer $b \in \mathbf{N}$ as input and runs in time $t(b)$. Its expected run time on input X is $\sum_{b\in\mathbf{N}} \Theta(b^{-10})t(X)$. If $t(b) = b^{10}$ then the expected run time is infinite. If $t(b) = b^8$ then the expected run time is $\Theta(1)$. Thus, small polynomial differences in the run time can have a huge impact on the expected run time. We notice that the run time on an input has to grow slower than the inverse of the probability that the input occurs.

Let us fix a formula φ and let r and μ be constants depending on φ. In this section we provide a model-checking algorithm whose run time on a graph G depends on the minimal value $b \in \mathbf{N}$ such that G is b-r-μ-partitionable. This means, we need to solve the model-checking problem on b-r-μ-partitionable graphs faster than the inverse of the probability that b is minimal.

Section 5 states that a graph from power-law-bounded graph classes is for some b not b-r-μ-partitionable with probability approximately $b^{-\mu^2}$ (we ignore the terms in r, μ and $\tilde{d}_\alpha(n)$ for now). Thus, the probability that a value b is minimal is approximately $b^{-\mu^2}$.

Let G be a graph and a be the minimal value such that G is b-r-μ-partitionable. In Section 6 we showed that all its r-neighborhoods are $O(\mu^{17}r^3b)$-r-$O(\mu)$-locally-protrusion-partitionable. The kernelization result from Section 7 states that such r-neighborhoods can be converted in linear time into $|\varphi|$-equivalent graphs of size approximately b^μ (we again ignore the factors independent of b for now). This means, using the naive model-checking algorithm, one can decide for an r-neighborhood G^r of G whether $G^r \models \varphi$ in time approximately $\|G\|b^{\mu|\varphi|}$. Thus, one can perform model-checking on all r-neighborhoods of G in time approximately $b^{\mu|\varphi|}\sum_v \|N_r^G(v)\|$. Using Gaifman's locality theorem, this (more or less) yields the answer to the model checking problem in the *whole* graph. Let G be a graph from a power-law-bounded random graph model. In summary, we have for every $b \in \mathbf{N}$:

- $b \in \mathbf{N}$ is the minimal value such that a graph is b-r-μ-partitionable with probability approximately $b^{-\mu^2}$.
- If $b \in \mathbf{N}$ is the minimal value such that G is b-r-μ-partitionable then we can decide whether $G \models \varphi$ in time approximately $b^{\mu|\varphi|}\sum_v \|N_r^G(v)\|$.

In this example one may choose $\mu = |\varphi|^2$ such that the run time grows slower than the inverse of the probability. We changed some numbers in these examples to simplify our arguments. Thus, in reality, μ needs to be chosen slightly differently.

The proofs of this section proceed as follows. We first use slightly nonstandard version of Gaifman locality [26, Lemma 8.2] and the kernelization result in Theorem 22 to solve the model-checking in b-r-μ-partitionable graphs, obtaining the following result (see [26, Lemma 8.4] for the proof).

▶ **Lemma 25.** *Let $\mu \in \mathbf{N}^+$. There exist functions ρ and f such that for every first-order sentence φ and every labeled graph G with at most $|\varphi|$ labels one can decide whether $G \models \varphi$ in time $f(\rho(|\varphi|), \mu) b^{\mu\rho(|\varphi|)} \sum_{v \in V(G)} \|G[N^G_{\rho(|\varphi|)}(v)]\|$, where $b \in \mathbf{N}^+$ is the minimal value such that G is b-$\rho(r)$-μ-partitionable.*

The run time of this algorithm depends not only on b but also on the sum of the sizes of all neighborhoods in a graph, which might be quadratic in the worst case. In order to get almost linear expected run time, we bound the expectation of this value in Lemma 18. We can now prove our main result.

▶ **Theorem 3.** *There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on every α-power-law-bounded random graph model in expected time $\tilde{d}_\alpha(n)^{f(|\varphi|)} n$.*

Proof. Let $(\mathcal{G}_n)_{n \in \mathbf{N}}$ be an α-power-law-bounded random graph model and φ be a first-order formula. We fix a $|\varphi|$-labeling function L and $n \in \mathbf{N}$. We consider labeled graphs with vertices $V(\mathcal{G}_n)$ whose underlying graph is distributed according to $\mathcal{G}_n$, and analyze the expected run time of the model-checking algorithm from Lemma 25 on these graphs.

Let ρ be the function from Lemma 25 and let $r = \rho(|\varphi|)$ and $\mu = \rho(|\varphi|)^2 + 100$. For every graph G there exists a value $b \in \mathbf{N}^+$ such that G is b-r-μ-partitionable (i.e., by setting $b = |V(G)|$, $A = V(G)$). Let A_b be the event that $b \in \mathbf{N}^+$ is the minimal value such that $\mathcal{G}_n$ is b-r-μ-partitionable and let R be the expected run time of the model-checking algorithm from Lemma 25. The expected run time of the algorithm is exactly $\sum_{b=1}^{\infty} \mathrm{E}[R \mid A_b] \Pr[A_b]$. We use Lemma 25 and 18 to bound

$$
\begin{aligned}
&\sum_{b=1}^{\infty} \mathrm{E}[R \mid A_b] \Pr[A_b] \\
\leq &\sum_{b=1}^{\infty} \mathrm{E}\Big[f'(r,\mu) b^{r\mu} \sum_{v \in V(\mathcal{G}_n)} \|\mathcal{G}_n[N^{\mathcal{G}_n}_r(v)]\| \mid A_b\Big] \Pr[A_b] \\
= &\sum_{b=1}^{\infty} f'(r,\mu) b^{r\mu} \,\mathrm{E}\Big[\sum_{v \in V(\mathcal{G}_n)} \|\mathcal{G}_n[N^{\mathcal{G}_n}_r(v)]\| \mid A_b\Big] \Pr[A_b] \\
\leq &\sum_{b=1}^{\infty} f'(r,\mu) b^{r\mu} (200 r \mu^3)^{O(r)} \tilde{d}_\alpha(n)^{O(\mu^6 r^2)} b^{-\mu^2/10} n \\
= &f'(r,\mu)(200 r \mu^3)^{O(r)} \tilde{d}_\alpha(n)^{O(\mu^6 r^2)} n \sum_{b=1}^{\infty} b^{-\mu^2/10 + r\mu}.
\end{aligned}
$$

Note that for $\mu = \rho(|\varphi|)^2 + 100$ and $r = \rho(|\varphi|)$ we have $\sum_{b=1}^{\infty} b^{-\mu^2/10 + r\mu} \leq \sum_{b=1}^{\infty} b^{-2} = O(1)$. This yields a run time of $\tilde{d}_\alpha(n)^{f(|\varphi|)} n$ for some function f. ◀

By substituting the values of $\tilde{d}_\alpha(n)$ and distinguishing three cases we obtain the following alternative form of our main result.

▶ **Theorem 4.** *Let $(\mathcal{G}_n)_{n \in \mathbf{N}}$ be a random graph model and $\varepsilon > 0$. There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ in expected time*

- $f(|\varphi|) n$ *if $(\mathcal{G}_n)_{n \in \mathbf{N}}$ is α-power-law-bounded for some $\alpha > 3$,*
- $\log(n)^{f(|\varphi|)} n$ *if $(\mathcal{G}_n)_{n \in \mathbf{N}}$ is α-power-law-bounded for $\alpha = 3$,*
- $f(|\varphi|, \varepsilon) n^{1+\varepsilon}$ *for all $\varepsilon > 0$ if $(\mathcal{G}_n)_{n \in \mathbf{N}}$ is α-power-law-bounded for every $2 < \alpha < 3$.*

9 Implications for Various Graph Models

A wide range of unclustered random graph models are α-power-law-bounded. In this section, we discuss the implications of our result for preferential attachment, Chung–Lu, and Erdős–Rényi graphs. A more detailed discussion with proofs can be found in Section 10 in the full version [26].

9.1 Preferential Attachment Model

The preferential attachment model [3, 64] may be the best-known model for complex networks. In this model, graphs are created by a random process that iteratively adds new vertices and randomly connects them to already existing ones, where the attachment probability is proportional to the current degree of a vertex. The preferential attachment process exhibits small world behavior [24] and has been widely recognized as a reasonable explanation of the heavy tailed degree distribution of complex networks [7]. It has a vanishing clustering coefficient [8], but there exist extensions of the model that admit clustering [73].

Recent efficient model-checking algorithms on random graph models only worked on random graph models that asymptotically almost surely (a.a.s.) are nowhere dense [44, 22]. It is known that preferential attachment graphs are not a.a.s. nowhere dense [22] and even a.a.s. somewhere dense [27], thus previous techniques do not work.

We define G^n_m to be the preferential attachment graph with n vertices and m edges per vertex. Usually, the parameter m is considered to be constant. We obtain efficient algorithms even if we allow m to be a function of the size of the network. For a function $m(n)\colon \mathbf{N} \to \mathbf{N}$ we define $(G^n_{m(n)})_{n\in\mathbf{N}}$ to be the random graph model where the number of edges per vertex grows according to $m(n)$. Previous work [29] implies that this model is α-power-law-bounded ([26, Lemma 10.1]), which immediately implies the following model checking result.

▶ **Corollary 26.** *Let $m\colon \mathbf{N} \to \mathbf{N}$. There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on the preferential attachment model $(G^n_{m(n)})_{n\in\mathbf{N}}$ in expected time*

- $\log(n)^{f(|\varphi|)}n$ *if* $m(n) = \log(n)^{O(1)}$,
- $f(|\varphi|,\varepsilon)n^{1+\varepsilon}$ *for every* $\varepsilon > 0$ *if* $m(n) = O(n^\varepsilon)$ *for every* $\varepsilon > 0$.

9.2 Chung–Lu Model

This model generates random graphs that fit a certain degree sequence and has been studied extensively [12, 13, 14]. The degree sequence is defined by a power-law distribution with exponent α. One can easily show that this model is α-power-law-bounded [26, Lemma 10.3]. We can therefore characterize the tractability of the labeled model-checking problem on Chung–Lu graphs based on α.

▶ **Corollary 27.** *Let $\mathcal{G}$ be the Chung–Lu random graph model with exponent α. There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on $\mathcal{G}$ in expected time*

- $f(|\varphi|)n$ *if* $\alpha > 3$,
- $\log(n)^{f(|\varphi|)}n$ *if* $\alpha = 3$.

Furthermore, if $2.5 \leq \alpha < 3$, $\alpha \in \mathbf{Q}$ then one cannot solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on $\mathcal{G}$ in expected FPT *time unless* AW$[*] \subseteq$ FPT/poly.

Previously, the model-checking problem has been known to be tractable on Chung–Lu graphs with exponent $\alpha > 3$, and hard on Chung–Lu graphs with exponent $2.5 \leq \alpha < 3$. The important case $\alpha = 3$ was open. Furthermore, the previous tractability result assumes

the maximum expected degree of a Chung–Lu graph with exponent α to be at most $O(n^{1/\alpha})$, while in the canonical definition of Chung–Lu graphs it is $\Theta(n^{1/(\alpha-1)})$. Our results hold for the canonical definition. The missing case $\alpha < 2.5$ is still open. We believe it can be proven to be hard with similar techniques as for $2.5 \leq \alpha < 3$.

9.3 Erdős–Rényi Model

One of the earliest and most intensively studied random graph models is the Erdős–Rényi model [31]. We say $G(n, p(n))$ is a random graph with n vertices where each pair of vertices is connected independently uniformly at random with probability $p(n)$. Many properties of Erdős–Rényi graphs are well studied, including but not limited to, threshold phenomena, the sizes of components, diameter, and length of paths [9]. With a three-line argument [26, Lemma 10.8], we obtain a fine grained picture over the tractability of the model-checking problem on sparse Erdős–Rényi graphs.

▶ **Corollary 28.** *There exists a function f such that one can solve p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ on $G(n, p(n))$ in expected time*

- $f(|\varphi|)n$ *if* $p(n) = O(1/n)$,
- $\log(n)^{f(|\varphi|)}n$ *if* $p(n) = \log(n)^{O(1)}/n$,
- $f(|\varphi|, \varepsilon)n^{1+\varepsilon}$ *for every* $\varepsilon > 0$ *if* $p(n) = O(n^{\varepsilon}/n)$ *for every* $\varepsilon > 0$.

The third case has been shown previously by Grohe [44]. Furthermore, under reasonable assumptions (AW[$*$] $\not\subseteq$ FPT/poly) we know that p-MC$(\mathrm{FO}, \mathfrak{G}_{lb})$ cannot be decided in expected FPT time on denser Erdős–Rényi graphs with $p(n) = n^{\delta}/n$ for some $0 < \delta < 1$, $\delta \in \mathbf{Q}$ [28].

10 Conclusion

We define α-power-law-bounded random graphs which generalize many unclustered random graphs models. We provide a structural decomposition of neighborhoods of these graphs and use it to obtain a meta-algorithm for deciding first-order properties in the the preferential attachment-, Erdős–Rényi-, Chung–Lu- and configuration random graph model.

There are various factors to consider when evaluating the practical implications of this result. The degree distribution of most real world networks is similar to a power-law distribution with exponent between two and three [15], but our algorithm is only fast for exponents at least three. This leaves many real world networks where our algorithm is slow. However, it has been shown that the model-checking problem (with labels) becomes hard on these graphs if we assume independently distributed edges [28].

So far, we do not know whether the model-checking problem is hard or tractable on clustered random graphs. If a random graph model is 3-power-law-bounded then one can show that the expected number of triangles is polylogarithmic (via union bound of all possible embeddings of a triangle). Therefore, random models with clustering, such as the Kleinberg model [50], the hyperbolic random graph model [53, 11], or the random intersection graph model [47], which have a high number of triangles currently do not fit into our framework (see [26, Section 10.5] for a proof that random intersection graphs are not α-power-law-bounded for any α). This is unfortunate, since clustering is a key aspect of real networks [72]. In the future, we hope to extend our results to clustered random graph models. We observe that some clustered random graph models can be expressed as *first-order transductions* of α-power-law-bounded random graph models. For example the random intersection graph model is a transduction of a sparse Erdős–Rényi graph. We believe this connection can be

used to transfer tractability results to clustered random graphs. If we can efficiently compute for a clustered random graph model $\mathcal{G}$ a pre-image of a transduction that is distributed like an α-power-law-bounded random graph then we can efficiently solve p-MC(FO, $\mathfrak{G}_{lb}$) on $\mathcal{G}$. The same idea is currently being considered for solving the model checking problem for transductions of sparse graph classes (e.g. structurally bounded expansion classes) [40].

In our algorithm, we use Gaifman's locality theorem to reduce our problem to r-neighborhoods of the input graph. In this construction the value of r can be exponential in the length of the formula [39]. On the other hand, the small world property states that the radius of real networks is rather small. This means, even for short formulas our neighborhood-based approach may practically be working on the whole graph instead of neighborhoods. It would be interesting to analyze for which values of r practical protrusion decompositions according to Theorem 6 exist in the real world.

At last, a big problem with all parameterized model-checking algorithms is their large run time dependence on the length of the formula. Grohe and Frick showed that already on trees every first-order model-checking algorithm takes worst-case time at least $f(|\varphi|)n$ where f is a non-elementary tower function [38]. So far, it is unclear whether this also holds in the average-case setting. The results presented in this paper have a non-elementary dependence on the length of the formula. We are curious whether one can find average-case model-checking algorithms with elementary expected FPT run time. In summary, many more obstacles need to be overcome to obtain a truly practical general purpose meta-algorithm for complex networks.

Abstract

We consider a fundamental online scheduling problem in which jobs with processing times and deadlines arrive online over time at their release dates. The task is to determine a feasible preemptive schedule on m machines that maximizes the number of jobs that complete before their deadline. Due to strong impossibility results for competitive analysis, it is commonly required that jobs contain some *slack* $\varepsilon > 0$, which means that the feasible time window for scheduling a job is at least $1 + \varepsilon$ times its processing time. In this paper, we answer the question on how to handle commitment requirements which enforce that a scheduler has to guarantee at a certain point in time the completion of admitted jobs. This is very relevant, e.g., in providing cloud-computing services and disallows last-minute rejections of critical tasks. We present the first online algorithm for handling commitment on parallel machines for arbitrary slack ε. When the scheduler must commit upon starting a job, the algorithm is $\Theta(\frac{1}{\varepsilon})$-competitive. Somewhat surprisingly, this is the same optimal performance bound (up to constants) as for scheduling without commitment on a single machine. If commitment decisions must be made before a job's slack becomes less than a δ-fraction of its size, we prove a competitive ratio of $\mathcal{O}(\frac{1}{\varepsilon-\delta})$ for $0 < \delta < \varepsilon$. This result nicely interpolates between commitment upon starting a job and commitment upon arrival. For the latter commitment model, it is known that no (randomized) online algorithms admits any bounded competitive ratio.

1 Introduction

We consider the following fundamental online scheduling model: jobs from an unknown job set arrive online over time at their *release dates* r_j. Each job has a *processing time* $p_j \geq 0$ and a *deadline* d_j. There are m identical machines to process these jobs or a subset of them. A job is said to *complete* if it receives p_j units of processing time within the interval $[r_j, d_j)$. We allow *preemption*, i.e., the processing of a job can be interrupted at any time. We distinguish schedules *with* and *without migration*. If we allow migration, then a preempted job can resume processing on any machine whereas it must run completely on the same machine otherwise. In the three-field notation this problem is $P \,|\, \text{online } r_j, \text{pmtn} \,|\, \sum(1 - U_j)$ [16].

In a feasible schedule, two jobs are never processing at the same time on the same machine. The number of completed jobs in a feasible schedule is called *throughput*. The task is to find a feasible schedule with maximum throughput.

As jobs arrive online, we cannot hope to find an optimal schedule [12]. To assess the performance of online algorithms, we resort to standard *competitive analysis*. This means, we compare the throughput of an online algorithm with the throughput achievable by an optimal offline algorithm that knows the job set in advance.

It is well-known that "tight" jobs with $d_j - r_j \approx p_j$ prohibit competitive online decision making as jobs must start immediately and do not leave a chance for observing online arrivals [6]. Thus, it is commonly required that jobs contain some *slack* $\varepsilon > 0$, i.e., every job j satisfies $d_j - r_j \geq (1+\varepsilon)p_j$. The competitive ratio of our online algorithm will be a function of ε; the greater the slack, the better should the performance of our algorithm be. This slackness parameter has been considered in previous work, e.g., in [2, 4, 8, 14, 15, 24, 26]. Other results for scheduling with deadlines use speed scaling, which can be viewed as another way to add slack to the schedule, e.g., [1, 3, 17, 18, 25].

In this paper, we focus on the question how to handle *commitment* requirements in online throughput maximization. Modeling commitment addresses the issue that a good-throughput schedule may abort jobs close to their deadlines in favor of many shorter and more urgent tasks [13], which may not be acceptable for the job owner. Consider a company that starts outsourcing mission-critical processes to external clouds and that needs a guarantee that jobs complete before a certain time point when they cannot be moved to another computing cluster anymore. In other situations, a commitment to complete jobs might be required even earlier just before starting the job, e.g., for a faultless copy of a database [8].

Different commitment models have been formalized [2, 8, 24]. The requirement to commit at a job's release date has been ruled out for online throughput maximization by strong impossibility results (even for randomized algorithms) [8]. We distinguish *(i) commitment upon job admission* and *(ii) δ-commitment*. In the first model, an algorithm may discard a job any time before its start, we say its admission. This reflects a situation such as the faultless copy of a database. In the second model, δ-commitment, an online algorithm must commit to complete a job when its remaining slack is not less than a δ-fraction of the job size, for $0 < \delta < \varepsilon$. The latest time for committing to job j is then $d_j - (1+\delta)p_j$. This models an early enough commitment (parameterized by δ) for mission-critical jobs. Recently, a first unified approach has been presented for these models in [8]. Gaps in the performance bounds remained and it was left open if scheduling with commitment is even "harder" than without commitment.

In this work, we give tight results for online throughput maximization on parallel machines and answer the "hardness" question to the negative. We give an algorithm that achieves the provably best competitive ratio (up to constants) for the aforementioned commitment models. Somewhat surprisingly, we show that the same competitive ratio of $\mathcal{O}(\frac{1}{\varepsilon})$ can be achieved for both, scheduling *without* commitment and *with* commitment upon admission. Further, our algorithm does not require job migration. For parallel machines, our algorithm is the first online algorithm with bounded competitive ratio for arbitrary slack parameter ε.

Previous results

Preemptive online scheduling with hard deadlines and models for admission control have been studied rigorously, see, e.g., [5, 14, 15] and references therein. Already in the 90s several impossibility results were shown for jobs without slack [6, 7, 21–23]. The only positive result independent of slack for online throughput maximization without commitment seems to be a randomized $\mathcal{O}(1)$-competitive single-machine algorithm [20]. The best possible deterministic algorithm in this setting is $\Theta(1/\varepsilon)$-competitive for instances with ε-slack [8].

Throughput maximization with commitment has attracted researchers more recently [2, 8, 24]. We summarize the state-of-the art for the particular problem of online throughput maximization with commitment. For a single machine, Chen et al. [8] presented a universal algorithmic framework, which achieved bounded competitive ratios for several commitment models and even the tight result for scheduling without commitment. More precisely, their algorithm is $\mathcal{O}(1/\varepsilon^2)$-competitive for commitment upon admission and $\mathcal{O}(\varepsilon/((\varepsilon-\delta)\delta^2))$-competitive, for $0 < \delta < \varepsilon$, in the δ-commitment model. This improved on an earlier algorithm by Azar et al. [2] for the *δ-commitment model* (in the context of truthful mechanisms for a weighted setting) that is $\mathcal{O}(1/\varepsilon^2)$-competitive if the slack ε is sufficiently large. Chen et al. showed a lower bound of $\Omega(1/\varepsilon)$ for deterministic scheduling algorithms without commitment, which is tight in that model and also holds for the more restrictive commitment models. A significant gap between lower and upper bounds remained. On parallel machines, there is a competitive algorithm for online throughput maximization with commitment if the slack ε is sufficiently large [2].

In a natural generalization of our problem, jobs have associated individual weights and we aim for a schedule with maximum weighted throughput. The special case with each job j satisfying $w_j = p_j$ (aka machine utilization) is well understood. A simple greedy algorithm achieves the best possible competitive ratio $\Theta(1/\varepsilon)$ [11, 14] on a single machine in both commitment models, even for commitment upon arrival. For scheduling with commitment on m parallel identical machines there is an $\mathcal{O}(\sqrt[m]{1/\varepsilon})$-competitive algorithm and an almost matching lower bound [26]. It is worth mentioning that machine utilization without commitment even allows for constant competitive ratios independent of slack [6, 21, 22, 27]. General weighted (and even unweighted) throughput maximization is much less tractable. For general weights, there is no bounded competitive ratio possible in any of the aforementioned commitment models [2, 8, 24]. For weighted throughput maximization without commitment requirements there is an $\mathcal{O}(1/\varepsilon^2)$-competitive online algorithm [24].

The power of migration has been investigated in several contexts: While it is typically large in online scheduling, cf. machine-utilization [26] and resource-minimization [9, 10], we show that, in our online setting, the guarantees that can be achieved by migratory and non-migratory algorithms are within a constant factor, similar to the offline problem [19].

Our results and techniques

Our main result is one algorithm that is best possible (up to constant factors) for online throughput maximization with and without commitment on parallel identical machines. Our algorithm does not migrate jobs and still achieves a competitive ratio that matches the general lower bound for migratory algorithms.

For scheduling with commitment upon admission, we give an (up to constant factors) optimal online algorithm with competitive ratio $\Theta(1/\varepsilon)$. For scheduling with δ-commitment, our result interpolates between the models commitment upon starting a job and commitment upon arrival. If $\delta \leq \varepsilon/2$, the competitive ratio is $\Theta(1/\varepsilon)$ which is best possible [8]. For $\delta \to \varepsilon$, the commitment requirements essentially implies commitment upon job arrival which has unbounded competitive ratio [8]. Note that this is the first online algorithm with bounded competitive ratio for arbitrary slackness parameter ε.

▶ **Theorem 1.** *Consider throughput maximization on parallel identical machines with or without migration. There is an $\mathcal{O}(\frac{1}{\varepsilon-\delta'})$-competitive online algorithm with commitment where $\delta' = \varepsilon/2$ in the commitment upon admission model and $\delta' = \max\{\delta, \varepsilon/2\}$ in the δ-commitment model.*

Clearly, scheduling with commitment is more restrictive than without commitment. Hence, our algorithm is also (up to constants) optimal for the problem $P \,|\, \text{online } r_j, \text{pmtn} \,|\, \sum(1-U_j)$ without any commitment requirements as its competitive ratio matches the lower bound [8].

▶ **Theorem 2.** *There is a $\Theta(1/\varepsilon)$-competitive algorithm for online throughput maximization on parallel identical machines without commitment requirements, with and without migration.*

The challenge in online scheduling with commitment is that, once we committed to complete a job, the remaining slack of this job has to be spent very carefully. The key is a job admission scheme which is implemented by different parameters. The high-level objectives are:

- **(i)** never start a job for the first time if its remaining slack is too small (parameter δ),
- **(ii)** during the processing of a job, admit only significantly shorter jobs (parameter γ), and
- **(iii)** for each admitted shorter job, block some time period (parameter β) during which no other jobs of similar size are accepted.

While the first two goals are quite natural and have been used before [8, 24], the third goal is crucial for our new tight result. The intuition is the following: suppose we committed to complete a job with processing time 1 and have only a slack of $\mathcal{O}(\varepsilon)$ left before the deadline of this job. Suppose that c substantially smaller jobs of size $1/c$ arrive where c is the competitive ratio we aim for. On the one hand, if we do not accept any of them, we cannot hope to achieve c-competitiveness. On the other hand, accepting too many of them fills up the slack and, thus, leaves no room for even smaller jobs. The idea is to keep the flexibility for future small jobs by grouping jobs of similar size (within a factor two) into classes. This gives the fine-grained classification of jobs which is crucial for our new tight result. We distinguish two time periods with different class structures that guide acceptance. During the *scheduling interval* of a job j, we have a more restrictive acceptance scheme that ensures the completion of j whereas in the *blocking period* we guarantee the completion of previously accepted jobs. In contrast, the previous algorithm in [8] uses one long region with a uniform acceptance threshold and is then too conservative in accepting jobs.

As a key contribution on the technical side, we give a strong bound on the processing volume of any feasible non-migratory schedule in terms of the accepted volume of a certain class of online algorithms. It is crucial for our analysis and might be of independent interest.

2 The blocking algorithm

In this section, we describe the *blocking algorithm* which handles scheduling with commitment. We assume that the slackness constant $\varepsilon > 0$ and, in the δ-commitment model, $0 < \delta < \varepsilon$ are given. If δ is not part of the input or if $\delta \leq \varepsilon/2$, we set $\delta = \frac{\varepsilon}{2}$.

The algorithm never migrates jobs between machines, i.e., a job is only processed by the machine that initially started to process it, we say the job has been *admitted* to this machine. Moreover, our algorithm commits to completing a job upon admission. Hence, its remaining slack has to be spent very carefully on admitting other jobs while being competitive. As our algorithm does not migrate jobs, it transfers the admission decision to the shortest admitted and not yet completed job on each machine. Then, a job only admits significantly shorter jobs and prevents the admission of too many jobs of similar size. To this end, the algorithm maintains two types of intervals for each admitted job, a *scheduling interval* and a *blocking period*. A job can only be processed in its scheduling interval. Thus, it has to complete in this interval while admitting other jobs. Job j only admits jobs that are smaller by a factor of $\gamma = \frac{\delta}{16} < 1$. For an admitted job k, job j creates a blocking period of length at most βp_k, where $\beta = \frac{16}{\delta}$, which blocks the admission of similar-length jobs (cf. Figure 1).

For **scheduling**, the algorithm follows the *Shortest Processing Time (SPT)* order for the set of uncompleted jobs assigned to a machine, which is independent of the admission scheme. SPT ensures that, in the blocking periods of any job k admitted by j, j has highest priority.

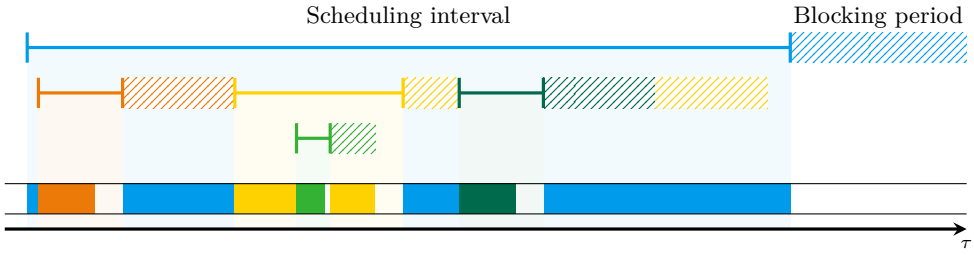

Figure 1 Scheduling interval, blocking period, and processing intervals.

For **admitting** jobs, the algorithm keeps track of *available* jobs at any time point τ. A job j with $r_j \leq \tau$ is called available if it has not yet been admitted to a machine by the algorithm and its deadline is not too close, i.e., $d_j - \tau \geq (1+\delta)p_j$.

Whenever a job j is available at a time τ when there is a machine i such that this time is not contained in the scheduling interval of any other job, the shortest such job j is immediately admitted to i, creating the scheduling interval $S(j) = [\tau, \tau + (1+\delta)p_j) := [a_j, e_j)$ and an empty blocking period $B(j) = \emptyset$. In general, however, the blocking period is a finite union of time intervals associated with job j, and its size is the sum of lengths of the intervals, denoted by $|B(j)|$. Four types of events trigger a decision of the algorithm at time τ: the release of a job, the end of a blocking period, the end of a scheduling interval, and the admission of a job. In any of these four cases, the algorithm calls the class admission routine. This subroutine iterates over all machines i and checks if j, the shortest job on i whose scheduling interval contains τ, can admit the currently shortest available job $j^\star$.

To this end, any admitted job j classifies available jobs k with $r_k \in S(j)$ and $p_k < \gamma p_j$ depending on their processing time. More precisely, job j maintains a *class structure* $(\mathcal{C}_c(j))_{c\in\mathbb{N}_0}$ where $\mathcal{C}_c(j)$ contains all jobs k that are available at some time during $S(j)$ and satisfy $\frac{\gamma}{2^{c+1}}p_j \leq p_k < \frac{\gamma}{2^c}p_j$. Only jobs $k \in \mathcal{C}_c(j)$ for $c \in \mathbb{N}_0$ qualify for admission by j. Upon admission by j, job $j^\star$ obtains two disjoint consecutive intervals, the *scheduling interval* $S(j^\star) = [a_{j^\star}, e_{j^\star})$ and the *blocking period* $B(j^\star)$ of size at most $\beta p_{j^\star}$. At the admission of job $j^\star$, the blocking period $B(j^\star)$ is planned to start at $e_{j^\star}$, the end of $j^\star$'s scheduling interval. During $B(j^\star)$ of job $j^\star \in \mathcal{C}_c(j)$, j only admits jobs k of *higher* classes, i.e., $k \in \mathcal{C}_{c'}(j)$ for $c' > c$. Particularly, j only admits job $j^\star \in \mathcal{C}_c(j)$ if the blocking period of the last job in $\mathcal{C}_c(j)$ admitted to the same machine has completed.

Hence, when job j decides if it admits the currently shortest available job $j^\star$ at time τ, it makes sure that $j^\star$ indeed belongs to a class $\mathcal{C}_c(j)$ and that no higher class $c' \geq c$ is blocking τ, i.e., it checks that $\tau \notin B(k)$ for all jobs $k \in \mathcal{C}_{c'}(j)$ admitted to the same machine. In this case, we say that $j^\star$ is a *child* of j and that j is the *parent* of $j^\star$, denoted by $\pi(j^\star) = j$. If job $j^\star$ is admitted at time τ by job j, the algorithm sets $a_{j^\star} = \tau$ and $e_{j^\star} = a_{j^\star} + (1+\delta)p_{j^\star}$ and assigns the scheduling interval $S(j^\star) = [a_{j^\star}, e_{j^\star})$ to $j^\star$.

If $e_{j^\star} \leq e_j$, the routine sets $f_{j^\star} = \min\{e_j, e_{j^\star} + \beta p_{j^\star}\}$ which determines $B(j^\star) = [e_{j^\star}, f_{j^\star})$. As the scheduling and blocking periods of children k of j are supposed to be disjoint, we have to **update the blocking periods**. First consider the job $k \in \mathcal{C}_{c'}(j)$ for $c' < c$ admitted to the same machine whose blocking period contains τ (if it exists), and let $[e'_k, f'_k)$ be the maximal interval of $B(k)$ containing τ. We set $f''_k = \min\{e_j, f'_k + (1+\delta+\beta)p_{j^\star}\}$ and replace the interval $[e'_k, f'_k)$ by $[e'_k, \tau) \cup [\tau + (1+\delta+\beta)p_{j^\star}, f''_k)$. For all other jobs $k \in \mathcal{C}_{c'}(j)$ with $B(k) \cap [\tau, \infty) \neq \emptyset$ admitted to the same machine, we replace the remaining part of their

blocking period $[e'_k, f'_k)$ by $[e'_k + (1+\delta+\beta)p_{j^\star}, f''_k)$ where $f''_k := \min\{e_j, f'_k + (1+\delta+\beta)p_{j^\star}\}$. In this update we follow the convention $[e, f) = \emptyset$ if $f \leq e$. Observe that the length of the blocking period might decrease due to such updates.

Note that $e_{j^\star} > e_j$ is also possible as j does not take the end of its own scheduling interval e_j into account when admitting jobs. Thus, the scheduling interval of $j^\star$ would end outside j's scheduling interval and inside j's blocking period. During $B(j)$, $\pi(j)$, the parent of j, did not allocate the interval $[e_j, e_{j^\star})$ for completing jobs admitted by j but for ensuring its own completion. Hence, the completion of both $j^\star$ and $\pi(j)$ is not necessarily guaranteed anymore. To prevent this, we **modify all scheduling intervals** $S(k)$ (including $S(j)$) of jobs admitted to the same machine that contain time τ and the corresponding blocking periods $B(k)$. For each job k admitted to the same machine with $\tau \in S(k)$ (i.e., including j) and $e_{j^\star} > e_k$ we set $e_k = e_{j^\star}$. We also update their blocking periods (in fact, single intervals) to reflect their new starting points. If the parent $\pi(k)$ of k does not exist, $B(k)$ remains empty; otherwise we set $B(k) := [e_k, f_k)$ where $f_k = \min\{e_{\pi(k)}, e_k + \beta p_k\}$. Note that, after this update, the blocking intervals of any but the largest such job will be empty. Moreover, the just admitted job $j^\star$ does not get a blocking period in this special case.

During the analysis of the algorithm, we show that any admitted job j still completes before $a_j + (1+\delta)p_j$ and that $e_j \leq a_j + (1+2\delta)p_j$ holds in retrospective for all admitted jobs j. Thus, any job j that admits another job $j^\star$ tentatively assigns this job a scheduling interval of length $(1+\delta)p_{j^\star}$ but, for ensuring j's completion, it is prepared for losing $(1+2\delta)p_{j^\star}$ time units of its scheduling interval $S(j)$. We summarize the blocking algorithm in Algorithm 1.

Algorithm 1 Blocking algorithm.

            3. call admission routine
        else
            i ← i + 1
```

Roadmap for the analysis

During the analysis, it is sufficient to concentrate on instances with small slack, as also noted in [8]. For $\varepsilon > 1$ we run the blocking algorithm with $\varepsilon = 1$, which only tightens the commitment requirement, and obtain constant competitive ratios. Thus, we assume $0 < \varepsilon \leq 1$. Moreover, in the δ-commitment model, committing to the completion of a job j at an earlier point in time clearly satisfies committing at a remaining slack of δp_j. Therefore, we may assume $\delta \in [\frac{\varepsilon}{2}, \varepsilon)$.

The blocking algorithm does not migrate any job. In the analysis, we first compare the throughput of our algorithm to the solution of an optimal non-migratory schedule. We then use a well-known result by Kalyanasundaram and Pruhs to compare this to an optimal solution that may exploit migration. Here, ω_m is the maximal ratio of the throughput of an optimal migratory schedule to the throughput of an optimal non-migratory schedule [19].

▶ **Theorem 3** (Theorem 1.1 in [19]). *$\omega_m \leq (6m - 5)/m$.*

The proof of our results consists of two parts. In the first part, Section 3, we show that the blocking algorithm completes all admitted jobs on time. The second part, Section 4, is to show that the blocking algorithm admits sufficiently many jobs to be competitive.

3 Completing all admitted jobs on time

We show that the blocking algorithm finishes every admitted job on time in Theorem 5. Our choice of parameters guarantees that Inequality (1) is satisfied.

As the blocking algorithm does not migrate jobs, it suffices to consider each machine individually in this section. The proof relies on the following observations: (i) the sizes of admitted jobs belonging to different classes of job j are geometrically decreasing, (ii) the scheduling intervals of jobs are completely contained in the scheduling intervals of their parents, and (iii) scheduling in Shortest Processing Time order guarantees that job j has highest priority in the blocking periods of its children. We start by proving the following technical lemma about the length of the final scheduling interval of an admitted job j. In the proof we use that $\pi(k) = j$ for two jobs j and k implies that $p_k < \gamma p_j$.

▶ **Lemma 4.** *Let $0 < \delta < \varepsilon$ be fixed. If $\gamma > 0$ satisfies $(1 + 2\delta)\gamma \leq \delta$, then the length of the scheduling interval $S(j)$ of an admitted job j is upper bounded by $(1 + 2\delta)p_j$. Moreover, $S(j)$ contains the scheduling intervals of all descendants of j.*

Proof. By definition of the blocking algorithm, the end point e_j of the scheduling interval of job j is only modified when j or one of j's descendants admits another job. Let us consider such a case: If job j admits a job $j^\star$ whose scheduling interval does not fit the scheduling interval of j, we set $e_j = e_{j^\star} = a_{j^\star} + (1+\delta)p_{j^\star}$ to accommodate the scheduling interval $S(j^\star)$ within $S(j)$. The same modification is applied to any ancestor k of j with $e_k < e_{j^\star}$. This implies that, after such a modification of the scheduling interval, neither j nor any affected ancestors k of j are the smallest jobs in their scheduling intervals anymore. In particular, no job whose scheduling interval was modified in such a case at time τ is able to admit jobs after τ. Hence, any job j can only admit other jobs within the interval $[a_j, a_j + (1 + \delta)p_j)$. In particular, $a_{j^\star} \leq a_j + (1 + \delta)p_j$ for any job $j^\star$ with $\pi(j^\star) = j$.

Thus, by induction, it is sufficient to show that $a_{j^\star} + (1 + 2\delta)p_{j^\star} \leq a_j + (1 + 2\delta)p_j$ for admitted jobs $j^\star$ and j with $\pi(j^\star) = j$ in order to prove the lemma. Note that $\pi(j^\star) = j$ implies $p_{j^\star} < \gamma p_j$. Thus,

$$a_{j^\star} + (1 + 2\delta)p_{j^\star} \leq (a_j + (1 + \delta)p_j) + (1 + 2\delta)\gamma p_j \leq a_j + (1 + 2\delta)p_j,$$

where the last inequality follows from the assumption $(1 + 2\delta)\gamma \leq \delta$. ◀

▶ **Theorem 5.** *Let $0 < \delta < \varepsilon$ be fixed. If $0 < \gamma < 1$ and $\beta \geq 1$ satisfy*

$$\frac{\beta/2}{\beta/2 + (1+2\delta)}\left(1 + \delta - 2(1+2\delta)\gamma\right) \geq 1, \tag{1}$$

then the blocking algorithm completes a job j admitted at $a_j \leq d_j - (1+\delta)p_j$ on time.

Our choice of parameters guarantees that Inequality (1) is satisfied.

Proof. Let j be a job admitted by the blocking algorithm with $a_j \leq d_j - (1+\delta)p_j$. Hence, showing that a job j completes before time $d'_j := a_j + (1+\delta)p_j$ proves the theorem. Due to scheduling in SPT order, each job j has highest priority in its own scheduling interval if the time point does not belong to the scheduling interval of a descendant of j. Thus, it suffices to show that at most δp_j units of time in $[a_j, d'_j)$ belong to scheduling intervals $S(k)$ of descendants of j. By Lemma 4, the scheduling intervals of any descendant k' of a child k of j is contained in $S(k)$. Hence, it is sufficient to only consider K, the set of children of j. In order to bound the contribution of each child $k \in K$, we partition K into two sets. The first set K_1 contains all children of j that where admitted as the first jobs in their class $\mathcal{C}_c(j)$. The set K_2 contains the remaining jobs.

We start with K_2. Consider a job $k \in \mathcal{C}_c(j)$ admitted by j. By Lemma 4, we know that $|S(k)| = (1+\mu\delta)p_k$ where $1 \leq \mu \leq 2$. Let $k' \in \mathcal{C}_c(j)$ be the previous job admitted by j in class c. Then, $B(k') \subseteq [e_{k'}, e_k)$. Since scheduling and blocking periods of children of j are always disjoint, j had highest scheduling priority in $B(k')$. Hence, during $B(k') \cup S(k)$ job j was processed for at least $|B(k')|$ units of time. In other words, j was processed for at least a $\frac{|B(k')|}{|B(k') \cup S(k)|}$-fraction of $B(k') \cup S(k)$. We can rewrite this ratio by

$$\frac{|B(k')|}{|B(k') \cup S(k)|} = \frac{\beta p_{k'}}{\beta p_{k'} + (1+\mu\delta)p_k} = \frac{\nu\beta}{\nu\beta + (1+\mu\delta)},$$

where $\nu := \frac{p_{k'}}{p_k} \in (\frac{1}{2}, 2]$. By differentiating with respect to ν and μ, we observe that the last term is increasing in ν and decreasing in μ. Thus, we can lower bound this expression by

$$\frac{|B(k')|}{|B(k') \cup S(k)|} \geq \frac{\beta/2}{\beta/2 + (1+2\delta)}.$$

Therefore, j was processed for at least a $\frac{\beta/2}{\beta/2+(1+2\delta)}$-fraction in $\bigcup_{k\in K} B(k) \cup \bigcup_{k\in K_2} S(k)$.

We now consider the set K_1. The total processing volume of these jobs is bounded by $\sum_{c=0}^{\infty} \frac{\gamma}{2^c} p_j = 2\gamma p_j$. By Lemma 4, we know that $|S(k)| \leq (1+2\delta)p_k$. Combining these two observations, we obtain $\left|\bigcup_{k\in K_1} S(k)\right| \leq 2(1+2\delta)\gamma p_j$. Combining the latter with the bound for K_2, we conclude that j is scheduled for at least

$$\left|[a_j, d'_j) \setminus \bigcup_{k\in K} S(k)\right| \geq \frac{\beta/2}{\beta/2 + (1+2\delta)}\big((1+\delta) - 2(1+2\delta)\gamma\big)p_j \geq p_j$$

units of time, where the last inequality follows from Equation (1). Thus, j completes before $d'_j = a_j + (1+\delta)p_j \leq d_j$. ◀

4 Admitting sufficiently many jobs

After proving that the blocking algorithm completes all admitted jobs on time, we show that the blocking algorithm admits enough jobs to achieve the competitive ratio of Theorem 1.

4.1 Key lemma on the size of non-admitted jobs

For the proof of the main result in this section, we rely on the following strong, structural lemma about the volume processed by a feasible non-migratory schedule in some time interval and the size of jobs admitted by a certain class of online algorithms in the same time interval. Let σ be a feasible non-migratory schedule. Let ALG be a non-migratory online algorithm satisfying the following two properties: (i) ALG never admits a job j later than $d_j - (1+\delta)p_j$ for $0 < \delta < \varepsilon$ and (ii) retrospectively, for each time τ, there is a threshold $u_\tau \in (0, \infty]$ such that any available job j with $d_j - \tau \geq (1+\delta)p_j$ that was not admitted by ALG at τ satisfies $p_j \geq u_\tau$. We will show that our blocking algorithm satisfies (i) and (ii) for a non-trivial u_τ that allows us to bound the volume of any feasible schedule.

Without loss of generality, we assume that σ completes all jobs on time that it started. Let X^σ be the jobs completed by σ and not admitted by ALG. For $1 \leq i \leq m$, let X_i^σ be the jobs in X^σ processed by machine i. Let C_x be the completion time of job $x \in X^\sigma$ in σ.

▶ **Lemma 6.** *Let σ and ALG be defined as above. Let $0 \leq \zeta_1 \leq \zeta_2$ and fix $x \in X_i^\sigma$ as well as $Y \subset X_i^\sigma \setminus \{x\}$. If*

(R) $r_x \geq \zeta_1$ as well as $r_y \geq \zeta_1$ for all $y \in Y$,
(C) $C_x \geq C_y$ for all $y \in Y$, and
(P) $\sum_{y \in Y} p_y \geq \frac{\varepsilon}{\varepsilon - \delta}(\zeta_2 - \zeta_1)$

hold, then $p_x \geq u_{\zeta_2}$ where u_{ζ_2} is the upper bound imposed by ALG at time ζ_2. In particular, if $u_{\zeta_2} = \infty$, then no such job x exists.

Proof. We show the lemma by contradiction. More precisely, we show that, if $p_x < u_{\zeta_2}$, the schedule σ cannot complete x on time and, hence, is not feasible.

Remember that $x \in X_i^\sigma$ implies that ALG did not admit job x at any point τ. At time ζ_2, there are two possible reasons why x was not admitted: $p_x \geq u_{\zeta_2}$ or $d_x - \zeta_2 < (1+\delta)p_x$. In case of the former, the statement of the lemma holds. Thus, let us assume $p_x < u_{\zeta_2}$ and, therefore, $d_x - \zeta_2 < (1+\delta)p_x$ has to hold. As job x arrived with a slack of at least εp_x at its release date r_x and $r_x \geq \zeta_1$ by assumption, we have

$$\zeta_2 - \zeta_1 \geq \zeta_2 - d_x + d_x - r_x > -(1+\delta)p_x + (1+\varepsilon)p_x = (\varepsilon - \delta)p_x. \tag{2}$$

As all jobs in Y complete earlier than x by Assumption (C) and are only released after ζ_1 by (R), the volume processed by σ in $[\zeta_1, C_x)$ on machine i is greater than $\frac{\varepsilon}{\varepsilon - \delta}(\zeta_2 - \zeta_1) + p_x$ by (P). Moreover, σ can process at most a volume of $(\zeta_2 - \zeta_1)$ on machine i in $[\zeta_1, \zeta_2)$. These two bounds imply that σ has to process job parts with a processing volume of at least

$$\frac{\varepsilon}{\varepsilon - \delta}(\zeta_2 - \zeta_1) + p_x - (\zeta_2 - \zeta_1) > \frac{\delta}{\varepsilon - \delta}(\varepsilon - \delta)p_x + p_x = (1+\delta)p_x$$

in $[\zeta_2, C_x)$, where the inequality follows using Inequality (2). Thus, $C_x > \zeta_2 + (1+\delta)p_x > d_x$ which contradicts the feasibility of σ.

Observe that the online algorithm ALG admits the shortest available job that satisfies $p_j \leq u_\tau$. In particular, if $u_\tau = \infty$ for some time point τ, ALG admits the shortest job if there is one available. Hence, for $0 \leq \zeta_1 \leq \zeta_2$ with $u_{\zeta_2} = \infty$, there does not exist a job $x \in X_i^\sigma$ and a set $Y \subset X_i^\sigma \setminus \{x\}$ satisfying (R), (C), and (P) for any machine i. ◀

4.2 Admitting sufficiently many jobs

▶ **Theorem 7.** *An optimal non-migratory (offline) algorithm can complete at most a factor $\alpha + 4$ more jobs on time than admitted by the blocking algorithm where $\alpha := \frac{\varepsilon}{\varepsilon - \delta}\left(2\beta + \frac{1+2\delta}{\gamma}\right)$.*

For proving the theorem, we fix an instance and an optimal offline algorithm Opt. Let X be the jobs that Opt scheduled and the blocking algorithm did not admit. We assume without loss of generality that Opt completes all jobs in X on time. Let J be the jobs that the blocking algorithm scheduled. Then, $X \cup J$ clearly is a superset of the jobs that Opt scheduled. Hence, to show the theorem it is sufficient to prove that $|X| \leq (\alpha+3)|J|$. Let $\overline{X} \subseteq X$ be the jobs scheduled on the machine with the *highest* throughput and let $\underline{J} \subseteq J$ be the jobs scheduled on the machine with the *lowest* throughput. In Lemma 11 we develop a charging scheme of $\overline{X}$ to jobs in $\underline{J}$ such that no job gets charged more than $\alpha+3$ jobs.

Without loss of generality, we assume that the union of all scheduling intervals of jobs in J, i.e., $\bigcup_{j\in J} S(j)$, forms one interval. If this assumption does not hold, we consider each maximal interval in $\bigcup_{j\in J} S(j)$ separately. Instead of directly charging the jobs in $\overline{X}$ to jobs in $\underline{J}$ we take a detour and charge jobs in $\overline{X}$ to intervals that cover $\bigcup_{j\in J} S(j)$. The idea behind our charging scheme is that Opt is not able to schedule arbitrarily many jobs during a scheduling interval or a blocking period created by the blocking algorithm. Intuitively, jobs that were released during a scheduling interval or a blocking period and not admitted by the algorithm have to satisfy certain lower bounds on their processing times. Thus, the charging scheme relies on the release date r_x and the size p_x of a job $x \in \overline{X}$ as well as on the precise structure of the intervals created by the blocking algorithm. The number of jobs we charge to one interval will depend on the relative length of the interval.

We retrospectively consider the interval structure created by the algorithm on the machine that schedules $\underline{J}$; let this w.l.o.g. be the first machine. Let T be the set of all time points corresponding to the admission of a new job, the end of a scheduling interval, and the start as well as the end of a blocking period of jobs in $\underline{J}$. Index the elements in T by their actual value, i.e., $\tau_1 < \tau_2 < \ldots < \tau_{|T|}$. Let $\mathcal{I}$ be the set of intervals of the form $I_t := [\tau_t, \tau_{t+1})$ for $1 \leq t < |T|$. The next lemma holds as the admission of a job adds at most three time points.

▶ **Fact 8.** *The set $\mathcal{I}$ contains at most $3|\underline{J}|$ intervals.*

For analyzing the competitive ratio of our algorithm, we first charge jobs $x \in \overline{X}$ to intervals $I_t \in \mathcal{I}$ and then assign this subset to the job that was "responsible" for not admitting other jobs during I_t because of its scheduling interval or because of its blocking period. In Lemma 11, we show that a job j is assigned at most $\frac{\varepsilon}{\varepsilon-\delta}(2\beta + \frac{1+2\delta}{\gamma}) = \alpha$ jobs and that each interval I_t gets at most one job. Fact 8 bounds the number of intervals in $\mathcal{I}$. Combining these observations then proves that $|\overline{X}| \leq (\alpha+3)|\underline{J}|$ and, thus, $|X| \leq (\alpha+3)|J|$.

Consider a time point $\tau \in \bigcup_{j\in J} S(j)$. Let $j \in J$ be the shortest job on machine i such that $\tau \in S(j) \cup B(j)$. The blocking algorithm only admits an available job k to machine i in two cases: (i) $\tau \in S(j)$ and $p_k < \gamma p_j$ or (ii) $\tau \in B(j)$ and k belongs to a smaller class of the parent of j. Condition (ii) clearly is satisfied if $p_k < p_j/2$. This implies that at any time τ the blocking algorithm maintains a threshold $u_{\tau,i}$ for each machine i so that only available jobs smaller than this threshold qualify for admission to machine i. Note that the admission of a job k at time τ to machine i decreases the threshold $u_{\tau,i}$. If τ does not belong to a scheduling interval of a job on machine i, we set $u_{\tau,i} = \infty$. By taking the maximum of these upper bounds, we obtain a time-dependent threshold u_τ that guides the admission decisions of the blocking algorithm. Hence, the conditions of Lemma 6 are met by the our algorithm.

Note that these upper bounds only change when a scheduling interval starts or ends, or when an interval belonging to a blocking period starts or ends. For an interval $I_t \in \mathcal{I}$ we define $\underline{u_t}$ as the threshold on the machine with the lowest throughput, i.e., $\underline{u_t} := u_{\tau_{t,1}} \in (0, \infty]$. If $\underline{u_t} = \infty$, then the interval $I_t \in \mathcal{I}$ does not belong to the scheduling interval of a job in J and $u_\tau = \infty$ for all $\tau \in I_t$. Then the next lemma holds.

▶ **Fact 9.** *In every interval $I_t = [\tau_t, \tau_{t+1}) \in \mathcal{I}$ the upper bound u_τ created by the blocking algorithm is lower bounded by $u_{\tau_t,1}$, i.e., $u_\tau \geq \underline{u_t}$ for all $\tau \in I_t$.*

The charging scheme developed in Lemma 11 is based on a careful modification of the following partition $(F_t)_{1\leq t<|T|}$ of the set $\overline{X}$. Fix an interval $I_t \in \mathcal{I}$ and define the set $F_t \subset \overline{X}$ as the set that contains all jobs $x \in \overline{X}$ released during I_t, i.e., $F_t := \{x \in \overline{X} : r_x \in I_t\}$. As, upon release, each job is available, the next corollary directly follows from Fact 9.

▶ **Fact 10.** *For all jobs $x \in F_t$ it holds $p_x \geq \underline{u_t}$. In particular, if $\underline{u_t} = \infty$, then $F_t = \emptyset$.*

In fact, the charging scheme maintains this property and only assigns jobs in $\overline{X}$ to intervals I_t if $p_x \geq \underline{u_t}$. In particular, no job will be assigned to an interval with $\underline{u_t} = \infty$.

We now formalize how many jobs in $\overline{X}$ we will assign to a specific interval I_t. Let $\varphi_t := \left\lfloor \frac{\varepsilon}{\varepsilon-\delta} \frac{\tau_{t+1}-\tau_t}{\underline{u_t}} \right\rfloor + 1$ be the *target number* of I_t if $\underline{u_t} < \infty$ and $\varphi_t = 0$ if $\underline{u_t} = \infty$.

If $\underline{u_t} < \infty$, let $j_t \in \underline{J}$ be the *smallest* job with $\tau_t \in S(j) \cup B(j)$. Except for one job per interval $I_t \in \mathcal{I}$ which remains assigned to I_t, the jobs assigned to I_t will be accounted for by j_t. Suppose that each of the sets F_t satisfies $|F_t| \leq \varphi_t$. Then, at most $\frac{\varepsilon}{\varepsilon-\delta} \frac{\tau_{t+1}-\tau_t}{\underline{u_t}}$ will be charged to job j_t because of interval I_t. By definition of $\underline{u_t}$, we have $\underline{u_t} \geq \gamma p_{j_t}$ if $I_t \subseteq S(j_t)$ and, if $I_t \subseteq B(j_t)$, we have $\underline{u_t} \geq p_{j_t}/2$. The total length of intervals I_t for which $j = j_t$ holds sums up to at most $(1+2\delta)p_j$ for $I_t \subseteq S(j)$ and to at most $2\beta p_j$ for $I_t \subseteq B(j)$. Hence, in total, the charging scheme assigns at most $\frac{\varepsilon}{\varepsilon-\delta}(2\beta + \frac{1+2\delta}{\gamma}) = \alpha$ jobs in $\overline{X}$ to job $j \in \underline{J}$. In combination with Fact 8, that bounds the number of intervals in $\mathcal{I}$, this would imply Theorem 7. In general, $|F_t| \leq \varphi_t$ does not have to be true as Opt may preempt jobs and process the parts during several intervals I_t. In the remainder of this section, we show that there exists another partition $(G_t)_{1\leq t<|T|}$ of the jobs in $\overline{X}$ such that $|G_t| \leq \varphi_t$ holds.

▶ **Lemma 11.** $|\overline{X}| \leq \alpha|\underline{J}| + |\mathcal{I}|$.

Proof. As observed before it suffices to show that there is a partition $\mathcal{G} = \left(G_t\right)_{1\leq t<|T|}$ such that $|G_t| \leq \varphi_t$ and $\bigcup_{1\leq t<|T|} G_t = \overline{X}$ in order to prove the lemma. The high-level idea of this proof is the following: Consider an interval $I_t = [\tau_t, \tau_{t+1})$. If F_t does not contain too many jobs, i.e., $|F_t| \leq \varphi_t$, we would like to set $G_t = F_t$. Otherwise, we find a later interval $I_{t'}$ with $|F_{t'}| < \varphi_{t'}$ such that we can assign the excess jobs in F_t to $I_{t'}$.

In order to repeatedly apply Lemma 6, we only assign such excess jobs $x \in F_t$ to $G_{t'}$ if their processing time is at least the threshold of $I_{t'}$, i.e., $p_x \geq \underline{u_{t'}}$. Then, by our choice of parameters, a set $G_{t'}$ with $\varphi_{t'}$ many jobs of size at least $\underline{u_{t'}}$ "covers" the interval $I_{t'} = [\tau_{t'}, \tau_{t'+1})$ as often as required by (P) in Lemma 6, i.e.,

$$\sum_{x\in G_{t'}} p_x \geq \varphi_{t'} \cdot \underline{u_{t'}} = \left(\left\lfloor \frac{\varepsilon}{\varepsilon-\delta} \frac{\tau_{t'+1}-\tau_{t'}}{\underline{u_{t'}}} \right\rfloor + 1 \right) \cdot \underline{u_{t'}} \geq \frac{\varepsilon}{\varepsilon-\delta}(\tau_{t'+1}-\tau_{t'}). \tag{3}$$

The proof consists of two parts: the first one is to inductively (on t) construct the partition $\mathcal{G} = \left(G_t\right)_{1\leq t<|T|}$ of $\overline{X}$ with $|G_t| \leq \varphi_t$. The second one is the proof that a job $x \in G_t$ satisfies $p_x \geq \underline{u_t}$. During the construction of $\mathcal{G}$ we define temporary sets $A_t \subset \overline{X}$ for intervals I_t. The set G_t is chosen as a subset of $F_t \cup A_t$ of appropriate size. In order to apply Lemma 6 to each job in A_t individually, alongside A_t, we construct a set $Y_{x,t}$ and a time $\tau_{x,t} \leq r_x$ for each job $x \in \overline{X}$ that is added to A_t. Let C^*_x be the completion time of some job $x \in \overline{X}$ in the optimal schedule Opt. The second part of the proof is to show that x, $\tau_{x,t}$, and $Y_{x,t}$ satisfy

(R) $r_y \geq \tau_{x,t}$ for all $y \in Y_{x,t}$,
(C) $C^*_x \geq C^*_y$ for all $y \in Y_{x,t}$, and
(P) $\sum_{y\in Y_{x,t}} p_y \geq \frac{\varepsilon}{\varepsilon-\delta}(\tau_t - \tau_{x,t})$.

Then, x, $Y = Y_{x,t}$, $\zeta_1 = \tau_{x,t}$, and $\zeta_2 = \tau_t$ satisfy the conditions of Lemma 6 and we can deduce that the processing time of x is at least the threshold at time τ_t, i.e., $p_x \geq u_{\tau_t} \geq \underline{u_t}$.

Constructing $\mathcal{G} = (G_t)_{1 \leq t \leq |T|}$. We inductively construct the sets G_t in the order defined by their indices. For simplicity, we add a singleton as last interval, i.e., $I_{|T|} = \{\tau_{|T|}\}$ with $\varphi_{|T|} = 0$. We start by setting $A_t = \emptyset$ for all intervals $1 \leq t \leq |T|$. We define $Y_{x,t} = \emptyset$ for each job $x \in \overline{X}$ and each interval I_t. The preliminary value of the time $\tau_{x,t}$ is the minimum of the start point τ_t of the interval I_t and the release date r_x of x, i.e., $\tau_{x,t} := \min\{\tau_t, r_x\}$. We refer by *step* t to the step in the construction where G_t was defined.

Starting with $t = 1$, let I_t be the next interval to consider during the construction. Depending on the cardinality of $F_t \cup A_t$, we have to distinguish two cases. If $|F_t \cup A_t| \leq \varphi_t$, we set $G_t = F_t \cup A_t$.

If $|F_t \cup A_t| > \varphi_t$, we order the jobs in $F_t \cup A_t$ in increasing order of completion times in Opt. The first φ_t jobs are assigned to G_t while the remaining $|F_t \cup A_t| - \varphi_t$ jobs are added to A_{t+1}. In this case, we might have to redefine the times $\tau_{x,t+1}$ and the sets $Y_{x,t+1}$ for the jobs x that were newly added to A_{t+1}. Fix such a job x. If there is no job z in the just defined set G_t that has a smaller release date than $\tau_{x,t}$, we set $\tau_{x,t+1} = \tau_{x,t}$ and $Y_{x,t+1} = Y_{x,t} \cup G_t$. Otherwise let $z \in G_t$ be a job with $r_z < \tau_{x,t}$ that has the smallest time $\tau_{z,t}$. We set $\tau_{x,t+1} = \tau_{z,t}$ and $Y_{x,t+1} = Y_{z,t} \cup G_t$.

Finally, we also construct $G_{|T|}$ this way. As we will show that $p_x \geq \underline{u}_{|T|}$ for all $x \in G_{|T|}$, we will get that $G_{|T|} = \emptyset$ (since $\underline{u}_{|T|} = \infty$) and therefore $G_{|T|} \leq \varphi_{|T|} = 0$.

Bounding the size of the jobs in G_t. We consider the intervals again in increasing order of their indices and show by induction that any job x in G_t satisfies $p_x \geq \underline{u_t}$ which implies $G_t = \emptyset$ if $\underline{u_t} = \infty$. Clearly, if $x \in F_t \cap G_t$, Fact 10 guarantees $p_x \geq \underline{u_t}$. Hence, in order to show the lower bound on the processing time of $x \in G_t$, it is sufficient to consider jobs in $G_t \setminus F_t \subset A_t$. To this end, we show that for such jobs (R), (C), and (P) are satisfied. Then, Lemma 6 guarantees that $p_x \geq u_{\tau_t} \geq \underline{u_t}$. Therefore, $A_t = \emptyset$ if $\underline{u_t} = \infty$ as the global bound is also unbounded, i.e., $u_{\tau_t} \geq \underline{u_t} = \infty$, by Fact 9.

By construction, $A_1 = \emptyset$. Hence, (R), (C), and (P) are satisfied for each job $x \in A_1$.

Assume that the conditions (R), (C), and (P) are satisfied for all $x \in A_t$ for all $1 \leq t < s$. Hence, for $t < s$, the set G_t only contains jobs x with $p_x \geq \underline{u_t}$. Let $t \geq s$ be the first index with $A_t \neq \emptyset$ and fix $x \in A_t$. We want to show that $p_x \geq \underline{u_t}$. By induction and by Fact 10, $p_y \geq \underline{u_{t-1}}$ holds for all $y \in G_{t-1}$. Because x did not fit in G_{t-1}, $|G_{t-1}| = \varphi_{t-1}$.

We distinguish two cases based on the jobs in G_{t-1}. If there is no $z \in G_{t-1}$ with $r_z < \tau_{x,t-1}$, then $\tau_{x,t} = \tau_{x,t-1}$, and (R) and (C) are satisfied by construction and by induction. For (P), consider

$$\begin{aligned}\sum_{y \in Y_{x,t}} p_y &= \sum_{y \in Y_{x,t-1}} p_y + \sum_{y \in G_{t-1}} p_y \geq \frac{\varepsilon}{\varepsilon - \delta}(\tau_{t-1} - \tau_{x,t-1}) + \underline{u_{t-1}} \cdot \varphi_{t-1} \\ &> \frac{\varepsilon}{\varepsilon - \delta}(\tau_{t-1} - \tau_{x,t-1}) + \frac{\varepsilon}{\varepsilon - \delta}(\tau_t - \tau_{t-1}) = \frac{\varepsilon}{\varepsilon - \delta}(\tau_t - \tau_{x,t})\,,\end{aligned}$$

where the first inequality holds by induction.

If there is a job $z \in G_{t-1}$ with $r_z < \tau_{x,t-1} \leq \tau_{t-1}$, then $z \in A_{t-1}$. In step t, we chose z with minimal $\tau_{z,t-1}$. Thus, $r_y \geq \tau_{y,t-1} \geq \tau_{z,t-1}$ for all $y \in G_{t-1}$ and $r_x \geq \tau_{x,t-1} > r_z \geq \tau_{z,t-1}$. Moreover, by induction, $r_y \geq \tau_{z,t-1}$ holds for all $y \in Y_{z,t-1}$. Thus, $\tau_{x,t}$ and $Y_{x,t}$ satisfy (R). For (C), consider that $C^*_x \geq C^*_y$ for all $y \in G_{t-1}$ by construction and, thus, $C^*_x \geq C^*_z \geq C^*_y$ also holds for all $y \in Y_{z,t-1}$. For (P), observe that

$$\sum_{y\in Y_{x,t}} p_y = \sum_{y\in Y_{z,t-1}} p_y + \sum_{y\in G_{t-1}} p_y \geq \frac{\varepsilon}{\varepsilon-\delta}(\tau_{t-1}-\tau_{z,t-1}) + \underline{u_{t-1}}\cdot\varphi_{t-1}$$
$$\geq \frac{\varepsilon}{\varepsilon-\delta}(\tau_{t-1}-\tau_{z,t-1}) + \frac{\varepsilon}{\varepsilon-\delta}(\tau_t-\tau_{t-1}) \geq \frac{\varepsilon}{\varepsilon-\delta}(\tau_t-\tau_{x,t}).$$

Here, the first inequality follows by induction and the second by definition of $\underline{u_{t-1}}$ and φ_{t-1}. Hence, Lemma 6 implies $p_x \geq u_{\tau_t} \geq \underline{u_t}$.

Showing $|\overline{X}| \leq \alpha|\underline{J}| + |\mathcal{I}|$. By construction, we know that $\bigcup_{t=1}^{|T|} G_t = \overline{X}$. We start with considering intervals I_t with $\underline{u_t} = \infty$. Then, I_t is not covered by a scheduling interval on machine i. Thus, $u_\tau = \infty$ for all $\tau \in I_t$ and $F_t = \emptyset$ by Fact 10. In the previous part we have seen that the conditions for Lemma 6 are satisfied. Hence, $G_t = \emptyset$ if $\underline{u_t} = \infty$. For t with $\underline{u_t} < \infty$, we have $|G_t| = \varphi_t = \left\lfloor \frac{\varepsilon}{\varepsilon-\delta}\frac{\tau_{t+1}-\tau_t}{\underline{u_t}} \right\rfloor + 1$. As explained before, we assign these jobs (except the additive one) to j_t, the shortest job in $\underline{J}$ with $I_t \subseteq S(j) \cup B(j)$, without assigning more than α jobs in $\overline{X}$ to a particular job in $\underline{J}$. Hence, the number of jobs in $\overline{X}$ is indeed bounded by $\alpha|\underline{J}| + |\mathcal{I}|$. ◀

Proof of Theorem 7. As discussed before, the union $X \cup J$ of X, the jobs only scheduled by Opt, and J, the jobs admitted by the blocking algorithm, is a superset of the jobs that Opt completed. Lemma 11 shows that $|\overline{X}| \leq \alpha|\underline{J}| + |\mathcal{I}|$.Combining this with the bound on $\mathcal{I}$ given in Fact 8, we conclude

$$\textsc{Opt} \leq m\cdot|\overline{X}| + |J| \leq m\,(\alpha+3)\,|\underline{J}| + |J| \leq (\alpha+4)\,|J|.$$ ◀

Proof of Theorem 1. In Theorem 5 we show that the blocking algorithm completes all admitted jobs J on time. This implies that the blocking algorithm is feasible for the model commitment upon admission. As no job $j \in J$ is admitted later than $d_j - (1+\delta)p_j$, this shows that the blocking algorithm also solves scheduling with δ-commitment. Theorem 1.1 in [19] (Theorem 3) gives a bound on the optimal migratory schedule in terms of an optimal non-migratory solution. In Theorem 7, we bound an optimal non-migratory solution Opt by $|J|$, the throughput of the blocking algorithm. Combining these theorems shows that the blocking algorithm achieves a competitive ratio of $c = 6(\alpha+4) = 6\left(\frac{\varepsilon}{\varepsilon-\delta}\left(2\beta + \frac{1+2\delta}{\gamma}\right) + 4\right)$. Our choice of parameters $\beta = \frac{16}{\delta}$ and $\gamma = \frac{\delta}{16}$ implies $c \in \mathcal{O}\left(\frac{\varepsilon}{(\varepsilon-\delta)\delta}\right)$. In the case where $\delta \leq \varepsilon/2$, we run the algorithm with parameter $\delta' = \varepsilon/2$. Hence, $c \in \mathcal{O}\left(\frac{1}{\varepsilon-\delta'}\right) = \mathcal{O}\left(\frac{1}{\varepsilon}\right)$. If $\delta > \varepsilon/2$, then we set $\delta' = \delta$ in our algorithm. Thus, $\frac{\varepsilon}{\delta'} \in \mathcal{O}(1)$ and, again, $c \in \mathcal{O}\left(\frac{1}{\varepsilon-\delta'}\right)$. ◀

Conclusion

We close the major questions regarding online throughput maximization with and without commitment requirements and give an optimal online algorithm on identical parallel machines for the problem $P\,|\,\text{online } r_j, \text{pmtn}\,|\,\sum(1-U_j)$. It remains open whether the problem, where m is not part of the input, admits an online algorithm with a better competitive ratio as is the case for $Pm\,|\,\text{online } r_j, \text{pmtn}\,|\,\sum p_j(1-U_j)$ [26].

Another interesting question asks whether randomization allows for improved results. On a single machine, there is indeed an $\mathcal{O}(1)$-competitive randomized algorithm for scheduling without commitment, even without any slack assumption [20]. We are not aware of any lower bound that rules out a similar result on multiple machines. Further research directions include generalizations such as weighted throughput maximization. While strong lower bounds exist for handling weighted throughput with commitment [8], there remains a gap for the problem without commitment.

Abstract

The line graph of a graph G is the graph $L(G)$ whose vertex set is the edge set of G and there is an edge between $e, f \in E(G)$ if e and f share an endpoint in G. A graph is called line graph if it is a line graph of some graph. We study the Line-Graph-Edge Deletion problem, which asks whether we can delete at most k edges from the input graph G such that the resulting graph is a line graph. More precisely, we give a polynomial kernel for Line-Graph-Edge Deletion with $\mathcal{O}\left(k^5\right)$ vertices. This answers an open question posed by Falk Hüffner at Workshop on Kernels (WorKer) in 2013.

1 Introduction

For a family $\mathcal{G}$ of graphs, the general $\mathcal{G}$-Graph Modification problem asks whether we can modify a graph G into a graph in $\mathcal{G}$ by performing at most k simple operations. Typical examples of simple operations well-studied in the literature include vertex deletion, edge deletion, edge addition, or a combination of edge deletion and addition. We call these problems $\mathcal{G}$-Vertex Deletion, $\mathcal{G}$-Edge Deletion, $\mathcal{G}$-Edge Addition, and $\mathcal{G}$-Edge Editing, respectively. By a classical result by Lewis and Yannakakis [20], $\mathcal{G}$-Vertex Deletion is NP-complete for all non-trivial hereditary graph classes. The situation is quite different for the edge modification problems. Earlier efforts for edge deletion problems [13, 24], though having produced fruitful concrete results, shed little light on a systematic answer, and it was noted that such a generalization is difficult to obtain.

$\mathcal{G}$-Graph Modification problems have been extensively investigated for graph classes $\mathcal{G}$ that can be characterized by a finite set of forbidden induced subgraphs. We say that a graph is $\mathcal{H}$-free if it contains none of the graphs in $\mathcal{H}$ as an induced subgraph. For this special case, the $\mathcal{H}$-free Vertex Deletion is well understood. If $\mathcal{H}$ contains a graph on at least two vertices, then all of these problems are NP-complete, but admit a $c^k n^{\mathcal{O}(1)}$ algorithm [4], where c is the size of the largest graph in $\mathcal{H}$ (the algorithms with running time $f(k)n^{\mathcal{O}(1)}$ are called fixed-parameter tractable (FPT) algorithms [7, 11]). On the other hand, the NP-hardness proof of Lewis and Yannakakis [20] excludes algorithms with running time $2^{o(k)}n^{\mathcal{O}(1)}$ under the Exponential Time Hypothesis (ETH) [18]. Finally, as observed by Flum and Grohe [15] a simple application of sunflower lemma [14] gives a *kernel* with $\mathcal{O}\left(k^c\right)$ vertices, where c is again the size of the largest graph in $\mathcal{H}$. A kernel is a polynomial time preprocessing algorithm which outputs an equivalent instance of the same problem such that the size of the reduced instance is bounded by some function $f(k)$ that depends only on

k. We call the function $f(k)$ the size of the kernel. It is well-known that any problem that admits an FPT algorithm admits a kernel. Therefore, for problems with FPT algorithms one is interested in polynomial kernels, i.e., kernels whose size is a polynomial function.

For the edge modification problems, the situation is more complicated. While all of these problems also admit $c^k n^{\mathcal{O}(1)}$ time algorithm, where c is the maximum number of edges in a graph in $\mathcal{H}$ [4], the P vs NP dichotomy is still not known. Only recently Aravind et al. [1] gave the dichotomy for the special case when $\mathcal{H}$ contains precisely one graph H. From the kernelization point of view, the situation is also more difficult. The reason is that deleting or adding an edge to a graph can introduce a new copy of H and this might further propagate. Hence, we cannot use the sunflower lemma to reduce the size of the instance. Cai asked the question whether H-free Edge Deletion admits a polynomial kernel for all graphs H [3]. Kratsch and Wahlström [19] showed that this is probably not the case and gave a graph H on 7 vertices such that H-free Edge Deletion and H-free Edge Editing does not admit a polynomial kernel unless coNP $\subseteq$ NP/poly. Consequently, it was shown that this is not an exception, but rather a rule [5, 16]. Indeed the result by Cai and Cai [5] shows that H-free Edge Deletion, H-free Edge Addition, and H-free-Edge Editing do not admit a polynomial kernel whenever H or its complement is a path or a cycle with at least 4 edges or a 3-connected graph with at least 2 edges missing. Very recently, Marx and Sandeep [21] gave a list of nine graphs, all on 5 vertices such that if H-free-Edge Editing does not admit a kernel for any of these nine graphs under standard complexity assumptions, then H-free-Edge Editing admits a polynomial kernel for $|H| \geq 5$ if and only if H is either empty or complete graph. They also provided a similar characterization for H-free Edge Deletion and H-free Edge Editing. This suggests that actually the H-free edge modification problems with a polynomial kernels are rather rare and only for small graphs H. Recently, Eiben, Lochet, and Saurabh [12] announced a polynomial kernel for the case when H is a paw, which leaves only one last graph on 4 vertices for which the kernelization of H-free edge modification problems remains open, namely $K_{1,3}$ known also as the claw.

The class of claw-free graphs is a very well studied class of graphs with some interesting algorithmic properties. The most prominent example is probably the algorithm of Sbihi [22] for computing the maximum independent set in polynomial time. It also has been extensively studied from a structural point of view, and Chudnosky and Seymour proposed, after a series of papers, a complete characterization of claw-free graphs [6]. Because of such a characterization, it seems reasonable to believe that a polynomial kernel for Claw-free Edge Deletion exists. However, the characterization of Chudnosky and Seymour is quite complex, which makes it hard to use. For this reason, as noted by Cygan et al. [8], trying to show the existence of a polynomial kernel in the cases of sub-classes of claw-free graphs seems like a good first step to try to understand this problem. In this paper, we prove the result for the most famous such class, line graphs.

▶ **Theorem 1.** *Line-Graph Edge Deletion admits a kernel with $\mathcal{O}\left(k^5\right)$ vertices.*

Overview of the Algorithm

As the first step of the kernelization algorithm, we use the characterization of line graphs by forbidden induced subgraphs to find a set S of at most $6k$ vertices such that for every vertex $v \in S$, $G - (S \setminus \{v\})$ is a line graph. This is simply done by a greedy edge-disjoint packing of forbidden induced subgraphs. Having the set S, we use the algorithm by Degiorgi and Simon [9] to find a partition of edges of $G - S$ into cliques such that each vertex is in precisely 2 cliques. Let $\mathcal{C} = \{C_1, \ldots, C_q\}$ be the cliques in the partition. Since $G - (S \setminus \{v\})$

is also a line graph, it is a rather simple consequence of Whitney's isomorphism theorem that the neighborhood of v can be covered by constantly many cliques of $\mathcal{C}$. Furthermore, we will show that if a clique C in $\mathcal{C}$ has more than $k+7$ vertices then the optimal solution does not contain an edge in C. Hence, we can partition the cliques in $\mathcal{C}$ into two groups "large" and "small". Note that if the optimal solution contains an edge in some small clique C, then for this change to be necessary, it has to be propagated from S by modifying small cliques on some clique-path from S to C using only small cliques. We will therefore define the distance of a clique to S, without going into too many details in here, to be basically the length of a shortest clique-path from the clique to S using only small cliques. Since there are only $\mathcal{O}(|S|)$ cliques in immediate neighborhood of S and the number of cliques in the neighborhood of a small clique is bounded by its size, we obtain that there are at most $\mathcal{O}\left(k^d\right)$ cliques at distance at most d. Our main contribution and most technical part of our proof is to show that we can remove the edges covered by cliques at distance at least 5 from G. This is covered in Section 4. Afterwards we end up with an instance with all cliques in $\mathcal{C}$ at distance at least 5 from S being singletons. As discussed above there are only $\mathcal{O}\left(k^4\right)$ cliques at distance at most 4 and because large cliques stay intact in any optimal solution, it suffices to keep $k+7$ vertices in each large clique, which leads to the desired kernel of size $\mathcal{O}\left(k^5\right)$.

2 Preliminaries

We assume familiarity with the basic notations and terminologies in graph theory. We refer the reader to the standard book by Diestel [10] for more information. Given a graph G and a set of edges $F \subseteq E(G)$, we denote by $G - F$ the graph whose set of vertices is $V(G)$ and set of edges is the set $E(G) \setminus F$. Given two vertices $u, v \in V(G)$, we let the *distance* between u and v in G, denoted $\mathrm{dist}_G(u,v)$), be the number of edges on a shortest path from u to v. Furthermore, for $S \subseteq V(G)$ and $u \in V(G)$ we let $\mathrm{dist}_G(u,S) = \min_{v \in S} \mathrm{dist}_G(u,v)$). We omit the subscript G, if the graph is clear from the context.

Parameterized Algorithms and Kernelization. For a detailed illustration of the following facts the reader is referred to [7, 11]. A *parameterized problem* is a language $\Pi \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a finite alphabet; the second component k of instances $(I,k) \in \Sigma^* \times \mathbb{N}$ is called the *parameter*. A parameterized problem Π is *fixed-parameter tractable* if it admits a *fixed-parameter algorithm*, which decides instances (I,k) of Π in time $f(k) \cdot |I|^{\mathcal{O}(1)}$ for some computable function f.

A *kernelization* for a parameterized problem Π is a polynomial-time algorithm that given any instance (I,k) returns an instance (I',k') such that $(I,k) \in \Pi$ if and only if $(I',k') \in \Pi$ and such that $|I'| + k' \leq f(k)$ for some computable function f. The function f is called the *size* of the kernelization, and we have a polynomial kernelization if $f(k)$ is polynomially bounded in k. It is known that a parameterized problem is fixed-parameter tractable if and only if it is decidable and has a kernelization. However, the kernels implied by this fact are usually of superpolynomial size.

A *reduction rule* is an algorithm that takes as input an instance (I,k) of a parameterized problem Π and outputs an instance (I',k') of the same problem. We say that the reduction rule is *safe* if (I,k) is a *yes*-instance if and only if (I',k') is a *yes*-instance. In order to describe our kernelization algorithm, we present a series of reduction rules.

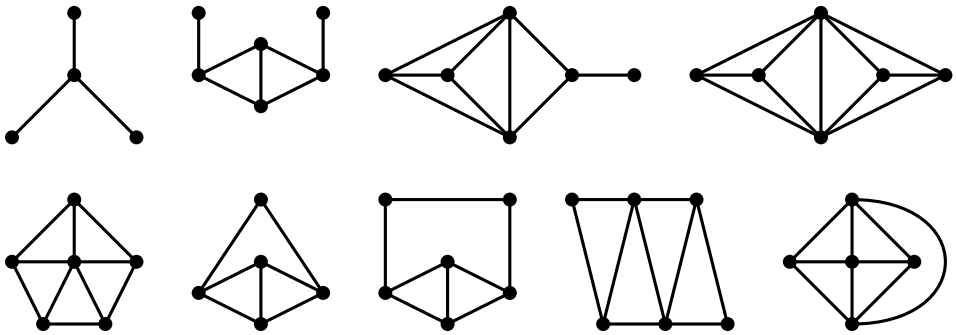

Figure 1 The nine minimal non-line graphs, from characterization of line graphs by forbidden induced subgraphs of Beineke [2]. Note that all of these graphs have at most 6 vertices.

Line graphs. Given a graph G, its *line graph* $L(G)$ is a graph such that each vertex of $L(G)$ represents an edge of G and two vertices of $L(G)$ are adjacent if and only if their corresponding edges share a common endpoint (are incident) in G. It is well known that if the line graphs of two connected graphs G_1 and G_2 are isomorphic then either G_1 and G_2 are K_3 and $K_{1,3}$, respectively, or G_1 and G_2 are isomorphic as well (Whitney's isomorphism theorem [23], see also Theorem 8.3 in [17]). We say that a graph H is a line graph, if there exists a graph G such that $H = L(G)$. Note that in this paper we only consider simple graphs, *i.e.*, the graphs without loops or multiple edges and in particular we also only consider line graphs of simple graphs. Formally, we then study the following parameterized problem:

Line-Graph-Edge Deletion	
Input:	A graph $G = (V, E)$ and $k \in \mathbb{N}$.
Parameter:	k.
Question:	Is there a set of edges $F \subseteq E(G)$ such that $G - F$ is a line graph and $\lvert F\rvert \leq k$.

We call a set of edges $F \subseteq V(G)$ such that $G - F$ is a line graph a *solution* for G. A solution F is *optimal*, if there does not exists a solution F' such that $|F'| < |F|$. To obtain our kernel, we will make use of several equivalent characterizations of line graphs.

▶ **Theorem 2** (see, e.g., Theorem 8.4 in [17]). *The following statements are equivalent:*

(1) *G is a line graph.*

(2) *The edges of G can be partitioned into complete subgraphs in such a way that no vertex lies in more than two of the subgraphs.*

(3) *G does not have $K_{1,3}$ as an induced subgraph, and if two odd triangles (triangles with the property that there exists another vertex adjacent to an odd number of triangle vertices) share a common edge, then the subgraph induced by their vertices is K_4.*

(4) *None of nine graphs of Figure 1 is an induced subgraph of G.*

3 Structure of Line Graphs

To obtain our kernel, we heavily rely on different characterizations of line graphs given by Theorem 2. The two main characterizations used throughout the paper are given in points (2) and (4) To ease the presentation of our techniques, we will define a notion of a *clique partition witness* for G, whose existence is implied by the point (2) of Theorem 2. Let G be a line graph, a *clique partition witness* for G is a set $\mathcal{C} = \{C_1, \ldots, C_q\}$ be such that:

- $C_i \subseteq V(G)$ for all $i \in [q]$,
- $G[C_i]$ is a complete graph for all $i \in [q]$, that is every C_i is a clique in G,
- $|C_i \cap C_j| \leq 1$ for all $i \neq j \in [q]$,
- every $v \in V(G)$ is in exactly two sets in $\mathcal{C}$, and
- for every edge $uv \in E(G)$ there exists exactly one set $C_i \in \mathcal{C}$ such that $\{u, v\} \subseteq C_i$.

Note that by Theorem 2, G is a line graph if and only if there exists a clique partition witness for G. The following three observations follow directly from the definition of clique partition witness and will be useful throughout the paper.

▶ **Observation 3.** *If $\mathcal{C}$ is clique partition witness for G then every clique in $\mathcal{C}$ is either a singleton, K_2, or a maximal clique in G.*

▶ **Observation 4.** *If $\mathcal{C}$ is clique partition witness for G, then every maximal clique in G of size at least 4 is in $\mathcal{C}$.*

▶ **Observation 5.** *If $\mathcal{C}$ is clique partition witness for G, then any clique of G which is not a sub-clique of some element of $\mathcal{C}$ is a triangle.*

We would like to point out that given a line graph G one can find a clique partition witness for G for example by using an algorithm of Degiorgi and Simon [9] for recognition of line graphs in polynomial time. In the following lemma, we sketch the main procedure of their algorithm together with necessary modifications to actually output a clique partition witness instead of the underlying graph H such that $G = L(H)$, for completeness.

▶ **Lemma 6.** *Given a graph G, there is an algorithm that in time $\mathcal{O}(|E(G)| + |V(G)|)$ decides whether G is a line graph and if so, constructs a clique partition witness for G.*

Proof. The algorithm by Degiorgi and Simon construct the input graph G by adding vertices one at a time, at each step it chooses a vertex to add that is already adjacent to at least one previously-added vertex. That is it construct graphs G_1, G_2, …, $G_n = G$ such that G_i is a connected subgraph of G on i vertices. At each step it maintains a graph H_i such that G_i is a line graph of H_i. In here, we can actually keep a clique partition witness $\mathcal{C}_i$ for G_i such that there is a bijection φ_i between vertices of H_i and clique in $\mathcal{C}_i$ such that $uv \in E(H_i)$ if and only if $|\varphi_i(u) \cap \varphi_i(v)| = 1$.

The algorithm heavily relies on the Whitney's isomorphism theorem that implies that if the underlying graph of G_i has at least 4 vertices, then the underlying graph H_i is unique up to isomorphism. When adding a vertex v to a graph G_i for $i \leq 4$, the algorithm simply brute-forces the possibilities for H_i and $\mathcal{C}_i$.

When adding a vertex v to G_i when $i > 4$, let S be the subgraph of H_i formed by the edges that correspond to the neighbors of v in G_i. Check that S has a vertex cover consisting of one vertex or two non-adjacent vertices, *i.e.*, there are cliques C_1 and C_2 in $\mathcal{C}_i$ with $C_i \cap C_2 = \emptyset$ and $S \subseteq C_1 \cap C_2$. If there are two vertices in the cover, add an edge (corresponding to v) that connects these two vertices in H_i and add v to both C_1 and C_2. If there is only one vertex u in the cover, then add a new vertex to H_i, adjacent to this vertex, add v to the clique $\varphi_i(u)$ in $\mathcal{C}_i$ and add a new clique $\{v\}$ to $\mathcal{C}_i$ to create $\mathcal{C}_{i+1}$. ◀

3.1 Level Structure of Instances

For the rest of the paper, let G be the input graph and let S be a set of at most $6k$ vertices such that for every $v \in S$ the graph $G - (S \setminus \{v\})$ is a line graph. We let $\mathcal{C} = \{C_1, \ldots, C_q\}$ be a clique partition witness for $G - S$. The goal of this subsection is to split the cliques in

$\mathcal{C}$ to levels such that 1) each level contains only bounded number of cliques (that are not singletons) and 2) if we do not remove any edge at level i, then we do not need to remove any edge at level $j > i$. We will later show that we do not need to remove any edges in cliques in level 5. The following lemma is useful to define/bound the number of cliques at the first level, i.e., cliques that interact with S.

▶ **Lemma 7.** *For every vertex $v \in S$ there are at most two cliques $C_1, C_2 \in \mathcal{C}$ such that v is adjacent to all vertices in $C_1 \cup C_2$ and to at most 6 vertices in $V(G) \setminus (S \cup C_1 \cup C_2)$.*

Proof. By the choice of the set S, it follows that $G - (S \setminus \{v\})$ is a line graph. Let $\mathcal{C}'$ be clique partition witness for $G - (S \setminus \{v\})$. By definition, there are at most two cliques C'_1 and C'_2 in $\mathcal{C}'$ that contains v and all its neighbors. If $|C'_i| \geq 5$, for some $i \in \{1, 2\}$, then by Observation 4, $C'_i \setminus \{v\}$ is a clique in $\mathcal{C}$ and we can set C_i to be $C'_i \setminus \{v\}$. Else $|C'_i \setminus v| \leq 3$ and C'_i contributes to at most 3 neighbors of v in $G - S$. ◀

The following lemma shows that cliques of size at least $k+7$ can serve as kind of separators that will never be changed by a solution of size at most k. Hence, we can remove all cliques separated from S by large cliques. Moreover, it allows us to define the $(i+1)$-st level by only considering the cliques of size at most $k+6$ at level i.

▶ **Lemma 8.** *Let $C \in \mathcal{C}$ such that $|C| \geq k+7$ and let $A \subset E(G)$ be an optimal solution for G. Then $A \cap E(G[C]) = \emptyset$. Moreover, the clique partition witness $\mathcal{C}'$ for $G - A$ contains a clique C' such that $C' \setminus S = C$.*

Proof. Let $\{u, v\} \in A$ such that $\{u, v\} \subseteq C$. Clearly there are at most $k-1$ vertices w in C such that either $\{u, w\} \in A$ or $\{w, v\} \in A$. Let $x \in C$ be such that xv, xu are edges in $G - A$. Similarly, there are at most $k-1$ non-edges to u, v, x in $G - A$, so let $y \in C$ be a vertex such that yu, yv, yx are edges in $G - A$. Repeating the same argument once again, there is $z \in C$ such that zu, zv, zx, zy are edges in $G - A$. However, the subgraph of $G - A$ induced on u, v, x, y, z is K_5 minus an edge, which is one of the forbidden induced subgraphs in the characterization of line graphs.

The moreover part follows from the following argument. Since $|C| \geq k + 7 \geq 4$ and, by Observation 4 it follows that the clique partition witness $\mathcal{C}'$ contains a maximal clique $C' \supseteq C$. It remains to show that no vertex in $V(G) \setminus (S \cup C)$ is in C'. Every vertex in $V(G) \setminus S$ is in two cliques C_1, C_2 in $\mathcal{C}$ that cover all its incident edges in $G - S$. If none of these two cliques is C, then C intersect each of these two cliques in at most 1 vertex. It follows that, because $|C| \geq 3$, there is no vertex in $V(G) \setminus (S \cup C)$ adjacent to all vertices of C. ◀

Let us now partition the cliques in $\mathcal{C}$ into two parts $\mathcal{C}_{<k+7}$ and $\mathcal{C}_{\geq k+7}$ such that $\mathcal{C}_{<k+7}$ contains precisely all the cliques in $\mathcal{C}$ with less than $k+7$ vertices and $\mathcal{C}_{\geq k+7}$ contains the remaining cliques. We will refer to the cliques in $\mathcal{C}_{<k+7}$ as *small* cliques and the cliques in $\mathcal{C}_{\geq k+7}$ as *large* cliques. Intuitively, if we are forced to delete some edge in $G - S$, then this change had to be propagated from S only by changes in small cliques.

We are now ready to define the level structure on the cliques in $\mathcal{C}$. We divide the cliques in $\mathcal{C}$ into levels $\mathcal{L}_1, \mathcal{L}_2, \ldots, \mathcal{L}_p$, for some $p \in \mathbb{N}$, that intuitively reflects on how far from S the clique $C \in \mathcal{C}$ is if we consider a shortest path using only small cliques. We will define the levels recursively as follows. By Lemma 7 for every vertex $v \in S$ there exists at most two cliques $C_1, C_2 \in \mathcal{C}$ such that v is adjacent to all vertices in $C_1 \cup C_2$ and to at most 6 vertices in $V(G) \setminus (S \cup C_1 \cup C_2)$. Now, for a vertex $v \in S$, let $\mathcal{N}^v$ denote the set of cliques that contains C_1, C_2 and all the cliques in $\mathcal{C}$ that contain at least one of the neighbors of v in $V(G) \setminus (S \cup C_1 \cup C_2)$. We let $\mathcal{L}_1$ be precisely the set $\bigcup_{v \in S} \mathcal{N}^v$. Note that vertices in

$C_1 \cup C_2$ can each appear in one other clique that is not in $\mathcal{N}^v$ and in particular there are cliques that contain a vertex adjacent to a vertex in S and are not in $\mathcal{L}_1$. For $i > 1$, we then let $\mathcal{L}_i$ be the set of cliques C in $\mathcal{C} \setminus (\bigcup_{j\in\{1..i-1\}} \mathcal{L}_j)$ such that there is a small clique C' in the previous level (*i.e.*, $C' \in \mathcal{L}_{i-1} \cap \mathcal{C}_{<k+7}$) such that $C \cap C'$ is not empty.

▶ **Observation 9.** *Let $C \in \mathcal{C}$ and w a vertex in C. If w has a neighbor in S, then either $C \in \mathcal{L}_1 \cup \mathcal{L}_2$ or w is in a large clique.*

Proof. Let $v \in S$ be a neighbor of w. Then $\mathcal{N}^v \subseteq \mathcal{L}_1$ contains a clique C' with $w \in C'$. Clearly C' intersects C in w. Hence either C' is a large clique or by the definition of $\mathcal{L}_2$ the clique C is in $\mathcal{L}_1 \cup \mathcal{L}_2$. ◀

Let $p \in \mathbb{N}$ be such that $\mathcal{L}_p \neq \emptyset$ and $\mathcal{L}_{p+1} = \emptyset$. While the following Reduction Rule is not completely necessary and would be subsumed by Reduction Rule 2, we include it to showcase some of the ideas needed for the proof in a simplified setting.

▶ **Reduction Rule 1.** *Remove all vertices in $V(G) \setminus S$ that are not in a clique in $\bigcup_{i\in[p]} \mathcal{L}_i$.*

Proof of safeness. Let H be the resulting graph and let $\mathcal{C}_H$ be a set of cliques of H obtained from $\mathcal{C}$, by taking all cliques in $\bigcup_{i\in[p]} \mathcal{L}_i$ and for every clique in $C \in (\mathcal{C} \setminus \bigcup_{i\in[q]} \mathcal{L}_i)$, $\mathcal{C}_H$ contains $C \cap V(H)$, if it is nonempty. Since H is an induced subgraph of G and line graphs can be characterized by a set for forbidden induced subgraphs, it follows that for every $A \in E(G)$, if $G - A$ is a line graph, then $H - A$ is a line graph. It remains to show that if there is a set of edges $A \in E(H)$ such that $|A| \leq k$ and $H - A$ is a line graph, then $G - A$ is also a line graph. Let A be such a set of edges of minimum size and let $\mathcal{C}_A$ be a clique partition witness for $H - A$. It suffices to show that for every clique in $C \in (\mathcal{C}_H \setminus \bigcup_{i\in[p]} \mathcal{L}_i)$, it holds that $C \in \mathcal{C}_A$. If this is the case, we get a clique partition witness for $G - A$ by replacing the cliques of $\mathcal{C}_H \setminus \bigcup_{i\in[p]} \mathcal{L}_i$ in $\mathcal{C}_A$ by $\mathcal{C} \setminus \bigcup_{i\in[p]} \mathcal{L}_i$.

Now, $C \in (\mathcal{C}_H \setminus \bigcup_{i\in[p]} \mathcal{L}_i)$ means that all cliques intersecting C are large. Moreover, because all vertices in H are in some clique on some level, by Lemma 8, for each clique $C_1 \in \mathcal{C}_H$ that intersect C there is a clique in $C'_1 \in \mathcal{C}_A$ that is the union of C_1 and some vertices in S. Hence, all vertices in C are already in at least one clique in $\mathcal{C}_A \setminus C$ and all the edges incident to exactly one vertex in C are already covered by these cliques. And hence every clique that contains a vertex in C and intersects every other clique in $\mathcal{C}_A$ in at most one vertex has to be a subset of C. Moreover, the cliques in $\mathcal{C}_A$ that are subsets of C have to be vertex disjoint, since every vertex is in at most 2 cliques in $\mathcal{C}_A$. Hence, if C is not in $\mathcal{C}_A$, then some of the edges in C have to be in A, but replacing all the subsets of C in $\mathcal{C}_A$ by C gives a clique partition witness for $H - A'$ for some $A' \subsetneq A$ which contradicts the fact that A is of minimum size. ◀

We will also say that $C \in \mathcal{C}$ is at $\mathcal{L}$-distance d from S, denoted by $\text{dist}^{\mathcal{L}}(C)$, if C is in $\mathcal{L}_d$. We note that $\mathcal{C}$ still contains some cliques that are not in any of $\mathcal{L}_i$'s. We will let $\text{dist}^{\mathcal{L}}(C) = \infty$ for such a clique C. We can now upper bound the number of cliques at $\mathcal{L}$-distance d from S.

▶ **Lemma 10.** *There are at most $14|S|(k+6)^{d-1}$ cliques in $\mathcal{C}$ at level d,* i.e., *in $\mathcal{L}_d$.*

Proof. By the definition of $\mathcal{L}_1 = \bigcup_{v\in S} \mathcal{N}^v$, where $\mathcal{N}^v$ denote the set of cliques that contains C_1, C_2 and all the cliques in $\mathcal{C}$ that contain at least one of the neighbors of v in $V(G) \setminus (S \cup C_1 \cup C_2)$. By Lemma 7 for every vertex $v \in S$ there exists at most two cliques $C_1, C_2 \in \mathcal{C}$ such that v is adjacent to all vertices in $C_1 \cup C_2$ and to at most 6 vertices in $V(G) \setminus (S \cup C_1 \cup C_2)$. Since every vertex appears in two cliques of $\mathcal{C}$, it follows that $|\mathcal{N}^v| \leq 14$ and consecutively

$\mathcal{L}_1$ contains at most $14|S|$ cliques. Now by the definition of $\mathcal{L}_d$ we know that for any $d \geq 2$ a clique is at level d if and only if it shares a vertex with a small clique at level $d-1$. Since no three cliques in $\mathcal{C}$ can share a vertex the number of cliques at level d is at most the number of vertices in the small cliques at level $d-1$ and the lemma follows by a simple induction on d. ◀

The remainder of the algorithm consists of two steps. First, in Section 4, we show that we can remove all edges from cliques that are at $\mathcal{L}$-distance at least 5 from S. Afterwards, due to Lemma 10, we are left with only $\mathcal{O}\left(k^4\right)$ non-singleton cliques in $\mathcal{C}$. To finish the algorithm in Section 5, for each clique $C \in \mathcal{C}$ that is not a singleton, we mark an arbitrary subset of $k+7$ vertices in C and remove all unmarked vertices from G. It is then rather straightforward consequence of Lemma 8 that this rule is safe and we get an equivalent instance with $\mathcal{O}\left(k^5\right)$ vertices.

4 Bounding the Distance from S

The purpose of this section is to show that it is only necessary to keep the cliques in $\mathcal{C}$ that are at $\mathcal{L}$-distance at most 4 from S (and adding a singleton for vertices covered by exactly one clique at $\mathcal{L}$-distance at most 4). To do so, we need to show that there is always a solution that does not change the cliques at $\mathcal{L}$-distance 5 at all. For this purpose, we first need to understand the interaction of cliques at $\mathcal{L}$-distance 4 from S with the solution. The first step will be to show that there is an optimal solution A with clique partition witness $\mathcal{C}_A$ such that all cliques in $\mathcal{C}_A$ that share an edge with a clique in $\mathcal{C}$ at $\mathcal{L}$-distance at least 4 from S are actually subcliques of a clique in $\mathcal{C}$ (when restricted to $G-S$). It is a simple consequence of Lemma 8 that this is true for any clique that intersect a large clique in an edge. Hence, we can only care about cliques in $\mathcal{C}_A$ that intersect a small clique C in an edge. By Observation 9, no vertex in C has a neighbor in S. It then follows by Observation 5 that any clique in $\mathcal{C}_A$ that intersects C in an edge and is not a subclique of a clique in $\mathcal{C}$ is indeed a triangle. This leads us to the following definition.

▶ **Definition 11** (bad triangle). *Let $A \subseteq E(G)$ be such that $G-A$ is a line graph and let $\mathcal{C}_A$ be a clique partition witness of $G-A$. A triangle $xyz \in \mathcal{C}_A$ is said to be* bad *if it is not a sub-clique of a clique in $\mathcal{C}$, and one of the edges of the triangle, say xy, is an edge contained in a clique of $\mathcal{L}$-distance at least 4 from S.*

▶ **Lemma 12.** *There exists an optimal solution without any bad triangle.*

Proof. Let A be an optimal solution and $\mathcal{C}_A$ the clique partition witness of $G-A$. Suppose xyz is a bad triangle and let C_1, C_2 and C_3 be the elements of $\mathcal{C}$ containing the edges xy, yz and zx respectively. See also Figure 2 for an illustration. Since xyz is a bad triangle, no clique in $\mathcal{C}_A$ is a superset of C_i, $i \in \{1,2,3\}$ and it is a simple consequence of Lemma 8 that C_i is a small clique. By definition of bad triangle, at least one of C_1, C_2, and C_3 is at $\mathcal{L}$-distance at least 4 from S and hence all of these cliques are at $\mathcal{L}$-distance at least 3 from S. Let X (resp. Y, Z) denote the other clique of $\mathcal{C}_A$ containing x (reps. y, z). Let us define $X_1 = X \cap C_1, X_3 = X \cap C_3, Y_1 = Y \cap C_1, Y_2 = Y \cap C_2, Z_3 = Z \cap C_3$ and $Z_2 = Z \cap C_2$.

Let $C_1' = X_1 \cup Y_1$, $C_2' = Y_2 \cup Z_2$ and $C_3' = Z_3 \cup X_3$. Note that C_i' is a sub-clique of C_i for $i \in [3]$. Now for every $i \in [3]$ we will update C_i' as follows. As long as there exists an edge e in C_i' such that e belongs to $K_i \in \mathcal{C}_A$, K_i is a sub-clique of C_i and $K_i \not\subseteq C_i'$, we set $C_i' := C_i' \cup K_i$ (see also Figure 2b). When this process stops, C_i' corresponds to the union of a set of elements of $\mathcal{C}_A : K_1^i, \ldots, K_{l_i}^i$ which are sub-cliques of C_i, and C_i'. Moreover, for

any edge e of C'_i which is strictly contained in another clique of $\mathcal{C}_A$ (meaning this clique is not e), then this clique has to be a triangle by Observation 5, as the clique of $\mathcal{C}$ containing e is C_i. Let $e^i_1, \dots, e^i_{s_i}$ denote the set of such edges and let $C^i_1, \dots, C^i_{s_i}$ be the triangles of $\mathcal{C}_A$ containing these edges. Note that $|A \cap C'_1| \geq s_1$, as for any edge e^1_j, either x or y has to be non adjacent to each extremity in $G - A$ or the edge would be in two cliques of $\mathcal{C}_A$ (the same statement is also correct for $|A \cap C'_2|$ and $|A \cap C'_3|$). Let A' be the set obtained from A by

- Removing all the edges of $A \cap C'_1$, $A \cap C'_2$ and $A \cap C'_3$.
- Adding one of the two edges of C^i_j different from e^i_j for every $i \in [3]$ and $j \in [s_i]$ (see Figure 2c illustrating the replacement of C^j_i in $\mathcal{C}_A$ by its proper subclique in $\mathcal{C}_{A'}$ implied by this addition of an edge in A'.).

▷ Claim 13. A' is a set of edges not larger than A and such that $G - A'$ is a line graph with fewer bad triangles than $G - A$.

Proof. The fact that $|A'| \leq |A|$ follows from the fact that $|A \cap C'_i| \geq s_i$ for all $i \in [3]$. To see that $G - A'$ is a line graph, let us show that $\mathcal{C}_{A'}$ defined as follows is a clique partition witness for $G - A'$. Let $\mathcal{C}_{A'}$ be the set defined from $\mathcal{C}_A$ by

- Removing C_A, X, Y, Z, every C^i_j for $i \in [3]$, $j \in [s_i]$, every K^i_j for every $i \in [3]$ and $j \in [l_i]$ and every edge which are contained in one of the C'_i.
- Adding C'_i for $i \in [3]$ and for every $i \in [3]$ and $j \in [s_i]$ the edge of C^i_j which has not been removed from A, as well as singletons for vertices belonging to only one clique.

First it is clear that any set added to $\mathcal{C}'_A$ is a clique as A' does not contain any edge in $A \cap C'_1$, $A \cap C'_2$ and $A \cap C'_3$ and these sets are cliques of G.

Now take B and C two cliques of $\mathcal{C}'_A$. If B and C belong to $\mathcal{C}_A$, then clearly their intersection has size at most 1. If one belongs to $\mathcal{C}_A$ and the other is the remaining edge of C^i_j for $i \in [3]$ and $j \in [s_i]$, then it is also clear as it is true for C^i_j. For $i, j \in [3]^2$, C'_i and C'_j also intersect on one vertex, because C_i and C_j do and moreover, the cliques of $\mathcal{C}_A$ intersecting C'_i on two vertices are exactly the C^i_j, so if $B = C'_i$ and $A \in \mathcal{C}_A$, the intersection has also size at most 1, and we covered all the cases for $|C \cap B|$.

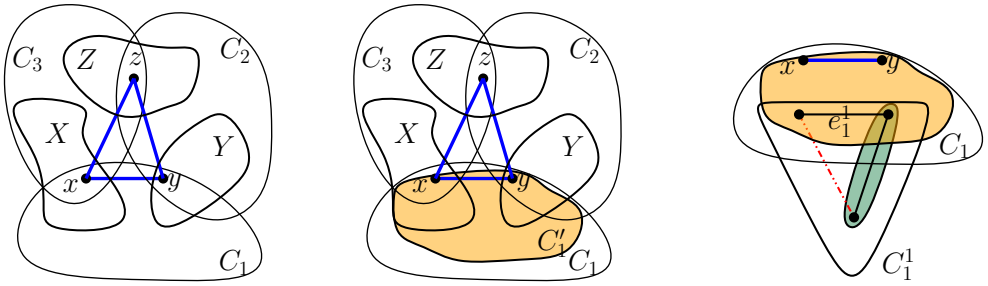
Now for every vertex $x \in V(G)$, if x does not belong to C'_1, C'_2 and C'_3, then it belongs to the same cliques as in $\mathcal{C}_A$ (where the C^i_j have been reduced to an edge and a singleton). For the vertices of C'_1, C'_2 and C'_3 different from x, y, z, we replaced one sub-clique of C_i by another. Finally x belongs to C'_1 and C'_3, y to C'_1 and C'_2 and z to C'_2 and C'_3.

Suppose uv is an edge of $E(G - A')$. If uv belongs to one of the C'_i, then by definition of the C^i_j and because we removed all these triangles, uv only belongs to one clique. For the other edges of $E(G - A')$, the fact that uv belongs to exactly one clique of $\mathcal{C}'_A$ follows from the fact that A' differs on those edges from A only because we added some edges of the C^i_j, and $\mathcal{C}_A$ differs on these vertices only because we changed C^i_j into the remaining edge outside C'_i.

Overall $\mathcal{C}_{A'}$ is indeed a clique partition for $G - A'$. Moreover, to obtain it, we removed at least one bad triangle from $\mathcal{C}_A$ (C_A) without adding one. This ends the proof of the claim. ◁

Finally, we can repeat the process until $\mathcal{C}_{A'}$ is without any bad triangles, which ends the proof of the lemma. ◀

Before we show that indeed all cliques at $\mathcal{L}$-distance at least 5 from S are intact in some optimal solution, we show another auxiliary lemma that is rather simple consequence of Lemma 12, namely that there is a clique partition witness for some optimal solution A such that no two cliques $\mathcal{C}_A$ that intersect the same clique $C \in \mathcal{C}$ at $\mathcal{L}$-distance at least 4 from S in an edge can intersect. This is important later to show that indeed no vertex in a clique $C \in \mathcal{C}$ at $\mathcal{L}$-distance 5 from S will be in two cliques in $\mathcal{C}_A$ that are not subsets of C.



(a) A bad triangle xyz in $\mathcal{C}_A$. C_1, C_2, C_3 are three cliques in $\mathcal{C}$ containing xy, yz, and xz respectively. $X, Y, Z \in \mathcal{C}_A$ are the cliques containing x, y, z other than xyz.

(b) C'_1 is the inclusion minimal clique such that $(X \cup Y) \cap C_1 \subseteq C'_1 \subseteq C_1$ and for all $K \in \mathcal{C}_A$ if $K \subseteq C_1$ and $|K \cap C'_1| \geq 2$, then $K \subseteq C'_1$. C'_2 and C'_3 are defined analogously.

(c) C^1_1 intersects C'_1 in an edge e^1_1. C^1_1 is replaced by an edge other than e^1_1. This forces to include one edge in C^1_1 to a solution A'. However, this can be seen as replacing an edge between $\{x, y\}$ and endpoints of e^1_1 that is in A.

Figure 2 The treatment of bad triangles. Let $A \subseteq E(G)$ be an optimal solution, $\mathcal{C}_A$ a clique partition witness for A. A bad triangle xyz together with cliques X, Y, Z, as defined in Subfigure 2a are replaced by cliques C'_1, C'_2, and C'_3 defined in Subfigure 2b. Subfigure 2c shows the treatment of cliques in $\mathcal{C}_A$ that intersect C'_i in an edge. By definition of C'_i, such clique is not a subclique of C_i and hence a triangle.

▶ **Lemma 14.** *There exists an optimal solution $A \subseteq E(G)$ without any bad triangles and clique partition witness $\mathcal{C}_A$ for $G - A$ such that for every $C \in \mathcal{C}$ of $\mathcal{L}$-distance at least 4 and every $w \in C$, if C^w_1 and C^w_2 are the two cliques in $\mathcal{C}_A$ containing w, then either $C^w_1 \cap C = \{w\}$ or $C^w_2 \cap C = \{w\}$.*

Proof. Let $A \subseteq E(G)$ be an optimal solution for G without any bad triangles and clique partition witness $\mathcal{C}_A$ for $G - A$ minimizing the number of pairs (C, w) for which C is at $\mathcal{L}$-distance at least 4, $w \in C$ and the two cliques, denoted C^w_1 and C^w_2, in $\mathcal{C}_A$ containing w intersect C in two vertices. Furthermore, it follows from Lemma 8 that C is a small clique, as the clique containing C as a subclique in $\mathcal{C}_A$ would intersect C^w_1 in two vertices. Since there are no bad triangles and C is at $\mathcal{L}$-distance at least 4, it follows that $C^w_1 \subseteq C$ and $C^w_2 \subseteq C$ and in particular $C^w_1 \cup C^w_2$ is a clique in G. Indeed, our goal is to replace C^w_1 and C^w_2 by a clique D such that $C^w_1 \cup C^w_2 \subseteq D \subseteq C$. We start by setting $D = C^w_1 \cup C^w_2$. We will also keep a track of cliques we will remove from $\mathcal{C}_A$. This set will be $\mathcal{D}$ and initialize it as $\mathcal{D} = \{C_1, C_2\}$.

As in the proof of Lemma 12, the only reason why we cannot replace C_1 and C_2 by D and obtain a solution that removes a subset of edges of A is because there exist two vertices $v_1, v_2 \in D$ and a clique $C_{12} \in \mathcal{C}_A$ with $\{v_1, v_2\} \subseteq C_{12}$. Observe that by our assumption there is no bad triangle and $C_{12} \subseteq C$. We let $D = D \cup C_{12}$ and $\mathcal{D} = \mathcal{D} \cup C_{12}$ and repeat until there is no such pair of vertices. Note that every vertex in G is in at most two cliques of $\mathcal{C}_A$. Therefore, this process has to stop after at most $2|C|$ steps.

When there are no two vertices in D that appear together in a different clique, we remove $\mathcal{D}$ from $\mathcal{C}_A$ and replace it by D and $\{v\}$. For every vertex that appears in D, we removed one clique that it appeared in. Hence, every vertex appears in at most 2 cliques and we can always add a singleton to clique partition witness for vertices that are only in one clique. Moreover, no two cliques intersect in two vertices, since D is the only clique we added, and we removed/changed all the cliques that intersected D in at least two vertices. Finally, all edges in $G - A$ remain covered, we only potentially covered some additional edges in D.

Note that this procedure does not introduce any bad triangles or new pair (C', w') for which C' is at $\mathcal{L}$-distance at least 4, $w' \in C'$ and the two cliques in $\mathcal{C}_A$ containing w' intersect C' in two vertices. As it also removes one such pair, we obtain a contradiction with the choice of A. We can therefore deduce that A does not contain such pair (C, w) and the lemma follows. ◀

Finally, we can state the main lemma of this section.

▶ **Lemma 15.** *There exists an optimal solution A for G and a clique partition witness $\mathcal{C}_A$ for $G - A$ such that for every clique $C \in \mathcal{C}$ at $\mathcal{L}$-distance at least 5 it holds that $C \in \mathcal{C}_A$.*

Proof. Let A be an optimal solution without any bad triangles and clique partition witness $\mathcal{C}_A$ for $G - A$ such that for every $C \in \mathcal{C}$ of $\mathcal{L}$-distance at least 4 and every $w \in C$, if C_1^w and C_2^w are the two cliques in $\mathcal{C}_A$ containing w, then either $C_1^w \cap C = \{w\}$ or $C_1^w \cap C = \{w\}$. Note that existence of such a solution is guaranteed by Lemma 14. Moreover let $(A, \mathcal{C}_A)$ be such an optimal solution satisfying properties in Lemma 14 that minimizes the number of cliques $C \in \mathcal{C}$ of $\mathcal{L}$-distance at least 5 such that $C \notin \mathcal{C}_A$. We claim that A satisfies the properties of the lemma.

For a contradiction let $C \in \mathcal{C}$ be a clique at $\mathcal{L}$-distance at least 5 and let $C_1, \ldots, C_p$ be the cliques in $\mathcal{C}_A$ that intersects C in at least 2 vertices. Since there is no bad triangle, it follows that $C_i \subseteq C$ for all $i \in [p]$ and by optimality of A, $p = 1$ (else $\bigcup_{i\in[p]} C_i$ is missing at least one edge). We claim that $C = C_1$. Else let $v \in C \setminus C_1$. Note that C is a small clique and hence by Observation 9 v does not have a neighbor in S. In particular all neighbors of v are covered by two cliques in $\mathcal{C}$, one of those cliques is C and let the other clique be C^v. Moreover, Let C_1^v and C_2^v be the two cliques in $\mathcal{C}_A$ containing v. Since $v \in C \setminus C_1$ both C_1^v and C_2^v are subsets of C^v. However, C^v is either a large clique and $\mathcal{C}_A$ contains C^v and the cliques C_1^v and C_2^v are C^v and $\{v\}$ respectively, or C^v is a small clique, in which case C^v is at $\mathcal{L}$-distance at least 4 from S, because it shares a vertex with the clique C at $\mathcal{L}$-distance at least 5 from S. It follows by the choice of A that either $C^v \cap C_1^v = \{v\}$ or $C^v \cap C_2^v = \{v\}$, but then again either C_1^v or C_2^v is the singleton $\{v\}$. However then the clique partition witness $(\mathcal{C}_A \setminus \{C_1, \{v\}\}) \cup \{C_1 \cup \{v\}\}$ defines a better solution. It follows that indeed $C \in \mathcal{C}_A$ for all cliques in $\mathcal{C}$ at $\mathcal{L}$-distance at least 5 in G. ◀

We are now ready to present our main reduction rule. Note that it would seem that we could remove just the vertices that do no appear in a clique at distance at most 4. However, because of the large cliques in at the first four levels, we would be potentially left with many cliques at $\mathcal{L}$-distance infinity that we cannot remove because all of their vertices are in a large clique at $\mathcal{L}$-distance at most 4 from S. While this case could have been dealt with separately, we can actually show a stronger claim, *i.e.,* that we can remove all edges from G that are covered by a clique at $\mathcal{L}$-distance at least 5 from S. Note that in this case we cannot easily claim that if (G, k) is YES-instance then so is the reduced instance and we crucially need the fact that cliques at $\mathcal{L}$-distance at least 5 are kept in clique partition witness of some optimal solution.

▶ **Reduction Rule 2.** *Remove all edges $uv \in E(G)$ such that $\{u, v\} \subseteq C$ for some clique C with $\text{dist}^{\mathcal{L}}(C) \geq 5$. Afterwards remove all isolated vertices from G.*

Let $\mathcal{D}$ be the set of cliques at $\mathcal{L}$-distance at least 5 from S, V_5 the set of vertices that appear in a clique in $\mathcal{D}$ and in a clique in $\mathcal{C} \setminus \mathcal{D}$ and G' be the graph obtained after applying the reduction rule and let $\mathcal{C}' = (\mathcal{C} \setminus \mathcal{D}) \cup \bigcup_{v\in V_5} \{v\}$. Note that $\mathcal{C}'$ is a clique partition witness for $G' - S$ and that $\{v\}$, for $v \in V_5$, is a clique at $\mathcal{L}$-distance at least 5.

Proof of safeness. Let $\mathcal{D}$, V_5, G', $\mathcal{C}'$ be as described above and let A be an optimal solution for G', that is $G' - A$ is a line graph, and let $\mathcal{C}_A$ be clique partition witness for $G' - A$. By Lemma 15, we can assume that $\bigcup_{v \in V_5}\{v\} \subseteq \mathcal{C}_A$. We will show that $(\mathcal{C}_A \setminus \bigcup_{v \in V_5}\{v\}) \cup \mathcal{D}$ is a clique partition witness for $G - A$. Clearly each edge in $G - A$ is either covered by $(\mathcal{C}_A \setminus \bigcup_{v \in V_5}\{v\})$ or by $\mathcal{D}$. It is also easy to see that every vertex is in precisely two cliques. Moreover, two cliques in $\mathcal{D}$ intersect in at most 1 vertex, because $\mathcal{D} \subseteq \mathcal{C}$ and similarly two cliques in $\mathcal{C}_A$ intersect in at most one vertex. Finally, let $D \in \mathcal{D}$ and $C \in (\mathcal{C}_A \setminus \bigcup_{v \in V_5}\{v\})$. Clearly, $D \cap C \subseteq V_5$. Moreover, for $\{u, v\} \subseteq D$, the edge uv is not in G' and hence $\{u, v\} \not\subseteq C$. Hence, $|D \cap C| \leq 1$.

On the other hand, let A be an optimal solution for G and a clique partition witness $\mathcal{C}_A$ for $G - A$ such that for every clique $C \in \mathcal{C}$ at $\mathcal{L}$-distance at least 5 it holds that $C \in \mathcal{C}_A$. Note that the existence of $(A, \mathcal{C}_A)$ is guaranteed by Lemma 15. We claim that $G' - A$ is a line graph. By the choice of $(A, \mathcal{C}_A)$, it follows that $\mathcal{D} \subseteq \mathcal{C}_A$. Moreover, for every edge e that is covered by a clique in $\mathcal{D}$ it holds that $e \notin E(G')$. It follows rather straightforwardly that $\mathcal{C}_A \setminus \mathcal{D} \cup \bigcup_{v \in V_5}\{v\}$ is indeed a clique partition witness for $G' - A$. ◀

5 Finishing the Proof

Suppose now that G, S, and $\mathcal{C}$ correspond to the instance after applying Reduction Rules 1 and 2. Clearly all cliques in $\mathcal{C}$ are either at $\mathcal{L}$-distance at most 4 from S or there are singletons at distance 5 or infinity, depending on whether the singleton intersects a small or a large clique, respectively. It follows from Lemma 10 that there are at most $\mathcal{O}\left(k^4\right)$ cliques at distance at most 4. We let M be any minimal w.r.t. inclusion set of vertices such that for every clique C in $\mathcal{C}$ at $\mathcal{L}$-distance at most 4 it holds that $|M \cap C| \geq \min\{|C|, k + 7\}$. Such a set M can be easily obtained by including arbitrary $\min\{|C|, k + 7\}$ vertices from every clique C at distance at most 4 and then removing the vertices v such that $|(M \setminus \{v\}) \cap C| \geq \min\{|C|, k + 7\}$ for all $C \in \mathcal{C}$ at $\mathcal{L}$-distance at most 4. From this construction it is easy to see that $|M| = \mathcal{O}\left(k^5\right)$.

▶ **Reduction Rule 3.** *Remove all vertices in $V(G) \setminus (S \cup M)$ from G.*

Proof of safeness. Let the clique partition witness $\mathcal{C}'$ for $G - (S \cup M)$ be $\{C \cap M \mid C \in \mathcal{C}, C \cap M \neq \emptyset\}$. Since line graphs are characterized by a finite set of forbidden induced subgraphs, it is easy to see that if $G - A$ is a line graph, for some $A \subseteq E(G)$, then $G[S \cup M] - A = (G - A)[S \cup M]$ is also a line graph. For the other direction, let $A \subseteq E(G)$ be such that $G[S \cup M] - A$ is line graph. We will show that $G - A$ is a line graph. Let $\mathcal{C}_A$ be a clique partition witness for $G[S \cup M] - A$. Now let $\mathcal{C}'_A$ be the set we obtain from $\mathcal{C}_A$ by adding to it all the singleton cliques in $\mathcal{C}$ that do not contain a marked vertex and for every clique $C \in \mathcal{C}_A$ for which there exists $C' \in \mathcal{C}$ with $C \setminus S \subseteq C'$, we replace C by $C' \cup (C \cap S)$.

First let us verify that every vertex in $V(G)$ is in precisely two cliques in $\mathcal{C}'_A$. It is easy to see that this holds for $v \in S \cup M$, because $\mathcal{C}_A$ is a clique partition witness for $G[S \cup M] - A$ and we only added new cliques containing vertices in $V(G) \setminus (M \cup S)$ or extended existing cliques in $\mathcal{C}_A$ by vertices in $V(G) \setminus (M \cup S)$. Now let $v \in V(G) \setminus M$ and let $C_1, C_2 \in \mathcal{C}$ be two cliques that contain v. Because all cliques in $\mathcal{C}$ at $\mathcal{L}$-distance at least 5 are singletons and we keep all vertices of the cliques at $\mathcal{L}$-distance at most 4 of size less than $k + 7$, it follows that C_1 and C_2 either both contain at least $k + 7$ vertices or one of them, say C_2, is a singleton and the other, C_1, contains at least $k + 7$ vertices. If C_2 is a singleton, then $C_2 \in \mathcal{C}'_A$. Else for C_i, $i \in \{1, 2\}$, with $|C_i| \geq k + 7$ there is $C'_i \in \mathcal{C}'$ with $|C'_i| \geq k + 7$ and $C'_i \subseteq C_i$. By Lemma 8, $\mathcal{C}_A$ contains a clique C_i^A such that $C_i^A \setminus S = C'_i \setminus C_i$. By the construction of $\mathcal{C}'_A$ it now follows

that $\mathcal{C}'_A$ contains $C_i^A \cup C_i$. From Lemma 7 it follows that if $u \in S$ is adjacent to at least 7 vertices in a clique in $\mathcal{C}$, then it is adjacent to the whole clique. Hence $C_i^A \cup C_i$ indeed induces a complete subgraph of $G - A$. It follows that v is indeed in precisely two cliques in $\mathcal{C}'_A$. Note that above also shows that the sets in $\mathcal{C}'_A$ induce cliques in $G - A$. Furthermore every edge in $G - A$ either has both endpoints in $S \cup M$ and are covered by a clique C in $\mathcal{C}_A$ such that $\mathcal{C}'_A$ contains a superset of C, or they are in the same clique of size at least $k + 7$ in $\mathcal{C}$ that is a subset of a clique in $\mathcal{C}'_A$ as well.

It remains to show that $|C_1 \cap C_2| \leq 1$ for all cliques in $\mathcal{C}'_A$. If $|C_1 \cap C_2| \geq 2$, then at least one of the vertices in $C_1 \cap C_2$ has to be outside $S \cup M$. But then from the above discussion follows that $C_1 \setminus S$ and $C_2 \setminus S$ are in $\mathcal{C}$, $|C_1 \setminus S| \geq k + 7$, $|C_2 \setminus S| \geq k + 7$ and at least $k + 7$ vertices from each of $C_1 \setminus S$ and $C_2 \setminus S$ are in $G[S \cup M]$. Clearly, $C_1 \setminus S$ and $C_2 \setminus S$ intersect in at most one vertex, let us denote it u, and the other vertices in the intersection of C_1 and C_2 are in S. Let v be arbitrary vertex in $C_1 \cap C_2 \cap S$. Note that v is adjacent to at least 7 vertices in both $C_1 \setminus S$ and $C_2 \setminus S$ and by Lemma 7 it is adjacent to all vertices in $(C_1 \cup C_2) \setminus S$. Since $G - (S \setminus \{v\})$ is a line graph, it follows that $G[(C_1 \cup C_2) \setminus (S \setminus \{v\})]$ is a line graph. Every vertex in $C_1 \setminus (S \cup \{u\})$ is in exactly one other clique in $\mathcal{C}$. This clique intersects $C_2 \setminus (S \cup \{u\})$ in at most one vertex. Therefore, there is a pair of vertices $w_1 \in C_1 \setminus (S \cup \{u\})$, $w_2 \in C_2 \setminus (S \cup \{u\})$ such that $w_1 w_2 \notin E(G)$. Now uvw_1 and uvw_2 are two odd triangles (any vertex in $C_i \setminus (S \cup \{u, w_i\})$ is adjacent to three vertices of the triangle uvw_i) that share a common edge, however uvw_1w_2 is not a K_4. Hence, $G[(C_1 \cup C_2) \setminus (S \setminus \{v\})]$ is not a line graph, a contradiction. It follows that if two cliques in $\mathcal{C}$ of size at least $k + 7$ intersect in a vertex in $G - S$, then no vertex in S is adjacent to both cliques and consequently no two cliques in $\mathcal{C}'_A$ intersect in at least two vertices.

It follows that $\mathcal{C}'_A$ is indeed a clique partition witness for $G - A$ and by point (2) in Theorem 2, $G - A$ is indeed a line graph. ◀

We are now ready to prove Theorem 1.

▶ **Theorem 1.** *Line-Graph Edge Deletion admits a kernel with $\mathcal{O}(k^5)$ vertices.*

Proof. We start the algorithm by finding the set S of at most $6k$ vertices such that for every $v \in S$ the graph $G - (S \setminus \{v\})$ is a line graph. This is simply done by greedily finding maximal set of pairwise edge-disjoint forbidden induced subgraphs. Afterwards, we construct a clique partition witness $\mathcal{C}$ for $G - S$ by using the algorithm of Lemma 6. Finally, we apply Reduction Rules 1, 2, and 3 in this order. By the discussion above Reduction Rule 3, after applying all the reduction rules, the resulting instance has $\mathcal{O}(k^5)$ vertices. The correctness of the kernelization algorithm follows from the safeness proofs of the reduction rules. ◀

6 Concluding Remarks

In this paper, we positively answered the open question from WorKer 2013 about kernelization of Line-Graph-Edge Deletion by giving a kernel for the problem with $\mathcal{O}(k^5)$ vertices. Our techniques crucially depend on the structural characterization of the line graphs. We believe that similar techniques could lead also to polynomial kernels for Line-Graph-Edge Addition and Line-Graph-Edge Editing. In particular, a result similar to Lemma 8 still holds when we allow addition of the edges. However, we were not able to bound the distance from S. Main difficulty seems to be the possibility of merging of some small cliques into one in a clique partition witness. It is also worth noting that the line graphs of multigraphs (*i.e.,* graphs that allow multiple edges between the same pair of vertices) have a similar structural characterization with the main difference being that the cliques in a clique partition witness

can intersect in more than just one vertex. The kernelization of the edge deletion (as well as addition or editing) to a line graph of a multigraph remains open as well. Finally, the kernelization of Claw-free Edge Deletion as well as of the edge deletion to some of the other natural subclasses of claw-free graphs remain wide open.

Abstract

We show that a constant factor approximation of the shortest and closest lattice vector problem w.r.t. any ℓ_p-norm can be computed in time $2^{(0.802+\varepsilon)\,n}$. This matches the currently fastest constant factor approximation algorithm for the shortest vector problem w.r.t. ℓ_2. To obtain our result, we combine the latter algorithm w.r.t. ℓ_2 with geometric insights related to coverings.

1 Introduction

The *shortest vector problem* (SVP) and the *closest vector problem* (CVP) are important algorithmic problems in the geometry of numbers. Given a rational lattice

$$\mathcal{L}(B) = \{B\mathbf{x} \,:\, \mathbf{x} \in \mathbb{Z}^n\}$$

with $B \in \mathbb{Q}^{n\times n}$ and a target vector $\mathbf{t} \in \mathbb{Q}^n$ the closest vector problem asks for lattice vector $\mathbf{v} \in \mathcal{L}(B)$ minimizing $\|\mathbf{t} - \mathbf{v}\|$. The *shortest vector problem* asks for a *nonzero* lattice vector $\mathbf{v} \in \mathcal{L}(B)$ of minimal norm. When using the ℓ_p norms for $1 \le p \le \infty$, we denote the problems by SVP_p resp. CVP_p.

Much attention has been devoted to the hardness of approximating SVP and CVP. In a long sequence of papers, including [42, 7, 32, 10, 18, 28, 23] it has been shown that SVP and CVP are hard to approximate to within almost polynomial factors under reasonable complexity assumptions. The best polynomial-time approximation algorithms have exponential approximation factors [29, 41, 8].

The first algorithm to solve CVP for any norm that has exponential running time in the dimension only was given by Lenstra [30]. The running time of his procedure is $2^{O(n^2)}$ times a polynomial in the encoding length. In fact, Lenstra's algorithm solves the more general *integer programming* problem. Kannan [27] improved this to $n^{O(n)}$ time and polynomial space. It took almost 15 years until Ajtai, Kumar and Sivakumar presented a randomized algorithm for SVP_2 with time and space $2^{O(n)}$ and a $2^{O(1+1/\varepsilon)n}$ time and space algorithm for $(1+\varepsilon)$-CVP_2 [8, 9]. Here $(1+\varepsilon)$-CVP_2 is the problem of finding a lattice vector, whose

distance to the target is at most $1+\varepsilon$ times the minimal distance. Blömer and Naewe [14] extended the randomized sieving algorithm of Ajtai et al. to solve SVP_p and obtain a $2^{O(n)}$ time and space exact algorithm for SVP_p and an $O(1+1/\varepsilon)^{2n}$ time algorithm to compute a $(1+\varepsilon)$ approximation for CVP_p. For CVP_∞, one has a faster approximation algorithm. Eisenbrand et al. [20] showed how to boost any constant approximation algorithm for CVP_∞ to a $(1+\varepsilon)$-approximation algorithm in time $O(\log(1+1/\varepsilon))^n$. Recently, this idea was adapted in [36] to all ℓ_p norms, showing that $(1+\varepsilon)$ approximate CVP_p can be solved in time $O(1+1/\varepsilon)^{n/\min(2,p)}$ by boosting the deterministic CVP algorithm for general (even asymmetric) norms with a running time of $(1+1/\varepsilon)^n$ that was developed by Dadush and Kun [16].

The first deterministic singly-exponential time and space algorithm for exact CVP_2 (and SVP_2) was developed by [33]. The fastest exact algorithms for SVP_2 and CVP_2 run in time and space $2^{n+o(n)}$ [3, 1, 6]. Single exponential time and space algorithms for exact CVP are only known for ℓ_2. Whether CVP and the more general integer programming problem can be solved in time $2^{O(n)}$ is a prominent mystery in algorithms.

Recently there has been exciting progress in understanding the *fined grained complexity* of exact and constant approximation algorithms for CVP [2, 12, 5]. Under the assumption of the *strong exponential time hypothesis (SETH)* and for $p \neq 0 \pmod 2$, exact CVP_p cannot be solved in time $2^{(1-\varepsilon)d}$. Here d is the *ambient dimension* of the lattice, which is the number of vectors in a basis of the lattice. Under the assumption of a *gap-version* of the strong exponential time hypothesis *(gap-SETH)* these lower bounds also hold for the approximate versions of CVP_p. More precisely, for each $\varepsilon > 0$ there exists a constant $\gamma_\varepsilon > 1$ such that there exits no $2^{(1-\varepsilon)d}$ algorithm that computes a γ_ε-approximation of CVP_p.

Unfortunately, the currently fastest algorithms for CVP_p resp. SVP_p do not match these lower bounds, even for large approximation factors. These algorithms are based on randomized sieving, [8, 9]. Many lattice vectors are generated that are then, during many stages, subtracted from each other to obtain shorter and shorter vectors w.r.t. ℓ_p (resp. any norm) until a short vector is found. However, the algorithm needs to start out with sufficiently many lattice vectors just to guarantee that two of them are close. This issue directly relates to the *kissing number* (w.r.t. some norm) which is the maximum number of unit norm balls that can be arranged so that they touch another given unit norm ball. In the setting of sieving, this is the number of vectors of length r that are needed to guarantee that the difference of two of them is strictly smaller than r. Among all known upper bounds on the kissing numbers, the best (i.e. smallest) upper bound is known for ℓ_2 and equals $2^{0.401n}$, [26]. For ℓ_2 the fastest such approximation algorithms require time $2^{0.802n}$ - the square of the kissing number w.r.t. ℓ_2. For ℓ_∞ the kissing number equals 3^n-1 which is also an upper bound on the kissing number for any norm. The current best constant factor approximation algorithms for SVP_∞ and CVP_∞ require time 3^n, their counterparts w.r.t. ℓ_p require even more time, see [4, 35]. This then suggests the question, originally raised by Aggarwal et al. in [2] for ℓ_∞, whether the kissing number w.r.t. ℓ_p is a natural lower bound on the running time of SVP_p resp. CVP_p.

Our results indicate otherwise. For constant approximation factors, we are able to reduce these problems w.r.t. ℓ_p to another lattice problem but w.r.t. ℓ_2. This directly improves the running time of the algorithms for ℓ_p norms that hinge on the kissing number. Furthermore, given that the development of algorithms for ℓ_2 has been much more dynamic than for arbitrary ℓ_p norms and the difficulty of establishing hardness results for ℓ_2, there is hope to find still faster algorithms for SVP_2 that may not even rely on the kissing number w.r.t. ℓ_2. It is likely that this would then improve the situation for ℓ_p norms as well.

Our *main results* are resumed in the following theorem.

▶ **Theorem.** *For each $\varepsilon > 0$, there exists a constant γ_ε such that a γ_ε approximate solution to CVP_p, as well as to SVP_p for $p \in [1, \infty]$ can be found in time $2^{(0.802+\varepsilon)n}$.*

Our main idea is to use coverings in order to obtain a constant factor approximation to the shortest resp. closest vector w.r.t. ℓ_p by using a (approximate) shortest vector algorithm w.r.t. ℓ_2. We need to distinguish between the cases $p \in [2, \infty]$ and $p \in [1, 2)$. For $p \in [2, \infty]$, we show that exponentially many short vectors w.r.t. ℓ_2 cannot all have large pairwise distance w.r.t. ℓ_p. This follows from a bound on the number of ℓ_p norm balls scaled by some constant that are required to cover the ℓ_2 norm ball of radius $n^{1/2-1/p}$. The final procedure is then to sieve w.r.t. ℓ_2 and to pick the smallest non zero pairwise difference w.r.t. ℓ_p of the (exponentially many) generated lattice vectors. This yields a constant factor approximation to the shortest resp. closest vector w.r.t. ℓ_p, $p \in [2, \infty]$. For $p \in [1, 2)$, we use a more direct covering idea. There is a collection of at most $2^{\varepsilon n}$ balls w.r.t. ℓ_2, whose union contains the ℓ_p norm ball but whose union is contained in the ℓ_p norm ball scaled by some constant. This leads to a simple algorithm for ℓ_p norms ($p \in [1, 2)$) by using the approximate closest vector algorithm w.r.t. ℓ_2 from this paper.

This paper is organized as follows. In Section 2 we present the main idea for $p = \infty$ that also applies to the case $p \geq 2$. In Section 3 we first reintroduce the list-sieve method originally due to [34] but with a slightly more general viewpoint, we resume this in Theorem 4. We then present in detail our approximate CVP_∞ resp. SVP_∞ algorithm and extend this idea resp. algorithm to ℓ_p, $p \geq 2$. This is Theorem 5. Finally, in Section 4, using the covering technique from Section 2 and our approximate CVP_2 algorithm from Section 3.1, we show how to solve approximate CVP_p for $p \in [1, 2)$. This is Theorem 8.

2 Covering balls with boxes

We now outline our main idea in the setting of an approximate SVP_∞ algorithm. Let us assume that the shortest vector of $\mathcal{L}$ w.r.t. ℓ_∞ is $\mathbf{s} \in \mathcal{L} \setminus \{0\}$. We can assume that the lattice is scaled such that $\|\mathbf{s}\|_\infty = 1$ holds. The euclidean norm of $\mathbf{s}$ is then bounded by $\sqrt{n}$. Suppose now that there is a procedure that, for some constant $\gamma > 1$ independent of n, generates distinct lattice vectors $\mathbf{v}_1, \ldots, \mathbf{v}_N \in \mathcal{L}$ of length at most $\|\mathbf{v}_i\|_2 \leq \gamma\sqrt{n}$.

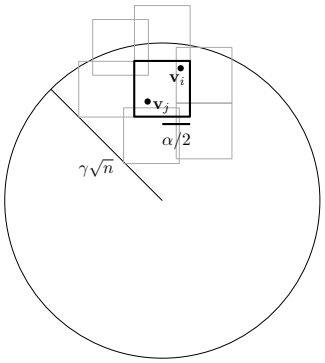

Figure 1 The difference $\mathbf{v}_i - \mathbf{v}_j$ is an α-approximate shortest vector w.r.t. ℓ_∞.

How large does the number of vectors N have to be such that we can guarantee that there exist two indices $i \neq j$ with

$$\|\mathbf{v}_i - \mathbf{v}_j\|_\infty \leq \alpha, \tag{1}$$

where $\alpha \geq 1$ is the approximation guarantee for SVP_∞ that we want to achieve? Suppose that N is larger than the minimal number of copies of the box $(\alpha/2)B_\infty^n$ that are required to cover the ball $\sqrt{n}B_2^n$. Here $B_p^n = \{x \in \mathbb{R}^n \,:\, \|x\|_p \leq 1\}$ denotes the unit ball w.r.t. the ℓ_p-norm. Then, by the pigeon-hole principle, two different vectors $\mathbf{v}_i$ and $\mathbf{v}_j$ must be in the same box. Their difference satisfies (1) and thus is an α-approximate shortest vector w.r.t. ℓ_∞, see Figure 1.

Thus we are interested in the *translative covering number* $N(\sqrt{n}B_2^n, aB_\infty^n)$, which is the number of translated copies of the box aB_∞^n that are needed to cover the ℓ_2-ball of radius $\sqrt{n}$. In the setting above, a is the constant $\alpha/(2\gamma)$. For this procedure to be efficient, we need $N(\sqrt{n}B_2^n, aB_\infty^n)$ to be relatively small for a large enough - this is equivalent to decreasing the number of vectors N we need to generate by worsening (increasing) the approximation guarantee α. Since $2^{O(n)}\operatorname{vol}(B_\infty^n) = \operatorname{vol}(\sqrt{n}B_2^n)$ and by a simple covering argument, we have that $N(\sqrt{n}B_2^n, B_\infty^n) \leq 2^{Cn}$. This gives hope that by taking a large enough (but independent of n), we can decrease $N(\sqrt{n}B_2^n, aB_\infty^n)$ to, say, $2^{0.401n}$ or $2^{\varepsilon n}$ for $\varepsilon > 0$.

Covering problems like these have received considerable attention in the field of convex geometry, see [11, 37]. These techniques rely on the classical *set-cover problem* and the logarithmic integrality gap of its standard LP-relaxation, see, e.g. [43, 15]. To keep this paper self-contained, we briefly explain how this can be applied to our setting.

If we cover the finite set $(1/n)\mathbb{Z}^n \cap \sqrt{n}B_2^n$ with cubes whose centers are on the grid $(1/n)\mathbb{Z}^n$, then by increasing the side-length of those cubes by an additive $1/n$, one obtains a full covering of $\sqrt{n}B_2^n$. Thus we can focus on the corresponding *set-covering problem* with ground set $U = (1/n)\mathbb{Z}^n \cap \sqrt{n}B_2^n$ and sets

$$S_t = U \cap aB_\infty^n + t,\, t \in (1/n)\,\mathbb{Z}^n,$$

ignoring empty sets. An element of the ground set is contained in exactly $|(1/n)\mathbb{Z}^n \cap aB_\infty^n|$ many sets. Therefore, by assigning each element of the ground set the fractional value $1/|(1/n)\mathbb{Z}^n \cap aB_\infty^n|$, one obtains a feasible fractional covering. The weight of this fractional covering is

$$\frac{T}{|(1/n)\mathbb{Z}^n \cap aB_\infty^n|}$$

where T is the number of sets. Clearly, if a cube intersects $\sqrt{n}B_2^n$, then its center is contained in the *Minkowski sum* $\sqrt{n}B_2^n + aB_\infty^n$ and thus the weight of the fractional covering is

$$\frac{|(\sqrt{n}B_2^n + aB_\infty^n) \cap \frac{1}{n}\mathbb{Z}^n|}{|\frac{1}{n}\mathbb{Z}^n \cap aB_\infty^n|} = O\left(\frac{\operatorname{vol}(\sqrt{n}B_2^n + aB_\infty^n)}{\operatorname{vol}(aB_\infty^n)}\right)$$

Since the size of the ground-set is bounded by $n^{O(n)}$ and since the integrality gap of the set-cover LP is at most the logarithm of this size, one obtains

$$N(\sqrt{n}B_2^n, aB_\infty^n) \leq \operatorname{poly}(n)\,\frac{\operatorname{vol}(\sqrt{n}B_2^n + aB_\infty^n)}{\operatorname{vol}(aB_\infty^n)} \tag{2}$$

By *Steiner's formula*, see [22, 40, 24], the volume of $K + tB_2^n$ is a polynomial in t, with coefficients $V_j(K)$ only depending on the convex body K:

$$\operatorname{vol}(K + tB_2^n) = \sum_{j=0}^{n} V_j(K)\operatorname{vol}(B_2^{n-j})t^{n-j}$$

For $K = aB_\infty^n$, $V_j(K) = (2a)^j\binom{n}{j}$. Setting $t = \sqrt{n}$, the resulting expression has been evaluated in [25, Theorem 7.1].

▶ **Theorem 1** ([25]). *Denote by* H *the binary entropy function and let* $\phi \in (0,1)$ *the unique solution to*

$$\frac{1-\phi^2}{\phi^3} = \frac{2a^2}{\pi} \tag{3}$$

Then

$$\mathrm{vol}(aB_\infty^n + \sqrt{n}B_2^n) = O(2^{n[\mathrm{H}(\phi)+(1-\phi)\log(2a)+\frac{\phi}{2}\log(\frac{2\pi e}{\phi})]})$$

Using this bound in inequality (2) and simplifying, we find

$$N(\sqrt{n}B_2^n, aB_\infty^n) \leq \mathrm{poly}(n)\, 2^{n[\mathrm{H}(\phi)+\frac{\phi}{2}\log(\frac{2\pi e}{\phi})]}$$

Both $\mathrm{H}(\phi)$ and $\frac{\phi}{2}\log(\frac{2\pi e}{\phi})$ decrease to 0 as ϕ decreases to 0. Since ϕ, the unique solution to (3), satisfies $\phi \leq \sqrt[3]{(\pi/2)}a^{-\frac{2}{3}}$, we obtain the following bound.

▶ **Lemma 2.** *For each* $\varepsilon > 0$*, there exists* $a_\varepsilon \in \mathbb{R}_{>0}$ *independent of* n*, such that*

$$N(\sqrt{n}B_2^n, a_\varepsilon B_\infty^n) \leq 2^{\varepsilon n}.$$

Going back to the idea for an approximate SVP_∞ algorithm, we will use Lemma 2 with $\varepsilon = 0.401$. If we generate $2^{0.401n}$ distinct lattice vectors of euclidean length at most $\gamma\sqrt{n}$, then there must exist a pair of lattice vectors with pairwise distance w.r.t. ℓ_∞ shorter than $2\gamma a_{0.401}$. We find it by trying out all possible pairwise combinations, this takes time $2^{0.802n}$.

The main idea for approximate SVP_p is similar. Set $\tilde{\mathbf{s}}$ the shortest vector in $\mathcal{L}$ w.r.t. ℓ_p and scale the lattice so that $\|\tilde{\mathbf{s}}\|_p = 1$. The euclidean norm of $\tilde{\mathbf{s}}$ is bounded by $n^{1/2-1/p}$. Again, we can consider the question of how many different lattice vectors there have to be within a ball of radius $\gamma n^{1/2-1/p}$ so that we can guarantee that there exist two lattice vectors with constant pairwise distance w.r.t. ℓ_p. This leads us to consider the translative covering number $N(n^{1/2-1/p}B_2^n, aB_p^n)$. Since $n^{-1/p}B_\infty^n \subseteq B_p^n$, the following is immediate from Lemma 2.

▶ **Lemma 3.** *For each* $\varepsilon > 0$*, there exists* $a_\varepsilon \in \mathbb{R}_{>0}$ *independent of* n*, such that*

$$N(n^{1/2-1/p}B_2^n, a_\varepsilon B_p^n) \leq 2^{\varepsilon n}.$$

3 Approximate CVP_p for $p \geq 2$

We now describe our main contribution. As we mentioned already, SVP_2 can be approximated up to a constant factor in time $2^{(0.802+\varepsilon)n}$ for each $\varepsilon > 0$. This follows from a careful analysis of the *list sieve* algorithm of Micciancio and Voulgaris [34], see [31, 38]. The running time and space of this algorithm is directly related to the *kissing number* of the ℓ_2-norm. The running time is the square of the best known upper bound by Kabatiansky and Levenshtein [26].

The main insight of our paper is that the current list-sieve variants can be used to approximate SVP_p and CVP_p by testing all pairwise differences of the generated lattice vectors.

3.1 List sieve

We begin by describing the list-sieve method [34] to a level of detail that is necessary to understand our main result. Our exposition follows closely the one given in [38]. Let $\mathcal{L}(B)$ be a given lattice and $\mathbf{s} \in \mathcal{L}$ be an unknown lattice vector. This unknown lattice vector $\mathbf{s}$ is typically the shortest, respectively closest vector in $\mathcal{L}(B)$.

The list-sieve algorithm has two stages. The input to the *first stage* of the algorithm is an LLL-reduced lattice basis B of $\mathcal{L}(B)$, a constant $\varepsilon > 0$ and a guess μ on the length of $\mathbf{s}$ that satisfies

$$\|\mathbf{s}\|_2 \leq \mu \leq (1 + 1/n)\|\mathbf{s}\|_2. \tag{4}$$

The first stage then constructs a list of lattice vectors $L \subseteq \mathcal{L}(B)$ that is random. This list of lattice vectors is then passed on to the second stage of the algorithm.

The *second stage* of the algorithm proceeds by sampling points $\mathbf{y}_1, \ldots, \mathbf{y}_N$ uniformly and independently at random from the ball

$$(\xi_\varepsilon \cdot \mu)B_2^n,$$

where ξ_ε is an explicit constant depending on ε only. It then transforms these points via a deterministic algorithm $\texttt{ListRed}_L$ into lattice points

$$\texttt{ListRed}_L(\mathbf{y}_1), \ldots, \texttt{ListRed}_L(\mathbf{y}_N) \in \mathcal{L}(B).$$

The deterministic algorithm $\texttt{ListRed}_L$ uses the list $L \subseteq \mathcal{L}(B)$ from the first stage.

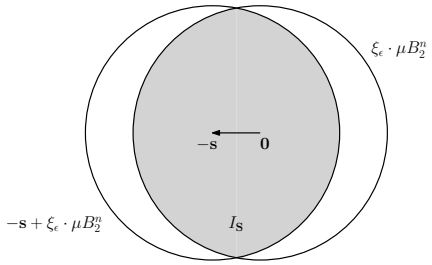

Figure 2 The lens $I_\mathbf{s}$.

As we mentioned above, the list $L \subseteq \mathcal{L}(B)$ that is used by the deterministic algorithm $\texttt{ListRed}_L$ is random. We will show the following theorem in the next section. The novelty compared to the literature is the reasoning about *pairwise differences* lying in *centrally symmetric* sets. In this theorem, $\varepsilon > 0$ is an arbitrary constant, ξ_ε as well as c_ε are explicit constants and K is some centrally symmetric set. Furthermore, we assume that μ satisfies (4).

The theorem reasons about an area $I_\mathbf{s}$ that is often referred as the *lens*, see Figure 2. The lens was introduced by Regev as a conceptual modification to facilitate the proof of the original AKS algorithm [39].

$$I_\mathbf{s} = (\xi_\varepsilon \cdot \mu)B_2^n \cap (-\mathbf{s} + (\xi_\varepsilon \cdot \mu)B_2^n) \tag{5}$$

▶ **Theorem 4.** *With probability at least* $1/2$*, the list* L *that was generated in the first stage satisfies the following. If* $\mathbf{y}_1, \cdots, \mathbf{y}_N$ *are chosen independently and uniformly at random within* $B_2^n(0, \xi_\varepsilon\mu)$ *then*

i) *The probability of the event that two different samples* $\mathbf{y}_i, \mathbf{y}_j$ *satisfy*

$$\mathbf{y}_i, \mathbf{y}_j \in I_\mathbf{s} \text{ and } \texttt{ListRed}_L(\mathbf{y}_i) - \texttt{ListRed}_L(\mathbf{y}_j) \in K$$

is at most twice the probability of the event that two different samples $\mathbf{y}_i, \mathbf{y}_j$ *satisfy*

$$\texttt{ListRed}_L(\mathbf{y}_i) - \texttt{ListRed}_L(\mathbf{y}_j) \in K + \mathbf{s}$$

ii) *For each sample* $\mathbf{y}_i$ *the probability of the event*

$$\|\texttt{ListRed}_L(\mathbf{y}_i)\|_2 \leq c_\varepsilon \|\mathbf{s}\|_2 \text{ and } \mathbf{y}_i \in I_\mathbf{s}$$

is at least $2^{-\varepsilon n}$.

The complete procedure, i.e. the construction of the list L in stage one and applying $\texttt{ListRed}_L$ to the N samples $\mathbf{y}_1, \ldots, \mathbf{y}_n$ in stage two takes time $N2^{(0.401+\varepsilon)n} + 2^{(0.802+\varepsilon)n}$ and space $N + 2^{(0.401+\varepsilon)n}$.

The proof of Theorem 4 follows verbatim from Pujol and Stehlé [38], see also [31]. In [38], $\mathbf{s}$ is a shortest vector w.r.t. ℓ_2. But this fact is never used in the proof and in the analysis. Part ii) follows from Lemma 5 and Lemma 6 in [38]. Their probability of a sample being in the lens $I_\mathbf{s} \subseteq \xi \|\mathbf{s}\|_2 B_2^n$ depends only on ξ (corresponding to our ξ_ε). By choosing ξ large enough, this happens with probability at least $2^{-\varepsilon n}$. Their Lemma 6 then guarantees that the list L, with probability $1/2$, when $\mathbf{y}_i \sim I_\mathbf{s}$ is sampled uniformly, returns a lattice vector of length at most $r_0 \|\mathbf{s}\|_2$ (r_0 corresponds to our c_ε). This corresponds to part ii) in our setting. The size of their list (denoted by N_T) is bounded above by $2^{(0.401+\delta)n}$ where $\delta > 0$ decreases to 0 as the ratio r_0/ξ increases, this is their Lemma 4.

Finally, part i) also follows from Pujol and Stehlé [38]. It is in their proof of correctness, Lemma 7, involving the lens $I_\mathbf{s}$. We briefly comment on our general viewpoint. Given $\mathbf{y} \sim (\xi \cdot \mu)B_2^n$, the algorithm computes the linear combination w.r.t. to the lattice basis $\mathbf{b}_1, \ldots, \mathbf{b}_n$

$$\mathbf{y} = \sum_{i=1}^n \lambda_i \mathbf{b}_i$$

and then the *remainder*

$$\mathbf{y} \pmod{\mathcal{L}} = \sum_{i=1}^n \lfloor \lambda_i \rfloor \mathbf{b}_i.$$

The important observation is that this remainder is the same for all vectors $\mathbf{y} + \mathbf{v}$, $\mathbf{v} \in \mathcal{L}$. Next, it keeps reducing (minus) the remainder w.r.t. the list, as long as the length decreases. This results in a vector of the form

$$-\mathbf{y} \pmod{\mathcal{L}} - \mathbf{v}_1 - \cdots - \mathbf{v}_k, \text{ for some } \mathbf{v}_i \in L.$$

The output $\texttt{ListRed}_L(\mathbf{y})$ is then

$$-\mathbf{y} \pmod{\mathcal{L}} - \mathbf{v}_1 - \cdots - \mathbf{v}_k + \mathbf{y} \in \mathcal{L}.$$

The algorithm bases its decisions on $\mathbf{y} \pmod{\mathcal{L}}$ and not on $\mathbf{y}$ directly. This is why one can imagine that, after $\mathbf{y} \pmod{\mathcal{L}}$ has been created, one applies a bijection τ of the ball $\tau(\cdot) : \xi\mu B_2^n \to \xi\mu B_2^n$ on $\mathbf{y}$ with probability $1/2$. For $\mathbf{y} \in I_\mathbf{s}$ one has $\tau(\mathbf{y}) = \mathbf{y} + \mathbf{s}$. We refer to [38] for the definition of τ. Since τ is a bijection and preserves the measure, the result of applying $\tau(\mathbf{y})$ with probability $1/2$ is distributed uniformly. This means that for $\mathbf{y} \in I_s$ this modified but equivalent procedure outputs $\texttt{ListRed}_L(\mathbf{y})$ or $\texttt{ListRed}_L(\mathbf{y}) + \mathbf{s}$, both with probability $1/2$. If $\texttt{ListRed}_L(\mathbf{y}_i) - \texttt{ListRed}_L(\mathbf{y}_j) \in K$, we toss a coin for i and j each. With probability $1/2$, their difference is in $\pm K + \mathbf{s}$.

3.2 Approximation to CVP_p and SVP_p for $p \in [2, \infty]$

We now combine Theorem 4 with the covering ideas presented in Section 2.

▶ **Theorem 5.** *For $p \geq 2$, there is a randomized algorithm that computes with constant probability a constant factor (depending on ε) approximation to CVP_p and SVP_p respectively. The algorithm runs in time $2^{(0.802+\varepsilon)n}$ and it requires space $2^{(0.401+\varepsilon)n}$.*

In short, the algorithm is the standard list-sieve algorithm with a slight twist: *Check all pairwise differences.*
We first present in detail the case $p = \infty$. Even though there is an approximation preserving reduction from SVP to CVP, [21], we present separately the case SVP and CVP to highlight the ideas from Section 2 and Theorem 4. The case $p \geq 2$ then follows from this, we briefly comment on it.

Proof for $p = \infty$. We assume that the list L that was computed in the first stage satisfies the properties described in Theorem 4. Recall that this is the case with probability at least $1/2$.
We first consider SVP_∞. By Lemma 2, there is $a > 0$ such that $N(\sqrt{n}B_2^n, aB_\infty^n) \leq 2^{0.401n}$. Let $\mathbf{s}$ be a shortest vector w.r.t. ℓ_∞ and let $\mu > 0$ such that $\|\mathbf{s}\|_2 \leq \mu < (1 + \frac{1}{n}) \|\mathbf{s}\|_2$ as above. Since $\|\mathbf{s}\|_2 \leq \sqrt{n} \|\mathbf{s}\|_\infty$ we have $N(c_\varepsilon \|\mathbf{s}\|_2 B_2^n, c_\varepsilon a \|\mathbf{s}\|_\infty B_\infty^n) \leq 2^{0.401n}$. This means that, if $\lceil 2^{0.401n} \rceil + 1$ lattice vectors are contained in the ball $c_\varepsilon \|\mathbf{s}\|_2 B_2^n$ at least two of them have ℓ_∞-distance bounded by $2c_\varepsilon a$ which is a constant.

Set $N = 2 \cdot \lceil 2^{(\varepsilon+0.401)n} + 1 \rceil$ and $\{\mathbf{y}_1, \ldots, \mathbf{y}_N\} \overset{iid}{\sim} B_2^n(0, \xi_\varepsilon \mu)$ uniformly and independently at random. By Theorem 4 ii) and by the Chebychev inequality, see [38], the following event has probability at least $1/2$.

(Event A): There is a subset $S \subseteq \{1, \ldots, N\}$ with $|S| = \lceil 2^{0.401n} \rceil + 1$ such that for each $i \in S$

$$\mathbf{y}_i \in I_{\mathbf{s}} \text{ and } \|\,\mathtt{ListRed}_L(\mathbf{y}_i)\|_2 \leq c_\varepsilon \|\mathbf{s}\|_2. \tag{6}$$

This event is the disjoint union of the event $A \cap B$ and $A \cap \overline{B}$, where B denotes the event where the vectors $\mathtt{ListRed}_L(\mathbf{y}_i)$, $\mathbf{y}_i \in I_{\mathbf{s}}$ are all distinct. Thus

$$\Pr(A) = \Pr(A \cap B) + \Pr(A \cap \overline{B}).$$

The probability of at least one of the events $A \cap B$ and $A \cap \overline{B}$ is bounded below by $1/4$. In the event $A \cap B$, there exists $i \neq j$ such that

$$\|\,\mathtt{ListRed}_L(\mathbf{v}_i) - \mathtt{ListRed}_L(\mathbf{v}_j)\|_\infty \leq 2c_\varepsilon a.$$

By Theorem 4 i) with $K = \{0\}$ one has

$$\Pr(A \cap \overline{B}) \leq 2 \Pr\left(\exists i \neq j \;:\; \mathtt{ListRed}_L(\mathbf{v}_i) - \mathtt{ListRed}_L(\mathbf{v}_j) = \mathbf{s}\right).$$

Therefore, with constant probability, there exist $i, j \in \{1, \ldots, N\}$ with

$$0 < \|\,\mathtt{ListRed}_L(\mathbf{y}_i) - \mathtt{ListRed}_L(\mathbf{y}_j)\|_\infty \leq 2c_\varepsilon a.$$

We try out all the pairs of N elements, which amounts to $N^2 = 2^{(0.802+\varepsilon')n}$ additional time.

We next describe how list-sieve yields a constant approximation for CVP_∞. Let $\mathbf{w} \in \mathcal{L}(B)$ be the closest lattice vector w.r.t. ℓ_∞ to $\mathbf{t} \in \mathbb{R}^n$ and let $\mu > 0$ such that $\|\mathbf{t} - \mathbf{w}\|_2 \leq \mu < (1 + \frac{1}{n}) \|\mathbf{t} - \mathbf{w}\|_2$. We use Kannan's embedding technique [27] and define a new lattice $\mathcal{L}'$ with basis

$$\widetilde{B} = \begin{pmatrix} B & \mathbf{t} \\ 0 & \frac{1}{n}\mu \end{pmatrix} \in \mathbb{Q}^{(n+1)\times(n+1)},$$

Finding the closest vector to $\mathbf{t}$ w.r.t. ℓ_∞ in $\mathcal{L}(B)$ amounts to finding the shortest vector w.r.t. ℓ_∞ in $\mathcal{L}'(\widetilde{B}) \cap \{\mathbf{x} \in \mathbb{R}^{n+1} \ : \ x_{n+1} = \frac{1}{n}\mu\}$. The vector $\mathbf{s} = (\mathbf{t} - \mathbf{w}, \frac{1}{n}\mu)$ is such a vector and its euclidean length is smaller than $(1 + \frac{1}{n})\mu$. Let $a > 0$ be such that

$$N(\sqrt{n}B_2^n, aB_\infty^n) \leq 2^{0.401n}.$$

This means that there is a covering of the n-dimensional ball $(c_\varepsilon \|\mathbf{s}\|_2)B_2^{n+1} \cap \{\mathbf{x} \in \mathbb{R}^{n+1} \ : \ x_{n+1} = 0\}$ by $2^{0.401n}$ translated copies of K, where

$$K = (c_\varepsilon \cdot a(1 + 1/n)\|\mathbf{s}\|_\infty)B_\infty^{n+1} \cap \{\mathbf{x} \in \mathbb{R}^{n+1} \ : \ x_{n+1} = 0\}. \tag{7}$$

(The factor $(1 + 1/n)$ is a reminiscent of the embedding trick, $\mathbf{s}$ is $n + 1$ dimensional.) Similarly, we may cover $(c_\varepsilon \|\mathbf{s}\|_2)B_2^{n+1} \cap \{\mathbf{x} \in \mathbb{R}^{n+1} \ : \ x_{n+1} = k \cdot \frac{\mu}{n}\}$ for all $k \in \mathbb{Z}$ (such that the intersection is not empty) by translates of K. There are only $2c_\varepsilon(n + 1) + 1$ such layers to consider and so $(2c_\varepsilon(n + 1) + 1)2^{0.401n}$ translates of K suffice. The last component of a lattice vector of $\mathcal{L}'$ is of the form $k \cdot \frac{\mu}{n}$ and it follows that these translates of K cover all lattice vectors of euclidean norm smaller than $c_\varepsilon \|\mathbf{s}\|_2$, see Figure 3.

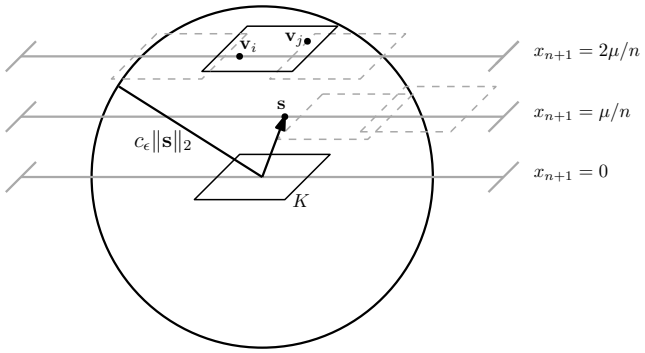

Figure 3 Covering the lattice points with translates of K.

.

Set $N = \lceil (2c_\varepsilon(n+1)+2)2^{(\varepsilon+0.401)n} \rceil$ and sample again $\{\mathbf{y}_1, \ldots, \mathbf{y}_N\} \overset{iid}{\sim} B_2^n(0, \xi_\varepsilon \mu)$ uniformly and independently at random. By Theorem 4 ii) and by the Chebychev inequality, see [38], the following event has a probability at least $1/2$.

(Event A'): There is a subset $S \subseteq \{1, \ldots, N\}$ with $|S| = (2c_\varepsilon(n + 1) + 1)2^{0.401n} + 1$ such that for each $i \in S$

$$\mathbf{y}_i \in I_\mathbf{s} \text{ and } \|\,\mathtt{ListRed}_L(\mathbf{y}_i)\|_2 \leq c_\varepsilon \|\mathbf{s}\|_2. \tag{8}$$

In this case, there exists a translate of K that holds at least two vectors $\mathtt{ListRed}_L(\mathbf{y}_i)$ and $\mathtt{ListRed}_L(\mathbf{y}_j)$ for different samples $\mathbf{y}_i$ and $\mathbf{y}_j$, see Figure 3 with $\mathbf{v}_i, \mathbf{v}_j \in \mathcal{L}'$ instead. Thus, with probability at least $1/2$, there are $i, j \in [N]$ with $\mathbf{y}_i, \mathbf{y}_j \in I_\mathbf{s}$ such that

$$\mathtt{ListRed}_L(\mathbf{y}_i) - \mathtt{ListRed}_L(\mathbf{y}_j) \in 2K$$

Theorem 4 i) implies that, with probability at least $1/4$, there exist different samples $\mathbf{y}_i$ and $\mathbf{y}_j$ such that

$$\mathtt{ListRed}_L(\mathbf{y}_i) - \mathtt{ListRed}_L(\mathbf{y}_j) \in 2K + \mathbf{s}$$

In this case, the first n coordinates of $\mathtt{ListRed}_L(\mathbf{y}_i) - \mathtt{ListRed}_L(\mathbf{y}_j)$ can be written of the form $\mathbf{t} - \mathbf{v}$ for $\mathbf{v} \in \mathcal{L}$ and the first n coordinates on the right hand side are of the of the form $(\mathbf{t} - \mathbf{w}) + \mathbf{z}$, where $\mathbf{z} \in \mathcal{L}'$ and $\|\mathbf{z}\|_\infty \leq 2c_\varepsilon(1 + 1/n)a \|\mathbf{s}\|_\infty = 2c_\varepsilon(1 + 1/n)a \|\mathbf{t} - \mathbf{w}\|_\infty$. In particular, the lattice vector $\mathbf{v} \in \mathcal{L}$ is a $2ac_\varepsilon(1 + 1/n) + 1$ approximation to the closest vector to $\mathbf{t}$. Since we need to try out all pairs of the N elements, this takes time $N^2 = 2^{(0.802+\varepsilon')n}$ and space N. ◀

▶ Remark 6. For clarity we have not optimized the approximation factor. There are various ways to do so. We remark that for SVP_∞ we actually get a smaller approximation factor than the one that we describe. Let $\tilde{a}$ be such that $N(\sqrt{n}B_2^n, \tilde{a}B_\infty^n) \leq 2^{0.802n}$, the algorithm described above yields a $2c_\varepsilon\tilde{a}$ approximation instead of a $2c_\varepsilon a$ approximation to the shortest vector. This follows by applying the *birthday paradox* in the way that it was used by Pujol and Stehlé [38]. The same argument also applies to CVP_∞. Finally, we remark that in the case of SVP we have not really used property i) of Theorem 4. We only use this property to ensure that the generated vectors are different. It is plausible that this can be done more efficiently or with a better approximation factor.

Proof continued, $p \geq 2$. For SVP_p, $p \geq 2$, we define $\mathbf{s}$ to be shortest vector w.r.t. ℓ_p instead. Since $\|\mathbf{s}\|_2 \leq n^{1/2-1/p} \|\mathbf{s}\|_p$, we simply use Lemma 3 instead of Lemma 2 to conclude that there is some $a > 0$ such that if we have a set of $2^{0.401n}$ different lattice vectors of (euclidean) length smaller than $c_\varepsilon \|\mathbf{s}\|_2$, then two of them must have pairwise distance smaller than $2c_\varepsilon a$ w.r.t. ℓ_p.
For CVP_p, we define $\mathbf{w}$ to be the closest lattice vector to $\mathbf{t}$ w.r.t. ℓ_p. Both $\mathbf{s}$ and $\mathcal{L}'$ are defined analogously. We will need to replace the convex body K in (7) by

$$K = (c_\varepsilon \cdot a(1 + 1/n)\|\mathbf{s}\|_p)B_p^{n+1} \cap \{\mathbf{x} \in \mathbb{R}^{n+1} \ : \ x_{n+1} = 0\}.$$

The respective algorithms for SVP_p and CVP_p and the proof of correctness now follow from the case $p = \infty$. In particular, we can use the same parameters c_ε and a.

For the important case $p = 2$ we note that we can chose $a = 1$. This yields a approximation to the closest vector with the approximation guarantee c_ε matching that of the fastest approximate shortest vector problem w.r.t. ℓ_2, see [31]. ◀

4 Approximate CVP_p for $p \in [1, 2)$

In the previous section, we have extended the approximate SVP_2 solver to yield constant factor approximations to SVP_p and CVP_p for $p \in [2, \infty]$ in time $2^{(0.802+\varepsilon)n}$. From simple volumetric considerations, the technique from the previous section cannot be adapted to solve SVP_p and CVP_p for $p \in [1, 2)$ (in single exponential time). Instead, we can use a simple covering technique similar to the one considered by Eisenbrand et al. in [20]. We first show that for any constant $\varepsilon > 0$, there is a constant $a_\varepsilon > 0$, so that the crosspolytope B_1^n can be covered by $2^{\varepsilon n}$ balls (w.r.t. ℓ_2) with radius $(a_\varepsilon/\sqrt{n})$ and whose union is contained inside the crosspolytope scaled by a_ε. A similar covering also exists for B_p^n. Using the centers of these balls as targets, we can use the approximate CVP_2 algorithm to solve approximate CVP_1 resp. CVP_p. This is also similar to the technique of Dadush et al. in [17] resp. [16] where they cover general norm balls with M-ellipsoids to solve SVP and CVP w.r.t. to this norm by using the CVP_2 algorithm due to [33]. Unfortunately, there is only an upper bound of 2^{Cn} for some (large) constant $C > 0$ on the number of required M-ellipsoids, for our purpose we need a finer estimate. To achieve this, we rely on the set-covering idea and volume computations as outlined in Section 2. The following analogue to Lemma 2 is shown in the appendix.

▶ **Lemma 7.** *For each $\varepsilon > 0$, there exists $a_\varepsilon \in \mathbb{R}_{>0}$ independent of n such that*

$$\frac{\mathrm{vol}(B_1^n + (a_\varepsilon/\sqrt{n})B_2^n)}{\mathrm{vol}((a_\varepsilon/\sqrt{n})B_2^n)} \leq 2^{\varepsilon n}.$$

We now sketch the covering procedure for CVP_1 and SVP_1. Up to scaling the lattice and a guess on the distance of the closest (resp. shortest) lattice vector $\mathbf{v}$ to the target $\mathbf{t}$, we may assume that $1 - 1/n \leq \|\mathbf{v} - \mathbf{t}\|_1 \leq 1$ (resp. $1 - 1/n \leq \|\mathbf{v}\|_1 \leq 1$). We uniformly sample a point $\mathbf{x}$, [19], within $\mathbf{t} + B_1^n + (a_\varepsilon/\sqrt{n})B_2^n$ (set $\mathbf{t} = 0$ for SVP_1) and place a ball of radius $a_\varepsilon/\sqrt{n}$ around $\mathbf{x}$ (or $\mathbf{x}'$, the closest point to $\mathbf{x}$ in B_1^n, see Fig. 4).

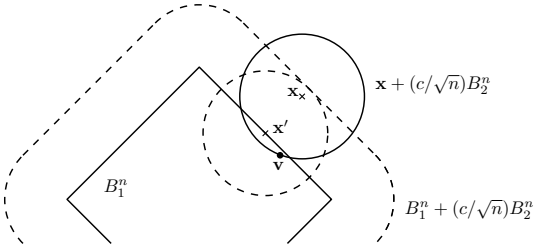

Figure 4 Generating a covering of B_1^n by $(c/\sqrt{n})B_2^n$.

.

By Lemma 7, with probability at least $2^{-\varepsilon n}$, $\mathbf{v}$ is covered by $\mathbf{x} + (a_\varepsilon/\sqrt{n})B_2^n$. Running the c-approximate (randomized) CVP_2 algorithm with target $\mathbf{x}$ (provided $\|\mathbf{v} - \mathbf{x}\|_2 \leq (a_\varepsilon/\sqrt{n})$), a lattice vector $\mathbf{w} \in \mathbf{x} + (c \cdot a_\varepsilon/\sqrt{n})B_2^n \subseteq \mathbf{t} + c \cdot (a_\varepsilon + 1)B_1^n$ is returned. The lattice vector $\mathbf{w}$ is thus a $c \cdot (a_\varepsilon + 1)$ approximation to the closest (resp. shortest) vector. In general, we run the c-approximate CVP_2 algorithm $O(\mathrm{poly}(n)2^{\varepsilon n})$ times with targets uniformly chosen within $\mathbf{t} + B_1^n + (a_\varepsilon/\sqrt{n})B_2^n$ and only output the closest of the resulting lattice vectors if it is within $c \cdot (a_\varepsilon + 1)B_1^n$. This ensures that, if there is lattice vector $\mathbf{v}$ in $\mathbf{t} + B_1^n$, a constant factor approximation to $\|\mathbf{t} - \mathbf{v}\|_1$ is found with high probability.
The same covering technique can be applied to B_p^n, $p \in (1, 2)$. By Hölder's inequality,

$$B_p^n \subseteq n^{1-1/p}B_1^n \text{ and } n^{1/2-1/p}B_2^n \subseteq B_p^n.$$

The first of these inclusions implies that for any $\varepsilon > 0$, we can pick the same constant a_ε as in Lemma 7 and cover B_p^n by at most $2^{\varepsilon n}$ translates of $a_\varepsilon n^{1/2-1/p}B_2^n$.

$$\frac{\mathrm{vol}(B_p^n + cn^{1/2-1/p}B_2^n)}{\mathrm{vol}(cn^{1/2-1/p}B_2^n)} \leq \frac{\mathrm{vol}(n^{1-1/p}B_1^n + cn^{1/2-1/p}B_2^n)}{\mathrm{vol}(cn^{1/2-1/p}B_2^n)} = \frac{\mathrm{vol}(B_1^n + (c/\sqrt{n})B_2^n)}{\mathrm{vol}((c/\sqrt{n})B_2^n)}$$

The second inclusion implies that these translates do not overlap B_p^n by more then a constant factor. It is then straightforward to adapt the boosting procedure described for CVP_1 to CVP_p. Using the approximate CVP_2 algorithm from the previous section then implies the following algorithm.

▶ **Theorem 8.** *There is a randomized algorithm that computes with constant probability a constant (depending on ε) factor approximation to CVP_p, $p \in [1, 2)$. The algorithm runs in time $2^{(0.802+\varepsilon)n}$ and requires space $2^{(0.401+\varepsilon)n}$.*

5 Proof of Lemma 7

Recall that the volume of $K + tB_2^n$ is a polynomial in t, with coefficients $V_j(K)$ that only depend on the convex body K:

$$\mathrm{vol}(K + tB_2^n) = \sum_{j=0}^{n} V_j(K)\,\mathrm{vol}(B_2^{n-j})t^{n-j}$$

The coefficients $V_j(K)$ are known as the intrinsic volumes of K. The intrinsic volumes of the crosspolytope B_1^n were computed by Betke and Henk in [13], and are given by the following formulae:

$$V_n(B_1^n) = \frac{2^n}{n!}$$

and for $0 \le j \le n-1$

$$V_j(B_1^n) = 2^n \binom{n}{j+1} \frac{\sqrt{j+1}}{j!\sqrt{\pi}^{n-j}} \cdot \int_0^\infty e^{-x^2} \left(\int_0^{x/\sqrt{j+1}} e^{-y^2}\,dy \right)^{n-j-1} dx$$

Given that the upper bound of Lemma 7 is exponential in n, we do not care about polynomial factors in n. For the sake of brevity, we will hide these polynomial factors by "$\lesssim$", i.e. $\mathrm{poly}(n) \lesssim 1$. This already simplifies the intrinsic volumes and, for $1 \le j \le n$:

$$V_j(B_1^n) \lesssim \frac{2^j}{j!}\binom{n}{j}$$

The volume of the $k-$dimensional ball B_2^k is given by

$$\mathrm{vol}(B_2^k) = \frac{\pi^{k/2}}{\Gamma(k/2+1)}$$

$\Gamma(\cdot)$ is the Gamma function. For $n \in \mathbb{N}$, we have $\Gamma(n+1) = n!$. By Stirling's formula we have the following estimate on $\Gamma(\cdot)$.

$$\left(\frac{z}{e}\right)^z \lesssim \Gamma(z+1) \lesssim \left(\frac{z}{e}\right)^z$$

With these estimates at hand, we can now prove Lemma 7.

$$\begin{aligned}
\frac{\mathrm{vol}(B_1^n + (c/\sqrt{n})B_2^n)}{\mathrm{vol}((c/\sqrt{n})B_2^n)} &= \frac{\sum_{j=0}^n V_j(B_1^n)\,\mathrm{vol}(B_2^{n-j})(c/\sqrt{n}))^{n-j}}{(c/\sqrt{n})^n\,\mathrm{vol}(B_2^n)} \\
&\lesssim \sum_{j=0}^{n} \frac{2^j\,n!}{j!(n-j)!j!} \frac{n^{j/2}}{c^j} \frac{\mathrm{vol}(B_2^{n-j})}{\mathrm{vol}(B_2^n)} \\
&\lesssim \sum_{j=0}^{n} \frac{(2e)^j\,n^n}{j^j\,(n-j)^{n-j}j^j} \frac{n^{j/2}}{c^j} \frac{n^{n/2}}{(n-j)^{(n-j)/2}(2\pi e)^{j/2}} \\
&\lesssim \sum_{j=0}^{n} \frac{n^{3n/2}n^{j/2}}{j^{2j}(n-j)^{3(n-j)/2}} \left(\frac{2e}{\pi c^2}\right)^{j/2} \\
&\overset{(j=\phi\,n)}{\lesssim} \max_{\phi\in[0,1]} \frac{e^{(3/2)\ln(n)n+\ln(n)n\phi/2}}{e^{2\ln(\phi n)\phi n+(3/2)\ln((1-\phi)n)(1-\phi)n}} \left(\frac{2e}{\pi c^2}\right)^{\phi n/2} \\
&\lesssim \max_{\phi\in[0,1]} e^{-2\ln(\phi)\phi n-2\ln(1-\phi)(1-\phi)n} \left(\frac{2e}{\pi c^2}\right)^{\phi n/2} \\
&= \max_{\phi\in[0,1]} 2^{2\,\mathrm{H}(\phi)n} \left(\frac{2e}{\pi c^2}\right)^{\phi n/2}
\end{aligned}$$

In passing to the second last line, we have added the factor $e^{-(1/2)\ln(1-\phi)(1-\phi)n}$ which is always greater than 1 for $\phi \in [0,1]$. $\mathrm{H}(\cdot)$ is the binary entropy function, i.e. $H(\phi) = -\ln(\phi)\phi - \ln(1-\phi)(1-\phi)$. $\mathrm{H}(\phi) \leq 1$ for $\phi \in [0,1]$ and $\mathrm{H}(\phi) = \mathrm{H}(1-\phi) \to 0$ monotonically as $\phi \to 0$. Thus, for some fixed c, the above expression reaches a maximum for some $\phi \in (0,1)$. If we increase c, we see that the ϕ^* realizing the maximum will decrease which then implies the lemma. This can be shown formally by fixing some c and taking a derivative w.r.t. ϕ. This will then show that the maximum is reached when $\phi^* = \Theta(\frac{1}{\sqrt{c}})$.
Thus, for any $\varepsilon > 0$, we can chose c large enough so that Lemma 7 holds.

Abstract

We study the problem of maximizing a monotone submodular function subject to a Multiple Knapsack constraint (SMKP) . The input is a set I of items, each associated with a non-negative weight, and a set of bins having arbitrary capacities. Also, we are given a submodular, monotone and non-negative function f over subsets of the items. The objective is to find a subset of items $A \subseteq I$ and a packing of these items in the bins, such that $f(A)$ is maximized.

SMKP is a natural extension of both Multiple Knapsack and the problem of monotone submodular maximization subject to a knapsack constraint. Our main result is a nearly optimal polynomial time $(1 - e^{-1} - \varepsilon)$-approximation algorithm for the problem, for any $\varepsilon > 0$. Our algorithm relies on a refined analysis of techniques for constrained submodular optimization combined with sophisticated application of tools used in the development of approximation schemes for packing problems.

1 Introduction

Submodular optimization has recently attracted much attention as it provides a unifying framework capturing many fundamental problems in combinatorial optimization, economics, algorithmic game theory, networking, and other areas. Furthermore, submodularity also captures many real world practical applications where economy of scale is prevalent. Classic examples of submodular functions are coverage functions [9], matroid rank functions [3] and graph cut functions [10]. A recent survey on submodular functions can be found in [1].

Submodular functions are defined over sets. Given a ground set I, a function $f : 2^I \to \mathbb{R}_{\geq 0}$ is called *submodular* if for every $A \subseteq B \subseteq I$ and $u \in I \setminus B$, $f(A+u)-f(A) \geq f(B+u)-f(B)$.[1] This reflects the diminishing returns property: the marginal value from adding $u \in I$ to a solution diminishes as the solution set becomes larger. A set function $f : 2^I \to \mathbb{R}$ is *monotone* if for any $A \subseteq B \subseteq I$ it holds that $f(A) \leq f(B)$. While in many cases, such as coverage and matroid rank function, the submodular function is monotone, this is not always the case (cut functions are a classic example).

The focus of this work is optimization of monotone submodular functions. In [19] Nemhauser and Wolsey presented a greedy based $(1 - e^{-1})$-approximation for maximizing a monotone submodular function subject to a cardinality constraint, along with a matching lower bound in the oracle model. A $(1 - e^{-1})$ hardness of approximation bound is also known for the problem under P $\neq$ NP, due to the hardness of max-k-cover [9] which is a special case. The greedy algorithm of [19] was later generalized to monotone submodular optimization with a knapsack constraint [16, 21].

A major breakthrough in the field was the continuous greedy algorithm presented in [22]. Initially used to derive a $(1 - e^{-1})$-approximation for maximizing a monotone submodular function subject to a matroid constraint, the algorithm has become a primary tool in the development of monotone submodular maximization algorithms subject to various other constraints. These include d-dimensional knapsack constraints [17], and combinations of d-dimensional knapsack and matroid constraints [7]. A variant of the continuous greedy algorithm for non-monotone functions is given in [11].

In the *multiple knapsack problem* (MKP) we are given a set of items, where each item has a weight and a profit, and a set of bins of arbitrary capacities. The objective is to find a packing of a subset of the items that respects the bin capacities and yields a maximum profit. The problem is one of the most natural extensions of the classic Knapsack problem that arises in the context of Virtual Machine (VM) allocation in cloud computing. The practical task is to assign VMs to physical machines such that capacity constraints are satisfied, while maximizing the profit of the cloud provider. A submodular cost function allows cloud providers to offer complex cost models to high-volume customers, where the price customers pay for each VM can depend on the overall number of machines used by the customer.

A *polynomial time approximation scheme* for MKP was first presented by Chekuri and Khanna [5]. The authors also ruled out the existence of a *fully polynomial time approximation scheme* for the problem. An *efficient* polynomial time approximation scheme was later developed by Jansen [14, 15].

1.1 Our Results

In this paper we consider the *submodular multiple knapsack problem* (SMKP). The input consists of a set of n items I and m bins B. Each item $i \in I$ is associated with a weight $w_i \geq 0$, and each bin $b \in B$ has a capacity $W_b \geq 0$. We are also given an oracle to a non-negative monotone submodular function $f : 2^I \to \mathbb{R}_{\geq 0}$. A feasible solution to the problem is a tuple of m subsets $(A_b)_{b \in B}$ such that for every $b \in B$ it holds that $\sum_{i \in A_b} w_i \leq W_b$. The value of a solution $(A_b)_{b \in B}$ is $f\left(\bigcup_{b \in B} A_b\right)$. The goal is to find a feasible solution of maximum value.[2]

[1] Equivalently, for every $A, B \subseteq I$: $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$.

[2] We note that the set of bins B is part of the input for SMKP, thus the number of bins is non-constant. This is one difference between SMKP and the problem of maximizing a submodular set function subject to d knapsack constraints (or, a d-dimensional knapsack constraint) where d is fixed (for more details see, e.g., [17]).

The problem is a natural generalization of both Multiple Knapsack [5] (where f is modular or linear), and the problem of monotone submodular maximization subject to a knapsack constraint [21] (where $m = 1$). Our result is stated in the next theorem.

▶ **Theorem 1.** *For any $\varepsilon > 0$, there is a randomized $(1 - e^{-1} - \varepsilon)$-approximation algorithm for SMKP.*

As mentioned above, a $(1 - e^{-1})$ hardness of approximation bound is known for the problem under P $\neq$ NP, due to the hardness of max-k-cover [9] which is a special case of SMKP. This is a vast improvement over previous results. Feldman presented in [12] a $\left(\frac{e-1}{3e-1} - o(1)\right) \approx 0.24$-approximation for the special case of identical bin capacities, along with a $\frac{1}{9}$-approximation for general capacities. To the best of our knowledge, this is the best known approximation ratio for the problem.[3]

In very recent work, carried out independently of our work, Sun et al. [20] present a *deterministic* greedy based $(1 - e^{-1} - \varepsilon)$-approximation for the special case of identical bins. They also derive a randomized $(1 - e^{-1} - \varepsilon)$-approximation for the special case where the ratio between the capacity of the largest and smallest bins is a constant. In this paper we give a randomized algorithm for the most general case, based on a different approach (as described below).

1.2 Tools and Techniques

Our algorithm relies on a refined analysis of techniques for submodular optimization subject to d-dimensional knapsack constraints [17, 4, 7], combined with sophisticated application of tools used in the development of approximation schemes for packing problems [8].

At the heart of our algorithm lies the observation that SMKP for a large number of identical bins (i.e., $\forall b \in B,\ W_b = W$ for some $W \geq 0$) can be easily approximated via a reduction to the problem of maximizing a submodular function subject to a 2-dimensional knapsack constraint (see, e.g., [17]). Given such an SMKP instance and $\varepsilon > 0$, we partition the items to *small* and *large*, where an item $i \in I$ is small if $w_i \leq \varepsilon W$ and large otherwise. We further define a *configuration* to be a subset of large items which fits into a single bin, and let $\mathcal{C}$ be the set of all configurations. It follows that for fixed $\varepsilon > 0$, the number of configurations is polynomial.

Using the above we define a new submodular optimization problem, to which we refer as the *block-constraint* problem. We define a new universe E which consists of all configurations $\mathcal{C}$ and all small items, $E = \mathcal{C} \cup \{\{i\} |\ i \text{ is small}\}$. We also define a new submodular function $g : 2^E \to \mathbb{R}_{\geq 0}$ by $g(T) = f\left(\bigcup_{A \in T} A\right)$. Now, we seek a subset of elements $T \subseteq E$ such that T has at most $m = |B|$ configurations, i.e., $|T \cap \mathcal{C}| \leq m$, and the total weight of sets selected is at most $m \cdot W$; namely, $\sum_{A \in T} w(A) \leq m \cdot W$, where $w(A) = \sum_{i \in A} w_i$.

It is easy to see that the optimal value of the block-constraint problem is at least the value of the optimum for the original instance. Moreover, a solution T for the block-constraint problem can be used to generate a solution for the SMKP instance with only a small loss in value. As there are no more than m configurations, and all other items are small, the items in T can be easily packed into $(1+\varepsilon)m+1$ bins of capacity W using First Fit. Then, it is possible

[3] Sun et al. [20] indicate that a $\left(1 - e^{1-e^{-1}} - o(1)\right) \approx 0.468$-approximation for the problem can be derived using the techniques of [4]. We note that this derivation is non-trivial (no details were given in [4]).

to remove $\varepsilon m + 1$ of the bins while maintaining at least $\frac{m}{\varepsilon m+1} \geq \frac{1}{1+2\varepsilon}$ of the solution value, for $m \geq \frac{1}{\varepsilon}$. Once these $\varepsilon m + 1$ bins are removed, we have a feasible solution for the SMKP instance. The block-constraint problem can be viewed as monotone submodular optimization subject to a 2-dimensional knapsack constraint. Thus, a $(1 - e^{-1} - \varepsilon)$-approximate solution can be found efficiently [17].

Our approximation algorithm for SMKP is based on a generalization of the above. We refer to a set of bins of identical capacity as a *block*, and show how to reduce an SMKP instance into a submodular optimization problem with a d-dimensional knapsack constraint, in which d is twice the number of blocks plus a constant. While, generally, this problem cannot be solved for non-constant d, we use a refined analysis of known algorithms [17, 7] to show that the problem can be efficiently solved if the blocks admit a certain structure, to which we refer as *leveled*.

We utilize a grouping technique, inspired by the work of Fernandez de la Vega and Lueker [8], to convert a general SMKP instance to a leveled instance. We sort the bins in decreasing order by capacity and then partition them into levels, where level t, $t \geq 0$, has N^{2+t} bins, divided into N^2 consecutive blocks, each containing N^t bins. We decrease the capacity of each bin to the smallest capacity of a bin in the same block. While the decrease in capacity generates the leveled structure required for our algorithm to work, it only slightly decreases the optimal solution value. The main idea is that given an optimal solution, each block of decreased capacity can now be used to store the items assigned to the subsequent block on the same level. Also, the items assigned to N blocks from each level can be evicted, while only causing a reduction of $\frac{1}{N}$ to the profit (as only N of the N^2 blocks of the level are evicted). These evicted blocks are then used for the items assigned to the first block in the next level.

2 Preliminaries

Our analysis utilizes several basic properties of submodular functions. Given a monotone submodular function $f : 2^I \to \mathbb{R}_{\geq 0}$ and a set $S \subseteq I$, we define $f_S : 2^I \to \mathbb{R}_{\geq 0}$ by $f_S(A) = f(S \cup A) - f(S)$. It follows that f_S is a monotone, non-negative submodular function. The proof of the next claim is given in Appendix A.

▷ Claim 2. Let $f : 2^I \to \mathbb{R}_{\geq 0}$ be a non-negative, monotone and submodular function, and let $E \subseteq 2^I \times X$ for some set X (each element of E is a pair (S, h) with $S \subseteq I$ and $h \in X$). Then function $g : 2^E \to \mathbb{R}_{\geq 0}$ defined by $g(A) = f\left(\cup_{(S,h)\in A} S\right)$ is non-negative, monotone and submodular.

While Claim 2 is essential for our algorithm, it is important to emphasize it does not hold for non-monotone submodular functions.

Many modern submodular optimization algorithms rely on the submodular *Multilinear Extension* ([3, 17, 18, 23, 11, 2]). Given a function $f : 2^I \to \mathbb{R}_{\geq 0}$, its multilinear extension is $F : [0, 1]^I \to \mathbb{R}_{\geq 0}$ defined as:

$$F(\bar{x}) = \sum_{S \subseteq I} f(S) \prod_{i \in S} \bar{x}_i \prod_{i \in I \setminus S} (1 - \bar{x}_i).$$

The multilinear extension can be interpreted as an expectation of a random variable. Given $\bar{x} \in [0, 1]^I$ we say that a random set X is distributed according to $\bar{x}$, $X \sim \bar{x}$, if $\Pr(i \in X) = \bar{x}_i$ and the events $(i \in X)_{i \in I}$ are independent. It follows that $F(\bar{x}) = \mathbb{E}_{X \sim \bar{x}}[f(X)]$.

The continuous greedy of [3] can be used to find approximate solution for maximization problems of the form $\max F(\bar{x})$ s.t. $\bar{x} \in P$, where F is the multilinear extension of a monotone submodular function f, and P is a down-monotone polytope. The algorithm uses two oracles, one for f and another which given $\bar{\lambda} \in \mathbb{R}^I$ returns a vector $\bar{x} \in P$ such that $\bar{x} \cdot \bar{\lambda}$ is maximal. The algorithm returns $\bar{x} \in P$ such that $F(\bar{x}) \geq (1 - e^{-1}) \max_{\bar{y} \in P} F(\bar{y})$.

We use $\mathcal{I} = (I, w, B, W, f)$ to denote an SMKP instance consisting of a set of items I with weights w_i for $i \in I$, a set of bins B with capacities W_b for $b \in B$, and objective function f. Given a set $A \subseteq I$, let $w(A) = \sum_{i \in A} w_i$. We denote by $\mathrm{OPT}(\mathcal{I})$ the optimal solution value for the instance $\mathcal{I}$.

3 The Approximation Algorithm

In this section we present our approximation algorithm for SMKP. Given an instance $\mathcal{I}$ of the problem, let $A^* = \cup_{b \in B} A^*_b$ be an optimal solution of value $OPT(\mathcal{I})$. We first observe that there exists a constant size subset $A = \cup_{b \in B} A_b$, where $A_b \subseteq A^*_b$, satisfying the following property: the value gained from any item in $i \in A^* \setminus A$ is small relative to $OPT(\mathcal{I})$. Thus, our algorithm initially enumerates over all possible partial assignments of constant size. Each assignment is then extended to an approximate solution for $\mathcal{I}$. Among all possible partial assignments and the respective extensions the algorithm returns the best solution. Thus, from now on we restrict our attention to finding a solution for the *residual* problem, obtained by fixing the initial partial assignment.

Formally, given an SMKP instance, $\mathcal{I} = (I, w, B, W, f)$, a feasible partial solution $(A_b)_{b \in B}$ and $\xi \in \mathbb{N}$, we define the *residual* instance $\mathcal{I}' = (I', w, B, W', f')$ with respect to $(A_b)_{b \in B}$ and ξ as follows. Let $A = \cup_{b \in B} A_b$ and set $I' = \left\{ i \in I \setminus A \;\middle|\; f_A(\{i\}) \leq \frac{f(A)}{\xi} \right\}$. The weights of the items remain the same and so is the set of bins. For every $b \in B$ we set $W'_b = W_b - w(A_b)$. Finally, the objective function of the residual instance is $f' = f_A$.

▶ **Lemma 3.** *Let $\mathcal{I}$ be an SMKP instance, $\xi \in \mathbb{N}$, and $(A^*_b)_{b \in B}$ an optimal solution for $\mathcal{I}$ such that $A^*_{b_1} \cap A^*_{b_2} = \emptyset$ for any $b_1, b_2 \in B$, $b_1 \neq b_2$. If $\sum_{b \in B} |A^*_b| \geq \xi$ there is a feasible solution $(A_b)_{b \in B}$ for $\mathcal{I}$ such that $A_b \subseteq A^*_b$ for any $b \in B$, $\sum_{b \in B} |A_b| = \xi$, and $(A^*_b \setminus A_b)_{b \in B}$ is a feasible solution for the residual instance of $\mathcal{I}'$ w.r.t $(A_b)_{b \in B}$ and ξ.*

Proof. Let $(A^*_b)_{b \in B}$ be an optimal solution to the SMKP instance. Define $A^* = \cup_{b \in B} A^*_b$ and order the items of A^* by their *marginal values*. That is $A^* = \{a_1, \ldots, a_r\}$ where $f_{T_{\ell-1}}(\{a_\ell\}) = \max_{a \in A^* \setminus T_{\ell-1}} f_{T_{\ell-1}}(\{a\})$ with $T_\ell = \{a_1, \ldots, a_\ell\}$ for every $1 \leq \ell \leq r$ (also, $T_0 = \emptyset$). Define $(A_b)_{b \in B}$ by $A_b = A^*_b \cap \{a_1, \ldots, a_\xi\}$ for every $b \in B$ and $A = \cup_{b \in B} A_b$. We therefore have $A = \{a_1, \ldots, a_\xi\}$.

For any $b \in B$ it holds that $w(A_b) \leq w(A^*_b) \leq W_b$, and thus $(A_b)_{b \in B}$ is a feasible solution for $\mathcal{I}$. Furthermore, for any $b \in B$ it holds that $A_b \subseteq A^*_b$ by definition. As the sets $(A^*_b)_{b \in B}$ are disjoint it follows that $\sum_{b \in B} |A_b| = \xi$.

Let $\mathcal{I}' = (I', w, B, W', f')$ be the residual instance of $\mathcal{I}$ w.r.t $(A_b)_{b \in B}$ and ξ. We are left to show that $(A^*_b \setminus A_b)_{b \in B}$ is a feasible solution for $\mathcal{I}'$. For every $\xi < i \leq r$ and $1 \leq \ell \leq \xi$ it holds that $f_A(\{a_i\}) \leq f_{T_{\ell-1}}(\{a_i\}) \leq f_{T_{\ell-1}}(\{a_\ell\})$ where the first inequality follows from the submodularity of f and the second by the definition of a_ℓ. Combining the last inequality with $f' = f_A$ we obtain,

$$\xi \cdot f'(\{a_i\}) = \xi \cdot f_A(\{a_i\}) \leq \sum_{\ell=1}^{\xi} f_{T_{\ell-1}}(\{a_\ell\}) = f(A) - f(\emptyset) \leq f(A).$$

Thus, $a_i \in I'$, implying that $A^*_b \setminus A_b \subseteq I'$ for any $b \in B$. Furthermore, for any $b \in B$,

$$w(A^*_b \setminus A_b) = w(A^*_b) - w(A_b) \leq W_b - w(A_b) = W'_b.$$

It follows that $(A^*_b \setminus A_b)_{b \in B}$ is a solution to the residual instance. ◀

Next, we observe that instances of SMKP are easier to solve when the number of distinct bin capacities is small (e.g., uniform bin capacities), leading us to consider *bin blocks*:

▶ **Definition 4.** *For a given instance of SMKP we say that a subset of bins $\tilde{B} \subseteq B$ is a* block *if all the bins in $\tilde{B}$ have the same capacity, i.e., for bins b_1 and b_2 belonging to the same block it holds that $W_{b_1} = W_{b_2}$.*

Following an enumeration over partial assignments, our algorithm reduces the number of blocks by altering the bin capacities. To this end, we use a specific structure that we call *leveled*, defined as follows.

▶ **Definition 5.** *For any $N \in \mathbb{N}$, we say that a partition $(B_j)_{j=0}^k$ of a set B of bins with capacities $(W_b)_{b \in B}$ is* N-leveled *if B_j is a block, and $|B_j| = N^{\lfloor \frac{j}{N^2} \rfloor}$ for all $0 \leq j \leq k$.*

By the above definition, we can view each set of consecutive blocks of the same size as a *level*. For $0 \leq j \leq k$, block j belongs to level $\ell = \lfloor \frac{j}{N^2} \rfloor$. Thus, for $\ell \geq 0$, the number of bins in each block increases by factor of N when moving from level ℓ to level $\ell + 1$.

In Section 3.1 we give Algorithm 2 which generates an N-leveled partition of the bins, $\tilde{B} = \cup_{j=0}^k \tilde{B}_j$ with the capacities of the bins $(W_b)_{b \in B}$ modified to $(\tilde{W}_b)_{b \in \tilde{B}}$. We show that solving the problem with these new bin capacities may cause only a small harm to the optimal solution value. In particular, we prove (in Section 3.1) the following.

▶ **Lemma 6.** *Given a set of bins B, capacities $(W_b)_{b \in B}$ and a parameter N, Algorithm 2 returns in polynomial time a subset of bins $\tilde{B} \subseteq B$, capacities $(\tilde{W}_b)_{b \in \tilde{B}}$ and an N-leveled partition $(\tilde{B}_j)_{j=0}^k$ of $\tilde{B}$, such that*

1. *The bin capacities satisfy $\tilde{W}_b \leq W_b$, for all $b \in \tilde{B}$.*
2. $\mathrm{OPT}(\tilde{\mathcal{I}}) \geq \left(1 - \frac{1}{N}\right) \mathrm{OPT}(\mathcal{I})$, *for any SMKP instance $\mathcal{I} = (I, w, B, W, f)$ and $\tilde{\mathcal{I}} = (I, w, \tilde{B}, \tilde{W}, f)$.*

Once the instance is N-leveled, we proceed to solve the problem (fractionally) and apply randomized rounding to obtain an integral solution (see Section 3.2). Algorithm 4 utilizes efficiently the leveled structure of the instance. Instead of having a separate constraint for each bin in a block − to bound the total size of the items packed in this bin − we use only two constraints for each block. The first constraint is a knapsack constraint referring to the total capacity of a block, and the second constraint restricts the number of *configurations* assigned to the block.[4] Thus, the number of constraints significantly decreases if the blocks are large. Since leveled instances also have a constant number of blocks consisting of a *single* bin, those are handled separately via the notion of δ-restricted SMKP.

An input for *δ-restricted SMKP* includes the same parameters as an input for SMKP, and also a subset $B^r \subseteq B$ of *restricted* bins. A solution for δ-restricted SMKP is a feasible assignment $(A_b)_{b \in B}$ satisfying also the property that $\forall b \in B^r$ the items assigned to b are relatively small; namely, for any $i \in A_b$ $w_i \leq \delta W_b$.

[4] We defined a configuration in Section 1.2.

Given the N-leveled instance of our problem, we turn the blocks of a single bin (that is blocks $\tilde{B}_j$ such that $|\tilde{B}_j| = 1$) to be *restricted*. We note that while items of weight greater than δW_b may be assigned to these blocks in some optimal solution, the overall number of such items is bounded by a constant. Indeed, our initial enumeration guarantees that evicting these items from an optimal solution may cause only small harm to the optimal solution value, allowing us to consider the instance as δ-restricted.

In Section 3.2 we show the following bound on the performance guarantee of Algorithm 4, which uses randomized rounding. The algorithm is parameterized by $\mu \in (0, 0.1)$ (to be determined). Suppose we are given a δ-restricted SMKP instance $\mathcal{I}$, such that the unrestricted bins are partitioned into blocks, i.e., $B \setminus B^r = B_1 \cup \ldots \cup B_k$, and $\upsilon = \max_{i \in I} f(\{i\}) - f(\emptyset)$.

▶ **Lemma 7.** *For $\mu \in (0, 0.1)$, Algorithm 4 returns a feasible solution $(S_b)_{b \in B}$ such that $\mathbb{E}\left[f(\cup_{b \in B} S_b)\right] \geq (1 - e^{-1})\frac{(1-\mu)^2}{1+\mu}(1 - \gamma)\mathrm{OPT}(\mathcal{I})$, where*

$$\gamma = \exp\left(-\frac{\mu^3}{16} \cdot \frac{\mathrm{OPT}(\mathcal{I})}{\upsilon}\right) + |B^r| \exp\left(-\frac{\mu^2}{12} \cdot \frac{1}{\delta}\right) + 2 \cdot \sum_{j=1}^{k} \exp\left(-\frac{\mu^2}{12}|B_j|\right).$$

Algorithm 1 gives the pseudocode of our approximation algorithm for general SMKP instances. The algorithm uses several configuration parameters that will be set in the proof of Lemma 8.

Algorithm 1 Algorithm for SMKP.

Input : An SMKP instance $\mathcal{I} = (I, w, B, W, f)$ and the parameters N, ξ, δ and μ.

1 **forall** *feasible assignments $A = (A_b)_{b \in B}$ such that $\sum_{b \in B} |A_b| \leq \xi$* **do**

2 Let $\mathcal{I}' = (I', w, B, W', f')$ be the residual instance of $\mathcal{I}$ w.r.t $(A_b)_{b \in B}$ and ξ.

3 Run Algorithm 2 with the bins B and capacities $(W'_b)_{b \in B}$. Let $\tilde{B}$ and $(\tilde{W}_b)_{b \in \tilde{B}}$ be the output, and $\tilde{B} = \cup_{j=0}^{k} \tilde{B}_j$ the partition of $\tilde{B}$ to leveled blocks. Let $\tilde{\mathcal{I}} = (I', w, \tilde{B}, \tilde{W}, f')$ be the resulting instance.

4 Let $\tilde{\mathcal{I}}_R$ be the δ-restricted SMKP instance of $\tilde{\mathcal{I}}$ with the restricted bins $\tilde{B}^r = \cup_{j=0}^{\min\{N^2-1,k\}} \tilde{B}_j$.

5 Solve $\tilde{\mathcal{I}}_R$ using Algorithm 4 with parameter μ, and the partition $\tilde{B} \setminus \tilde{B}^r = \cup_{j=1}^{k} \tilde{B}_j$. Denote the returned assignment by $(\tilde{S}_b)_{b \in \tilde{B}}$, and let $S_b = \tilde{S}_b$ for $b \in \tilde{B}$ and $S_b = \emptyset$ for $b \in B \setminus \tilde{B}$.

6 If $f(\cup_{b \in B}(A_b \cup S_b))$ is higher than the value of the current best solution, set $(A_b \cup S_b)_{b \in B}$ as the current best solution.

7 **end**

8 Return the best solution found.

▶ **Lemma 8.** *For any $\varepsilon > 0$, there are parameters N, ξ, δ, μ such that, for any SMKP instance $\mathcal{I}$, Algorithm 1 returns a solution of expected value at least $(1 - e^{-1} - \varepsilon)\mathrm{OPT}(\mathcal{I})$.*

Proof. We start by setting the parameter values. The reason for selecting these values will become clear later. Given a fixed $\varepsilon \in (0, 0.1)$, there is $\mu \in (0, 0.1)$ such that $\frac{(1-\mu)^2}{1+\mu} \geq (1 - \varepsilon^2)$. By the Monotone Convergence Theorem,

$$\lim_{N \to \infty} 2N^2 \cdot \sum_{t=1}^{\infty} \exp\left(-\frac{\mu^2 \cdot N^t}{12}\right) = \sum_{t=1}^{\infty} \lim_{N \to \infty} 2N^2 \exp\left(-\frac{\mu^2 \cdot N^t}{12}\right) = 0.$$

It follows that there are $N > \frac{1}{\varepsilon^2}$ and $\delta > 0$ such that

$$N^2 \exp\left(-\frac{\mu^2}{12} \cdot \frac{1}{\delta}\right) + 2N^2 \cdot \sum_{t=1}^{\infty} \exp\left(-\frac{\mu^2}{12} N^t\right) < \frac{\varepsilon^2}{2}. \tag{1}$$

Finally, we select ξ such that $\xi \geq \frac{N^2}{\varepsilon^2 \delta}$ and $\exp\left(-\frac{\mu^3}{16}\frac{\xi}{5}\right) \leq \frac{\varepsilon^2}{2}$.

Let $\mathcal{I} = (I, w, B, W, f)$ be an SMKP instance, and let $(A_b^*)_{b \in B}$ be an optimal solution for $\mathcal{I}$. Assume w.l.o.g that $A_{b_1}^* \cap A_{b_2}^* = \emptyset$ for any $b_1, b_2 \in B$, $b_1 \neq b_2$. Define $A^* = \cup_{b \in B} A_b^*$. If $|A^*| \leq \xi$, there is an iteration of Line 1 in which $A_b^* = A_b$ for all $b \in B$. Therefore, in this iteration we have at Line 6 $f(\cup_{b \in B}(A_b \cup S_b)) \geq f(A^*)$, and the algorithm returns a solution of value at least $f(A^*)$. Otherwise, by Lemma 3, there is a feasible solution $(A_b)_{b \in B}$ such that $A_b \subseteq A_b^*$, $\sum_{b \in B} |A_b^*| = \xi$ and $(A_b^* \setminus A_b)_{b \in B}$ is a feasible solution to $\mathcal{I}'$, the residual instance of $\mathcal{I}$ w.r.t $(A_b)_{b \in B}$ and ξ. It follows that there is an iteration of Line 1 which considers this solution $(A_b)_{b \in B}$. We focus on this iteration for the rest of the analysis.

Let $A = \cup_{b \in B} A_b$. If $f(A) \geq (1 - e^{-1}) f(A^*)$ then when the algorithm reaches Line 6 it holds that $f(\cup_{b \in B}(A_b \cup S_b)) \geq f(A) \geq (1 - e^{-1}) f(A^*)$; therefore, the algorithm returns a $(1 - e^{-1})$-approximation in this case. Henceforth, we assume that $f(A) \leq (1 - e^{-1}) f(A^*)$. Then,

$$f'(\cup_{b \in B}(A_b^* \setminus A_b)) = f'(A^* \setminus A) = f(A^*) - f(A) \geq \frac{f(A)}{1 - e^{-1}} - f(A) = \frac{1}{e - 1} f(A). \tag{2}$$

As $(A_b^* \setminus A_b)_{b \in B}$ is a feasible solution for $\mathcal{I}'$, it holds that $\mathrm{OPT}(\mathcal{I}') \geq f'(A^* \setminus A)$. Therefore, by Lemma 6 and the choice of N, it holds that

$$\mathrm{OPT}(\tilde{\mathcal{I}}) \geq \left(1 - \frac{1}{N}\right) f'(A^* \setminus A) \geq (1 - \varepsilon^2) f'(A^* \setminus A), \tag{3}$$

where $\mathcal{I}'$ is the instance output by Algorithm 2. Let $(D_b)_{b \in \tilde{B}}$ by an optimal solution for $\tilde{\mathcal{I}}$. Consider $(D_b^r)_{b \in \tilde{B}}$ where $D_b^r = D_b \setminus \{i \in D_b | w_i > \delta \cdot \tilde{W}_b\}$ for $b \in \tilde{B}^r$ (the set $\tilde{B}^r$ is defined in Line 4) and $D_b^r = D_b$ for $b \in \tilde{B} \setminus \tilde{B}^r$. It follows that D_b^r is a solution for the δ-restricted SMKP instance $\tilde{\mathcal{I}}_R$. As for any $b \in \tilde{B}^r$, $|\{i \in D_b | w_i > \delta \cdot \tilde{W}_b\}| \leq \frac{1}{\delta}$, we have that

$$\mathrm{OPT}\left(\tilde{\mathcal{I}}_R\right) \geq f'\left(\cup_{b \in \tilde{B}} D_b^r\right) \geq \mathrm{OPT}\left(\tilde{\mathcal{I}}\right) - \frac{N^2}{\delta \cdot \xi} f(A) \geq (1 - \varepsilon^2) f'\left(A^* \setminus A\right) - \varepsilon^2 \cdot f(A). \tag{4}$$

The second inequality follows from the definition of residual instance, and the third inequality from (3) and the choice of ξ. Since $f'(A^* \setminus A) \geq \frac{1}{e-1} f(A)$ and $\varepsilon \in (0, 0.1)$, it follows that $\mathrm{OPT}(\tilde{\mathcal{I}}_R) \geq \frac{f(A)}{5}$.

By Lemma 7, we have that

$$\mathbb{E}\left[f'(\cup_{b \in \tilde{B}} \tilde{S}_b)\right] \geq (1 - e^{-1}) \frac{(1 - \mu)^2}{1 + \mu} (1 - \gamma) \mathrm{OPT}(\tilde{\mathcal{I}}_R) \geq (1 - e^{-1})(1 - \varepsilon^2)(1 - \gamma) \mathrm{OPT}(\tilde{\mathcal{I}}_R), \tag{5}$$

where

$$\begin{aligned} \gamma &= \exp\left(-\frac{\mu^3}{16} \cdot \frac{\mathrm{OPT}(\tilde{\mathcal{I}}_R)}{\xi^{-1} f(A)}\right) + |\tilde{B}^r| \exp\left(-\frac{\mu^2}{12} \cdot \frac{1}{\delta}\right) + 2 \cdot \textstyle\sum_{j=N^2}^{k} \exp\left(-\frac{\mu^2}{12} |\tilde{B}_j|\right) \\ &\leq \exp\left(-\frac{\mu^3}{16} \cdot \frac{\xi}{5}\right) + N^2 \exp\left(-\frac{\mu^2}{12} \cdot \frac{1}{\delta}\right) + 2 \cdot N^2 \cdot \textstyle\sum_{t=1}^{\infty} \exp\left(-\frac{\mu^2}{12} N^t\right) \leq \varepsilon^2. \end{aligned} \tag{6}$$

The first equality uses $f'(\{i\}) \leq \xi^{-1} f(A)$ (by the definition of $\mathcal{I}'$). The first inequality holds since $\mathrm{OPT}(\tilde{\mathcal{I}}_R) \geq \frac{f(A)}{5}$, $|\tilde{B}^r| \leq N^2$ and there are at most N^2 blocks $\tilde{B}_j$ of size N^t. The second inequality uses (1) and the choice of ξ. Combining (6) with (5) and (4), we obtain

$$\mathbb{E}\left[f(\cup_{b\in B}(A_b \cup S_b))\right] \geq f(A) + \mathbb{E}\left[f'(\cup_{b\in\tilde{B}})\tilde{S}_b)\right] \geq f(A) + (1-e^{-1})(1-\varepsilon^2)^2\mathrm{OPT}(\tilde{\mathcal{I}}_R)$$
$$\geq f(A) + (1-e^{-1})(1-\varepsilon^2)^3 f'(A^* \setminus A) - \varepsilon^2 f(A) \geq (1-e^{-1}-\varepsilon)f(A^*).$$

Hence, in this iteration the solution considered in Line 6 has expected value at least $(1-e^{-1}-\varepsilon)f(A^*)$. This completes the proof of the lemma. ◀

▶ **Lemma 9.** *For any constant parameters N, ξ, δ and μ, Algorithm 1 returns a feasible solution for the input instance in polynomial time.*

Proof. We first note that for any fixed parameter values the algorithm has a polynomial running time. The number of assignments considered in Line 1 can be trivially bounded by $(n \cdot m)^{\xi}$. As Algorithms 2 and 4 are polynomial in their input size, the operations in each iteration are also done in polynomial time.

For each iteration of Line 1, by Lemma 7, $(\tilde{S}_b)_{b\in\tilde{B}}$ is a feasible solution to $\tilde{\mathcal{I}}_R$. Therefore, for any $b \in B$ either $w(S_b) = w(\emptyset) \leq W'_b$ or $w(S_b) = w(\tilde{S}_b) \leq \tilde{W}_b \leq W'_b$, where the last equality follows from Lemma 6. Therefore, $w(A_b \cup S_b) \leq w(A_b) + W'_b \leq W_b$. Hence, the solution considered in each iteration is feasible for the input instance. ◀

Theorem 1 follows from Lemmas 8 and 9.

3.1 Structuring the Instance

In this section we present Algorithm 2 and prove Lemma 6. Our technique for generating an N-leveled partition can be viewed as a variant of the linear grouping technique of [8] which requires the use of *non-uniform* group sizes (each group of bins then becomes a *block*). Given a set of bins B with capacities $(W_b)_{b\in B}$, we sort the bins in non-increasing order by capacities. We now use the numbering $B = \{1, \ldots, m\}$, where $W_1 \geq W_2 \geq \ldots \geq W_m$. To generate an N-leveled partition of the bins and the modified capacities, we define groups (or blocks) of bins, where each group j consists of $N^{\lfloor \frac{j}{N^2} \rfloor}$ consecutive bins, for $j \geq 0$. Starting from the first bin, we keep generating such groups as long as there are enough bins to form a group of the desired size. We omit the remaining bins and decrease the capacity of each bin to the minimal capacity of a bin in its group. We formalize this procedure in Algorithm 2.

Algorithm 2 Structure in Blocks.

Input : A set of bins B, capacities $(W_b)_{b\in B}$ and N.

1 Let $B = \{1, \ldots, m\}$ where $W_1 \geq W_2 \geq \ldots \geq W_m$.

2 Let $k = \max\left\{\ell \in \mathbb{N} \;\middle|\; \sum_{r=0}^{\ell} N^{\lfloor \frac{r}{N^2} \rfloor} \leq m\right\}$.

3 Define $\tilde{B}_j = \left\{b \;\middle|\; \sum_{r=0}^{j-1} N^{\lfloor \frac{r}{N^2} \rfloor} < b \leq \sum_{r=0}^{j} N^{\lfloor \frac{r}{N^2} \rfloor}\right\}$ for $0 \leq j \leq k$.

4 Let $\tilde{B} = \cup_{j=0}^{k} \tilde{B}_j$, and $\tilde{W}_b = \min_{b'\in\tilde{B}_j} W_{b'}$ for all $0 \leq j \leq k$ and $b \in \tilde{B}_j$.

5 Return $\tilde{B}$, $(\tilde{W}_b)_{b\in\tilde{B}}$ and the partition $(\tilde{B}_j)_{j=0}^{k}$.

The following standard result for submodular functions is used in the proof of Lemma 6.

▶ **Lemma 10.** *Let $h : 2^{\Omega} \to \mathbb{R}_{\geq 0}$ be a monotone submodular function, and let $S_{i,1}, \ldots, S_{i,N} \subseteq \Omega$ for $1 \leq i \leq M$. Then for every $1 \leq i \leq M$ there is $1 \leq j_i^* \leq N$ such that*

$$h\left(\bigcup_{i=1}^{M} \bigcup_{1\leq j\leq N,\ j\neq j_i^*} S_{i,j}\right) \geq \left(1 - \frac{1}{N}\right) h\left(\bigcup_{i=1}^{M}\bigcup_{j=1}^{N} S_{i,j}\right).$$

The proof for the Lemma is given in Appendix A.

Proof of Lemma 6. By construction, we have that $(\tilde{B}_j)_{j=0}^{k}$ is an N-leveled partition of $(\tilde{W}_b)_{b\in\tilde{B}}$ and $\tilde{W}_b \leq W_b$ for any $b \in \tilde{B}$. Also, Algorithm 2 has a polynomial running time.

To complete the proof we need to show Property 2 in the lemma. Let $\mathcal{I} = (I, w, B, W, f)$ be an SMKP instance, and let $\tilde{\mathcal{I}} = (I, w, \tilde{B}, \tilde{W}, f)$ be the instance with bins and capacities generated (as output) by Algorithm 2. We need to show that $\mathrm{OPT}(\tilde{\mathcal{I}}) \geq \left(1 - \frac{1}{N}\right)\mathrm{OPT}(\mathcal{I})$.

Let $A_1^*, \ldots, A_m^*$ be an optimal solution for $\mathcal{I}$, and $A^* = \cup_{b\in B} A_b^*$. We modify this solution using a sequence of steps, eventually obtaining a feasible solution for $\tilde{\mathcal{I}}$. The latter is used to lower bound $\mathrm{OPT}(\tilde{\mathcal{I}})$. Define $\tilde{B}_{k+1} = B \setminus \tilde{B}$. We note that $\tilde{B}_{k+1}$ may be empty. We partition $\{\tilde{B}_j \mid 0 \leq j \leq k+1\}$ into *levels* and *super-blocks*. We consider each N^2 consecutive blocks to be a *level*, and each N consecutive blocks within a level to be a *super-block*. Formally, level t is

$$\mathcal{L}_t = \left\{j \mid t \cdot N^2 \leq j < \min\{(t+1)N^2,\ k+2\}\right\}$$

for $0 \leq t \leq \ell$ with $\ell = \left\lfloor \frac{k+1}{N^2} \right\rfloor$. Also, super-block r of level t is

$$\mathcal{S}_{t,r} = \left\{j \mid t \cdot N^2 + r \cdot N \leq j < t \cdot N^2 + (r+1) \cdot N\right\}$$

for $0 \leq r < N$ and level $0 \leq t < \ell$ (we do not partition the last level to super-blocks). It follows that $B = \cup_{t=0}^{\ell} \cup_{j\in\mathcal{L}_t} \tilde{B}_j$ and $\mathcal{L}_t = \cup_{r=0}^{N-1} \mathcal{S}_{t,r}$ for $0 \leq t < \ell$. Furthermore, for any $j \in \mathcal{L}_t$, $j \neq k+1$ it holds that $|\tilde{B}_j| = N^t$ and $|\tilde{B}_{k+1}| < N^\ell$. Essentially, all the blocks of level t are of the same size.

We modify $A_1^*, \ldots, A_m^*$ using the following steps. First, in each level (except the last one) we evict all the bins from a singe super-block. Since there are N super-blocks in each of these levels, this may decrease the value of the assignment at most by factor $\frac{1}{N}$. Then, we slightly shuffle the content of the bins in all levels (except the last one). In each level, we place the content of the bins of the last super-block in bins of the evicted super-block in the same level. As the bins are ordered by capacity, this will keep the assignment feasible with respect to the original capacities. In the last step, for each level (except level 0) we move the content of the bins from the first block to the bins of the last super-block in the previous level (the two sets of bins have the same cardinality), and content of bins from other blocks (except level 0) to the previous block from the same level. This yields a feasible assignment for the leveled instance. We formally describe these steps in the following.

Eviction: We first evict a super-block of bins from each level (except the last one). Let $R = \cup_{b\in\mathcal{L}_\ell} A_b^*$ be the subset of items assigned to the last level. By Lemma 10, for any $0 \leq t < \ell$ there is r_t^* such that

$$\begin{aligned} f_R\left(\bigcup_{t=0}^{\ell-1} \bigcup_{0\leq r<N,\ r\neq r_t^*} \bigcup_{j\in\mathcal{S}_{t,r}} \bigcup_{b\in\tilde{B}_j} A_b^*\right) &\geq \left(1-\frac{1}{N}\right) f_R\left(\bigcup_{t=0}^{\ell-1}\bigcup_{r=0}^{N-1} \bigcup_{j\in\mathcal{S}_{t,r}} \bigcup_{b\in\tilde{B}_j} A_b^*\right) \\ &= \left(1-\frac{1}{N}\right) f_R(A^*). \end{aligned}$$

Define $T_1, \ldots, T_m$ by $T_b = \emptyset$ for any $b \in \bigcup_{t=0}^{\ell-1} \bigcup_{j\in\mathcal{S}_{t,r_t^*}} \tilde{B}_j$, and $T_b = A_b^*$ for any $b \in B \setminus \left(\bigcup_{t=0}^{\ell-1} \bigcup_{j\in\mathcal{S}_{t,r_t^*}} \tilde{B}_j\right)$. Then,

$$f\left(\bigcup_{b\in B} T_b\right) = f(R) + f_R\left(\bigcup_{t=0}^{\ell-1} \bigcup_{0\leq r<N-1,\ r\neq r_t^*} \bigcup_{j\in\mathcal{S}_{t,r}} \bigcup_{b\in\tilde{B}_j} A_b^*\right) \geq \left(1-\frac{1}{N}\right) f(A^*).$$

It also holds that $T_1, \ldots, T_m$ is a feasible solution for $\mathcal{I}$.

Shuffling: We generate a new assignment $\tilde{T}_1, \ldots, \tilde{T}_m$ such that $\cup_{b\in B}\tilde{T}_b = \cup_{b\in B}T_b$ and the last super-blocks in each level (except the last one) is empty. This property is obtained by moving the content of the bins in super-block $N-1$ to the bins of super-block r_t^* for every $0 \le t < \ell$.

We define $(\tilde{T}_b)_{b\in B}$ as follows. For any $0 \le t < \ell$, $j \in \mathcal{S}_{t,r_t^*}$ let $\varphi_t : \bigcup_{j\in\mathcal{S}_{t,r_t^*}} \tilde{B}_j \to \bigcup_{j\in\mathcal{S}_{t,N-1}} \tilde{B}_j$ be a bijection (since $\left|\bigcup_{j\in\mathcal{S}_{t,N-1}} \tilde{B}_j\right| = \left|\bigcup_{j\in\mathcal{S}_{t,r_t^*}} \tilde{B}_j\right| = N \cdot N^t$, such a function exists). For any $b \in \bigcup_{j\in\mathcal{S}_{t,r_t^*}} \tilde{B}_j$ set $\tilde{T}_b = T_{\varphi_t(b)}$. By definition we have $\varphi_t(b) \ge b$; therefore, in this case

$$w(\tilde{T}_b) = w(T_{\varphi_t(b)}) \le W_{\varphi_t(b)} \le W_b.$$

For any $0 \le t < \ell$, $j \in \mathcal{S}_{t,N-1}$ and $b \in \tilde{B}_j$ set $\tilde{T}_b = \emptyset$. For any other bin $b \in B$ set $\tilde{T}_b = T_b$.

It follows that $\cup_{b\in B}\tilde{T}_b = \cup_{b\in B}T_b$, since $T_b = \emptyset$ for every $0 \le t < \ell$, $j \in \mathcal{S}_{t,r_t^*}$ and $b \in B_j$. Also, $(\tilde{T}_b)_{b\in B}$ is a feasible solution for $\mathcal{I}$.

Shifting: In this step we generate the assignment $(A_b)_{b\in\tilde{B}}$ which satisfies the properties in the lemma. As the bins of the last super-block in each level (except the last one) are vacant in $\tilde{T}_1, \ldots, \tilde{T}_m$, we use them for the content assigned to the first block of the next level. This can be done since N blocks of level t contain the same number of bins as a single block of level $t+1$. We also use blocks in levels greater than 0 which are not in the last super-block to store the content of the next block in the same level.

For any $0 < t \le \ell$ and $j \in \mathcal{L}_t$, consider a block $\tilde{B}_j$. Suppose that $j \ne t \cdot N^2$ and $j \notin \mathcal{S}_{t,N-1}$ where $t \ne \ell$; that is, $\tilde{B}_j$ is not the first block in the level, and is not in the last super-block of a level other than the last one. Then, let $\psi_j : \tilde{B}_j \to \tilde{B}_{j-1}$ be a bijection, and define $A_{\psi_t(b)} = \tilde{T}_b$ for any $b \in \tilde{B}_j$. If $j = t \cdot N^2$ (that is, $\tilde{B}_j$ is the first block in a level), let $\psi_j : \tilde{B}_j \to \bigcup_{j'\in\mathcal{S}_{t-1,N-1}} \tilde{B}_{j'}$ be a bijection, and define $A_{\psi_t(b)} = \tilde{T}_b$ for any $b \in \tilde{B}_j$. Finally, for any $0 \le j < N^2 - N$, let $\psi_j : \tilde{B}_j \to \tilde{B}_j$ be the identity function and define $A_{\psi_t(b)} = A_b = \tilde{T}_b$ for the single bin $b \in \tilde{B}_j$. For any bin $b \in \tilde{B}$ not handled in this process, set $A_b = \emptyset$.

We note that the definition is sound as the ranges of the functions ψ_j above do not intersect. Let $b \in \tilde{B}$. If $A_b = \emptyset$ then $w(A_b) \le \tilde{W}_b$. Otherwise, if $b \in \tilde{B}_j$ for $0 \le j < N^2 - N$ then $w(A_b) = w(\tilde{T}_b) < W_b \le \tilde{W}_b$. Finally, the only option left is that $b = \psi_{j'}(b')$ for some $0 < t \le \ell$, $j' \in \mathcal{L}_t$ and $b' \in \tilde{B}_{j'}$, such that $j' \ne t \cdot N^2$ and $j' \notin S_{t,N-1}$ if $t \ne \ell$. By definition, it holds that $b' \in \tilde{B}_j$ for some $j < j'$. Since the bins were ordered by capacity, we have

$$w(A_b) = w(A_{\phi_{j'}(b')}) = w(\tilde{T}_{b'}) \le W_{b'} \le \min_{b''\in\tilde{B}_j} W_{b''} = \tilde{W}_b.$$

Thus, the assignment is feasible with respect to the bins $\tilde{B}$ with capacities $\left(\tilde{W}_b\right)_{b\in\tilde{B}}$.

It also holds that for any $b \in B$ such that $\tilde{T}_b \ne 0$ there is $b' \in \tilde{B}$ such that $A_{b'} = \tilde{T}_b$. Therefore, $\bigcup_{b\in\tilde{B}} A_b = \bigcup_{b\in B} \tilde{T}_b = \bigcup_{b\in B} T_b$. Hence, $f(\cup_{b\in\tilde{B}} A_b) = f(\cup_{b\in B} T_b) \ge \left(1 - \frac{1}{N}\right) f(A^*)$. We conclude that $\mathrm{OPT}(\tilde{\mathcal{I}}) \ge \left(1 - \frac{1}{N}\right) \mathrm{OPT}(\mathcal{I})$. ◀

3.2 Solving a Continuous Relaxation and Rounding

In this section we give Algorithm 4 which outputs a solution satisfying Lemma 7. The input for the algorithm is a δ-restricted SMKP instance along with a partition $B \setminus B^r = B_1 \cup \ldots \cup B_k$ of the bins, where B_j is a block for all $1 \le j \le k$. Algorithm 4 uses Algorithm 3 as a subroutine which converts a solution for an auxiliary *block-constraint* problem into a solution for δ-restricted SMKP.

3.2.1 The Block-Constraint Problem

We now define the *block-constraint problem*, to be solved for a given instance $\mathcal{I}$ of δ-restricted SMKP, using the partition $B \setminus B^r = B_1 \cup \ldots \cup B_k$ and the parameter μ. The input for the block-constraint problem is a universe of elements E, a monotone submodular function $g : 2^E \to \mathbb{R}_{\geq 0}$ and a polytope $P \subseteq [0,1]^E$ (see below).

For simplicity, let $\{B_{k+1}, \ldots, B_\ell\} = \{\{b\} |\ b \in B^r\}$ be the set of blocks, each consisting of a single bin. Thus, $B = \cup_{j=1}^{\ell} B_j$. Denote the (uniform) capacity of the bins in block B_j by W_j^*, for $1 \leq j \leq \ell$. That is, for any $b \in B_j$ it holds that $W_j^* = W_b$. For $1 \leq j \leq k$, we say that an item $i \in I$ is *j-small* if $w_i \leq \mu \cdot W_j^*$, otherwise i is *j-large*. Let $I_j = \{\{i\} |\ i \text{ is } j\text{-small}\}$ for $1 \leq j \leq k$. For $k < j \leq \ell$ define $I_j = \{\{i\} \mid w_i \leq \delta W_j^*\}$.

A *j-configuration* is a subset of j-large items which can be packed into a single bin in B_j. That is, $C \subseteq I$ is a j-configuration if every item $i \in C$ is j-large and $w(C) \leq W_j^*$. Let $\mathcal{C}_j$ be the set of all j-configurations for $1 \leq j \leq k$ and $\mathcal{C}_j = \emptyset$ for $k < j \leq \ell$. As any j-configuration has at most μ^{-1} items, it follows that $|\mathcal{C}_j| \leq |I|^{\mu^{-1}}$, i.e., the number of configurations is polynomial in the size of $\mathcal{I}$. Furthermore, for $A \subseteq I$ such that $w(A) \leq W_j^*$, $1 \leq j \leq k$, there are $C \in \mathcal{C}_j$ and $S \subseteq I$ such that all the items in S are j-small and $A = C \cup S$. Our algorithm exploits this property.

Towards solving the block-constraint problem we define a submodular function g over a new universe of elements. Let $E = \{(S,j) |\ S \in \mathcal{C}_j \cup I_j,\ 1 \leq j \leq \ell\}$. Informally, the element $(S,j) \in E$ represents an assignment of all the items in S to a single bin $b \in B_j$. We now define $g : 2^E \to \mathbb{R}_{\geq 0}$ by $g(T) = f\left(\bigcup_{(S,j)\in T} S\right)$. By Claim 2, g is a submodular, monotone and non-negative function‘.

We define a polytope P for the instance $\mathcal{I}$ as follows.

$$P = \left\{ \bar{x} \in [0,1]^E \;\middle|\; \begin{array}{ll} \sum_{C \in \mathcal{C}_j} \bar{x}_{(C,j)} \leq |B_j| & \forall 1 \leq j \leq k \\ \sum_{S \in \mathcal{C}_j \cup I_j} w(S) \cdot \bar{x}_{(S,j)} \leq |B_j| \cdot W_j^* & \forall 1 \leq j \leq \ell \end{array} \right\} \tag{7}$$

The polytope represents a relaxed version of the capacity constraints over the bins. For each block B_j, $1 \leq j \leq k$, we only require that the *total weight* of items assigned to bins in B_j does not exceed the total capacity of the bins in this block. We also require that the number of j-configurations selected for B_j is no greater than the number of bins in this block.

Given an instance $\mathcal{I}$ of δ-restricted SMKP, along with the partition $B \setminus B^r = B_1 \cup \ldots \cup B_k$ and the parameter μ, we use for the *block-constraint problem* the universe E, the function g and the polytope $P \subseteq [0,1]^E$ as defined above.

We start by establishing a connection between the solution for the block-constraint problem for the given instance $\mathcal{I}$ and the optimal solution for δ-restricted SMKP on this instance. For a set $T \subseteq E$, we use $\bar{x}^T$ to denote the vector $\bar{x}^T \in \{0,1\}^E$ defined by $\bar{x}_e^T = 1$ for $e \in T$, and $\bar{x}_e^T = 0$ for $e \in E \setminus T$. Also, given a polytope Q and $\eta \geq 0$ we use the notation $\eta \cdot Q = \{\eta \bar{x} \mid \bar{x} \in Q\}$.

Our algorithm for solving δ-restricted SMKP on $\mathcal{I}$ solves first the block-constraint problem on this instance and then transforms the solution into a feasible solution for δ-restricted SMKP. We give the pseudocode for the transformation in Algorithm 3.

Algorithm 3 Employ a Block-Constraint Solution for SMKP.

Input : A δ-restricted SMKP instance $\mathcal{I} = (I, w, B, W, f)$, the partition of bins to block $\cup_{j=1}^{\ell} B_j$ and $T \subseteq E$.

1 Set $A_b = \emptyset$ for every $b \in B$.
2 Sort the elements (S, j) in T in decreasing order by the $w(S)$ values.
3 **for** *each* $(S, j) \in T$ *in the sorted order* **do**
4 | Set $A_b \leftarrow A_b \cup S$ where $b = \arg\min_{b \in B_j} w(A_b)$.
5 **end**
6 Return $(A_b)_{b \in B}$.

▶ **Lemma 11.** *Given an instance $\mathcal{I}$ of δ-restricted SMKP, consider the universe E and the polytope P as defined above. Then the following hold:*

1. *There is $T \subseteq E$, $\bar{x}^T \in P$ such that $g(T) \geq \mathrm{OPT}(\mathcal{I})$, where $\mathrm{OPT}(\mathcal{I})$ is the optimal solution value for δ-restricted SMKP on $\mathcal{I}$.*
2. *Given $T \subseteq E$ such that $\bar{x}^T \in (1-\mu) \cdot P$, Algorithm 3 returns in polynomial time a feasible solution $(A_b)_{b \in B}$ for δ-restricted SMKP instance $\mathcal{I}$ satisfying $f(\cup_{b \in B} A_b) = g(T)$.*

Proof. We start by proving part 1. Let $(A_b^*)_{b \in B}$ be an optimal solution for the δ-restricted SMKP instance, and let L_j be the set of all j-large items for $1 \leq j \leq k$ and $L_j = \emptyset$ for $k < j \leq \ell$. Define

$$T = \left(\bigcup_{j=1}^{k} \{(A_b^* \cap L_j, j) \mid b \in B_j\} \right) \cup \left(\bigcup_{j=1}^{\ell} \bigcup_{b \in B_j} \{(\{i\}, j) \mid i \in A_b^* \setminus L_j\} \right).$$

It can be easily shown that $g(T) = f(\cup_{b \in B} A_b^*)$. Furthermore, as $(A_b^*)_{b \in B}$ is a feasible solution, it holds that $\bar{x}^T \in P$.

We now prove part 2. Let $(A_b)_{b \in B}$ be the output of Algorithm 3 for the given input. We first note that $\cup_{b \in B} A_b = \cup_{(S,j) \in T} S$, and thus $g(T) = f(\cup_{b \in B} A_b)$.

For any $b \in B^r$, there is $k < j \leq \ell$ such that $B_j = \{b\}$. Therefore $A_b = \{i | (\{i\}, j) \in T\}$, and since $\bar{x}^T \in (1-\mu)P$ it follows that $w(A_b) \leq W_j^* = W_b$.

Let $1 \leq j \leq k$ and $b \in B_j$. Assume by negation that $w(A_b) > W_b = W_j^*$. Let $(S, j) \in T$ be the last element in T such that $S \neq \emptyset$ and S was added to A_b in Line 4. We conclude that $w(A_b \setminus S) > 0$, as otherwise $w(A_b) = w(S) \leq W_b$, by the definition of E. Therefore there are at least $|B_j|$ elements $(S', j) \in T$ such that $w(S') \geq w(S)$ (else, on the iteration of (S, j) there must be $b \in B_j$ with $A_b = \emptyset$). If $S \in \mathcal{C}_j$ then $w(S) > \mu \cdot W_j^*$ and thus

$$|\{S' \neq \emptyset |\ (S', j) \in T,\ S' \in \mathcal{C}_j\}| \ \geq\ |\{S' |\ (S', j) \in T,\ w(S') \geq w(S)\}| \ >\ |B_j|,$$

contradicting $\bar{x}^T \in (1-\mu)P$.

Therefore $S \notin \mathcal{C}_j$, and we can conclude that $S = \{i\}$ with $w_i \leq \mu \cdot W_j^*$. Thus, $w(A_b \setminus S) > (1-\mu) \cdot W_j^*$. Here, S has been allocated to A_b (which is itself a set of minimum weight). Then, for any $b' \in B_j$, we have $w(A_{b'}) \geq w(A_b) > (1-\mu) \cdot W_j^*$. Thus,

$$\sum_{(S', j) \in T} w(S') \geq \sum_{b' \in B_j} w(A_{b'}) > |B_j|(1-\mu) \cdot W_j^*,$$

contradicting $\bar{x}^T \in (1-\mu)P$. We conclude that $w(A_b) \leq W_b$.

Also, by definition, we have that for any $b \in B^r$ and $i \in A_b$ it holds that $w_i \leq \delta W_b$. Hence, $(A_b)_{b \in B}$ is a solution to the restricted SMKP instance. ◀

3.2.2 An Algorithm for δ-restricted SMKP

We are now ready to present our algorithm for δ-restricted SMKP. We note that in Line 3 of Algorithm 4 we use sampling by a solution vector $\bar{x}^*$, as defined in Section 2.

Algorithm 4 Solve and Round.

Input : A δ-restricted SMKP instance $\mathcal{I}$, a partition to blocks $B \setminus B^r = \cup_{j=k}^{j} B_j$, and a parameter $\mu > 0$.

1 Define E, g and P for the block-constraint problem on $\mathcal{I}$ and $\cup_{j=1}^{k} B_j$.
2 Let $G : [0,1]^E \to \mathbb{R}_{\geq 0}$ be the multilinear extension of g. Find a solution $\bar{x}^*$ for $\max_{\bar{x} \in \frac{1-\mu}{1+\mu} P} G(\bar{x})$ using the continuous greedy of [4].
3 Sample a set $T \sim \bar{x}^*$.
4 **if** $T \in (1-\mu)P$ **then**
5 Use Algorithm 3 to convert T into a solution $(A_b)_{b \in B}$ for δ-restricted SMKP on $\mathcal{I}$ and return $(A_b)_{b \in B}$.
6 **else**
7 Return $(A_b)_{b \in B}$ with $A_b = \emptyset$ for every $b \in B$.
8 **end**

For the analysis, consider first the running time. We note that, for any $\bar{\lambda} \in \mathbb{R}^E$, a vector $\bar{x} \in \frac{1-\mu}{1+\mu} P$ which maximizes $\bar{x} \cdot \bar{\lambda}$ can be found in polynomial time. Therefore, the continuous greedy in Line 2 runs in polynomial time. Thus, Algorithm 4 has a polynomial running time.

It remains to show that the algorithm returns a solution of expected value as stated in Lemma 7. The approach we use to prove the statement of the lemma is similar to the approach taken in [6]. In fact, it is possible to prove a variant of this claim using an approach of [17]. While eliminating the dependency on v, this will result in a more involved proof.

Proof of Lemma 7. For any $e \in E$ define X_e to be a random variable such that $X_e = 1$ if $e \in T$ and $X_e = 0$ otherwise. It follows that $(X_e)_{e \in E}$ are independent Bernoulli random variables, $\mathbb{E}[X_e] = \bar{x}^*_e$ and $T = \{e \in E | X_e = 1\}$.

We first consider blocks $k < j \leq \ell$. Let $k < j \leq \ell$ and $B_j = \{b\}$. Since $\bar{x}^* \in \frac{1-\mu}{1+\mu} P$, it follows that $\mathbb{E}\left[\sum_{(S,j) \in E} w(S) \cdot X_{(S,j)}\right] \leq \frac{1-\mu}{1+\mu} \cdot W_b$. Also, $w_{(S,j)} \leq \delta \cdot W_b$ for every $(S,j) \in E$. Using Chernoff's bound (Theorem 3.1 in [13], see also Lemma 15), we have

$$\Pr\left(\sum_{(S,j) \in T} w(S) > (1-\mu) W_b\right) \leq \exp\left(-\frac{\mu^2}{3} \cdot \frac{1-\mu}{1+\mu} \cdot \frac{1}{\delta}\right) \leq \exp\left(-\frac{\mu^2}{12} \cdot \frac{1}{\delta}\right), \tag{8}$$

with the last inequality following from $\mu \in (0, 0.1)$.

Now, let $1 \leq j \leq k$. For every $(S,j) \in E$ it holds that $w(S) \leq W^*_j$. Also, since $\bar{x}^* \in \frac{1-\mu}{1+\mu} P$, $\mathbb{E}\left[\sum_{(S,j) \in E} w(S) \cdot X_{(S,j)}\right] \leq \frac{1-\mu}{1+\mu} \cdot |B_j| W^*_j$, and $\mathbb{E}\left[\sum_{(S,j) \in E:\ S \in \mathcal{C}_j} 1 \cdot X_{(S,j)}\right] \leq \frac{1-\mu}{1+\mu} \cdot |B_j|$. Therefore, by Chernoff's bound (Theorem 3.1 in [13] and Lemma 15), we have

$$\Pr\left(\sum_{(S,j) \in T} w(S) > (1-\mu)|B_j| W^*_j\right) \leq \exp\left(-\frac{\mu^2}{3} \cdot \frac{1-\mu}{1+\mu} \cdot |B_j|\right) \leq \exp\left(-\frac{\mu^2}{12} \cdot |B_j|\right) \tag{9}$$

$$\Pr\left(\sum_{(S,j) \in T:\ S \in \mathcal{C}_j} 1 > (1-\mu)|B_j|\right) \leq \exp\left(-\frac{\mu^2}{3} \cdot \frac{1-\mu}{1+\mu} \cdot |B_j|\right) \leq \exp\left(-\frac{\mu^2}{12} \cdot |B_j|\right). \tag{10}$$

By Lemma 11, $\max_{\bar{z}\in P} G(\bar{z}) \geq \mathrm{OPT}(\mathcal{I})$. Since the second derivatives of G are non-positive (see [4]) it follows that $\max_{\bar{z}\in \frac{1-\mu}{1+\mu}P} G(\bar{z}) \geq \frac{1-\mu}{1+\mu}\mathrm{OPT}(\mathcal{I})$. As the continuous greedy of [4] yields a $(1-e^{-1})$-approximation for the problem of maximizing the multilinear extension subject to a polytope constraint, it follows that

$$G(\bar{x}^*) \geq (1-e^{-1})\frac{1-\mu}{1+\mu}\mathrm{OPT}(\mathcal{I}). \tag{11}$$

For any $(S,j) \in E$ we have $|S| \leq \mu^{-1}$, and from the submodularity of f, $g(\{(S,j)\}) - g(\emptyset) \leq \mu^{-1}\upsilon$ (recall that υ is defined in Lemma 7). Therefore, by the concentration bound of [6] (see Lemma 16), we have

$$\begin{aligned}&\Pr\left(g(T) \leq (1-e^{-1})\frac{(1-\mu)^2}{1+\mu}\mathrm{OPT}(\mathcal{I})\right) \leq \Pr\left(g(\{e\in E|X_e=1\}) \leq (1-\mu)G(\bar{x}^*)\right)\\ &\leq \exp\left(-\frac{\mu^3\cdot G(\bar{x}^*)}{2\upsilon}\right) \leq \exp\left(-\frac{\mu^3(1-e^{-1})}{2\upsilon}\frac{1-\mu}{1+\mu}\mathrm{OPT}(\mathcal{I})\right) \leq \exp\left(-\frac{\mu^3\cdot\mathrm{OPT}(\mathcal{I})}{16\cdot\upsilon}\right)\end{aligned} \tag{12}$$

The first and third inequality are due to (11).

Let ω be the event $\bar{x}^T \in (1-\mu)P$ and $g(T) \geq \frac{(1-\mu)^2}{1+\mu}(1-e^{-1})\mathrm{OPT}(\mathcal{I})$. By applying the union bound over (8), (9), (10) and (12), we have

$$\Pr(\omega) \geq 1-\left(|B^r|\exp\left(-\frac{\mu^2}{12}\frac{1}{\delta}\right) - 2\sum_{j=1}^{k}\exp\left(-\frac{\mu^2}{12}|B_j|\right) - \exp\left(-\frac{\mu^3}{16}\frac{\mathrm{OPT}(\mathcal{I})}{\upsilon}\right)\right) = 1-\gamma.$$

In case the event ω occurs, the algorithm executes Line 5, and by Lemma 11, $f(\cup_{b\in B}A_b) = f(T)$. Hence,

$$\mathbb{E}\left[f(\cup_{b\in B}A_b)\right] = \Pr(\omega)\cdot E\left[f(\cup_{b\in B}A_b)|\omega\right] \geq (1-\gamma)\frac{(1-\mu)^2}{1+\mu}(1-e^{-1})\mathrm{OPT}(\mathcal{I}).$$

Also, the algorithm either returns an empty solution when Line 7 executes, or Line 5 executes. In the latter case the solution is feasible by Lemma 11. Therefore the algorithm always returns a feasible solution. ◀

4 Discussion

In this paper we presented a randomized $(1-e^{-1}-\varepsilon)$-approximation for the monotone submodular multiple knapsack problem. Our algorithm relies on three main building blocks. The structuring technique (Section 3.1) which converts a general instance to a leveled instance, the reduction to the block-constraint problem (Section 3.2.1) and a refined analysis of known algorithms for submodular optimization with a d-dimensional knapsack constraint (Section 3.2.2). While the structuring technique and the refined analysis seem to be fairly robust, the reduction to the block-constraint problem proved to be limiting when generalizations of the problem were considered.

A notable example is the *non-monotone* submodular multiple knapsack problem, in which the set function f is non-monotone. Unfortunately, when f is non-monotone the function g used for solving the block-constraint problem is not submodular. A variant of the block-constraint problem which does not alter the set function may be used to overcome this hurdle. However, this variant limits the knapsacks utilization and degrades the approximation ratio. Our preliminary results for the non-monotone case guarantee an approximation ratio of $\frac{1}{2}\cdot e^{-\frac{1}{2}} - \varepsilon \approx 0.303 - \varepsilon$ using this approach.

Another natural generalization of SMKP is monotone submodular optimization subject to a multiple knapsack and a *matroid* constraints, in which the solution $(A_b)_{b\in B}$ must also satisfy $\cup_{b\in B} A_b \in \mathcal{M}$ for a matoid $\mathcal{M}$. However, the matroid properties are not preserved throughout the reduction to the block-constraint problem, rendering existing techniques for submodular optimization with matroid and d-dimensional knapsack constraints [6] ineffective.

On the positive side, we believe that the techniques described in this paper can be extended to handle the problem for maximizing a monotone submodular function subject to a multiple knapsack constraint and an additional d-dimensional knapsack constraint, for a fixed d. We defer the details to the full version of the paper.

A Basic Properties of Submodular Functions

▷ Claim 12. Let $f : 2^I \to \mathbb{R}_{\geq 0}$ be monotone and submodular function, then for any $A \subseteq B \subseteq I$ and $S \subseteq I$ it holds that $f(A \cup S) - f(A) \geq f(B \cup S) - f(B)$.

Proof. By the submodularity of f, we have

$$f(A \cup S) + f(B) \geq f(A \cup S \cup B) + f((A \cup S) \cap B) \geq f(B \cup S) + f(A)$$

where the second inequality follows from $A \subseteq (A \cup S) \cap B$ and the monotonicity of f. By rearranging the terms in the above we get

$$f(A \cup S) - f(A) \geq f(B \cup S) - f(B)$$

as required. ◁

▷ Claim 13. Let $f : 2^I \to \mathbb{R}_{\geq 0}$ be be a non-negative, monotone and submodular function, and let $S \subseteq I$. Then f_S is a submodular, monotone and non-negative function.

Proof. Let $A \subseteq I$. As f is monotone, we have

$$f_S(A) = f(S \cup A) - f(S) \geq 0.$$

That is, f is non-negative.

By claim 12, for any $A \subseteq B \subseteq I$ and $x \in I \setminus B$ it holds that

$$\begin{aligned} f_S(A \cup \{x\}) - f_S(A) &= f(S \cup A \cup \{x\}) - f(S \cup A) \\ &\geq f(S \cup B \cup \{x\}) - f(S \cup B) = f_S(B \cup \{x\}) - f_S(B). \end{aligned}$$

Therefore, f_S is submodular.

Finally, for $A \subseteq B \subseteq I$, as f is monotone we have that

$$f_S(A) = f(S \cup A) - f(S) \geq f(S \cup B) - f(S) = f_S(B).$$

Thus, f_S is also monotone. ◁

Proof of Claim 2. It is easy to see that g is non-negative, as f is non negative. In addition, for any two subsets $A \subseteq B \subseteq E$ we have $\cup_{(S,h)\in A} s \subseteq \cup_{(S,h)\in B} s$. Thus, since f is monotone, g is monotone as well.

All that is left to prove is that g is submodular. Consider subsets $A \subseteq B \subseteq E$ and $(S,h) \in E \setminus B$.

$$\begin{aligned} g(A \cup \{(S,h)\}) - g(A) &= f(\cup_{(S',h')\in A} S' \cup S) - f(\cup_{(S',h')\in A} s) \\ &\leq f(\cup_{(S',h')\in B} S' \cup S) - f(\cup_{(S',h')\in B} S') \\ &= g(B \cup \{(S,h)\}) - g(B). \end{aligned}$$

The inequality follows from Claim 12 and $\cup_{(S',h')\in A} S' \subseteq \cup_{(S',h')\in B} S'$. ◁

To prove Lemma 10 we first prove a special case of the lemma.

▶ **Lemma 14.** *Let $h : 2^{\Omega} \to \mathbb{R}_{\geq 0}$ be a submodular monotone and non-negative function, and let $S_1, \ldots, S_N \subseteq \Omega$. Then there is $1 \leq j^* \leq N$ such that*

$$h\left(\bigcup_{1\leq j\leq N,\ j\neq j^*} S_j\right) \geq \left(1 - \frac{1}{N}\right) h(S_1 \cup \ldots \cup S_N).$$

Proof. As h is submodular and monotone, using Claim 2, we have

$$\begin{aligned} h(S_1 \cup \ldots \cup S_N) - h(\emptyset) &= \sum_{j=1}^{N} \left(h(S_1 \cup \ldots \cup S_j) - h(S_1 \cup \ldots \cup S_{j-1})\right) \\ &\geq \sum_{j=1}^{N} \left(h\left(\bigcup_{j'=1}^{N} S_{j'}\right) - h\left(\bigcup_{1\leq j'\leq N, j'\neq j} S_{j'}\right)\right) \end{aligned}$$

Therefore there is $1 \leq j^* \leq N$ such that

$$h\left(\bigcup_{j=1}^{N} S_j\right) - h\left(\bigcup_{1\leq j\leq N, j\neq j^*} S_j\right) \leq \frac{1}{N}\left(h(S_1 \cup \ldots \cup S_N) - h(\emptyset)\right).$$

By rearranging the terms and using $h(\emptyset) \geq 0$ we obtain

$$h\left(\bigcup_{1\leq j\leq N, j\neq j^*} S_j\right) \geq \left(1 - \frac{1}{N}\right) h(S_1 \cup \ldots \cup S_N),$$

as required. ◀

Proof of Lemma 10. Let $h : 2^{\Omega} \to \mathbb{R}_+$ be a submodular, non-negative and monotone function, and $S_{i,1}, \ldots, S_{i,N} \subseteq \Omega$ for every $1 \leq i \leq M$.

Define $T_i = \bigcup_{j=1}^{N} S_{i,j}$. Now,

$$h\left(\bigcup_{i=1}^{M}\bigcup_{j=1}^{N} S_{i,j}\right) - h(\emptyset) = \sum_{i=1}^{M} h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}(T_i) = \sum_{i=1}^{M} h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}\left(\bigcup_{j=1}^{N} S_{i,j}\right).$$

By Lemma 14 for every $1 \leq i \leq M$ there is $1 \leq j_i^* \leq N$ such that

$$h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}\left(\bigcup_{1\leq j\leq N,\ j\neq j_i^*} S_{i,j}\right) \geq \left(1 - \frac{1}{N}\right) h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}(T_i).$$

Therefore,

$$\begin{aligned} h\left(\bigcup_{i=1}^{M}\bigcup_{1\le j\le M,\ j\neq j_i^*} S_{i,j}\right) - h(\emptyset) &= \sum_{i=1}^{M} h_{\left(\bigcup_{i'=1}^{i-1}\bigcup_{1\le j\le M,\ j\neq j_{i'}^*} S_{i',j}\right)}\left(\bigcup_{1\le j\le M,\ j\neq j_i^*} S_{i,j}\right) \\ &\ge \sum_{i=1}^{M} h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}\left(\bigcup_{1\le j\le M,\ j\neq j_i^*} S_{i,j}\right) \ge \left(1-\frac{1}{N}\right)\sum_{i=1}^{M} h_{\left(\bigcup_{i'=1}^{i-1} T_{i'}\right)}(T_i) \\ &= \left(1-\frac{1}{N}\right)\left(h\left(\bigcup_{i=1}^{M}\bigcup_{j=1}^{N} S_{i,j}\right) - h(\emptyset)\right). \end{aligned}$$

The first inequality follows from $h_{T_1}(A) \ge h_{T_2}(A)$ for any $T_1 \subseteq T_2 \subseteq \Omega$ and $A \subseteq \Omega$ due to Claim 2. As h is non-negative, we conclude that

$$h\left(\bigcup_{i=1}^{M}\bigcup_{1\le j\le M,\ j\neq j_i^*} S_{i,j}\right) \ge \left(1-\frac{1}{N}\right)\cdot h\left(\bigcup_{i=1}^{M}\bigcup_{j=1}^{N} S_{i,j}\right). \qquad \blacktriangleleft$$

B Chernoff Bounds

In the analysis of the algorithm we use the following Chernoff-like bounds.

▶ **Lemma 15** (Theorem 3.1 in [13]). *Let $X = \sum_{i=1}^{n} X_i \cdot \lambda_i$ where $(X_i)_{i=1}^{n}$ is a sequence of independent Bernoulli random variable and $\lambda_i \in [0,1]$ for $1 \le i \le n$. Then for any $\varepsilon \in (0,1)$ and $\eta \ge \mathbb{E}[X]$ it holds that*

$$\Pr\left(X > (1+\varepsilon)\eta\right) < \exp\left(-\frac{\varepsilon^2}{3}\eta\right)$$

▶ **Lemma 16** (Theorem 1.3 in [6]). *Let $I = \{1,\ldots,n\}$, $\upsilon > 0$ and $f : 2^I \to \mathbb{R}_+$ be a monotone submodular function such that $f(\{i\}) - f(\emptyset) \le \upsilon$ for any $i \in I$. Let $X_1,\ldots,X_n$ be independent random variables and $\eta = \mathbb{E}[f(\{i \in I | X_i = 1\})]$. Then for any $\varepsilon > 0$ it holds that*

$$\mathbb{E}[f(\{i \in I | X_i = 1\}) \le (1-\varepsilon)\eta] \le \exp\left(-\frac{\eta\cdot\varepsilon^2}{2\upsilon}\right)$$

Linear Expected Complexity for Directional and Multiplicative Voronoi Diagrams

Abstract

While the standard unweighted Voronoi diagram in the plane has linear worst-case complexity, many of its natural generalizations do not. This paper considers two such previously studied generalizations, namely multiplicative and semi Voronoi diagrams. These diagrams both have quadratic worst-case complexity, though here we show that their expected complexity is linear for certain natural randomized inputs. Specifically, we argue that the expected complexity is linear for: (1) semi Voronoi diagrams when the visible direction is randomly sampled, and (2) for multiplicative diagrams when either weights are sampled from a constant-sized set, or the more challenging case when weights are arbitrary but locations are sampled from a square.

1 Introduction

Given a set of point sites in the plane, the Voronoi diagram is the corresponding partition of the plane into cells, where each cell is the locus of points in the plane sharing the same closest site. This fundamental structure has a wide variety of applications. When coupled with a point location data structure, it can be used to quickly answer nearest neighbor queries. Other applications include robot motion planning, modeling natural processes in areas such as biology, chemistry, and physics, and moreover, the dual of the Voronoi diagram is the well known Delaunay triangulation. See the book [5] for an extensive coverage of the topic.

Many of the varied applications of Voronoi diagrams require generalizing its definition in one way or another, such as adding weights or otherwise altering the distance function, moving to higher dimensions, or considering alternative types of sites. While some of these generalizations retain the highly desirable linear worst-case complexity of the standard Voronoi diagram, many others unfortunately have quadratic worst-case complexity or more.

Within the field of Computational Geometry, particularly in recent years, there have been a number of works analyzing the expected complexity of various geometric structures when the input is assumed to have some form of randomness. Here we continue this line of work, by studying the expected complexity of two previously considered Voronoi diagram variants.

Directional and weighted Voronoi diagrams. A natural generalization to consider is when each site is only visible to some subset of the plane. Here we are interested in the so called visual restriction Voronoi diagram (VRVD) [6, 13], where a given site p is only visible to the subset of points contained in some cone with base point p and angle α_p. These diagrams model scenarios where the site has a restricted field of view, such as may be the case with various optical sensors or human vision. For example, in a football game, each player has their own field of view at any given time, and the location of the ball in the VRVD tells us which player is the closest to the ball among those who can see it. When the visible region for each site is a half-plane whose boundary passes through the site (i.e., a VRVD where $\alpha_p = \pi/2$ for each site p), such diagrams are called semi Voronoi diagrams [10]. Just like general VRVD's, semi Voronoi diagrams have $\Theta(n^2)$ worst-case complexity. Our expected analysis is shown for the semi Voronoi diagram case, however, we remark a similar analysis implies the same bounds hold more generally for VRVD's.

The other generalization we consider is when sites have weights. There are many natural ways to incorporate weights into the distance function of each site. Three of the most common are additive [14, 18, 19], power [3], and multiplicative [4] Voronoi diagrams (see also [5]). (For brevity, throughout we use the prefix *multiplicative*, rather than the more common *multiplicatively-weighted*.) For additive Voronoi diagrams the distance from a point x in the plane to a given site p is $d(x,p) = ||x-p|| + \alpha_p$, for some constant α_p, which can vary for each site. For power diagrams the distance is given by $d(x,p) = ||x-p||^2 - \alpha_p^2$. For multiplicative diagrams the distance is given by $d(x,p) = \alpha_p \cdot ||x-p||$. The worst-case complexity for additive and power diagrams is only linear [3, 19]. Here our focus is on multiplicative diagrams, whose worst-case complexity is known to be $\Theta(n^2)$ [4]. Multiplicative diagrams are used to model, for example, crystal growth where crystals grow together from a set of sites at different rates.

Previous expected complexity bounds. There are many previous results on the expected complexity of various geometric structures under one type of randomness assumption or another. Here we focus on previous results relating to Voronoi diagrams. For point sites in $\mathbb{R}^d$, the worst-case complexity of the Voronoi diagram is known to be $\Theta(n^{\lceil d/2 \rceil})$, however, if the sites are sampled uniformly at random from a d-ball or hypercube, for constant d, then the expected complexity is $O(n)$ [7, 12]. For a set of n point sites on a terrain consisting of m triangles, Aronov *et al.* [2] showed that, if the terrain satisfies certain realistic input assumptions then the worst-case complexity of the geodesic Voronoi diagram is $\Theta(m + n\sqrt{m})$. Under a relaxed set of assumption, Driemel *et al.* [11] showed that the expected complexity is only $O(n+m)$, when the sites are sampled uniformly at random from the terrain domain.

Relevant to the current paper, Har-Peled and Raichel [17] showed that, for any set of point site locations in the plane and any set of weights, if the weights are assigned to the points according to a random permutation, then the expected complexity of the multiplicative Voronoi diagram is $O(n \log^2 n)$. The motivation for this work came from Agarwal *et al.*[1], who showed that if one randomly fattens a set of segments in the plane, by taking the Minkowski sum of each segment with a ball of random radius, then the expected complexity of the union is near linear, despite having quadratic worst-case complexity. In a follow-up work to [17], Chang *et al.*[9] defined the candidate diagram, a generalization of weighted diagrams to multi-criteria objective functions, and showed that under similar randomized input assumptions the expected complexity of such diagrams is $O(n \operatorname{polylog} n)$.

Our results and significance. Our first result concerns semi Voronoi diagrams, where the visible region of each site is a half-plane whose bounding line passes through the site, and where the worst-case complexity is quadratic. For any set of site locations and bounding

lines, we show that if the visible side of each site's bounding line is sampled uniformly at random, then the expected complexity of the semi Voronoi diagram is linear, and $O(n \log^3 n)$ with high probability. To achieve this we argue that our randomness assumption implies that any point in the plane is likely to be visible by one of its k nearest neighbors, for large enough k. Thus within each cell of the order-k Voronoi diagram, one can argue the complexity of semi Voronoi diagram is $O(k^2)$, and so summing over all $O(nk)$ cells gives an $O(nk^3)$ bound. This is a variant of the candidate diagram approach introduced in [17]. Unfortunately, in general this approach requires k to be more than a constant, which will not yield the desired linear bound. Thus here, in order to get a linear bound, we give a new refined version of this approach, by carefully allowing k to vary as needed, in the end producing a diagram which is the union of order-k cells, for various values of k.

The main focus of the paper is the second part concerning multiplicative Voronoi diagrams, where the distance to each site is the Euclidean distance multiplied by some site-dependent weight, and where the worst-case complexity is quadratic. We first argue that if the weights are sampled from a set with constant size, then interestingly a similar refined candidate diagram approach yields a linear bound. Our main result, however, considers the more challenging case when no restrictions are made on the weights, but instead the site locations are sampled uniformly at random from the unit square. For this case we show that in any grid cell of side length $1/\sqrt{n}$ in the unit square the expected complexity of the multiplicative diagram is $O(1)$. This implies an $O(n)$ expected bound for the multiplicative diagram over the whole unit square. This improves over the $O(n \log^2 n)$ bound of [17] for this case, by using an interesting new approach which "stretches" sites about a given cell based on their weights, thus approximately transforming the weighted diagram into an unweighted one with respect to a given cell. As this main result is technically very challenging, it is placed last.

It is important to note the significance of our bounds being linear. Given a randomness assumption, one wishes to prove an optimal expected complexity bound, and for the diagrams we consider linear bounds are immediately optimal. However, even when a linear bound seems natural, many standard approaches to bounding the expected complexity yield additional log factors (e.g. [1, 9, 17]). That is, not only are linear bounds desirable, but also they are nontrivial to obtain. However, when they are obtained, they reveal the true expected complexity of the structure, free from artifacts of the analysis.

▶ Remark 1. Our paper focuses on diagram complexity not running time. However, Corollary 4 below shows our approach implies that the semi Voronoi diagram can be computed in $O(n \log^3 n)$ expected time in our randomized model, by using the previous quadratic time algorithm of Fan *et al.* [13] on appropriate subsets of sites. For the multiplicate Voronoi diagram, [17] remarked that their approach implied an $O(n \log^3 n)$ expected time algorithm in their model, which also covers all multiplicative models considered in the current paper.

2 Preliminaries

The standard Voronoi diagram: Let $S = \{s_1, s_2, ..., s_n\} \subset \mathbb{R}^2$ be a set of n point *sites* in the plane. Let $\|x - y\|$ denote the Euclidean distance from x to y, and for two sites $s_i, s_j \in S$ let $\beta(s_i, s_j)$ denote their bisector, that is the set of points x in plane such that $\|s_i - x\| = \|s_j - x\|$. Any site $s_i \in S$ induces a distance function $f_i(x) = \|s_i - x\|$ defined for any point x in the plane. For any subset $T \subseteq S$, the *Voronoi cell* of $s_i \in T$ with respect to T, $\mathcal{V}_{\text{cell}}(s_i, T) = \{x \in \mathbb{R}^2 \mid \forall s_j \in T \quad f_i(x) \leq f_j(x)\}$, is the locus of points in the plane having s_i as their closest site from T. We define the *Voronoi diagram* of T, denoted $\mathcal{V}(T)$, as the partition of the plane into Voronoi cells induced by the minimization diagram (see [15]) of the set of distance functions $\{f_i \mid s_i \in T\}$, that is the projection onto the plane of the lower envelope of the surfaces defined by these bivariate functions.

One can view the union, U, of the boundaries of the cells in the Voronoi diagram as a planar graph. Specifically, define a *Voronoi vertex* as any point in U which is equidistant to three sites in S (happening at the intersection of bisectors). For simplicity, we make the general position assumption that no point is equidistant to four or more sites. Furthermore, define a *Voronoi edge* as any maximal connected subset of U which does not contain a Voronoi vertex. (For each edge to have two endpoints we include the "point" at infinity, i.e., the graph is defined on the stereographic projection of the plane onto the sphere.) The complexity of the Voronoi diagram is then defined as the total number of Voronoi edges, vertices, and cells. As the cells are simply connected sets, which are faces of a straight-line planar graph, the overall complexity is $\Theta(n)$.

Order-k Voronoi diagram: Let S be a set of n point sites in the plane. The *order-k Voronoi diagram* of S is the partition of the plane into cells, where each cell is the locus of points having the same set of k nearest sites of S (the ordering of these k sites by distance can vary within the cell). It is not hard to see that this again defines a straight-line partition of the plane into cells where the edges on the boundary of a cell are composed of bisector pieces. The worst-case complexity of this diagram is $\Theta(k(n-k))$ (see [5, Section 6.5]).

We also consider the diagram where every point in a cell not only has the same k nearest sites, but also the same ordering of distances to these sites. We refer to this as the order-k *sequence* Voronoi diagram, known to have $O(nk^3)$ worst-case complexity (see Appendix B).

Semi Voronoi diagram: Let $S = \{s_1, s_2, ..., s_n\}$ be a set of n point sites in the plane, where for each s_i there is an associated closed half-plane $\mathsf{H}(s_i)$, whose boundary passes through s_i. We use $L(s_i)$ to denote the bounding line of $\mathsf{H}(s_i)$. For any point x in the plane and any site $s_i \in S$, we say that x and s_i are visible to each other when $x \in \mathsf{H}(s_i)$. Given a point x, let $S(x) = \{s_i \in S \mid x \in \mathsf{H}(s_i)\}$ denote the set of sites which are visible to x.

For any subset $T \subseteq S$, define the *semi Voronoi cell* of $s_i \in T$ with respect to T as, $\mathcal{SV}_{\text{cell}}(s_i, T) = \{x \in \mathsf{H}(s_i) \mid \forall s_j \in T \cap S(x) \quad \|x - s_i\| \leq \|x - s_j\|\}$. It is possible that there are points in the plane which are not visible by any site in S. If desired, this technicality can be avoided by adding a pair of sites far away from S which combined can see the entire plane. As before, semi Voronoi cells define a straight-line partition of the plane, where now the edges on the boundary of a cell are either portions of a bisector or of a half-plane boundary. In the worst case, the semi Voronoi diagram can have quadratic complexity [13].

Random semi Voronoi diagram: We consider semi Voronoi diagrams where the set of sites $S = \{s_1, \ldots, s_n\}$ is allowed to be any fixed set of n points in general position. For each site s_i, the line bounding the half-plane of s_i, $L(s_i)$, is allowed to be any fixed line in $\mathbb{R}^2$ passing through s_i. Such a line defines two possible visible closed half-spaces. We assume that independently for each site s_i, one of these two spaces is sampled uniformly at random.

An alternative natural assumption is that the normal of the half-plane for each site is sampled uniformly at random from $[0, 2\pi)$. Note our model is strictly stronger, that is any bound we prove will imply the same bound for this alternative formulation. This is because one can think of sampling normals from $[0, 2\pi)$, as instead first sampling directions for the bounding lines from $[0, \pi)$, and then sampling one of the two sides of each line for the normal.

Multiplicative Voronoi diagram: Let $S = \{s_1, s_2, ..., s_n\}$ be a set of n point sites in the plane, where for each site s_i there is an associated weight $w_i > 0$. Any site $s_i \in S$ induces a distance function $f_i(x) = w_i \cdot \|s_i - x\|$ defined for any point x in the plane. For any subset $T \subseteq S$, the

Voronoi cell of $s_i \in T$ with respect to T, $\mathcal{V}_{\text{cell}}(s_i, T) = \{x \in \mathbb{R}^2 \mid \forall s_j \in T \quad f_i(x) \leq f_j(x)\}$, is the locus of points in the plane having s_i as their closest site from T. The *multiplicative Voronoi diagram* of T, denoted $\mathcal{WV}(T)$, is the partition of the plane into Voronoi cells induced by the minimization diagram of the distance functions $\{f_i \mid s_i \in T\}$.

Note that unlike the standard Voronoi diagram, the bisector of two sites is in general an Apollonius disk, potentially leading to disconnected cells. Ultimately, the diagram still defines a planar arrangement and so its complexity, denoted by $|\mathcal{WV}(S)|$, can still be defined as the number of edges, faces, and vertices of this arrangement. Note the edges are circular arcs and straight line segments and thus are still constant complexity curves. In the worst case, the multiplicative Voronoi diagram has $\Theta(n^2)$ complexity [4].

3 The Expected Complexity of Random Semi Voronoi Diagrams

3.1 The probability of covering the plane

As it is used in our later calculations, we first bound the probability that for a given subset X of k sites of S that there exists a point in the plane not visible to any site in X.

▶ **Lemma 2.** *For any set $X = \{x_1, \ldots, x_k\}$ of k sites* $\mathbf{Pr}\left[\left(\bigcup_{x_i \in X} \mathcal{SV}_{\text{cell}}(x_i, X)\right) \neq \mathbb{R}^2\right] \leq (k(k+1)+2)/2^{k+1} = O(k^2/2^k)$.

Proof. Consider the arrangement of the k bounding lines $L(x_1), \ldots, L(x_k)$. Let $\mathcal{F}$ denote the set of faces in this arrangement (i.e., the connected components of the complement of the union of lines), and note that $|\mathcal{F}| \leq k(k+1)/2+1 = O(k^2)$. Observe that for any face $f \in \mathcal{F}$ and any fixed site $x_i \in X$, either every point in f is visible by x_i or no point in f is visible by x_i. Moreover, the probability that face f is not visible by site x_i is $\mathbf{Pr}[\mathsf{H}(x_i) \cap f = \emptyset] \leq 1/2$. Hence the probability that a face f is not visible by any of the k sites is

$$\mathbf{Pr}\left[\bigcup_{x_i \in X} \mathsf{H}(x_i) \cap f = \emptyset\right] \leq 1/2^k.$$

Hence the probability that at least one face in $\mathcal{F}$ is is not visible by any sites in X is

$$\mathbf{Pr}\left[\left(\bigcup_{x_i \in X} \mathcal{SV}_{\text{cell}}(x_i, X)\right) \neq \mathbb{R}^2\right] \leq \sum_{f \in \mathcal{F}} \mathbf{Pr}\left[\bigcup_{x_i \in X} \mathsf{H}(x_i) \cap f = \emptyset\right] \leq \frac{k(k+1)+2}{2^{k+1}} = O\left(\frac{k^2}{2^k}\right). \quad \blacktriangleleft$$

3.2 A simple near linear bound

Ultimately we can show that the expected complexity of a random semi Voronoi diagram is linear, however, here we first show that Lemma 2 implies a simple near linear bound which also holds with high probability. Specifically, we say that a quantity is bounded by $O(f(n))$ with high probability, if for any constant α there exists a constant β, depending on α, such that the quantity is at most $\beta \cdot f(n)$ with probability at least $1 - 1/n^\alpha$.

▶ **Lemma 3.** *Let $S = \{s_1, \ldots, s_n\} \subset \mathbb{R}^2$ be a set of n sites, where each site has a corresponding line $L(s_i)$ passing through s_i. For each s_i, sample a half-plane $\mathsf{H}(s_i)$ uniformly at random from the two half-planes whose boundary is $L(s_i)$. Then the expected complexity of the semi Voronoi diagram on S is $O(n \log^3 n)$, and moreover this bound holds with high probability.*

Proof. Let $k = c \log n$, for some constant c. Consider the order-k Voronoi diagram of S. First triangulate this diagram so the boundary of each cell has constant complexity. (Note triangulating does not asymptotically change the number of cells.) Fix any cell Δ in this triangulation, which in turn fixes some (unordered) set X of k-nearest sites. By Lemma 2,

$$\mathbf{Pr}\left[\left(\bigcup_{x_i \in X} \mathcal{SV}_{\text{cell}}(x_i, X)\right) \neq \mathbb{R}^2\right] = O(k^2/2^k) = O((c \log n)^2/2^{c \log n}) = O(1/n^{c-\varepsilon'}),$$

for any arbitrarily small value $\varepsilon' > 0$. Thus with polynomially high probability for every point in Δ its closest visible site will be in X. Now let T be the set of all $O(k(n-k)) = O(n \log n)$ triangles in the triangulation of the order-k diagram. Observe that the above high probability bound applies to any triangle $\Delta \in T$. Thus taking the union bound we have that with probability at least $1 - 1/n^{c-(1+\varepsilon)}$ (where $\varepsilon > \varepsilon' > 0$ is an arbitrarily small value), simultaneously for every triangle Δ, every point in Δ will be visible by one of its k closest sites. Let e denote this event happening (and $\overline{e}$ denote it not happening). Conditioning on e happening, there are only $O(k) = O(\log n)$ relevant sites which contribute to the semi Voronoi diagram of any cell Δ. Thus the total complexity of the semi Voronoi diagram restricted to any cell Δ is at most $O(\log^2 n)$, as the semi Voronoi diagram has worst-case quadratic complexity [13]. (Note that as Δ is a triangle, we can ignore the added complexity due to clipping the semi Voronoi diagram of these sites to Δ.) On the other hand, if $\overline{e}$ happens, then the worst-case complexity of the entire semi Voronoi diagram is still $O(n^2)$.

Now the complexity of the semi Voronoi diagram is bounded by the sum over the cells in the triangulation of the complexity of the diagram restricted to each cell. Thus the above already implies that with high probability the complexity of the semi Voronoi diagram is $O\big(\sum_{\Delta \in T} \log^2 n\big) = O(n \log^3 n)$. As for the expected value, by choosing c sufficiently large,

$$\begin{aligned}
&= \mathbf{E}\big[|\mathcal{SV}(S)| \;\big|\; e\big]\,\mathbf{Pr}[e] + \mathbf{E}\big[|\mathcal{SV}(S)| \;\big|\; \overline{e}\big]\,\mathbf{Pr}[\overline{e}] = O\left(\sum_{\Delta \in T} \log^2 n\right)\mathbf{Pr}[e] + O(n^2)\,\mathbf{Pr}[\overline{e}] \\
&= O(n \log^3 n)\,\mathbf{Pr}[e] + O(n^2)\,\mathbf{Pr}[\overline{e}] = O(n \log^3 n)\,\mathbf{Pr}[e] + O(n^2) \cdot (1/n^{c-(1+\varepsilon)}) \\
&= O(n \log^3 n) + O(1/n^{c-(3+\varepsilon)}) = O(n \log^3 n).
\end{aligned}$$

◀

The analysis of Lemma 3 immediately implies an algorithm with the same time bounds, by using the quadratic time algorithm for semi Voronoi diagrams of Fan *et al.* [13] for the subset of sites of each order-k cell.

▶ **Corollary 4.** *Let the input be as in Lemma 3. Then the semi Voronoi diagram can be computed in $O(n \log^3 n)$ expected time, and moreover this bound holds with high probability.*

Proof. Compute the order-k Voronoi diagram, for $k = c \log n$, where c is the constant determined in the proof of Lemma 3. Triangulate the diagram. Check if every point of every triangle is visible by one of its $k = \Theta(\log n)$ closest sites. If so, then compute the semi Voronoi diagram of the k nearest sites in each triangle, and clip it to the triangle. If not, ignore the triangles, and compute the semi Voronoi diagram of all n sites.

For $k = \Theta(\log n)$, the order-k diagram can be computed in $O(n \log^3 n)$ time [8]. Triangulating the diagram takes linear time in the complexity of the diagram. By Lemma 3, with high probability every point of every triangle is visible by one of its k closest sites. Thus with high probability the running time is $O(n \log^3 n)$, as computing the semi Voronoi diagram of the $k = \Theta(\log n)$ nearest sites in each triangle takes $O(\log^2 n)$ time per triangle, and thus $O(n \log^3 n)$ over all the $O(n \log n)$ triangles. If some triangle is not fully visible, then computing the semi Voronoi diagram of all n sites takes $O(n^2)$ time. Thus by the same expected analysis at the end of the proof of Lemma 3, the expected time is $O(n \log^3 n)$. ◀

3.3 An optimal linear bound

The previous subsection partitioned the plane based on the order-k Voronoi diagram, for $k = c \log n$, and then argued that simultaneously for all cells one of the k nearest sites will be visible. This argument is rather coarse, but instead of using a fixed large value for k, if one is more careful and allows k to vary, then one can argue the expected complexity is linear. Note that in the following, rather than using the standard unordered order-k Voronoi diagram, we use the more refined order-k *sequence* Voronoi diagram as defined above.

▶ **Theorem 5.** *Let $S = \{s_1, \ldots, s_n\} \subset \mathbb{R}^2$ be a set of n sites, where each site has a corresponding line $L(s_i)$ passing through s_i. For each s_i, sample a half-plane $\mathsf{H}(s_i)$ uniformly at random from the set of two half-planes whose boundary is $L(s_i)$ (i.e., each has $1/2$ probability). Then the expected complexity of the semi Voronoi diagram on S is $\Theta(n)$.*

Proof. Consider the partition of the plane by the first order Voronoi diagram of S, i.e., the standard Voronoi diagram. We iteratively refine the cells of this partition into higher order sequence Voronoi diagram cells. At each iteration we have a collection of order-i sequence Voronoi diagram cells, and for each cell we either mark it final and stop processing, or further refine the cell into its constituent order-$(i+1)$ sequence cells. Specifically, a cell Δ is marked final in the ith iteration if every point in Δ is visible by one of its i nearest sites, or when $i = n$ and the cell cannot be refined further. The process stops when all cells are marked final. Below we use F^k to denote the set of cells which were marked final in the kth iteration.

Let C^k be the set of all cells of the order-k sequence Voronoi diagram of S. Note that the order-k sequence Voronoi diagram can be constructed by iteratively refining lower order cells, and hence any cell seen at any point in the above process is a cell of the order-k sequence diagram for some value of k. So consider any cell $\Delta_j \in C^k$ of the order-k sequence diagram of S. Let $\#(\Delta_j)$ be the number of order-$(k+1)$ sequence diagram cells inside Δ_j, and let X_j be the indicator variable for the event that Δ_j is refined into its constituent order-$(k+1)$ sequence cells in the kth round of the above iterative process. Note that $\mathbf{Pr}[X_j = 1]$ is upper bounded by the probability that Δ_j has not been marked final by the end of the kth round, which in turn is bounded by Lemma 2. Thus letting Z^{k+1} be the random variable denoting the total number of order-$(k+1)$ sequence cells created in the above process, we have

$$\mathbf{E}\left[Z^{k+1}\right] = \mathbf{E}\left[\sum_{\Delta_j \in C^k} \#(\Delta_j) \cdot X_j\right] = \sum_{\Delta_j \in C^k} \#(\Delta_j) \cdot \mathbf{E}[X_j] = O\left(\frac{k^2}{2^k}\right) \cdot \sum_{\Delta_j \in C^k} \#(\Delta_j) = O\left(\frac{nk^5}{2^k}\right),$$

as $\sum \#(\Delta_j)$ is at most the total number of cells in the order-k sequence Voronoi diagram, which is bounded by $O(nk^3)$ (see Appendix B).

Using the same argument as in Lemma 3, the complexity of the random semi Voronoi diagram is bounded by $\sum_{k=1}^{n} |F^k| \cdot O(k^2)$. (If $k = n$ then a cell may not be fully visible, though the bound still applies as the worst-case complexity is $O(n^2)$.) Thus by the above, the expected complexity is

$$\mathbf{E}[|\mathcal{SV}(S)|] \leq \sum_{k=1}^{n} \mathbf{E}\left[|F^k|\right] \cdot O(k^2) \leq \sum_{k=1}^{n} \mathbf{E}\left[Z^k\right] \cdot O(k^2) \leq O\left(\sum_{k=1}^{n} \frac{nk^7}{2^k}\right) = O(n). \qquad \blacktriangleleft$$

▶ Remark 6. For simplicity the results above were presented for semi Voronoi diagrams, though they extend to the more general VRVD case, where the visibility region of s_i is determined by a cone with base point s_i and angle α_i, where the orientation of the cone is sampled uniformly at random. Specifically, the plane can be covered by a set of $(2\pi)/(\alpha_i/2) = 4\pi/\alpha_i$ cones around s_i each with angle $\alpha_i/2$. Any one of these smaller cones is completely contained

in the randomly selected α_i cone with probability $\alpha_i/(4\pi)$. If the α_i are lower bounded by a constant β, one can then prove a variant of Lemma 2 (and hence Lemma 3 and Theorem 5), as the arrangement of all these smaller cones still has $O(k^2)$ complexity, and the probability a face is not visible to any site is still exponential in k but with base proportional to $1-\beta/(4\pi)$.

4 The Expected Complexity of Multiplicative Voronoi Diagrams

In this section we consider the expected complexity of multiplicative Voronoi diagrams under different randomness assumptions. First, by using the approach from the previous section, we show that for any set of site locations, if each site samples its weight from a set of constant size c, then the expected complexity is $O(nc^6)$. Next, we consider the case when the sites can have arbitrary weights, but the site locations are sampled uniformly at random from the unit square. As making no assumptions on the weights makes the problem considerably more challenging, as a warm-up, we first assume the weights are in an interval $[1, c]$. In this case, we consider a $1/\sqrt{n}$ side length grid, and argue that locally in each grid cell the expected complexity of the multiplicative diagram is $O(c^4)$ (inspired by the approach in [11]), and thus over the entire unit square the complexity is $O(nc^4)$. Finally, we remove the bounded weight assumption, and argue that for any set of weights, the expected complexity is linear when site locations are sampled uniformly at random from the unit square, by introducing the notion of "stretched" sites.

4.1 Sampling from a small set of weights

▶ **Lemma 7.** *Let $W = \{w_1, w_2, ..., w_c\}$ be a set of non-negative real weights and let $S = \{s_1, s_2, s_3, \ldots, s_n\}$ be a set of point sites in the plane, where each site in S is assigned a weight independently and uniformly at random from W. Then the expected complexity of the multiplicative Voronoi diagram of S is $O(n \cdot c^6)$.*

Proof. Consider the partition of the plane determined by the unweighted first order Voronoi diagram of S, i.e., the standard Voronoi diagram. Following the strategy of the proof of Theorem 5, we iteratively refine the cells of this partition into higher order sequence Voronoi diagram cells, except now a cell Δ is marked final in the ith iteration if at least one of its i-nearest sites has weight $w_m = \min\{w_1, w_2, w_3, ..., w_c\}$. Analogous to the semi Voronoi diagram case, with this new definition if a cell Δ is marked final in the ith iteration then only its i unweighted nearest sites can contribute to the diagram within Δ. This is because one of these i nearest sites is both closer and has weight less than or equal to any site outside of the i nearest sites. Note also that the probability that k sites are all assigned weight larger than w_m is $(1-1/c)^k$. Using the same notation as in the proof of Theorem 5, we have

$$\begin{aligned}\mathbf{E}\left[Z^{k+1}\right] &= \mathbf{E}\left[\sum_{\Delta_j \in C^k} \#(\Delta_j) \cdot X_j\right] = \sum_{\Delta_j \in C^k} \#(\Delta_j) \cdot \mathbf{E}[X_j] \\ &= O\left((1-1/c)^k\right) \cdot \sum_{\Delta_j \in C^k} \#(\Delta_j) = O\left(nk^3(1-1/c)^k\right).\end{aligned}$$

As the worst-case complexity of the multiplicative Voronoi diagram of k sites is $O(k^2)$, overall the complexity of the multiplicative Voronoi diagram is bounded by $\sum_{k=1}^{n} |F^k| \cdot O(k^2)$. Thus by the above, the expected complexity is

$$\mathbf{E}[|\mathcal{WV}(S)|] \leq \sum_{k=1}^{n} \mathbf{E}\left[|F^k|\right] \cdot O(k^2) \leq \sum_{k=1}^{n} \mathbf{E}\left[Z^k\right] \cdot O(k^2) \leq O\left(\sum_{k=1}^{n} nk^5(1-1/c)^k\right) = O(n \cdot c^6),$$

where the last step is obtained by viewing the sum as a power series in $x = (1 - 1/c)$,

$$\sum_{k>0} k^5(1-1/c)^k = \sum_{k>0} k^5 x^k = \left(x \cdot \frac{d}{dx}\right) \sum_{k>0} k^4 x^k = \left(x \cdot \frac{d}{dx}\right)^5 \sum_{k>0} x^k = \left(x \cdot \frac{d}{dx}\right)^5 \frac{x}{1-x}$$
$$= \frac{(x^5 + 26x^4 + 66x^3 + 26x^2 + x)}{(1-x)^6} = 120c^6 - 360c^5 + 390c^4 - 180c^3 + 31c^2 - c = O(c^6). \quad \blacktriangleleft$$

4.2 Sampling site locations with bounded weights

In this section we argue that the expected complexity of the multiplicative Voronoi diagram is linear when the site locations are uniformly sampled and the weights are in a constant spread interval. In the next section we remove the bounded weight assumption. Thus the current section can be viewed as a warm-up, and serves to illustrate the extent to which assuming bounded weights simplifies the problem. However, as the results of the next section subsume those here, this section can be safely skipped if desired.

The following fact is used both in the proof of the lemma below and the next section.

▶ **Fact 8.** *Consider doing m independent experiments, where the probability of success for each experiment is α. Let X be the total number of times the experiments succeed. Then $\mathbf{E}[X^2] \leq \alpha m + \alpha^2 m^2 = \mathbf{E}[X] + \mathbf{E}[X]^2$.*

Note that the above fact holds since X is a binomial random variable, $Bin(\alpha, m)$, and so $\mathbf{E}[X^2] = \mathbf{Var}[X] + \mathbf{E}[X]^2 = m\alpha(1-\alpha) + (m\alpha)^2$.

▶ **Lemma 9.** *Let $S = \{s_1, s_2, s_3, ..., s_n\}$ be a set of point sites in the plane, where for some value $c \geq 1$, each site in S is assigned a weight $w_i \in [1, c]$. Suppose that the location of each site in S is sampled uniformly at random from the unit square U. Then the expected complexity of the multiplicative Voronoi diagram of S within U is $O(n \cdot c^4)$.*

Proof. Place a regular grid over U, where grid cells have side length $1/\sqrt{n}$. Fix any grid cell $\square = \square_{x,y}$, where $(x, y) \in \sqrt{n} \times \sqrt{n}$. We now argue that the expected complexity of the multiplicative Voronoi diagram within $\square$ is $O(c^4)$, and thus by linearity of expectation, the expected complexity over all n grid cells in U is $O(nc^4)$.

Let ρ be the random variable denoting the unweighted distance of the closest site in S to the center of the grid cell $\square$, and let X_ρ be the random variable denoting the number of points which contribute to the multiplicative Voronoi diagram in $\square$ conditioned on the value ρ. (For now ignore the contribution of the point at distance exactly ρ.) Observe that any point in S which contributes to the multiplicative Voronoi diagram within $\square$ must lie within the annulus centered at the center of $\square$, with inner radius ρ and outer radius $c(\rho + \sqrt{2/n})$. Conditioned on the value ρ, let α_ρ be the probability for a point to fall in this annulus, and let X_ρ be the binomial random variable $Bin(\alpha_\rho, n)$ representing the number of points which fall into this annulus. For now assume $\rho \leq 1/4$, in which case the region outside the disk centered at the center of $\square$ and with radius ρ has area at least $3/4$. We then have that

$$\mathbf{E}[X_\rho] \leq n\alpha_\rho \leq n\frac{(\pi(c(\rho + \sqrt{2/n}))^2 - \pi\rho^2)}{3/4}$$
$$= O(nc^2(\rho^2(1 - 1/c^2) + \rho/\sqrt{n} + 1/n)) = O(c^2 + n(c\rho)^2).$$

Let Y_ρ be the random variable denoting the complexity of the multiplicative Voronoi diagram within $\square$ when conditioned on the value ρ. As the worst-case complexity of the multiplicative Voronoi diagram is quadratic, we have $Y_\rho = O((1+X_\rho)^2) = O(1+X_\rho+X_\rho^2)$, where the plus 1 counts the point at distance exactly ρ. Thus using Fact 8, and again assuming $\rho \leq 1/4$,

$$\mathbf{E}[Y_\rho] = O(1+\mathbf{E}[X_\rho]+\mathbf{E}\left[X_\rho^2\right]) = O(c^2+n(c\rho)^2+(c^2+n(c\rho)^2)^2) = O(c^4(1+n\rho^2+n^2\rho^4)).$$

Now consider the event that $\rho \in [i/\sqrt{n},(i+1)/\sqrt{n}]$ for some integer i. For this to happen, the open disk with radius $i/\sqrt{n}$ centered at the center of $\square$ must be empty, and one of the n points must lie in the annulus with inner radius $i/\sqrt{n}$ and outer radius $(i+1)/\sqrt{n}$. Therefore,

$$\begin{aligned}\mathbf{Pr}\left[\rho \in [i/\sqrt{n},(i+1)/\sqrt{n}]\right] &\leq n\cdot(\pi((i+1)/\sqrt{n})^2-\pi(i/\sqrt{n})^2)\cdot(1-\pi(i/\sqrt{n})^2)^{n-1}\\ &= \pi(2i+1)\cdot(1-\pi i^2/n)^{n-1} \leq \pi(2i+1)e^{-\pi i^2(n-1)/n} \leq \pi(2i+1)e^{-i^2}.\end{aligned}$$

Furthermore, by the above, when $\rho \in [i/\sqrt{n},(i+1)/\sqrt{n}]$ and $\rho \leq 1/4$, we have

$$\mathbf{E}[Y_\rho] = O(c^4(1+n\rho^2+n^2\rho^4)) = O(c^4(1+(i+1)^2+(i+1)^4)),$$

and for $\rho \geq 1/4$ we have the trivial bound $\mathbf{E}[Y_\rho] = O(n^2)$.

Finally, let Y be the random variable denoting the complexity of the multiplicative Voronoi diagram within $\square$. By the law of total expectation we have,

$$\begin{aligned}\mathbf{E}[Y] &\leq \left(\sum_{i=0}^{\sqrt{n}/4-1}\mathbf{Pr}\left[\rho\in\left[\frac{i}{\sqrt{n}},\frac{(i+1)}{\sqrt{n}}\right]\right]\cdot O(c^4(1+(i+1)^2+(i+1)^4))\right)\\ &\quad+\left(\sum_{i=\sqrt{n}/4}^{\sqrt{n}}\mathbf{Pr}\left[\rho\in\left[\frac{i}{\sqrt{n}},\frac{(i+1)}{\sqrt{n}}\right]\right]\cdot O(n^2)\right)\\ &\leq \left(\sum_{i=0}^{\sqrt{n}/4-1}\frac{\pi(2i+1)}{e^{i^2}}\cdot O(c^4(1+(i+1)^2+(i+1)^4))\right)+\left(\sum_{i=\sqrt{n}/4}^{\sqrt{n}}\frac{\pi(2i+1)}{e^{i^2}}\cdot O(n^2)\right)\\ &= O(1)+\sum_{i=0}^{\sqrt{n}/4-1}\frac{\pi(2i+1)}{e^{i^2}}\cdot O(c^4(1+(i+1)^2+(i+1)^4))\\ &= O(1)+\sum_{i=0}^{\sqrt{n}/4}\frac{2i+1}{e^{i^2}}\cdot O(c^4(i+1)^4) = O(c^4)+O\left(\sum_{i=1}^{\sqrt{n}/4}\frac{c^4i^5}{e^{i^2}}\right) = O(c^4).\end{aligned}$$

◀

4.3 Sampling sites locations in general

In this section we argue that the expected complexity of the multiplicative Voronoi diagram is linear when the site locations are uniformly sampled. Here the weights can be any arbitrary set of positive values. Without loss of generality we can assume the smallest weight is exactly 1, as dividing all weights by the same positive constant does not change the diagram. Throughout, m denotes the maximum site weight, hence all weights are in the interval $[1,m]$.

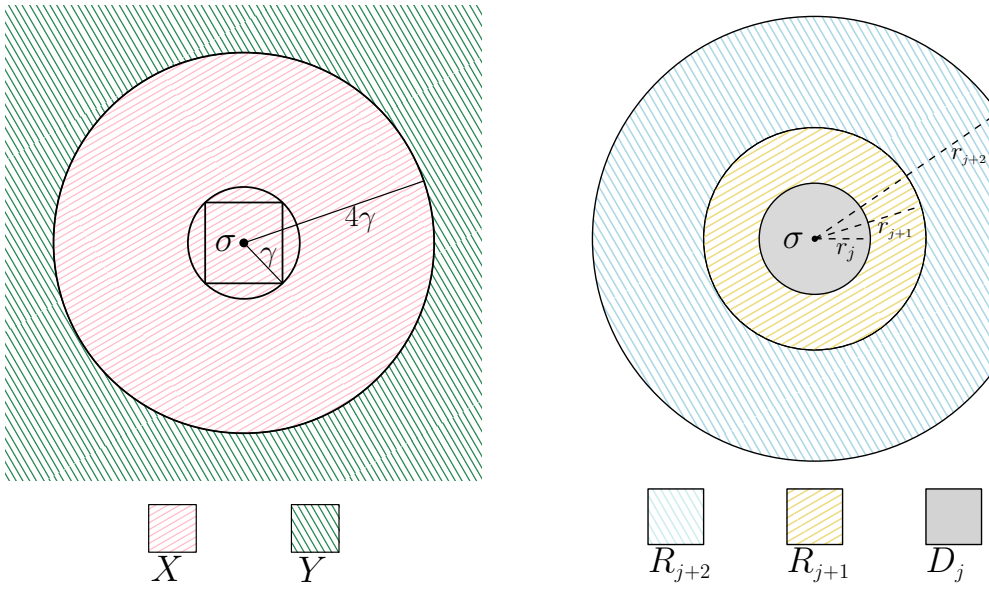
Let σ be an arbitrary point in the unit square. The high level idea is that we want to apply a transformation to the sites such that the weighted Voronoi diagram around σ can be interpreted as an unweighted Voronoi diagram. Specifically, for a site s with weight w and distance $d = ||s-\sigma||$, let the *stretched site* of s with respect to σ, denoted by t, be the point at Euclidean distance $w\cdot d$ from σ which lies on the ray from σ through s. That is, the weighted distance from s to σ is the same as the unweighted distance from t to σ.

So let σ be an arbitrary fixed point in the unit square, $S = \{s_1, \ldots, s_n\}$ be a set of sites with weights $\{w_1, \ldots, w_n\} \subset [1, m]$ whose positions have been uniformly sampled from the unit square, and let $T = \{t_1, \ldots, t_n\}$ be the corresponding set of stretched sites.

Let $\gamma = \sqrt{1/(2n)}$. Our goal is to argue that for any arbitrary choice of σ in U the expected complexity of the multiplicative Voronoi diagram in the ball $B(\sigma, \gamma)$ is constant, i.e., $\mathbf{E}[|\mathcal{WV}(S) \cap B(\sigma, \gamma)|] = O(1)$. Then by the grid argument in the previous section this immediately implies a linear bound on the expected complexity of the overall diagram in U. Namely, place a uniform grid over U, where the grid cell side length is $1/\sqrt{n}$. Then as each cell is contained in a ball $B(\sigma, \gamma)$ for some σ, and there are n cells overall, by the linearity of expectation the expected complexity of the overall diagram is $O(n)$.

At a high level, the idea is simple. We wish to argue that sites whose stretched location is far from σ will be blocked from contributing by sites whose stretched location is closer to σ. However, putting this basic plan into action is tricky and requires handling various edge cases. In particular, later it will become clear why we need to consider the following cases for where sites lie relative to σ.

▶ **Definition 10.** *For a fixed point σ in U, let X be the subset of S which falls in $B(\sigma, 4\gamma)$, i.e., $X = S \cap B(\sigma, 4\gamma)$. Let Y be the complement set, i.e., $Y = S \setminus X$. See Figure 4.1.*



(a) Sets X and Y from Definition 10, and the grid cell and γ radius ball centered at σ.

(b) Exponentially increasing radii, and rings R_{j+1}, R_{j+2} around disk D_j, all centered at σ.

Figure 4.1 Pictorial representations of some of the defined quantities from Section 4.3.

▶ Remark 11. In the following, we typically condition on the set of sites which fall in Y as being fixed, but not the actual precise locations of those sites. We refer to this as "Fixing Y". Ultimately the statements below hold regardless of what sites actually fall in Y.

Fix Y. Let r_1 be the radius such that the expected number of stretched sites from Y that are contained in $B(\sigma, r_1)$ is $n \cdot \pi(16\gamma)^2$. Observe that a site can only be moved further from σ after stretching, thus $r_1 \geq 16\gamma$. (Potentially r_1 is significantly larger.) Also, note that as Y is fixed, the value of r_1 is fixed.

For any integer $j > 0$, let D_j be the disk with radius $r_j = r_1 \times 2^{j-1}$, centered at σ. Moreover, define the rings $R_{j+1} = D_{j+1} \setminus D_j$, for any $j > 0$. See Figure 4.1.

▶ **Lemma 12.** *Consider two sites $s_j \in Y$, and s_i such that either $s_i \in Y$ or $s_i \in X$ with $w_i \leq w_j$. For any $k' \geq k \geq 1$, if $t_i \in D_k$ and $t_j \in R_{k'+2}$, then s_j cannot contribute to the multiplicative Voronoi diagram in $B(\sigma, \gamma)$.*

Proof. For site s_i, let $d_i = ||s_i - \sigma||$ and $d'_i = w_i \cdot d_i$. Similarly define d_j and d'_j for site s_j. Note that the furthest weighted distance of a point in $B(\sigma, \gamma)$ to s_i is $w_i \cdot (d_i + \gamma)$, and the closest weighted distance of a point in $B(\sigma, \gamma)$ to s_j is $w_j \cdot (d_j - \gamma)$. Thus it suffices to argue $w_i \cdot (d_i + \gamma) < w_j \cdot (d_j - \gamma)$, or equivalently $(w_i + w_j)\gamma < d'_j - d'_i$. To that end, observe $d'_j - d'_i \geq d'_j - d'_j/2 = d'_j/2$. Thus we only need to argue $(w_i + w_j)\gamma < d'_j/2$.

Case 1, $w_i \leq w_j$: In this case $(w_i + w_j)\gamma \leq w_j \cdot 2\gamma < w_j \cdot d_j/2 = d'_j/2$.

Case 2, $w_i > w_j$: In this case $(w_i + w_j)\gamma \leq w_i \cdot 2\gamma < w_i \cdot d_i/2 = d'_i/2 \leq d'_j/2$. ◀

Note that a site with weight 1 does not move after stretching. Thus as S always has a site with weight 1, there must be at least one stretched site in U. Therefore, if we define $Z - 1$ to be the smallest value of j such that $U \subseteq D_j$, then D_{Z-1} must contain a stretched site. Thus the above lemma implies any site which contributes to the multiplicative Voronoi diagram within $B(\sigma, \gamma)$ must lie within D_Z after being stretched, and so going forward we only consider stretched sites in D_Z.

▶ **Definition 13.** *Fix Y, and consider any $1 \leq j \leq Z - 2$. For $s_i \in Y$, let $p_{i,j}$ denote the probability that t_i is located in D_j. For $s_i \in Y$, let $q_{i,j}$ denote the probability that s_i is located in $U \setminus B(\sigma, 16\gamma)$ and t_i is located in $R_{j+2} \cup R_{j+1}$, conditioned on the event that no stretched sites from Y are located in D_j.*[1]

▶ **Lemma 14.** *Fix Y. For any $1 \leq j \leq Z - 2$ and $s_i \in Y$ we have $q_{i,j} \leq 32 \cdot p_{i,j}$.*

Proof. Note in the following we always take as given that $s_i \in Y$. Observe that

$$p_{i,j} = \mathbf{Pr}[t_i \in D_j] = \mathbf{Pr}[s_i \in U \cap B(\sigma, r_j/w_i)] = \frac{area((U \cap B(\sigma, r_j/w_i)) \setminus B(\sigma, 4\gamma))}{area(U \setminus B(\sigma, 4\gamma))}.$$

Then as the location of the sites in Y are independent, for $q_{i,j}$ we have,

$$\begin{aligned}
q_{i,j} &= \mathbf{Pr}[(s_i \in U \setminus B(\sigma, 16\gamma)) \cap (t_i \in D_{j+2} \setminus D_j) \mid \forall s_k \in Y, t_k \notin D_j] \\
&= \mathbf{Pr}[(s_i \in U \setminus B(\sigma, 16\gamma)) \cap (t_i \in D_{j+2} \setminus D_j) \mid t_i \notin D_j] \\
&= \mathbf{Pr}[(s_i \in U \setminus B(\sigma, 16\gamma)) \cap (t_i \in D_{j+2} \setminus D_j)] \,/\, \mathbf{Pr}[t_i \notin D_j] \\
&= \mathbf{Pr}[s_i \in (U \cap B(\sigma, 4r_j/w_i)) \setminus (B(\sigma, r_j/w_i) \cup B(\sigma, 16\gamma))] \,/\, \mathbf{Pr}[t_i \notin D_j] \\
&\leq \mathbf{Pr}[s_i \in (U \cap B(\sigma, 4r_j/w_i)) \setminus B(\sigma, 16\gamma)] \,/\, \mathbf{Pr}[t_i \notin D_j] \\
&= \frac{area((U \cap B(\sigma, 4r_j/w_i)) \setminus B(\sigma, 16\gamma))}{area(U \setminus B(\sigma, 4\gamma)) \cdot \mathbf{Pr}[t_i \notin D_j]} \leq \frac{16 \cdot area((U \cap B(\sigma, r_j/w_i)) \setminus B(\sigma, 4\gamma))}{area(U \setminus B(\sigma, 4\gamma)) \cdot \mathbf{Pr}[t_i \notin D_j]} \\
&= \frac{16 \cdot p_{ij}}{\mathbf{Pr}[t_i \notin D_j]} = \frac{16 \cdot p_{ij}}{1 - p_{ij}}.
\end{aligned}$$

If $p_{ij} \leq 1/2$, then the above implies $q_{ij} \leq 16 \cdot p_{ij}/(1 - p_{ij}) \leq 32 \cdot p_{ij}$. On the other hand, if $p_{ij} > 1/2$, then $p_{ij} > 1/2 \geq q_{ij}/2$. ◀

▶ **Fact 15.** *Fix Y. For any $1 \leq j \leq Z - 2$, consider the event, C_j, that j is the largest index such that there are no stretched sites from Y located in D_j. We have $\mathbf{Pr}[C_j] \leq \prod_{s_i \in Y}(1 - p_{i,j})$.*

[1] Note for $j \leq Z - 2$, $D_j \subsetneq U$, thus the condition that no stretched sites are in D_j has non-zero probability.

▶ **Lemma 16.** *Fix Y. Let ψ be the number of sites that fall outside $B(\sigma, 16\gamma)$ and contribute to the multiplicative Voronoi diagram within $B(\sigma, \gamma)$. Then we have*

$$\mathbf{E}\big[\psi^2\big] \leq O(1) + 2\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(1+3\sum_{s_i\in Y}q_{i,j}+\left(\sum_{s_i\in Y}q_{i,j}\right)^2\right)\right).$$

Proof. For $1 \leq j \leq Z-2$, let C_j be the event that j is the largest index such that D_j contains no stretched sites from Y. (Note for $i \neq j$, C_i and C_j are disjoint events.) If C_j occurs then only sites in $R_{j+1} \cup R_{j+2}$ can contribute to the weighted diagram in $B(\sigma, \gamma)$, based on Lemma 12. Let y_j be the random variable denoting the number of sites such that $s_i \notin B(\sigma, 16\gamma)$ and $t_i \in R_{j+1} \cup R_{j+2}$. If C_j occurs, then y_j is an upper bound on the number of sites which fall outside $B(\sigma, 16\gamma)$ and contribute to the weighted diagram in $B(\sigma, \gamma)$. Note we must also consider the event that C_j does not occur for any $j \geq 1$, namely there exist stretched sites from Y contained in D_1. Call this event C_0, and let y_0 be the random variable for the number of sites such that $s_i \notin B(\sigma, 16\gamma)$ and $t_i \in D_2$. By the law of total expectation,

$$\mathbf{E}\big[\psi^2\big] = \sum_{j=0}^{Z-2}(\mathbf{Pr}[C_j]\cdot\mathbf{E}\big[(y_j)^2 \mid C_j\big]),$$

where the sum stops at $Z-2$ since there always exists a stretched site with weight 1 in D_{Z-1} (by definition of Z), and so stretched sites outside of D_Z can be ignored.

So consider any $\mathbf{E}\big[(y_j)^2 \mid C_j\big]$ term, for some $j > 0$. Let A_j be the event that D_j contains no stretched sites from Y and let B_j be the event that R_{j+1} has a stretched site from Y, and observe that $C_j = A_j \cap B_j$. The following claim is intuitive, and its proof is in Appendix A.

▷ Claim 17. $\mathbf{E}\big[y_j^2 \mid C_j\big] \leq 2\,\mathbf{E}\big[(y_j+1)^2 \mid A_j\big]$.

The events, over all $s_i \in Y$, that s_i falls outside $B(\sigma, 16\gamma)$ while t_i is located in $R_{j+1} \cup R_{j+2}$, are independent. Moreover, this event for any $s_i \in Y$, when conditioned on A_j, has probability $q_{i,j}$ (see Definition 13). Hence conditioned on A_j, the random variable y_j has a Poisson Binomial distribution. Thus we have $\mathbf{E}[y_j \mid A_j] = \sum_{s_i\in Y}(q_{i,j})$, and the variance is then $\mathbf{Var}[y_j \mid A_j] = \sum_{s_i\in Y}(q_{i,j}(1-q_{i,j})) \leq \sum_{s_i\in Y}(q_{i,j}) = \mathbf{E}[y_j \mid A_j]$. Thus using the above claim,

$$\begin{aligned}\mathbf{E}\big[(y_j)^2 \mid C_j\big] &\leq 2\,\mathbf{E}\big[(y_j+1)^2 \mid A_j\big] = 2\,\mathbf{E}\big[1+2y_j+y_j^2 \mid A_j\big]\\ &= 2(1+2\,\mathbf{E}[y_j \mid A_j] + (\mathbf{Var}[y_j \mid A_j] + (\mathbf{E}[y_j \mid A_j])^2))\\ &\leq 2(1+3\,\mathbf{E}[y_j \mid A_j] + (\mathbf{E}[y_j \mid A_j])^2) \leq 2\left(1+3\sum_{s_i\in Y}q_{i,j}+\left(\sum_{s_i\in Y}q_{i,j}\right)^2\right).\end{aligned}$$

Suppose that $\mathbf{Pr}[C_0]\cdot\mathbf{E}\big[(y_0)^2|C_0\big] = O(1)$, then the lemma statement follows. Specifically, by Fact 15, $\mathbf{Pr}[C_j] \leq \prod_{s_i\in Y}(1-p_{i,j})$, for any $1 \leq j \leq Z-2$. Thus by the above,

$$\begin{aligned}\mathbf{E}\big[\psi^2\big] &= \sum_{j=0}^{Z-2}(\mathbf{Pr}[C_j]\cdot\mathbf{E}\big[(y_j)^2 \mid C_j\big])\\ &\leq O(1) + 2\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(1+3\sum_{s_i\in Y}q_{i,j}+\left(\sum_{s_i\in Y}q_{i,j}\right)^2\right)\right).\end{aligned}$$

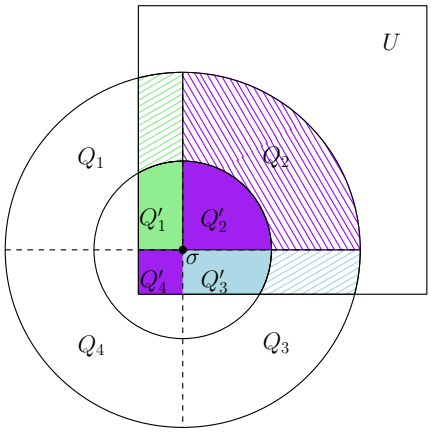


Figure 4.2 The locations of the four defined quarters for each disk, and how they intersect U.

Thus what remains is to show $\mathbf{Pr}[C_0] \cdot \mathbf{E}\left[(y_0)^2 | C_0\right] = O(1)$. First, observe that

$$\mathbf{Pr}[C_0]\,\mathbf{E}\left[(y_0)^2|C_0\right] = \mathbf{Pr}[C_0] \sum_{k=1}^{|Y|^2} k \cdot \mathbf{Pr}\left[(y_0)^2 = k | C_0\right] = \mathbf{Pr}[C_0] \sum_{k=1}^{|Y|^2} \frac{k \cdot \mathbf{Pr}\left[((y_0)^2 = k) \cap C_0\right]}{\mathbf{Pr}[C_0]}$$
$$= \sum_{k=1}^{|Y|^2} k \cdot \mathbf{Pr}\left[((y_0)^2 = k) \cap C_0\right] \leq \sum_{k=1}^{|Y|^2} k \cdot \mathbf{Pr}\left[(y_0)^2 = k\right] = \mathbf{E}\left[(y_0)^2\right].$$

Thus it suffices to argue $\mathbf{E}\left[(y_0)^2\right] = O(1)$.

For any $s_i \in Y$, let $q_{i,0}$ denote the probability that $s_i \notin B(\sigma, 16\gamma)$ while $t_i \in D_2$, then $\mathbf{E}[y_0] = \sum_{s_i \in Y} q_{i,0}$. Note that as $area(B(\sigma, r_2/w_i) \setminus B(\sigma, 16\gamma)) \leq 4 \cdot area(B(\sigma, r_1/w_i) \setminus B(\sigma, 4\gamma))$ it follows that $area((U \cap B(\sigma, r_2/w_i)) \setminus B(\sigma, 16\gamma)) \leq 4 \cdot area((U \cap B(\sigma, r_1/w_i)) \setminus B(\sigma, 4\gamma))$. This implies $q_{i,0} \leq 4 \cdot p_{i,1}$, and hence $\sum_{s_i \in Y} q_{i,0} \leq 4 \sum_{s_i \in Y} p_{i,1} = 4 \cdot n\pi(16\gamma)^2 = O(1)$, by the definition of r_1. Thus $\mathbf{E}[y_0] = O(1)$, and since y_0 has a Poisson Binomial distribution, $\mathbf{E}\left[(y_0)^2\right] = (\mathbf{E}[y_0])^2 + \mathbf{Var}[y_0] \leq (\mathbf{E}[y_0])^2 + \mathbf{E}[y_0] = O(1)$. ◀

▶ **Lemma 18.** *Let $P_j = \sum_{s_i \in Y} p_{i,j}$. Then for any $j \leq Z - 3$, we have $P_j \geq P_{j-1} + 1$.*

Proof. Note that by definition, the expected number of stretched sites from Y that are contained in $B(\sigma, r_1)$ is $n\pi(16\gamma)^2 > 2$, and thus $P_1 = (\sum_{s_i \in Y} p_{i,1}) > 2$.

We argue that for any $j \leq Z - 3$, that $area(U \cap D_j) \geq 2 \cdot area(U \cap D_{j-1})$. To this end, break D_j into 4 quarters, by cutting it with a vertical and horizontal line through σ. Let the quarters be labeled Q_1, Q_2, Q_3, and Q_4, in clockwise order, starting with the northwest quarter, see Figure 4.2. Similarly break D_{j-1} into quarters, Q'_1, Q'_2, Q'_3, and Q'_4, with the same clockwise labeling order. Recall that by definition $Z - 1$ is the smallest j such that $U \subseteq D_j$. Since $\sigma \in U$, this implies that for any $j \leq Z - 3$ at least one of the quarters of D_j is fully contained in U, and without loss of generality assume it is Q_2. Note that $area(D_j) = 4area(D_{j-1})$, thus this implies that $area(U \cap Q_2) = area(Q_2) = 2(area(Q'_2) + area(Q'_4)) \geq 2(area(U \cap Q'_2) + area(U \cap Q'_4))$. It is easy to argue that since $r_j = 2r_{j-1}$ that $area(U \cap Q_1) \geq 2area(U \cap Q'_1)$ and $area(U \cap Q_3) \geq 2area(U \cap Q'_3)$, thus summing over all quarters $area(U \cap D_j) \geq 2 \cdot area(U \cap D_{j-1})$.

This implies that $area(U \cap B(\sigma, r_j/w_i)) \geq 2 \cdot area(U \cap B(\sigma, r_{j-1}/w_i))$, which in turn implies $area((U \cap B(\sigma, r_j/w_i)) \setminus B(\sigma, 4\gamma)) \geq 2 \cdot area((U \cap B(\sigma, r_{j-1}/w_i)) \setminus B(\sigma, 4\gamma))$. Hence by Definition 13, $p_{i,j} \geq 2p_{i,j-1}$, and therefore $P_j \geq 2P_{j-1} \geq P_{j-1} + 1$. ◀

▶ **Lemma 19.** $\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(1+3\sum_{s_i\in Y}q_{i,j}+\left(\sum_{s_i\in Y}q_{i,j}\right)^2\right)\right)=O(1).$

Proof. We argue that $\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(\sum_{s_i\in Y}q_{i,j}\right)^{\alpha}\right)=O(1)$, where $\alpha=0$, 1, or 2, thus implying the lemma statement. By Lemma 14, $q_{i,j}\leq 32\cdot p_{i,j}$, and therefore

$$\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(\sum_{s_i\in Y}q_{i,j}\right)^{\alpha}\right)\leq\sum_{j=1}^{Z-2}\left(\left(\prod_{s_i\in Y}(1-p_{i,j})\right)\cdot\left(32\sum_{s_i\in Y}p_{i,j}\right)^{\alpha}\right)$$
$$\leq 32^{\alpha}\sum_{j=1}^{Z-2}\left(\left(e^{-\sum_{s_i\in Y}p_{i,j}}\right)\cdot\left(\sum_{s_i\in Y}p_{i,j}\right)^{\alpha}\right)=32^{\alpha}\sum_{j=1}^{Z-2}\left(\left(e^{-P_j}\right)\cdot\left(P_j\right)^{\alpha}\right),$$

where the last inequality follows as $1-x\leq e^{(-x)}$, and the last equality is by the definition of P_j from the Lemma 18 statement.

Note that by definition, the expected number of stretched sites from Y that are contained in $B(\sigma,r_1)$ is $n\pi(16\gamma)^2$, and thus $P_1=(\sum_{s_i\in Y}p_{i,1})>2$. Moreover, the function $x^{\alpha}e^{-x}$ is monotonically decreasing for $x>2$, and always has value less than 1, for $\alpha=0,1,$ or 2. Thus since by Lemma 18, $P_j\geq P_{j-1}+1$ for $j\leq Z-3$, and since $P_{Z-2}\geq P_{Z-3}$, we have,

$$\sum_{j=1}^{Z-2}P_j^{\alpha}\cdot e^{-P_j}\leq 1+\sum_{j=1}^{Z-3}P_j^{\alpha}\cdot e^{-P_j}\leq 1+\sum_{x=2}^{\infty}x^{\alpha}\cdot e^{-x}\leq 2+\int_2^{\infty}x^{\alpha}\cdot e^{-x}dx\leq 4,$$

for $\alpha=0,1,$ or 2. Combining the above two equalities thus yields the lemma statement. ◀

Now that we have the above lemmas for any fixed Y, we are finally ready to prove our main lemma (where Y is no longer assumed to be fixed).

▶ **Lemma 20.** *Let S be a set of n point sites in the plane, with arbitrary positive weights. Suppose that the location of each site in S is sampled uniformly at random from the unit square U. Then for any point $\sigma\in U$, $\mathbf{E}[|\mathcal{WV}(S)\cap B(\sigma,\gamma)|]=O(1)$.*

Proof. Let $\hat{\Psi}=S\cap B(\sigma,16\gamma)$ be the sites which fall in $B(\sigma,16\gamma)$ and let $\Psi=S\setminus\hat{\Psi}$ be the complement set. Let $\hat{\psi}$, ψ, be the random variables denoting the number of sites respectively from $\hat{\Psi}$, Ψ, which contribute to the multiplicative diagram in $B(\sigma,\gamma)$.

Recall that the worst-case complexity of the multiplicative diagram is quadratic in the number of sites. Thus it suffices to bound $\mathbf{E}\left[(\hat{\psi}+\psi)^2\right]\leq\mathbf{E}\left[2(\hat{\psi}^2+\psi^2)\right]=2(\mathbf{E}\left[\hat{\psi}^2\right]+\mathbf{E}\left[\psi^2\right])$. Thus we now show each of the above two expected value terms are constant. First, note that Lemma 16 and Lemma 19 combined imply that $\mathbf{E}\left[\psi^2\right]=O(1)$ (as those lemmas hold regardless of which sites fall in Y). Thus we only need to bound $\mathbf{E}\left[\hat{\psi}^2\right]$. Observe that clearly $|\hat{\Psi}|\geq\hat{\psi}$. To bound $|\hat{\Psi}|$, observe that $area(B(\sigma,16\gamma))=O(1/n)$, and thus $\mathbf{E}\left[|\hat{\Psi}|\right]=O(1)$. Moreover, the number of sites which fall into this ball is a binomial random variable. Thus by Fact 8, $\mathbf{E}\left[\hat{\psi}^2\right]\leq\mathbf{E}\left[|\hat{\Psi}|^2\right]\leq\mathbf{E}\left[|\hat{\Psi}|\right]+\mathbf{E}\left[|\hat{\Psi}|\right]^2=O(1)$. ◀

Consider placing a uniform grid with side length $1/\sqrt{n}$ over the unit square U. Then for any grid cell, if we set σ to be the center of the grid cell then $B(\sigma,\gamma)$ contains the grid cell, and hence the above lemma implies the expected complexity in the grid cell is constant. Thus using linearity of expectation over all n grid cells implies the following main theorem.

▶ **Theorem 21.** *Let S be a set of n point sites in the plane, with arbitrary positive weights. Suppose the location of each site in S is sampled uniformly at random from the unit square U. Then the expected complexity of the multiplicative Voronoi diagram of S within U is $O(n)$.*

A Claim Proof

Here we prove the claim from Lemma 16. Below is the restated claim.

▷ Claim 17. $\mathbf{E}\left[y_j^2 \mid C_j\right] \leq 2\,\mathbf{E}\left[(y_j+1)^2 \mid A_j\right]$.

Proof. Let y_j and $C_j = A_j \cap B_j$ be as defined in the proof of Lemma 16. Throughout j is fixed and so we drop the j subscripts. Thus we must prove $\mathbf{E}\left[y^2|A \cap B\right] \leq 2\,\mathbf{E}\left[(y+1)^2|A\right]$.

As the conditioning on A appears in all terms, for simplicity of exposition we write that we want to show $\mathbf{E}\left[y^2|B\right] \leq 2\,\mathbf{E}\left[(y+1)^2\right]$ where the conditioning on A is implicit.

Note that $y = y' + y''$, where y' is the number of stretched sites falling in R_{j+1} and y'' the number falling in R_{j+2}. Moreover, $(y'+y'')^2 \leq 2((y')^2 + (y'')^2)$.

▶ **Lemma 22.** $\mathbf{E}\left[(y'')^2 \mid y' \neq 0\right] \leq \mathbf{E}\left[(y'')^2\right]$.

Proof. Let $\alpha = \mathbf{E}\left[(y'')^2 \mid y' = 0\right]$ and $\beta = \mathbf{E}\left[(y'')^2 \mid y' \neq 0\right]$. It is easy to verify that $\alpha = \mathbf{E}\left[(y'')^2 \mid y' = 0\right] \geq \mathbf{E}\left[(y'')^2\right]$. Now, observe that

$$\begin{aligned}\mu = \mathbf{E}\left[(y'')^2\right] &= \mathbf{E}\left[(y'')^2 \mid y' = 0\right]\mathbf{Pr}[y' = 0] + \mathbf{E}\left[y''^2 \mid y' \neq 0\right]\mathbf{Pr}[y' \neq 0] \\ &= \alpha\,\mathbf{Pr}[y' = 0] + \beta(1 - \mathbf{Pr}[y' = 0]).\end{aligned}$$

Namely, μ is a convex combination of α and β, and since $\alpha \geq \mu$, it must be that $\beta \leq \mu$, as claimed. ◀

As $B = (y' \neq 0)$, by the above lemma and linearity of expectation we have

$$\mathbf{E}\left[y^2 \mid B\right] \leq 2\,\mathbf{E}\left[(y')^2 \mid y' \neq 0\right] + 2\,\mathbf{E}\left[(y'')^2 \mid y' \neq 0\right] \leq 2\,\mathbf{E}\left[(y')^2 \mid y' \neq 0\right] + 2\,\mathbf{E}\left[(y'')^2\right].$$

Observe that $2\,\mathbf{E}\left[(y'+1)^2\right] + 2\,\mathbf{E}\left[(y'')^2\right] \leq 2\,\mathbf{E}\left[(y+1)^2\right]$. Thus if we can prove that $\mathbf{E}\left[(y')^2 \mid y' \neq 0\right] \leq \mathbf{E}\left[(y'+1)^2\right]$, then the above implies that $\mathbf{E}\left[y^2 \mid B\right] \leq 2\,\mathbf{E}\left[(y+1)^2\right]$ as claimed.

So to prove $\mathbf{E}\left[(y')^2 \mid y' \neq 0\right] \leq \mathbf{E}\left[(y'+1)^2\right]$, note that $(y' \neq 0) = \cup_i X_i$, where X_i is the event that the ith stretched site is in R_{j+1}. Thus,

$$\begin{aligned}E[(y')^2 \mid y' \neq 0] = &E[(y')^2 \mid X_1] \cdot Pr[X_1] + E[(y')^2 \mid \overline{X_1} \cap X_2] \cdot Pr[\overline{X_1} \cap X_2] + \ldots \\ &+ E[y'^2 \mid \overline{X_1} \cap \ldots \cap \overline{X_{n-1}} \cap X_n] \cdot Pr[\overline{X_1} \cap \ldots \cap \overline{X_{n-1}} \cap X_n] \\ &+ E[(y')^2 \mid \overline{X_1} \cap \ldots \cap \overline{X_n}] \cdot Pr[\overline{X_1} \cap \ldots \cap \overline{X_n}].\end{aligned}$$

Note the last term above is zero and can be ignored. Also note that

$$Pr[X_1] + Pr[\overline{X_1} \cap X_2] + \ldots + Pr[\overline{X_1} \cap \ldots \cap \overline{X_{n-1}} \cap X_n] + Pr[\overline{X_1} \cap \ldots \cap \overline{X_n}] = 1.$$

Thus the claim follows if we can argue that each expectation in the above sum is upper bounded by $E[(y'+1)^2]$. So consider any term $E[(y')^2 \mid \overline{X_1} \cap \ldots \cap \overline{X_{k-1}} \cap X_k]$. Let z be the number of sites from $\{p_{k+1} \ldots p_n\}$ falling in R_{j+1}. Then since the points were sampled independently we have

$$\begin{aligned}E[(y')^2 \mid \overline{X_1} \cap \ldots \cap \overline{X_{k-1}} \cap X_k] &\leq E[(z+1)^2 \mid \overline{X_1} \cap \ldots \cap \overline{X_{k-1}} \cap X_k] \\ &\leq E[(z+1)^2] \leq E[(y'+1)^2].\end{aligned}$$ ◁

B Complexity Sketch

Here we give a very brief description of why the order-k sequence Voronoi diagram has $O(nk^3)$ worst-case complexity. First, recall that by standard lifting, the regular order-k diagram is described by the exact kth level in the arrangement of hyperplanes tangent to the unit paraboloid. Since we care about the ordering of the k sites, we are instead concerned with the at most k level. There is a shallow cutting covering the at most k level with $O(n/k)$ vertical prisms each intersecting $O(k)$ planes [16]. Each prism projects to a triangle in the plane, and thus within this triangle only $O(k)$ sites (corresponding to the planes intersecting the prism) are relevant. Note that $O(k)$ sites can define at most $O(k^4)$ different orderings as they define $O(k^2)$ bisectors and the the arrangment of these bisectors has $O(k^4)$ complexity. Thus the plane is covered by $O(n/k)$ triangles within which the order-k sequence Voronoi diagram has $O(k^4)$ complexity, and thus in total the complexity is $O(nk^3)$.

We remark that for the purposes of this paper an $O(nk^5)$ bound would have sufficed, and is trivial to obtain. Namely, the worst case complexity of the regular order-k diagram is $O(nk)$, and by the same argument, within each cell there can be at most $O(k^4)$ orderings.

Polynomial Time Approximation Schemes for Clustering in Low Highway Dimension Graphs

Abstract

We study clustering problems such as k-Median, k-Means, and Facility Location in graphs of low highway dimension, which is a graph parameter modeling transportation networks. It was previously shown that approximation schemes for these problems exist, which either run in quasi-polynomial time (assuming constant highway dimension) [Feldmann et al. SICOMP 2018] or run in FPT time (parameterized by the number of clusters k, the highway dimension, and the approximation factor) [Becker et al. ESA 2018, Braverman et al. 2020]. In this paper we show that a polynomial-time approximation scheme (PTAS) exists (assuming constant highway dimension). We also show that the considered problems are NP-hard on graphs of highway dimension 1.

1 Introduction

Clustering is a standard optimization task that seeks a "good" partition of a metric space, such that two points that are "close" should be in the same part. A good clustering of a dataset allows to retrieve and exploit data, and is therefore a common routine in data analysis. The underlying data can come from various sources and represent many different objects. In particular, it is often interesting to cluster geographic data. In that case, the metric space can be given by a transportation network, which can be modeled by graphs with low highway dimension.

In this article, we study some popular clustering objectives, namely Facility Location, k-Median, and k-Means, in graphs with constant highway dimension. The two latter problems seek to find a set S of k points called *centers* in a metric (V, dist) that minimizes $\sum_{v\in V}(\min_{f\in S}\mathrm{dist}(v,f))^p$, with $p=1$ for k-Median and $p=2$ for k-Means. The objective for Facility Location is slightly different: each point f of the metric space has an *opening cost* w_f, and the goal is to find a set S that minimizes $\sum_{f\in S} w_f + \sum_{v\in V}\min_{f\in S}\mathrm{dist}(v,f)$. These problems are APX-hard in general metric spaces [4].

To bypass the hardness of approximation known for these problems, researchers have considered low dimensional input, such as Euclidean spaces of fixed dimension, metrics with bounded doubling dimension, or with bounded genus. Many algorithmic tools were developed

for that purpose: in their seminal work, Arora et al. [3] gave the first polynomial time approximation scheme (PTAS) for k-Median in $\mathbb{R}^2$, which generalizes to a quasi-polynomial time approximation scheme (QPTAS) in $\mathbb{R}^d$ for fixed d. This result was generalized by Talwar [20], who gave a QPTAS for metrics with bounded doubling dimension, and more recently by Cohen-Addad et al. [10], who gave a near-linear time approximation scheme.

In this work we focus on transportation networks, for which it can be argued that metric spaces with bounded doubling dimension are not a suitable model: for instance, hub-and-spoke networks seen in air traffic networks do not have low doubling dimension. Therefore we study graphs with constant *highway dimension*, which formalize structural properties of such networks. The following definition is taken from Feldmann et al. [14]. Here the *ball* $\beta_v(r)$ of radius r around $v \in V$ is the set of all vertices at distance at most r from v.

▶ **Definition 1.** *The* highway dimension *of a graph G is the smallest integer h such that, for some universal constant $c > 4$, for every $r \in \mathbb{R}^+$, and every ball $\beta_v(cr)$ of radius cr, there are at most h vertices in $\beta_v(cr)$ hitting all shortest paths of length more than r that lie in $\beta_v(cr)$.*

For this class of graphs, the only known approximation algorithms for clustering that compute $(1+\varepsilon)$-approximations for any $\varepsilon > 0$ either run in quasi-polynomial time, i.e., QPTASs [14], or with runtime $f(h,k,\varepsilon) \cdot n$ for some exponential function f, i.e., parameterized approximation schemes [6, 8]. Thus an open problem is to identify polynomial-time approximation schemes (PTASs) for clustering in graphs of constant highway dimension.

1.1 Our results

Our main result is a PTAS for clustering problems on graphs of constant highway dimension. For convenience, we define slightly more general problems than those stated above. The k-Clustering^q problem is defined as follows. An instance $\mathcal{I}$ consists of a metric (V, dist), a set of *facilities* (or *centers*) $F \subseteq V$, and a *demand function* $\chi : V \to \mathbb{N}_0$. The goal is to find a set $S \subseteq F$ with $|S| \leq k$ minimizing $\sum_{v \in V} \chi(v) \cdot \min_{f \in S} \mathrm{dist}(v,f)^q$. We call all vertices $v \in V$ with $\chi(v) > 0$ the *clients* of $\mathcal{I}$. k-Median and k-Means are special cases of k-Clustering^q, where $q = 1$ and $q = 2$.

The input to the Facility Location^q problem is the same as for k-Clustering^q, but additionally each facility $f \in F$ has an *opening cost* $w_f \in \mathbb{R}^+$. The goal is to find a set $S \subseteq F$ minimizing $\sum_{f \in S} w_f + \sum_{v \in V} \chi(v) \cdot \min_{f \in S} \mathrm{dist}(v,f)^q$. Facility Location is a special case of Facility Location^q, where $q = 1$.

Our main theorem is the following, where $X = \max_{v \in V} \chi_{\mathcal{I}}(v)$ is the largest demand (note that for k-Median, k-Means, or Facility Location we typically have $X = 1$).

▶ **Theorem 2.** *For any $\varepsilon > 0$, a $(1+\varepsilon)$-approximation for k-Clustering^q and Facility Location^q can be computed in $(nX)^{(hq/\varepsilon)^{O(q)}}$ time on graphs of highway dimension h.*

In particular, this algorithm is much faster than the quasi-polynomial time approximation scheme of Feldmann et al. [14] for k-Median or Facility Location. The runtime of our algorithm also significantly improves over the exponential dependence on k in the approximation schemes of Becker et al. [6], Braverman et al. [8] for k-Median.

It has so far been open whether these clustering problems are NP-hard on graphs of constant highway dimension. We complement our main theorem by showing that they are NP-hard even for the smallest possible highway dimension. This answers an open problem given in [14]. Here the *uniform* Facility Location^q problem has unit opening costs for all facilities.

▶ **Theorem 3.** *The k-Clustering^q and uniform Facility Location^q problems are NP-hard on graphs of highway dimension* 1.

1.2 Related work

On clustering problems. The problems we focus on in this article are known to be APX-hard, even in Euclidean spaces (see e.g. [4]). In general metric spaces, the current best polynomial-time algorithm for Facility Location achieves a 1.488-approximation [19], while the best approximation factor is 2.67 for k-Median ([9]) and 6.357 for k-Means [2].

When restricting the class of graphs, a near-linear time approximation scheme for doubling metrics was developed in [10]; we will discuss the close relations between our work and this one in Section 1.3. Local search techniques also yield a PTAS in minor-free graphs or with bounded doubling dimension [11, 15], and a $\Theta(q)$-approximation for the k-Clustering^q problem in general metric spaces [17].

Another technique for dealing with clustering problems is to compute *coresets*, a compressed representation of the input. An ε-coreset is a weighted set of points such that for every set of centers, the cost for the original set of points is within a $(1+\varepsilon)$-factor of the cost for the coreset. Braverman et al. [8] recently proved that graphs with highway dimension h admit coreset of size $\widetilde{O}((k+h)^{O(1/\varepsilon)})$. This enables to compute a $(1+\varepsilon)$-approximation by enumerating all possible solutions of the coreset. However, this coreset does not have small highway dimension,[1] and thus cannot be used to boost our algorithms.

On highway dimension. The highway dimension was originally defined by Abraham et al. [1], who specifically chose balls of radius $4r$ in the Definition 1. Since the original definition in [1], several other definitions have been proposed. In particular, Feldmann et al. [14] proved that when choosing a radius cr in Definition 1 for any constant c strictly larger than 4, it is possible to exploit the structure of graphs with constant highway dimension in order to obtain a QPTAS for problems such as TSP, Facility Location, and Steiner Tree. As Abraham et al. [1] point out, the choice of the constant is somewhat arbitrary, and we use the above definition so that we may exploit the structural insights of [14] for our algorithm. These structural properties were also leveraged by Becker et al. [6] who gave a PTAS for the Bounded-Capacity Vehicle Routing problem, and a parameterized approximation scheme for the k-Center problem (which is essentially k-Clustering^q with $q=\infty$) and k-Median. In the lower bound side, Disser et al. [12] showed that Steiner Tree and TSP are weakly NP-hard even when the highway dimension is 1, i.e., each of them is NP-hard but an FPTAS exists for graphs of highway dimension 1.

It is worth mentioning that further definitions of the highway dimension exist (for a detailed discussion see [7, 14]). In particular, for a more general definition of the highway dimension than the one of Definition 1, Feldmann [13] gave a parameterized 3/2-approximation algorithm with runtime $2^{O(kh\log h)}n^{O(1)}$ for k-Center.

1.3 Our techniques

To obtain Theorem 2, we rely on the framework recently developed by Cohen-Addad et al. [10] for doubling metrics. More precisely, they show that the *split-tree decomposition* of Talwar [20] has some interesting properties, and exploit them to design their algorithm.

[1] Indeed, a subset of a metric with small highway dimension does not necessarily have small highway dimension as well: think of a star metric on which the center is removed.

Our main contribution is to provide a decomposition with similar properties in graphs with constant highway dimension. This is done relying on some structural properties of such graphs presented by Feldmann et al. [14]. We start by giving the outline of the algorithm from [10], and then explain how to carry the results over to the highway dimension setting.

On doubling metrics. The starting point of many approximation algorithms for doubling metrics is a decomposition of the metric, as presented in the following lemma.[2] A *hierarchical decomposition* $\mathcal{D}$ of a metric (V, dist) is a set of partitions $\mathcal{B}_0, \mathcal{B}_1, \ldots, \mathcal{B}_\lambda$, where $\mathcal{B}_i$ refines $\mathcal{B}_{i+1}$, i.e., every part $B \in \mathcal{B}_i$ is contained in some part of $\mathcal{B}_{i+1}$. Moreover, in $\mathcal{B}_0$ every part contains a singleton vertex, while $\mathcal{B}_\lambda$ contains only one part, namely V. For a point $v \in V$ and a radius $r > 0$, we say that the ball $\beta_v(r)$ is *cut at level* i if i is the largest integer for which the ball $\beta_v(r)$ is not contained in a single part of $\mathcal{B}_i$. For any subset $W \subseteq V$ we define $\lambda(W) = \lceil \log_2 \mathrm{diam}(W) \rceil$.

▶ **Lemma 4** (Reformulation of [20, 5] as found in [10]). *For any metric (V, dist) of doubling dimension d and any $\rho > 0$, there exists a polynomial-time computable randomized hierarchical decomposition $\mathcal{D} = \{\mathcal{B}_0, \ldots, \mathcal{B}_{\lambda(V)}\}$ such that:*

1. ***Scaling probability**: for any $v \in V$, radius r, and level i, we have $\Pr[\mathcal{D} \text{ cuts } \beta_v(r) \text{ at level } i] \leq 2^{O(d)} \cdot r/2^i$.*
2. ***Portal set:** every part $B \in \mathcal{B}_i$ where $\mathcal{B}_i \in \mathcal{D}$ comes with a set of* portals $P_B \subseteq B$ *that is*
   a. ***concise:** the size of the portal set is bounded by $|P_B| \leq 1/\rho^d$, and*
   b. ***precise:** for every node $u \in B$ there is a portal $p \in P_B$ with $\mathrm{dist}(u, p) \leq \rho 2^{i+1}$.*

We sketch briefly the standard use of this decomposition. For clustering problems, one can show that there exists a *portal-respecting solution* with near-optimal cost (see Talwar [20]). In this structured solution, each client connects to a facility via a *portal-respecting path* that enters and leaves any part B of $\mathcal{D}$ only through a node of the portal set P_B. Those portals therefore act as separators of the metric. A standard dynamic program approach can then compute the best portal respecting solution.

To ensure that there is a portal-respecting solution with near-optimal cost, one uses the preciseness property of the portal set: the distortion of connecting a client c with a facility f through portals instead of directly is bounded as follows. Let i be the level at which $\mathcal{D}$ *cuts* c and f, meaning that i is the maximum integer for which c and f lie in different parts of $\mathcal{B}_i$. At every level $j \leq i$, the distortion incurred by using portals is $\rho 2^j$. Hence the total distortion is $\sum_{j \leq i} \rho 2^j = \rho 2^{i+1}$. Now, property (1) of the decomposition ensures that c and f are cut at level i with probability $O(\mathrm{dist}(c, f)/2^i)$. Hence combining those two bounds over all levels ensures that, in expectation, the distortion between c and f is $O(\mathrm{dist}(c, f) \cdot \rho\lambda(V))$. Since $\lambda(V) = O(\log n)$, choosing $\rho = \varepsilon / \log n$ gives a distortion of $O(\varepsilon \,\mathrm{dist}(c, f))$. Summing over all clients proves that there exists a near-optimal portal-respecting solution.

The issue with this approach is that the number of needed portals is $O(\log^d n)$, and the dynamic program has a runtime that is exponential in this number. Thus the time complexity is quasipolynomial. The novelty of [10] is to show how to reduce the number of portals to a constant. The idea is to reduce the number of levels on which a client can be cut from its facility.

[2] We remark that in [10] the preciseness of Lemma 4 was expressed akin to the weaker property found in Lemma 5, which however would not lead to a near-linear time approximation scheme as claimed in [10], but rather a PTAS as shown in this work. This can however easily be alleviated for [10] by using the stronger preciseness as stated here in Lemma 4.

For this, they present a processing step of the instance, that helps deal with clients cut from their facility at a high level. Roughly speaking, their algorithm computes a constant factor approximation L, and a client c is called *badly-cut* if $\mathcal{D}$ cuts it from its closest facility of L at a level larger than $\log(\text{dist}(c, L)/\varepsilon)$. Every badly-cut client is moved to its closest facility of L. Moreover, every client at distance less than $\varepsilon \,\text{dist}(c, L)$ of its closest facility of L can be moved to it as well. It is then shown that this new instance $\mathcal{I}_{\mathcal{D}}$ has *small distortion*, which essentially means that any solution to $\mathcal{I}_{\mathcal{D}}$ can be converted to a solution of the original instance $\mathcal{I}$ while only losing a $(1+\varepsilon)$-factor in quality. In this instance $\mathcal{I}_{\mathcal{D}}$, all clients are cut from their closest facility of L at some level between $\log(\varepsilon \,\text{dist}(c, L))$ and $\log(\text{dist}(c, L)/\varepsilon)$. Using this property, it can be shown that c and its closest center in the optimal solution are also cut at a level in that range. As there are only $O(\log(1/\varepsilon))$ levels in this range, by the previous argument, the number of portals is a constant. (See Section 2 for formal definitions and lemmas.)

On highway dimension. The above arguments for doubling metrics hold thanks to Lemma 4. In this work, we show how to construct a similar decomposition for low highway dimension:

▶ **Lemma 5.** *Given a shortest-path metric* (V, dist) *of a graph with highway dimension* h*, a subset* $W \subseteq V$*, and* $\rho > 0$*, there exists a polynomial-time computable randomized hierarchical decomposition* $\mathcal{D} = \{\mathcal{B}_0, \dots, \mathcal{B}_{\lambda(W)}\}$ *of* W *such that:*

1. ***Scaling probability****: for any* $v \in V$*, radius* r*, and level* i*, we have* $\Pr[\mathcal{D} \text{ cuts } \beta_v(r) \text{ at level } i] \leq \sigma \cdot r/2^i$*, where* $\sigma = (h \log(1/\rho))^{O(1)}$*.*
2. ***Interface****: for any* $B \in \mathcal{B}_i$ *on level* $i \geq 1$ *there exists an interface* $I_B \subseteq V$*, which is*
   a. ***concise****:* $|I_B| \leq (h/\rho)^{O(1)}$*, and*
   b. ***precise****: for any* $u, v \in B$ *such that* u *and* v *are cut by* $\mathcal{D}$ *at level* $i-1$*, there exists* $p \in I_B$ *with* $\text{dist}(u, p) + \text{dist}(p, v) \leq \text{dist}(u, v) + 34 \cdot \rho 2^i$*.*

Our construction relies on the *town decomposition* from [14], which has the following properties: for a graph with highway dimension h and a given $\rho > 0$, every part T of the decomposition (called a *town*) has a set X_T of *hubs* with doubling dimension $O(h \log 1/\rho)$, such that for any two vertices u and v in different child towns of T, there is a vertex $x \in X_T$ such that $\text{dist}(u, x) + \text{dist}(x, v) \leq (1 + 2\rho) \cdot \text{dist}(u, v)$ – see Theorem 8 for more details.

This hub set X_T is similar to the portal set of Lemma 4, but has some fundamental differences: the first one is that the decomposition is deterministic, and so it may happen that a client and its facility are cut at a very high level – something that happens only with tiny probability in the doubling setting thanks to the scaling probability. Another main difference is that the size of X_T might be unbounded. As a consequence, it cannot be directly used as a portal set in a dynamic program. To deal with this, we combine the town decomposition with a hierarchical decomposition of each set X_T according to Lemma 4, to build an *interface* as stated in Lemma 5.

A further notable difference to portals is that the preciseness property of the resulting interface is weaker. In particular, while there is a portal close to each vertex of a part, the hubs can be far from some vertices as long as they lie close to the shortest path to other vertices, which however can be far (due to Lemma 9). As a consequence no analog of near-optimal portal-respecting paths exist. Instead, when connecting a client c with a facility f we need to use the interface point of I_B provided by the preciseness property of Lemma 5 close to the shortest path between c and f, where B contains both c and f. This shifts the perspective from externally connecting vertices of a part to vertices outside a part, as done for portals, to internally connecting vertices of parts, as done here.

As a consequence, we develop a dynamic program, which follows more or less standard techniques as for instance given in [3, 18], but needs to handle the weaker preciseness property of the interface. The main idea is to guess the distances from interface points to facilities while recursing on the decomposition $\mathcal{D}$ of Lemma 5. Due to the shifted perspective towards internally connecting vertices of parts, the runtime of the dynamic program depends exponentially on the *total* number of levels. However, it can be shown that it suffices to compute a solution on a carefully chosen subset W of the metric for which only a logarithmic number of levels of the decomposition need to be considered, and thus the runtime is polynomial.

1.4 Outline

After defining the concepts we use, and stating various structural lemmas in Section 2, we show how to incorporate our decomposition into the framework of [10]. The proof of Lemma 5 is then presented in Section 3. The formal algorithm is deferred to Section 4. We conclude the main body of this paper with the hardness proof of Theorem 3 in Section 5.

2 Preliminaries

On doubling metrics. The *doubling dimension* of a metric is the smallest integer d such that for any $r > 0$ and $v \in V$, the ball $\beta_v(2r)$ of radius $2r$ around v can be covered by at most 2^d balls of half the radius r. A doubling metric is a metric space where the doubling dimension is bounded. In those spaces, one can show the existence of small *nets*:

▶ **Definition 6.** *A* δ-net *of a metric* (V, dist) *is a subset of nodes* $N \subseteq V$ *with the property that every node in* V *is at distance at most* δ *from a net point of* N*, and each pair of net points of* N *are at distance more than* δ*.*

▶ **Lemma 7** ([16])**.** *Let* (V, dist) *be a metric space with doubling dimension* d*. If its diameter is* D*, and* N *is a* δ*-net of* V*, then* $|N| \leq 2^{d \cdot \lceil \log_2(D/\delta) \rceil}$*. Moreover, any subset* $W \subseteq V$ *has doubling dimension at most* $2d$*.*

On highway dimension. We note that for simplicity we will set $c = 8$ in Definition 1 throughout this paper, even if all claimed results are also true for other values of c. When we refer to a metric as having highway dimension h, we mean that it is the shortest-path metric of a graph of highway dimension h. The main result we will use about highway dimension is existence the of the following decomposition:

▶ **Theorem 8** ([14])**.** *Given a shortest-path metric* (V, dist) *of highway dimension* h*, and* $\rho > 0$*, there exists a polynomial-time computable deterministic hierarchical decomposition* $\mathcal{T}$*, called the* town decomposition*, such that every part* $T \in \mathcal{T}$*, called a* town*, has a set of* hubs[3] $X_T \subseteq T$ *with the following properties:*

a. ***doubling****: the doubling dimension of* X_T *is* $d = O(\log(h \log(1/\rho)))$*, and*

b. ***precise****: for any two vertices* u *and* v *in different child parts of* T*, there is a vertex* $x \in X_T$ *such that* $\mathrm{dist}(u, x) + \mathrm{dist}(x, v) \leq (1 + 2\rho) \cdot \mathrm{dist}(u, v)$*.*

The town decomposition behaves differently from those in Lemmas 4 and 5 in several ways. The main properties we will need here are the following.

▶ **Lemma 9** ([14])**.** *For any* $T \in \mathcal{T}$ *we have* $\mathrm{diam}(T) < \mathrm{dist}(T, V \setminus T)$*. Furthermore, for any child town* T' *of* T *we have* $\mathrm{diam}(T') \leq \mathrm{diam}(T)/2$*.*

[3] called *approximate core hubs* in [14].

On how to incorporate our decomposition into the framework of [10]. Assume we are given an instance $\mathcal{I}$ of k-Clustering^q or Facility Location^q on some metric (V, dist), together with a hierarchical decomposition $\mathcal{D}$ of the metric with the properties listed in Lemma 5. We start by defining the *badly cut* clients. In the following, we fix an optimal solution OPT and an approximate solution L, and we define $\tau(\varepsilon, q, \sigma) = \log_2(\sigma(q+1)^q/\varepsilon^{q+1})$.

▶ **Definition 10** (badly cut [10]). *Let (V, dist) be a metric of an instance $\mathcal{I}$ of k-Clustering^q or Facility Location^q, $\mathcal{D}$ be a hierarchical decomposition of the metric with scaling probability factor σ, and $\varepsilon > 0$. If L_v is the distance from v to the closest facility of an approximate solution L to $\mathcal{I}$, then a client c is* badly cut w.r.t. $\mathcal{D}$ *if the ball $\beta_c(3L_c/\varepsilon)$ is cut as some level i greater than $\log_2(3L_c/\varepsilon) + \tau(\varepsilon, q, \sigma)$.*

Similarly, if OPT_v is the distance from v to the closest facility of the optimum solution OPT of $\mathcal{I}$, then a facility $f \in L$ is badly cut w.r.t. $\mathcal{D}$ *if $\beta_f(3OPT_f)$ is cut at some level i greater than $\log_2(3OPT_f) + \tau(\varepsilon, q, \sigma)$.*

Given an instance $\mathcal{I}$ of k-Clustering^q or Facility Location^q and a decomposition $\mathcal{D}$ of the metric, a new instance $\mathcal{I}_\mathcal{D}$ is computed to get rid of badly cut clients. The instance $\mathcal{I}_\mathcal{D}$ is built from $\mathcal{I}$ by moving clients that are badly cut w.r.t. $\mathcal{D}$ to their closest facility in L.[4] For any client c of $\mathcal{I}_\mathcal{D}$ we denote by $\tilde{c}$ the original position of this client in $\mathcal{I}$, i.e., if $\tilde{c}$ is a badly cut client of $\mathcal{I}$ then $c = L(\tilde{c})$ and otherwise $c = \tilde{c}$. The set F of potential centers in unchanged, and thus any solution of $\mathcal{I}$ is a solution of $\mathcal{I}_\mathcal{D}$, and vice versa. Note that $\mathcal{I}_\mathcal{D}$ does not contain any badly cut client w.r.t. $\mathcal{D}$, and that the definition of $\mathcal{I}_\mathcal{D}$ depends on the randomness of $\mathcal{D}$.

To describe the properties we obtain for the new instance, given a solution S to any instance $\mathcal{I}_0$ of k-Clustering^q or Facility Location^q, we define $\text{cost}_{\mathcal{I}_0}(S) = \sum_{v \in V} \chi_{\mathcal{I}_0}(v) \cdot \text{dist}(v, S)^q$ to be the cost incurred by only the distances to the facilities. Given some $\varepsilon > 0$ and the computed instance $\mathcal{I}_\mathcal{D}$ from $\mathcal{I}$, we define

$$\nu_{\mathcal{I}_\mathcal{D}} = \max_{\text{solution } S} \left\{ \text{cost}_\mathcal{I}(S) - (1+2\varepsilon)\,\text{cost}_{\mathcal{I}_\mathcal{D}}(S)\ ,\ (1-2\varepsilon)\,\text{cost}_{\mathcal{I}_\mathcal{D}}(S) - \text{cost}_\mathcal{I}(S) \right\}.$$

If $B_\mathcal{D}$ denotes the set of badly cut facilities (w.r.t $\mathcal{D}$) of the solution L to $\mathcal{I}$ from which instance $\mathcal{I}_\mathcal{D}$ is constructed, we say that $\mathcal{I}_\mathcal{D}$ has *small distortion w.r.t. $\mathcal{I}$* if $\nu_{\mathcal{I}_\mathcal{D}} \le \varepsilon\,\text{cost}_\mathcal{I}(L)$, and there exists a *witness solution* $\hat{S} \subseteq F$ that contains $B_\mathcal{D}$ and for which $\text{cost}_{\mathcal{I}_\mathcal{D}}(\hat{S}) \le (1 + O(\varepsilon))\,\text{cost}_\mathcal{I}(\text{OPT}) + O(\varepsilon)\,\text{cost}_\mathcal{I}(L)$. Moreover, in the case of Facility Location^q, $\hat{S} = \text{OPT} \cup B_\mathcal{D}$ and $\sum_{f \in B_\mathcal{D}} w_f \le \varepsilon \cdot \sum_{f \in L} w_f$.

Based on these definitions, we now state the main tool we use from [10], and which exploits the scaling probability of our decomposition in Lemma 5 to obtain the required structure.

▶ **Lemma 11** ([10]). *Let (V, dist) be a metric, and $\mathcal{D}$ be a randomized hierarchical decomposition of (V, dist) with scaling probability factor σ. Let $\mathcal{I}$ be an instance of k-Clustering^q or Facility Location^q on (V, dist), with optimum solution OPT and approximate solution L. For any (sufficiently small) $\varepsilon > 0$, with probability at least $1 - \varepsilon$ (over $\mathcal{D}$), the instance $\mathcal{I}_\mathcal{D}$ constructed from $\mathcal{I}$ and L as descibed above has small distortion with a witness solution $\hat{S}$. Furthermore, every client c of $\mathcal{I}_\mathcal{D}$ is cut by $\mathcal{D}$ from its closest facility in $\hat{S}$ at level at most $\log_2(3L_{\tilde{c}}/\varepsilon + 4OPT_{\tilde{c}}) + \tau(\varepsilon, q, \sigma)$, where $\tilde{c}$ is the original position of c in $\mathcal{I}$.*

As a consequence of Lemma 11, a dynamic program can compute a solution recursively on the parts of $\mathcal{D}$ in polynomial time, as sketched in Section 1.3 and detailed in Section 4.

[4] More concretely, let $\chi_\mathcal{I}$ and $\chi_{\mathcal{I}_\mathcal{D}}$ be the demand functions of $\mathcal{I}$ and $\mathcal{I}_\mathcal{D}$, respectively. Initially we let $\mathcal{I}_\mathcal{D}$ be a copy of $\mathcal{I}$, so that in particular $\chi_{\mathcal{I}_\mathcal{D}} = \chi_\mathcal{I}$. Then, for each client c of $\mathcal{I}$ that is badly cut in L w.r.t. $\mathcal{D}$, if $L(c)$ denotes the closest facility of L to c, in $\mathcal{I}_\mathcal{D}$ we set $\chi_{\mathcal{I}_\mathcal{D}}(c) = 0$ and increase $\chi_{\mathcal{I}_\mathcal{D}}(L(c))$ by the value of $\chi_\mathcal{I}(c)$ in $\mathcal{I}$.

3 Decomposing the graph

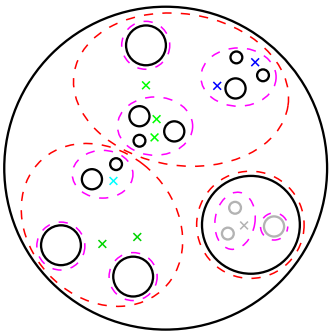

Figure 1 A town T and its child towns (black circles). The hubs (crosses) are decomposed by $\mathcal{X}_T$ (indicated by different colours). Parts $B \in \mathcal{B}_{i+1}$ (red dashed) are decomposed into parts on level i (pink dashed). Parts of $\mathcal{B}_{i-1}$ can lie in different towns (e.g., the child town of T with subtowns in grey).

This section is dedicated to the proof of Lemma 5. The general idea to construct $\mathcal{D}$ is as follows. For doubling metrics, to decompose a part at level i, it is enough to pick a random diameter $\delta \in [2^{i-2}, 2^{i-1})$ and divide the part into child parts of diameter δ. This is not doable in the highway dimension setting: if one wishes to decompose a town T, it cannot divide any of the child towns, since it is not possible to use the approximate core hubs of T to approximate paths inside one of the child towns. The big picture of our decomposition is therefore as follow. To decompose a town at level i, we group randomly (as in the doubling decomposition) the "small" child towns, and put every "big" child town in its own subpart. As we will see, this turns out to be enough.

In order to decompose a town T, we need the following definitions. For each child town T' of T we identify the *connecting hub* $x \in X_T$, which is some fixed closest hub of X_T to T', breaking ties arbitrarily. Moreover, given a hierarchical decomposition $\mathcal{X}_T = \{\mathcal{U}_0, \ldots, \mathcal{U}_{\lambda(X_T)}\}$ of X_T, we define for every i the *connecting i-cluster* of a child town T' of T to be the set $U \in \mathcal{U}_\ell$ on level $\ell = \min\{i, \lambda(X_T)\}$ containing the connecting hub of T'. We then follow the steps below, after choosing μ from the interval $(0, 1]$ uniformly at random (cf. Figure 1):

1. Given a town $T \in \mathcal{T}$, we apply Lemma 4 to find a randomized hierarchical decomposition $\mathcal{X}_T = \{\mathcal{U}_0, \ldots, \mathcal{U}_{\lambda(X_T)}\}$ of the hubs X_T of T.
2. Using $\mathcal{X}_T$, we define a randomized partial decomposition of $T \cap W$ as follows. For any i and $U \in \mathcal{U}_{\min\{i,\lambda(X_T)\}}$, let the set $A_i^U \subseteq T \cap W$ be the union of all $T' \cap W$ where T' is a child town of T with the following two properties:
   a. U is the connecting i-cluster of T', and
   b. $\mathrm{dist}(T', V \setminus T') \leq \mu 2^i$.

   Hence $\mathcal{A}_i^U$ contains all towns somewhat close to U, and with small diameter due to Lemma 9. We let $\mathcal{A}_i^T$ be the set containing each non-empty A_i^U.
3. Now, the hierarchical decomposition $\mathcal{D} = \{\mathcal{B}_0, \ldots, \mathcal{B}_{\lambda(W)}\}$ of W can be constructed inductively as follows. At the highest level $\lambda(W)$ of $\mathcal{D}$, W is partitioned in a single set: $\mathcal{B}_{\lambda(W)} = \{W\}$. Now, to decompose a part $B \in \mathcal{B}_{i+1}$ at level $i+1$, we do the following. Let $T \in \mathcal{T}$ be the inclusion-wise minimal town for which $B \subseteq T$. The "small" subtowns of T lying inside B are grouped according to step (2) (note that $\mathrm{dist}(T', V \setminus T')$ also bounds the diameter of T' by Lemma 9), and the other ones form individual subparts. More formally, the set $\mathcal{B}_i$ contains every part $A \in \mathcal{A}_i^T$ for which $A \subseteq B$, and also every set $T' \cap W$, where T' is a child town of T for which $T' \cap W \subseteq B$ and $T' \cap W$ was not covered by the previously added parts of $\mathcal{A}_i^T$, i.e., $T' \cap W \cap A = \emptyset$ for every $A \in \mathcal{A}_i^T$.

To prove that the constructed decomposition $\mathcal{D}$ has the desired properties –i.e. that it is indeed a hierarchical decomposition, with parts of bounded diameter and small scaling probability factor –, we begin with some auxiliary lemmas, of which the first one bounds the distance of a town to its connecting hub.

▶ **Lemma 12.** *If T' is a child town of T with connecting hub $x \in X_T$, then* $\operatorname{dist}(x, T') \leq (1 + 2\rho) \operatorname{dist}(T', V \setminus T')$.

Proof. Let T'' be the closest sibling town to T', and let $u \in T'$ and $v \in T''$ be the vertices defining the distance from T' to T'', i.e., $\operatorname{dist}(u, v) = \operatorname{dist}(T', T'') = \operatorname{dist}(T', V \setminus T')$. By Theorem 8, there is a hub $y \in X_T$ for which $\operatorname{dist}(u, y) + \operatorname{dist}(y, v) \leq (1 + 2\rho) \cdot \operatorname{dist}(u, v) = (1 + 2\rho) \cdot \operatorname{dist}(T', V \setminus T')$. This implies $\operatorname{dist}(y, T') \leq \operatorname{dist}(u, y) \leq (1 + 2\rho) \cdot \operatorname{dist}(T', V \setminus T')$. Since the connecting hub x of T' is at least as close to T' as y, the claim follows. ◀

Based on the above lemma, we next prove a key property that the diameter of any part of $\mathcal{B}_i \in \mathcal{D}$ is bounded.

▶ **Lemma 13.** *If $\rho \leq 1/2$, then the diameter of any part of $\mathcal{B}_i \in \mathcal{D}$ is less than 2^{i+4}.*

Proof. On the highest level $\lambda(W)$ of $\mathcal{D}$ the only part of $\mathcal{B}_{\lambda(W)}$ is W itself. As $\lambda(W) = \lceil \log_2 \operatorname{diam}(W) \rceil$ we get $\operatorname{diam}(W) \leq 2^{\lambda(W)+1}$, as required.

For any level $i < \lambda(W)$, a set in $\mathcal{B}_i$ is equal to a set $A \in \mathcal{A}_i^T$ for some town $T \in \mathcal{T}$ or it is equal to some set $T' \cap W$ for a child town T' of T. In the former case, the set A is equal to a set A_i^U for some cluster $U \in \mathcal{U}_\ell$ where $\ell = \min\{i, \lambda(X_T)\}$ and $\mathcal{U}_\ell \in \mathcal{X}_T$. The set A_i^U contains the union of sets $T' \cap W$ for child towns T' of T, for which their connecting hubs lie in U and $\operatorname{dist}(T', V \setminus T') \leq \mu 2^i \leq 2^i$, as $\mu \leq 1$. Thus from Lemma 12 we get $\operatorname{dist}(U, T') \leq (1 + 2\rho)2^i$, and by Lemma 9 we have $\operatorname{diam}(T') < \operatorname{dist}(T', V \setminus T') \leq 2^i$. The cluster U has diameter less than 2^{i+1} by Lemma 4, since it is part of the hierarchical decomposition $\mathcal{X}_T$ and lies on level $\ell \leq i$. Let u and v be the vertices of A_i^U defining the diameter of A_i^U, i.e., $\operatorname{dist}(u, v) = \operatorname{diam}(A_i^U)$. We may reach v from u by first crossing the child town T' that u lies in, then passing over to U, then crossing U, after which we pass over to the child town T'' containing v, and finally crossing this child town as well to reach v. Hence, assuming that $\rho \leq 1/2$ the diameter of A_i^U is bounded by

$$\begin{aligned}\operatorname{dist}(u, v) &\leq \operatorname{diam}(T') + \operatorname{dist}(U, T') + \operatorname{diam}(U) + \operatorname{dist}(U, T'') + \operatorname{diam}(T'') \\ &< 2 \cdot 2^i + 2 \cdot (1 + 2\rho)2^i + 2^{i+1} = (6 + 4\rho)2^i \leq 2^{i+3}\end{aligned}$$

Now consider the other case, when a set $B \in \mathcal{B}_i$ on level $i < \lambda(W)$ is equal to some set $T' \cap W$ for a child town T' of a town T. For such a child town T' there is no enforced upper bound on the distance to other child towns as before, and thus it is necessary to be more careful to bound the diameter of the part. Starting with $B = B_i$, let $B_i \subseteq B_{i+1} \subseteq \ldots \subseteq B_j$ be the longest chain of parts of increasing levels that are of the same type as B. More concretely, for every $\ell \in \{i, i+1, \ldots, j\}$ we have $B_\ell \in \mathcal{B}_\ell$ and B_ℓ is equal to some set $T'_\ell \cap W$ for a child town T'_ℓ of the inclusion-wise minimal town T_ℓ containing $B_{\ell+1}$. Note that in particular $j < \lambda(W)$. As we chose the longest such chain, on the next level $j + 1$ there is no such set containing B_j, which means that the set $B_{j+1} \in \mathcal{B}_{j+1}$ for which $B_j \subseteq B_{j+1}$ is either equal to a set $A \in \mathcal{A}_{j+1}^{T_{j+1}}$ for some town T_{j+1}, or $j + 1 = \lambda(W)$. In either case, from above we get $\operatorname{diam}(B_{j+1}) \leq 2^{j+4}$.

Note that for any $\ell \in \{i, i + 1, \ldots, j - 1\}$ the town T'_ℓ is a descendant town of $T'_{\ell+1}$, since $B_{\ell+1}$ is contained in $T'_{\ell+1}$ and T'_ℓ is a child town of the inclusion-wise minimal town T_ℓ containing $B_{\ell+1}$. By Theorem 8 and Lemma 9 we thus get $\operatorname{diam}(T'_\ell) \leq \operatorname{diam}(T'_{\ell+1})/2$,

which implies $\operatorname{diam}(T_i') \leq \operatorname{diam}(T_j')/2^{j-i}$. The set $B = B_i$ is contained in T_i', which means $\operatorname{diam}(B) \leq \operatorname{diam}(T_i')$. The town T_j is the inclusion-wise minimal town containing B_{j+1}, while at the same time the child town T_j' of T_j contains B_j. As $B_j \subseteq B_{j+1}$, this means that B_{j+1} both contains vertices inside and outside of T_j', and so $\operatorname{dist}(T_j', V \setminus T_j') \leq \operatorname{diam}(B_{j+1})$. By Lemma 9 we know that $\operatorname{diam}(T_j') \leq \operatorname{dist}(T_j', V \setminus T_j')$, and putting all these inequalities together we obtain

$$\begin{aligned}\operatorname{diam}(B) \leq \operatorname{diam}(T_i') \leq \operatorname{diam}(T_j')/2^{j-i} &\leq \operatorname{dist}(T_j', V \setminus T_j')/2^{j-i} \\ &\leq \operatorname{diam}(B_{j+1})/2^{j-i} \leq 2^{j+4}/2^{j-i} = 2^{i+4}.\end{aligned}$$ ◀

Using Lemma 13 it is not hard to prove the correctness of $\mathcal{D}$, which we turn to next. All statements marked with "⋆" are deferred to the full version of the paper, due to space constraints.

▶ **Lemma 14 (⋆).** *The tuple $\mathcal{D} = \{\mathcal{B}_0, \ldots, \mathcal{B}_{\lambda(V)}\}$ is a hierarchical decomposition of W.*

We now turn to proving the properties of Lemma 5, starting with the scaling probability.

▶ **Lemma 15.** *The decomposition $\mathcal{D}$ has scaling probability factor $\sigma = (h \log(1/\rho))^{O(1)}$.*

Proof. To prove the claim, we need to prove that for any $v \in W$, radius r, and level i, the probability that $\mathcal{D}$ cuts the ball $\beta_v(r)$ at level i is at most $(h \log(1/\rho))^{O(1)} \cdot r/2^i$. If $\mathcal{D}$ cuts $\beta_v(r)$ at level i, it means that $\beta_v(r)$ is fully contained in a part at level $i+1$: let $T \in \mathcal{T}$ be the inclusion-wise minimal town containing that part. There are two cases to consider: either $\beta_v(r)$ is cut by "small" parts, i.e. there exist two distinct parts $A, A' \in \mathcal{A}_i^T$ such that $v \in A$ and $u \in A'$ for some $u \in W \cap \beta_v(r)$, or not.

We start with the latter case, when $\beta_v(r)$ is not cut by small parts. If $\mathcal{D}$ cuts the ball at level i, there are distinct parts $B, B' \in \mathcal{B}_i$ such that $v \in B$ and $u \in B'$ for some $u \in W \cap \beta_v(r)$. Assume w.l.o.g. that $B \notin \mathcal{A}_i^T$ (which is possible to assume since $\beta_v(r)$ is not cut by small parts). By construction of the decomposition, there must be a child town T' of T, for which $B = T' \cap W$ and $\operatorname{dist}(T', V \setminus T') > \mu 2^i$. Note that $r \geq \operatorname{dist}(v, u) \geq \operatorname{dist}(T', B'') \geq \operatorname{dist}(T', V \setminus T') \geq \mu 2^i$, and hence $\mu \leq r/2^i$. The decomposition $\mathcal{D}$ can therefore only cut $\beta_v(r)$ on level i if $\mu < r/2^i$. Since μ is chosen uniformly at random from the interval $(0, 1]$, the probability is less than $r/2^i$.

We now turn to the other case, when $\beta_v(r)$ is cut by two small parts A_1 and A_2. The town T must have two child towns T_1 and T_2 for which $v \in T_1 \cap W \subseteq A_1$ and $u \in T_2 \cap W \subseteq A_2$. Let x_1 and x_2 be the connecting hubs of T_1 and T_2. The decomposition $\mathcal{D}$ cuts v and u on level i if and only if $\mathcal{X}_T$ cuts x_1 and x_2 on level $\ell = \min\{i, \lambda(X_T)\}$. Indeed, let U_1 and U_2 be the connecting i-clusters of T_1 and T_2: then $A_1 = A^i_{U_1}$ and $A_2 = A^i_{U_2}$, with $x_1 \in U_1, x_2 \in U_2$. Thus $\mathcal{D}$ cuts v and u on level i if and only if $U_1 \neq U_2$, i.e., if and only if $\mathcal{X}_T$ cuts x_1 and x_2 on level $\ell = \min\{i, \lambda(X_T)\}$.

To compute the probability that x_1 and x_2 are cut, it is necessary to bound the distance between them. As $v \in T_1$ and $u \in T_2$ while $u \in \beta_v(r)$, for each $j \in \{1, 2\}$ we have $\operatorname{dist}(T_j, V \setminus T_j) \leq \operatorname{dist}(T_1, T_2) \leq r$. By Lemma 12 the distance between T_j and its connecting hub $x_j \in X_T$ is thus at most $(1 + 2\rho)r$. Also, by Lemma 9 we have $\operatorname{diam}(T_j) < \operatorname{dist}(T_j, V \setminus T_j) \leq r$, and we get

$$\operatorname{dist}(x_1, x_2) \leq \operatorname{dist}(x_1, T_1) + \operatorname{diam}(T_1) + \operatorname{dist}(T_1, T_2) + \operatorname{diam}(T_2) + \operatorname{dist}(T_2, x_2) \leq (5 + 4\rho)r.$$

We can reformulate the above as follows: if $\mathcal{D}$ cuts the ball $\beta_v(r)$ at level i, and $\beta_v(r)$ is cut by some "small" parts A_1 and A_2, then $\mathcal{X}_T$ cuts the ball $\beta_{x_1}((5 + 4\rho)r)$ on level i, where x_1 is the hub defined for v above. We know that the probability of the latter event

is at most $2^{O(d)}(5+4\rho)r/2^i$ by Lemma 4, where $d = O(\log(h\log(1/\rho)))$ is the doubling dimension of X_T by Theorem 8. Hence the probability that $\mathcal{D}$ cuts the ball $\beta_v(r)$ at level i is bounded by $(h\log(1/\rho))^{O(1)} \cdot r/2^i$. Taking a union bound over the two considered cases proves the claim. ◀

To prove the remaining property of Lemma 5 for $\mathcal{D}$, for each $B \in \mathcal{B}_i$ we need to choose an interface I_B from the whole vertex set V. For this we use a carefully chosen net (see Definition 6) of the hubs of the inclusion-wise minimal town T containing B, as formalized in the following lemma.

▶ **Lemma 16.** *Given $B \in \mathcal{B}_i$ for some $\mathcal{B}_i \in \mathcal{D}$ and $i \geq 1$, let $T \in \mathcal{T}$ be the inclusion-wise minimal town containing B. We define the interface I_B to be a $\rho 2^i$-net of the set $Y_B = \{x \in X_T \mid \operatorname{dist}(x,B) \leq (1+2\rho)\operatorname{diam}(B)\}$. The interface I_B has the conciseness and preciseness properties of Lemma 5 for $\rho \leq 1/2$.*

Proof. We first prove that I_B is precise. Consider two vertices $u, v \in B$ that are cut at level $i-1$ by $\mathcal{D}$. This means there are two distinct parts $B', B'' \in \mathcal{B}_{i-1}$ on this level such that $v \in B'$ and $u \in B''$. By definition, both B' and B'' are unions of sets $T' \cap W$ where T' is a child town of the inclusion-wise minimal town T containing B. Also $B' \cap B'' = \emptyset$ by Lemma 14. This means that T has two child towns T_1 and T_2 for which $v \in T_1 \cap W \subseteq B'$ and $u \in T_2 \cap W \subseteq B''$. By Theorem 8, there is an approximate core hub $x \in X_T$ such that $\operatorname{dist}(u,x) + \operatorname{dist}(x,v) \leq (1+2\rho)\operatorname{dist}(u,v)$. In particular, $\operatorname{dist}(x,B) \leq \operatorname{dist}(u,x) \leq (1+2\rho)\operatorname{dist}(u,v) \leq (1+2\rho)\operatorname{diam}(B)$, as $u, v \in B$. This means that $x \in Y_B$. Since I_B is a $\rho 2^i$-net of Y_B, there is a hub $p \in I_B$ for which $\operatorname{dist}(x,p) \leq \rho 2^i$. By Lemma 13 we have $\operatorname{dist}(u,v) \leq \operatorname{diam}(B) \leq 2^{i+4}$ if $\rho \leq 1/2$, and so I_B is precise:

$$\begin{aligned}\operatorname{dist}(u,p) + \operatorname{dist}(p,v) &\leq \operatorname{dist}(u,x) + 2\cdot\operatorname{dist}(x,p) + \operatorname{dist}(x,v)\\ &\leq (1+2\rho)\operatorname{dist}(u,v) + \rho 2^{i+1} \leq \operatorname{dist}(u,v) + 2\rho\cdot 2^{i+4} + \rho 2^{i+1} \leq \operatorname{dist}(u,v) + 34\cdot\rho 2^i,\end{aligned}$$

To prove conciseness, recall that $\operatorname{diam}(B) \leq 2^{i+4}$ by Lemma 13, which means that $\operatorname{diam}(Y_B) \leq \operatorname{diam}(B) + 2(1+2\rho)\operatorname{diam}(B) \leq 5\cdot 2^{i+4}$ for $\rho \leq 1/2$. Since I_B is a $\rho 2^i$-net of Y_B, Lemma 7 implies $|I_B| \leq 2^{d\cdot\lceil\log_2(80/\rho)\rceil}$, where d is the doubling dimension of Y_B. Theorem 8 says that X_T has doubling dimension $O(\log(h\log(1/\rho)))$, and as $Y_B \subseteq X_T$ the same asymptotic bound holds for the doubling dimension d of Y_B by Lemma 7. Therefore we get $|I_B| \leq (h\log(1/\rho))^{O(\log(1/\rho))} = (h/\rho)^{O(1)}$, which concludes the proof. ◀

4 The algorithm

Let an instance $\mathcal{I}$ of the k-Clustering^q or Facility Location^q problem on a shortest-path metric (V, dist) of a graph G with highway dimension h, and maximum demand $X = \max_{v\in V}\chi_{\mathcal{I}}(v)$ be given. The algorithm performs the following steps:

1. compute a town decomposition $\mathcal{T}$ together with the hubs for each town as given by Theorem 8.
2. compute a hierarchical decomposition $\mathcal{D}$ according to Lemma 5, while simultaneously converting $\mathcal{I}$ into a *coarse* instance w.r.t. $\mathcal{D}$, meaning that there is a subset $W \subseteq V$ for which
   - the clients and facilities of $\mathcal{I}$ are contained in W, i.e., $F \cup \{v \in V \mid \chi_{\mathcal{I}}(v) > 0\} \subseteq W$, and
   - every part of $\mathcal{D}$ on level at most $\xi(W) = \lfloor \lambda(W) - 2\log_2(nX/\varepsilon)\rfloor$ has at most one facility, i.e., $|B \cap F| \leq 1$ for every $B \in \mathcal{B}_{\xi(W)}$.

3. compute the instance $\mathcal{I}_{\mathcal{D}}$ of small distortion as given by Lemma 11.
4. run a dynamic program on $\mathcal{I}_{\mathcal{D}}$ as given in Section 4.2, to compute an *optimum rounded interface-respecting solution* (see Section 4.1 for a formal definition), and output it as a solution to the input instance.

In a nutshell, the coarseness of the instances guarantees that only a logarithmic number of levels need to be considered by the dynamic program. This step loses a $(1+\varepsilon)$-factor in the solution quality. The dynamic program is only able to compute highly structured solutions, which are captured by the notion of *rounding* and *interface-respecting*. Due to this, another $(1+\varepsilon)$-factor in the solution quality is lost. In Section 4.1 we prove that the output of the dynamic program is a near-optimal solution to the input instance (proving Theorem 2), and we also detail step (4) of the algorithm. Then in Section 4.2 we describe the details of the dynamic program.

4.1 Approximating the distances

One caveat of the dynamic program is that the runtime is only polynomial if the the recursion depth is logarithmic. However when computing our decomposition on the whole metric (V, dist), the number of levels is $\lambda(V)+1 = \lceil \log_2 \mathrm{diam}(V) \rceil + 1$, which can be linear in the input size. Standard techniques can be used to reduce the number of levels to $O(\log(n/\varepsilon))$ when aiming for a $(1+\varepsilon)$-approximation by preprocessing the input metric. However, for graphs of bounded highway dimension these general techniques change the hub sets and we would have to be careful to maintain the properties we need, as given by Theorem 8. Therefore we adapt the standard techniques to our setting via the notion of *coarse* instances.

The following lemma shows that we can reduce any instance to a set of coarse ones, for which, as we will see, our dynamic program only needs to consider the highest $2\log_2(nX/\varepsilon)$ levels.

▶ **Lemma 17 (⋆).** *Let $\mathcal{I}$ be an instance of k-Clustering^q or Facility Location^q on a graph G of highway dimension h. There are polynomial-time computable instances $\mathcal{I}_1, \ldots, \mathcal{I}_b$ and respective hierarchical decompositions $\mathcal{D}_1, \ldots, \mathcal{D}_b$ with the properties given in Lemma 5 for any $\rho \leq 1/2$, such that for each $i \in \{1, \ldots, b\}$ the instance $\mathcal{I}_i$ is also defined on G and is coarse w.r.t. $\mathcal{D}_i$. Furthermore, if an α-approximation can be computed for each of the instances $\mathcal{I}_1, \ldots, \mathcal{I}_b$ in polynomial time, then for any $\varepsilon > 0$ a $(1+O(\varepsilon))\alpha$-approximation can be computed for $\mathcal{I}$ in polynomial time.*

Lemma 17 implies that if there is a PTAS for coarse instances, we also have a PTAS in general. Hence from now on we assume that the given instance $\mathcal{I}$ is coarse w.r.t. a hierarchical decomposition $\mathcal{D}$ of some subset W of the vertices of the input graph G, where $\mathcal{D}$ has bounded scaling probability factor and concise and precise interface sets in G according to Lemma 5 (for some value $\rho > 0$ specified later)

The next step of the algorithm is to compute a new instance $\mathcal{I}_{\mathcal{D}}$ with small distortion as given by Lemma 11. Recall that $\mathcal{I}_{\mathcal{D}}$ is obtained from $\mathcal{I}$ by moving badly cut clients to facilities of L. In particular, the instance $\mathcal{I}_{\mathcal{D}}$ is also coarse w.r.t. $\mathcal{D}$, which means that we may run our dynamic program on $\mathcal{I}_{\mathcal{D}}$.

The dynamic program exploits the interface sets of $\mathcal{D}$ by computing a near-optimum "interface-respecting" solution to $\mathcal{I}_{\mathcal{D}}$, i.e., a solution where clients are connected to facilities through interface points. Moreover, for the dynamic program to run in polynomial time it can only estimate the distances between interface points and facilities to a certain precision. In general, we denote by $\langle x \rangle_i = \min\{(35+\delta)\rho 2^i \mid \delta \in \mathbb{N} \text{ and } \rho\delta 2^i \geq x\}$ the value of x rounded to

the next multiple of $\rho 2^i$ and shifted by $35\rho 2^i$. We then define the *rounded interface-respecting distance* $\text{dist}'(v,u)$ from a vertex v to another vertex u as follows. If v and u are not cut at any level, i.e., $v = u$, then $\text{dist}'(v,u) = 0$. Otherwise, if $i \geq 1$ is the level of $\mathcal{D}$ such that there is a part $B \in \mathcal{B}_i$ with $v, u \in B$, and $\mathcal{D}$ cuts v and u at level $i-1$, we let

$$\text{dist}'(v,u) = \min\left\{ \text{dist}(v,p) + \langle \text{dist}(p,u) \rangle_i \mid p \in I_B \right\}.$$

Note that $\text{dist}'(\cdot,\cdot)$ does not necessarily fulfill the triangle inequality, and is also not symmetric. We therefore need the bounds of the following lemma.

▶ **Lemma 18.** *For any level $i \geq 1$ and vertices v and u that are cut by $\mathcal{D}$ on level $i-1$ we have $\text{dist}'(v,u) \leq \text{dist}(v,u) + 70 \cdot \rho 2^i$. Let $B \in \mathcal{B}_j$ be the part on some level $j \geq i$ with $v, u \in B$. For any $p \in I_B$ we have $\text{dist}'(v,u) \leq \text{dist}(v,u) + \langle \text{dist}(p,u) \rangle_j$.*

Proof. Let $B' \in \mathcal{B}_i$ be the part on level i containing both v and u. By Lemma 5 there is an interface point $p' \in I_{B'}$ such that $\text{dist}(v,p') + \text{dist}(p',u) \leq \text{dist}(v,u) + 34 \cdot \rho 2^i$. By definition of the rounding we also have $\langle \text{dist}(p',u) \rangle_i \leq \text{dist}(p',u) + 36 \cdot \rho 2^i$. Hence $\text{dist}'(v,u) \leq \text{dist}(v,p') + \langle \text{dist}(p',u) \rangle_i \leq \text{dist}(v,p') + \text{dist}(p',u) + 36 \cdot \rho 2^i \leq \text{dist}(v,u) + 70 \cdot \rho 2^i$.

The second part is obvious if $j = i$ from the definition of $\text{dist}'(v,u)$. If $j \geq i+1$, we use the above bound on $\text{dist}'(v,u)$ together with the additive shift of the rounding and the triangle inequality of $\text{dist}(\cdot,\cdot)$ to obtain

$$\begin{aligned}\text{dist}'(v,u) &\leq \text{dist}(v,u) + 70 \cdot \rho 2^i \leq \text{dist}(v,p) + \text{dist}(p,u) + 70 \cdot \rho 2^{j-1} \\ &\leq \text{dist}(v,p) + \langle \text{dist}(p,u) \rangle_j - 35 \cdot \rho 2^j + 70 \cdot \rho 2^{j-1} = \text{dist}(v,p) + \langle \text{dist}(p,u) \rangle_j. \text{◀}\end{aligned}$$

For any non-empty set S of facilities, we define $\text{dist}'(v,S) = \min_{f \in S}\{\text{dist}'(v,S)\}$, and for empty sets we let $\text{dist}'(v,\emptyset) = \infty$. Analogous to $\text{cost}_{\mathcal{I}_0}(S)$, for a solution S to some instance $\mathcal{I}_0$ we also define $\text{cost}'_{\mathcal{I}_0}(S)$ using $\text{dist}'(\cdot,\cdot)$ as

$$\text{cost}'_{\mathcal{I}_0}(S) = \sum_{v \in V} \chi_{\mathcal{I}_\mathcal{D}}(v) \cdot \text{dist}'(v,S)^q.$$

We show the following lemma, which translates between $\text{cost}'_{\mathcal{I}_\mathcal{D}}$ and $\text{cost}_\mathcal{I}$, and is implied by the preciseness of the interface sets and the fact that $\mathcal{I}_\mathcal{D}$ has small distortion. Recall that the set of facilities is the same in $\mathcal{I}$ and $\mathcal{I}_\mathcal{D}$, i.e., a solution to one of these instances is also a solution to the other.

▶ **Lemma 19 (⋆).** *Let $\mathcal{I}$ be an instance of k-Clustering^q or Facility Location^q with optimum solution OPT and approximate solution L. Let $\mathcal{I}_\mathcal{D}$ be an instance of small distortion for some $0 < \varepsilon < 1/2$, computed from L and a hierarchical decomposition $\mathcal{D}$ with precise interface sets for $\rho \leq \frac{\varepsilon^{q+4+1/q}}{280\sigma(q+1)^q}$ according to Lemma 5. For the witness solution $\hat{S}$ of $\mathcal{I}_\mathcal{D}$ we have $\text{cost}'_{\mathcal{I}_\mathcal{D}}(\hat{S}) \leq (1+O(\varepsilon))\,\text{cost}_\mathcal{I}(OPT) + O(\varepsilon)\,\text{cost}_\mathcal{I}(L)$. Moreover, for any solution S we have $\text{cost}_\mathcal{I}(S) \leq (1+O(\varepsilon))\,\text{cost}'_{\mathcal{I}_\mathcal{D}}(S) + O(\varepsilon)\,\text{cost}_\mathcal{I}(L)$.*

The next lemma states the properties of the dynamic program that for any coarse instance $\mathcal{I}_0$ computes an *optimal rounded interface-respecting solution*, which formally is a subset OPT' of facilities that minimizes $\text{cost}'_{\mathcal{I}_0}(\text{OPT}')$ with $|\text{OPT}'| \leq k$ for k-Clustering^q, while for Facility Location^q it minimizes $\text{cost}'_{\mathcal{I}_0}(\text{OPT}') + \sum_{f \in \text{OPT}'} w_f$. This step of the algorithm exploits the conciseness of the interface sets and the coarseness of the instance to bound the runtime. We prove the following lemma in Section 4.2.

▶ **Lemma 20.** *Let $\mathcal{I}_0$ be an instance of k-Clustering^q or Facility Location^q that for some $\varepsilon > 0$ is coarse w.r.t. a hierarchical decomposition $\mathcal{D}$ with concise interface sets for some $1/2 \geq \rho > 0$ according to Lemma 5. An optimum rounded interface-respecting solution for $\mathcal{I}_0$ can be computed in $(nX/\varepsilon)^{(h/\rho)^{O(1)}}$ time.*

We are now ready to put together the above lemmas to prove Theorem 2. Due to space constraints however, the formal proof is deferred to the full version of the paper.

4.2 The dynamic program (proof of Lemma 20)

We describe the algorithm for k-Clustering^q, and only mention in the end how to modify the algorithm to compute a solution for Facility Location^q.

The solution is computed by a dynamic program recursing on the decomposition $\mathcal{D}$. Let W be the vertex set that $\mathcal{D}$ decomposes, and which contains all clients and facilities of the coarse instance $\mathcal{I}$. Roughly speaking, the table of the dynamic program will have an entry for every part $B \in \mathcal{B}_i$ of $\mathcal{D}$ on all levels $i \geq \xi(W)$, for which it will estimate the distance from each interface point on all higher levels $j \geq i+1$ to the closest facility of the optimum solution. That is, if $\tilde{B} \in \mathcal{B}_j$ is a higher-level part for which $B \subseteq \tilde{B}$, then the distances from all interface points $I_{\tilde{B}}$ to facilities of the solution in $\tilde{B}$ will be estimated.

Here the estimation happens in two ways. First off, the distances to facilities outside of B have to be guessed. That is, there is an *external* distance function d_j^+ that assigns a distance to each interface point of $I_{\tilde{B}}$, anticipating the distance from such a point to the closest facility of $\tilde{B}$, if this facility lies outside of B. In order to verify whether the guess was correct, each entry for a part B on level i also provides an *internal* distance function d_j^-, which stores the distance from each interface point of $I_{\tilde{B}}$ on level $j \geq i+1$ to the closest facility, if the facility is guessed to lie inside of B.

The other way in which distances are estimated concerns the preciseness with which they are stored. The distance functions d_j^+ and d_j^- will only take rounded values $\langle x \rangle_j$ where $0 < x \leq 2^{j+5}$, or ∞ if no facility at the appropriate distance exists. In particular, if the facility of the solution in $\tilde{B}$ that is closest to $p \in I_{\tilde{B}}$ lies outside of B then $d_j^-(p) = \infty$, and if it lies inside of B then $d_j^+(p) = \infty$. If there is no facility of the solution in $\tilde{B}$ then both distance functions d_j^+ and d_j^- are set to ∞ for all $p \in I_{\tilde{B}}$. Note that this means that at least one of $d_j^+(p)$ and $d_j^-(p)$ is always set to ∞. Note also that the finite values in the domains of the distance functions admit to store the rounded distance to any facility in $\tilde{B}$ on level j, since the diameter of $\tilde{B}$ is at most 2^{j+4} by Lemma 13, and the distance from any $p \in I_{\tilde{B}}$ to $\tilde{B}$ is at most $(1+2\rho)\operatorname{diam}(\tilde{B})$ by Lemma 16, i.e., for any $f \in \tilde{B} \cap F$ we have $\operatorname{dist}(p,f) \leq (1+2\rho)2^{j+4} \leq 2^{j+5}$ using $\rho \leq 1/2$.

Formal definition of the table. Let us denote by I_B^j the interface set of the part $\tilde{B} \in \mathcal{B}_j$ on level $j \geq i+1$ containing $B \in \mathcal{B}_i$, i.e., $I_B^j = I_{\tilde{B}}$. Every entry of the dynamic programming table T is defined by a part $B \in \mathcal{B}_i$ of $\mathcal{D}$ on a level $i \in \{\xi(W), \ldots, \lambda(W)\}$, and two distance functions $d_j^+, d_j^- : I_B^j \to \{\langle x \rangle_j \mid 0 < x \leq 2^{j+5}\} \cup \{\infty\}$ for each $j \in \{i+1, \ldots, \lambda(W)\}$, such that $\max\{d_j^+(p), d_j^-(p)\} = \infty$ for all $p \in I_B^j$. Additionally, each entry comes with an integer $k' \in \{0, \ldots, k\}$, which is a guess on the number of facilities that the optimum solution contains in B.

In an entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ we store the rounded interface-respecting cost of connecting the clients of B to facilities that adhere to the distance functions. More concretely, let $S \subseteq F \cap B$ be any subset of facilities in B. We say that S is *compatible* with an entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ if $|S| = k'$, and for any $j \geq i+1$ the values of the distance functions for every interface point $p \in I_B^j$ are set to either

- $d_j^-(p) = \langle \operatorname{dist}(p,S) \rangle_j$ and $d_j^+(p) = \infty$, or
- $d_j^+(p) \leq \langle \operatorname{dist}(p,S) \rangle_j$ and $d_j^-(p) = \infty$.

Recall that $\text{dist}(v, \emptyset) = \infty$, and so the empty set $S = \emptyset$ is compatible with an entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ if $k' = 0$, and the values of all internal distance functions are set to ∞. Over all sets $S \subseteq F \cap B$ compatible with the entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ for $B \in \mathcal{B}_i$, the entry should store the minimum value of $C_B(S)$, which is defined as

$$C_B(S) = \sum_{v \in B} \chi_{\mathcal{I}_0}(v) \cdot \min \Big\{ \text{dist}'(v, S), \min_{\substack{j \geq i+1 \\ p \in I_B^j}} \big\{ \text{dist}(v, p) + d_j^+(p) \big\} \Big\}.$$

If there is no compatible set $S \subseteq F \cap B$ for the entry, then $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}] = \infty$.

On the highest level $i = \lambda(W)$, there are no distance functions to adhere to on levels $j \geq i + 1$, and thus any set $S \subseteq W$ of facilities is compatible with the entry for $B = W$ and $k' = |S|$. Furthermore, $\text{cost}'_{\mathcal{I}_0}(S)$ is equal to $C_W(S)$, since W contains all clients and facilities of the coarse instance $\mathcal{I}_0$. In particular, the entry of T for which $k' = k$ and $B = W$, will contain the objective function value of the optimum rounded interface-respecting solution to $\mathcal{I}_0$. Hence if we can compute the table T we can also output the optimum rounded interface-respecting solution via this entry.

Computing the table. We begin with a part $B \in \mathcal{B}_{\xi(W)}$ on the lowest considered level $\xi(W)$, for which we know that B contains at most one facility, as $\mathcal{I}_0$ is coarse. If B contains no facility, then only $S = \emptyset$ can be compatible with the entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ and computing the value of the entry is straightforward given the definition of $C_B(S)$, where all incompatible entries are set to ∞. If B contains one facility f, then any compatible set S is either empty or only contains f. We can thus check whether either of the two options is compatible with the entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ by checking if k' is set to 0 or 1, respectively, and checking that all values of the internal distance function are set correctly. Thereafter we can again use the definition of $C_B(S)$ to compute the values for both possible sets S and store them in the respective compatible entries. All incompatible entries are set to ∞.

Now fix a part $B \in \mathcal{B}_i$ that lies on a level $i > \xi(W)$. We show how to compute all entries $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ for all values k' and distance functions. By induction we have already computed the correct values of all entries of T for parts $B' \in \mathcal{B}_{i-1}$ where $B' \subseteq B$. We order these parts arbitrarily, so that $B'_1, \ldots, B'_b$ are the parts of $\mathcal{B}_{i-1}$ contained in B. We then define an auxiliary table $\hat{T}$ that is similar to the table T, but should compute the best compatible facility set in the union $B'_{\leq \ell} = \bigcup_{h=1}^{\ell} B'_h$ of the first ℓ subparts of B. Accordingly, $\hat{T}$ has an entry for each union of parts $B'_{\leq \ell}$, each $k' \in \{0, \ldots, k\}$, and distance functions $d_j^+, d_j^- : I_B^j \to \{\langle x \rangle_j \mid 0 < x \leq 2^{j+5}\} \cup \{\infty\}$ for each $j \in \{i, \ldots, \lambda(W)\}$, such that $\max\{d_j^+(p), d_j^-(p)\} = \infty$ for all $p \in I_B^j$. Here, naturally, $I_B^i = I_B$, i.e., the entry also takes the interface set of B into account.

Analogous to before, a set $S \subseteq F \cap B'_{\leq \ell}$ of facilities in the union is *compatible* with an entry $\hat{T}[B'_{\leq \ell}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$ if $|S| = k'$, and for any $j \geq i$ the values of the distance functions for every interface point $p \in I_B^j$ are set to either

- $d_j^-(p) = \langle \text{dist}(p, S) \rangle_j$ and $d_j^+(p) = \infty$, or
- $d_j^+(p) \leq \langle \text{dist}(p, S) \rangle_j$ and $d_j^-(p) = \infty$.

Over all sets $S \subseteq F \cap B'_{\leq \ell}$ compatible with $\hat{T}[B'_{\leq \ell}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$, the entry should store the minimum value of $\hat{C}_{\leq \ell}(S)$, which is defined as

$$\hat{C}_{\leq \ell}(S) = \sum_{v \in B'_{\leq \ell}} \chi_{\mathcal{I}_0}(v) \cdot \min \Big\{ \text{dist}'(v, S), \min_{\substack{j \geq i \\ p \in I_B^j}} \big\{ \text{dist}(v, p) + d_j^+(p) \big\} \Big\}.$$

If there is no compatible set $S \subseteq F \cap B'_{\leq \ell}$ for the entry, then $\hat{T}[B'_{\leq \ell}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] = \infty$.

To compute T using the auxiliary table $\hat{T}$, note that since $B = B'_{\leq b}$, any set $S \subseteq F \cap B$ is compatible with the entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ if and only if it is compatible with a corresponding entry $\hat{T}[B'_{\leq b}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$ for some internal distance function d_i^- on level i. Furthermore, if $d_i^+(p) = \infty$ for all $p \in I^i$, then $C_B(S) = \hat{C}_{\leq b}(S)$ for such a set S. Therefore we can easily compute the entry $T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ from $\hat{T}$ by setting

$$T[B, k', (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}] = \min_{d_i^-} \Big\{ \hat{T}[B'_{\leq b}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] \mid \forall p \in I_B^i : d_i^+(p) = \infty \Big\}.$$

Computing the auxiliary table. Also computing an entry of $\hat{T}$ for $B'_{\leq 1}$ is easy using the entries of T for B'_1, since $B'_1 = B'_{\leq 1}$ and so (taking the index shift of i into account) we have

$$\hat{T}[B'_{\leq 1}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] = T[B'_1, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}].$$

To compute entries of $\hat{T}$ for some $B'_{\leq \ell}$ where $\ell \geq 2$, we combine entries of table T for B'_ℓ with entries of table $\hat{T}$ for $B'_{\leq \ell-1}$. However we will only combine entries with distance functions that imply compatible solutions. More concretely, we say that distance functions $(d_j^+, d_j^-)_{j=i}^{\lambda(W)}$ for $B'_{\leq \ell}$, $(\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}$ for B'_ℓ, and $(\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}$ for $B'_{\leq \ell-1}$ are *consistent* if for every level $j \geq i$ and $p \in I_B^j$ we have one of

1. $d_j^+(p) = \delta_j^+(p) = \beta_j^+(p)$ and $d_j^-(p) = \delta_j^-(p) = \beta_j^-(p) = \infty$, or
2. $d_j^-(p) = \delta_j^-(p) = \beta_j^+(p)$ and $d_j^+(p) = \delta_j^+(p) = \beta_j^-(p) = \infty$, or
3. $d_j^-(p) = \delta_j^+(p) = \beta_j^-(p)$ and $d_j^+(p) = \delta_j^-(p) = \beta_j^+(p) = \infty$.

The algorithm now considers all sets of consistent distance functions to compute an entry $\hat{T}[B'_{\leq \ell}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$ for $\ell \geq 2$ by setting it to

$$\min \big\{ T[B'_\ell, k'', (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}] + \hat{T}[B'_{\leq \ell-1}, k' - k'', (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}] \mid k'' \in \{0, \ldots, k'\} \text{ and } (d_j^+, d_j^-)_{j=i}^{\lambda(W)}, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)} \text{ are consistent} \big\} \quad (1)$$

We now prove the correctness using two lemmas. The following lemma implies that if we only consider consistent distance functions to compute entries recursively, then the entries will store values for compatible solutions.

▶ **Lemma 21.** *Let $(d_j^+, d_j^-)_{j=i}^{\lambda(W)}$ for $B'_{\leq \ell}$, $(\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}$ for B'_ℓ, and $(\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}$ for $B'_{\leq \ell-1}$ be consistent distance functions, and let $S_1 = B'_\ell \cap F$ and $S_2 = B'_{\leq \ell-1} \cap F$ be facility sets. If S_1 is compatible with entry $T[B'_\ell, |S_1|, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}]$ and S_2 is compatible with entry $\hat{T}[B'_{\leq \ell-1}, |S_2|, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}]$, then the union $S = S_1 \cup S_2$ is compatible with entry $\hat{T}[B'_{\leq \ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$. Moreover, $\hat{C}_{\leq \ell}(S) = C_{B'_\ell}(S_1) + \hat{C}_{\leq \ell-1}(S_2)$.*

Proof. To prove compatibility of S with the entry $\hat{T}[B'_{\leq \ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$, it suffices to show that the distance functions are set correctly. Fix a level $j \geq i$ and an interface point $p \in I_B^j$. There are three cases to consider, according to the definition of consistency of the distance functions. In the first case, all three internal distance functions are set to ∞, and all external distance functions are set to the same value. In particular, since S_1 and S_2 are compatible with their respective entries, we have $d_j^+(p) = \delta_j^+(p) = \beta_j^+(p) \leq \min\{\langle \text{dist}(p, S_1) \rangle_j, \langle \text{dist}(p, S_2) \rangle_j\} = \langle \text{dist}(p, S) \rangle_j$, as $S = S_1 \cup S_2$. In the second case, $\beta_j^-(p) = \delta_j^+(p) = \infty$ and so $\beta_j^+(p) \leq \langle \text{dist}(p, S_2) \rangle_j$, since S_2 is compatible with its entry, and

$\delta_j^-(p) = \langle \text{dist}(p, S_1)\rangle_j$, since S_1 is compatible with its entry. Since we also have $\beta_j^+(p) = \delta_j^-(p)$ we get $\langle \text{dist}(p, S_1)\rangle_j \leq \langle \text{dist}(p, S_2)\rangle_j$, and hence $\langle \text{dist}(p, S)\rangle_j = \langle \text{dist}(p, S_1)\rangle_j$. Consistency furthermore implies $d_j^-(p) = \delta_j^-(p) = \langle \text{dist}(p, S)\rangle_j$ and $d_j^+(p) = \infty$. The third case is analogous to the second, and therefore S is compatible with its entry.

For the second part, we consider the contributions of vertices to the terms $\hat{C}_{\leq \ell}(S)$, $C_{B'_\ell}(S_1)$, and $\hat{C}_{\leq \ell-1}(S_2)$, and show that they are the same for $\hat{C}_{\leq \ell}(S)$ and for $C_{B'_\ell}(S_1) + \hat{C}_{\leq \ell-1}(S_2)$. For this we first fix a vertex $v \in B'_{\leq \ell-1}$, and in the following distinguish the cases where its contribution to $\hat{C}_{\leq \ell-1}(S_2)$ and $\hat{C}_{\leq \ell}(S)$ is due to a facility or an interface point.

The first case is that $\text{dist}'(v, S_2) \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\}$, i.e., the contribution of v to $\hat{C}_{\ell-1}(S_2)$ is given by a facility of S_2. Note that the consistency of the distance functions always implies that $\beta_j^+(p) = d_j^+(p)$ or $d_j^+(p) = \infty$ for any level $j \geq i$ and interface point $p \in I^j$, and so $\min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\} \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + d_j^+(p)\}$. At the same time $\text{dist}'(v, S) \leq \text{dist}'(v, S_2)$ as $S_2 \subseteq S$. We hence get that $\text{dist}'(v, S) \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + d_j^+(p)\}$, i.e., the contribution of v to $\hat{C}_\ell(S)$ is also given by a facility of S in this case. Thus to show that the contribution of v to $\hat{C}_{\ell-1}(S_2)$ and $\hat{C}_\ell(S)$ is the same, we need to show that $\text{dist}'(v, S) = \text{dist}'(v, S_2)$. Note that this is implied if $\text{dist}'(v, S) \geq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\}$, since we have $\text{dist}'(v, S) \leq \text{dist}'(v, S_2) \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\}$. Thus the following proves the claim, using that the contribution of v to $\hat{C}_\ell(S)$ is given by a facility of S.

▷ Claim 22. For $v \in B'_{\leq \ell-1}$, if $\text{dist}'(v, S) \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + d_j^+(p)\}$ then we have $\text{dist}'(v, S) = \text{dist}'(v, S_2)$ or $\text{dist}'(v, S) \geq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\}$.

Proof. Given $\text{dist}'(v, S) \leq \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + d_j^+(p)\}$, assume to the contrary that we have $\text{dist}'(v, S) < \min_{j \geq i,\, p \in I_B^j}\{\text{dist}(v, p) + \beta_j^+(p)\}$ and $\text{dist}'(v, S) \neq \text{dist}'(v, S_2)$, which, as $S = S_1 \cup S_2$, means $\text{dist}'(v, S) < \text{dist}'(v, S_2)$. The latter inequality implies that the value of $\text{dist}'(v, S)$ is obtained for some facility $f \in S_1 \subseteq B'_\ell$. In particular, $v \in B'_{\leq \ell-1}$ and $f \in B'_\ell$ are cut at level $i - 1$, and so there is an interface point $p \in I_B^i$ such that $\text{dist}'(v, S) = \text{dist}(v, p) + \langle \text{dist}(p, f)\rangle_i$, and f is the closest facility to p in S, i.e, $\langle \text{dist}(p, S)\rangle_i = \langle \text{dist}(p, f)\rangle_i$. Using the former of the assumed inequalities we get $\text{dist}(v, p) + \langle \text{dist}(p, f)\rangle_i = \text{dist}'(v, S) < \text{dist}(v, p) + \beta_i^+(p)$, and so we can conclude that $\langle \text{dist}(p, f)\rangle_i < \beta_i^+(p)$.

Using the inequality of the premise of the claim, we also get $\text{dist}(v, p) + \langle \text{dist}(p, f)\rangle_i = \text{dist}'(v, S) \leq \text{dist}(v, p) + d_i^+(p)$, i.e. $\langle \text{dist}(p, f)\rangle_i \leq d_i^+(p)$. Since S is compatible with entry $\hat{T}[B'_{\leq \ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$, we have $d_i^+(p) = \infty$ or $d_i^+(p) \leq \langle \text{dist}(p, S)\rangle_i$. In the latter case we would have $d_i^+(p) \leq \langle \text{dist}(p, S)\rangle_i = \langle \text{dist}(p, f)\rangle_i < \beta_i^+(p)$, which however cannot happen if the distance functions are consistent. Thus compatibility of S implies $d_i^+(p) = \infty$ and $d_i^-(p) = \langle \text{dist}(p, f)\rangle_i$. In particular, we can conclude that $d_i^-(p)$ has a finite value (as f exists) and $\beta_i^+(p)$ differs from $d_i^-(p)$. This can only mean that the third of the consistency properties applies to p at level i, and so $\beta_i^-(p) = d_i^-(p) = \langle \text{dist}(p, f)\rangle_i$.

In particular, also $\beta_i^-(p)$ has a finite value, and using the compatibility of S_2 with entry $\hat{T}[B'_{\leq \ell-1}, |S_2|, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}]$, we can conclude that there exists a facility $f' \in S_2 \subseteq B'_{\leq \ell-1}$ with $\langle \text{dist}(p, f')\rangle_i = \beta_i^-(p) = \langle \text{dist}(p, f)\rangle_i$. Now let $j \leq i$ be the level for which $v \in B'_{\leq \ell-1}$ and $f' \in B'_{\leq \ell-1}$ are cut at level $j - 1$ by $\mathcal{D}$. Lemma 18 implies $\text{dist}'(v, f') \leq \text{dist}(v, p) + \langle \text{dist}(p, f')\rangle_i$, but then we have

$$\text{dist}'(v, S_2) \leq \text{dist}'(v, f') \leq \text{dist}(v, p) + \langle \text{dist}(p, f')\rangle_i = \text{dist}(v, p) + \langle \text{dist}(p, f)\rangle_i = \text{dist}'(v, S),$$

which is a contradiction to $\text{dist}'(v, S) < \text{dist}'(v, S_2)$. ◁

The next case we consider is that $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\} < \text{dist}'(v,S)$, i.e., the contribution of v to $\hat{C}_\ell(S)$ is given by an interface point. As observed before, we have $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} \leq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$ and $\text{dist}'(v,S) \leq \text{dist}'(v,S_2)$, which implies $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} < \text{dist}'(v,S_2)$, i.e. in this case the contribution of v to $\hat{C}_{\ell-1}(S_2)$ is also given by an interface point. Note that it also implies $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$, and thus the following claim shows that the contribution of v to $\hat{C}_\ell(S)$ and $\hat{C}_{\ell-1}(S_2)$ is the same.

▷ Claim 23. For $v \in B'_{\leq \ell-1}$, if $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$ then we have $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} = \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$.

Proof. Given $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$, assume to the contrary that $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} \neq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$. As observed before, the consistency of the distance functions always implies $\beta_j^+(p) = d_j^+(p)$ or $d_j^+(p) = \infty$, and thus we must have $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} < \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$. Let $j \geq i$ and $p \in I_B^j$ be the level and interface point for which the minimum of the former term of this inequality is obtained. The inequality then implies $\beta_j^+(p) < d_j^+(p)$ for this particular point p and level j, which can only be the case if $\beta_j^+(p) < \infty$ and $d_j^+(p) = \infty$. The values of $\beta_j^+(p)$ and $d_j^+(p)$ can only differ if the second of the consistency properties applies to p at level j, and so $\beta_j^+(p) = d_j^-(p)$. Since $\beta_j^+(p) < \infty$, the compatibility of S with entry $\hat{T}[B'_{\leq \ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$, implies $\beta_j^+(p) = d_j^-(p) = \langle \text{dist}(p,S)\rangle_j$.

Now let $f \in S \subseteq B'_{\leq \ell}$ be the facility for which $\text{dist}'(v,S) = \text{dist}'(v,f)$ (which exists as $d_j^-(p) < \infty$). Let $j' \leq i$ be the level for which $v \in B'_{\leq \ell-1}$ and $f \in B'_{\leq \ell}$ are cut at level $j'-1$ by $\mathcal{D}$. By Lemma 18 we have $\text{dist}'(v,f) \leq \text{dist}(v,p) + \langle \text{dist}(p,f)\rangle_j$, since $j' \leq j$ and the part $B \in \mathcal{B}_i$ containing v and f is itself contained in some part $\tilde{B} \in \mathcal{B}_j$ with $v, f \in \tilde{B}$ and $p \in I_{\tilde{B}}$. But then,

$$\text{dist}'(v,S) \leq \text{dist}(v,p) + \langle \text{dist}(p,f)\rangle_j = \text{dist}(v,p) + \langle \text{dist}(p,S)\rangle_j = \text{dist}(v,p) + \beta_j^+(p).$$

However the last term is equal to $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$, which gives a contradiction to our premise $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$. ◁

So far we considered the case when the contribution of v to $\hat{C}_{\ell-1}(S_2)$ is given by a facility, or when the contribution of v to $\hat{C}_\ell(S)$ is given by an interface point. Thus the last case we consider is when the contribution of v to $\hat{C}_{\ell-1}(S_2)$ is given by an interface point, and the contribution of v to $\hat{C}_\ell(S)$ is given by a facility, i.e., $\min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\} < \text{dist}'(v,S_2)$ and $\text{dist}'(v,S) \leq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$. We need to show that $\text{dist}'(v,S) = \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$. First assume $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$. Due to Claim 23 this would imply $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$, which however contradicts our assumption to the contrary, i.e., that the contribution of v to $\hat{C}_\ell(S)$ is given by a facility. Hence we must instead have $\text{dist}'(v,S) \leq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$.

According to Claim 22, our assumption that $\text{dist}'(v,S) \leq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+d_j^+(p)\}$ implies $\text{dist}'(v,S) = \text{dist}'(v,S_2)$ or $\text{dist}'(v,S) \geq \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$. In the former case, together with our assumption that the contribution of v to $\hat{C}_{\ell-1}(S_2)$ is given by an interface point, we would get $\text{dist}'(v,S) > \min_{j\geq i,\ p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$, for which we saw above that this leads to a contradiction via Claim 23. Hence we are left with the other

implication of Claim 22, i.e., $\text{dist}'(v,S) \geq \min_{j\geq i,\, p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$. This together with our conclusion from above, i.e., $\text{dist}'(v,S) \leq \min_{j\geq i,\, p\in I_B^j}\{\text{dist}(v,p)+\beta_j^+(p)\}$, means that the contribution of v to $\hat{C}_\ell(S)$ and $\hat{C}_{\ell-1}(S_2)$ is the same.

By analogous arguments, the contribution of any $v \in B'_\ell$ to $C_{B'_\ell}(S_1)$ is the same as its contribution to $\hat{C}_{\leq\ell}(S)$. Since B'_ℓ and $B'_{\leq\ell-1}$ partition the set $B'_{\leq\ell}$, this means that $\hat{C}_{\leq\ell}(S) = C_{B'_\ell}(S_1) + \hat{C}_{\leq\ell-1}(S_2)$, as required. ◀

The next lemma implies that the compatible facility set minimizing $\hat{C}_{\leq\ell}(S)$ is considered as a solution when recursing over consistent distance functions.

▶ **Lemma 24** (⋆). *Let $S = B'_{\leq\ell} \cap F$ be a facility set of $B'_{\leq\ell}$ that is compatible with entry $\hat{T}[B'_{\leq\ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$, and let $S_1 = S \cap B'_\ell$ and $S_2 = S \cap B'_{\leq\ell-1}$. Then there exist distance functions $(\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}$ for B'_ℓ, and $(\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}$ for $B'_{\leq\ell-1}$ such that*

- *$(d_j^+, d_j^-)_{j=i}^{\lambda(W)}$, $(\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}$, and $(\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}$ are consistent, and*
- *the set S_1 is compatible with entry $T[B'_\ell, |S_1|, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}]$ and S_2 is compatible with entry $\hat{T}[B'_{\leq\ell-1}, |S_2|, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}]$.*

To argue that the algorithm sets the value of $\hat{T}[B'_{\leq\ell}, k', (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$ correctly via (1), consider a set $S \subseteq B'_{\leq\ell}$ that is compatible with this entry and minimizes $\hat{C}_{\leq\ell}(S)$. By induction, Lemma 24 implies $T[B'_\ell, |S_1|, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}] \leq C_{B'_\ell}(S_1)$ and $\hat{T}[B'_{\leq\ell-1}, |S_2|, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}] \leq \hat{C}_{\leq\ell-1}(S_2)$, where $S_1 = S \cap B'_\ell$ and $S_2 = S \cap B'_{\leq\ell-1}$. From (1) we therefore obtain $\hat{T}[B'_{\leq\ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] \leq C_{B'_\ell}(S_1) + \hat{C}_{\leq\ell-1}(S_2)$. By Lemma 21 only compatible sets are stored in an entry by induction, and so the definition of S implies $\hat{T}[B'_{\leq\ell}, |S|, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] = \hat{C}_{\leq\ell}(S)$, as required.

Bounding the runtime. To bound the size of the tables T and $\hat{T}$, note that since there are $\lambda(W) - \xi(W) + 1 \leq 2\log_2(nX/\varepsilon) + 2$ considered levels i, and each level $\mathcal{B}_i$ of $\mathcal{D}$ is a partition of W where $|W| \leq n$, there are at most $O(n\log(nX/\varepsilon))$ parts B considered by T in total. The other table $\hat{T}$ considers the same number of parts, since a set $B'_{\leq\ell}$ can be uniquely mapped to the part B'_ℓ. The number of possible values for k' is $k+1 = O(n)$. The domain $\{\langle x\rangle_j \mid 0 < x \leq 2^{j+5}\} \cup \{\infty\}$ of a distance function for level j has at most $\lceil 2^{j+5}/(\rho 2^j)\rceil + 1 = O(1/\rho)$ values, since $\langle x\rangle_j$ rounds a value to a multiple of $\rho 2^j$. The conciseness of the interface sets means that $|I_B^j| \leq (h/\rho)^{O(1)}$ according to Lemma 5. Hence there are at most $O(1/\rho)^{(h/\rho)^{O(1)}} = 2^{(h/\rho)^{O(1)}}$ possible distance functions. Since each entry of the table stores two distance functions for each of at most $2\log_2(nX/\varepsilon)+2$ levels, the total number of entries of T and $\hat{T}$ is at most

$$O(n\log(nX/\varepsilon)) \cdot n \cdot (2^{(h/\rho)^{O(1)}})^{O(\log(nX/\varepsilon))} = (nX/\varepsilon)^{(h/\rho)^{O(1)}}.$$

Computing an entry of a table is dominated by (1). Going through all values $k' \leq n$ and all possible consistent distance functions to compute (1), takes $n \cdot 2^{(h/\rho)^{O(1)}}$ time, as there are $2^{(h/\rho)^{O(1)}}$ possible distance functions. Hence the total runtime is $(nX/\varepsilon)^{(h/\rho)^{O(1)}}$, proving Lemma 20.

The Facility Location^q problem. To compute an optimum rounded interface-respecting solution to Facility Location^q, the tables T and $\hat{T}$ can ignore the number of open facilities k', i.e., they have respective entries $T[B, (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ and $\hat{T}[B'_{\leq\ell}, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$.

Accordingly, compatibility of facility sets with entries is defined as before, but ignoring the sizes of the sets. The value stored in each entry now also takes the opening costs of facilities into account. That is, for any set of facilities $S \subseteq F \cap B$ in a part B we define

$$C_B(S) = \sum_{v \in B} \chi_{\mathcal{I}_0}(v) \cdot \min\Big\{ \operatorname{dist}'(v,S), \min_{\substack{j \geq i+1 \\ p \in I_B^j}} \big\{ \operatorname{dist}(v,p) + d_j^+(p) \big\} \Big\} + \sum_{f \in S} w_f,$$

and an entry $T[B, (d_j^+, d_j^-)_{j=i+1}^{\lambda(W)}]$ stores the minimum value of $C_B(S)$ over all sets S compatible with the entry, or ∞ if no such set exists. For $S \subseteq F \cap B'_{\leq \ell}$ in a union of subparts $B'_{\leq \ell}$ we define

$$\hat{C}_{\leq \ell}(S) = \sum_{v \in B'_{\leq \ell}} \chi_{\mathcal{I}_0}(v) \cdot \min\Big\{ \operatorname{dist}'(v,S), \min_{\substack{j \geq i \\ p \in I_B^j}} \big\{ \operatorname{dist}(v,p) + d_j^+(p) \big\} \Big\} + \sum_{f \in S} w_f,$$

and an entry $\hat{T}[B'_{\leq \ell}, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}]$ stores the minimum value of $\hat{C}_{\leq \ell}(S)$ over all sets S compatible with the entry, or ∞ if no such set exists.

The entries of the tables can be computed in the same manner as before, but ingoring the sets sizes. In particular, the most involved recursion becomes

$$\hat{T}[B'_{\leq \ell}, (d_j^+, d_j^-)_{j=i}^{\lambda(W)}] = \min \big\{ T[B'_\ell, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}] + \hat{T}[B'_{\leq \ell-1}, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)}] \;\big|\; (d_j^+, d_j^-)_{j=i}^{\lambda(W)}, (\delta_j^+, \delta_j^-)_{j=i}^{\lambda(W)}, (\beta_j^+, \beta_j^-)_{j=i}^{\lambda(W)} \text{ are consistent} \big\}.$$

Note that if $S_1 = B'_\ell \cap F$ and $S_2 = B'_{\leq \ell-1} \cap F$ then these two sets are disjoint, and so $\sum_{f \in S} w_f = \sum_{f \in S_1} w_f + \sum_{f \in S_2} w_f$ for the union $S = S_1 \cup S_2$. Hence when proving $\hat{C}_{\leq \ell}(S) = C_{B'_\ell}(S_1) + \hat{C}_{\leq \ell-1}(S_2)$ for Lemma 21, we can ignore the facility opening costs, and the proof remains the same as before. All other arguments carry over, and thus an optimum rounded interface-respecting solution for an instance of Facility Location^q can also be computed in $(nX/\varepsilon)^{(h/\rho)^{O(1)}}$ time.

5 Hardness for graphs of highway dimension 1

For both k-Clustering^q and Facility Location^q we present the same reduction from the NP-hard satisfiability problem (SAT), in which a boolean formula φ in conjunctive normal form is given, and a satisfying assignment of its variables needs to be found.

For a given SAT formula φ with k variables and ℓ clauses we construct a graph G_φ as follows. For each variable x we introduce a path $P_x = (t_x, u_x, f_x)$ with two edges of length 1 each. The two endpoints t_x and f_x are facilities of F and the additional vertex u_x is a client, i.e., $\chi(u_x) = 1$. For each clause C_i, where $i \in [\ell]$, we introduce a vertex v_i and add the edge $v_i t_x$ for each variable x such that C_i contains x as a positive literal, and we add the edge $v_i f_x$ for each x for which C_i contains x as a negative literal. Every edge incident to v_i has length $(11c)^i$ for the constant $c > 4$ due to Definition 1, and v_i is also a client, i.e., $\chi(v_i) = 1$. In case of Facility Location^q, every facility $f \in F$ has cost $w_f = 1$, i.e., we construct an instance of the uniform version of the problem.

▶ **Lemma 25.** *The constructed graph G_φ has highway dimension 1.*

Proof. Fix a scale $r > 0$ and let $i = \lfloor \log_{11c}(r/5) + 1 \rfloor$. Note that $\beta_w(cr)$ cannot contain any edge incident to a vertex v_j for $j \geq i+1$, since the length of every such edge is $(11c)^j \geq 11cr/5 > 2cr$ and the diameter of $\beta_w(cr)$ is at most $2cr$. Thus if $\beta_w(cr)$ contains a vertex v_j for $j \geq i+1$, then $\beta_w(cr)$ contains only v_j, and there is nothing to prove. Note

also that any path in $\beta_w(cr)$ that does not use v_i has length at most $2 + \sum_{j=1}^{i-1}(2(11c)^j + 2)$, since any such path can contain at most two edges incident to a vertex v_j and the paths P_x of length 2 are connected only through edges incident to vertices v_j. The length of such a path is thus strictly shorter than

$$2 + 2\left(\frac{(11c)^i}{11c-1} - 1\right) + 2i \leq 5(11c)^{i-1} \leq r,$$

where the first inequality holds since $i \geq 1$ and $c > 4$. Hence the only paths that need to be hit by hubs on scale r are those passing through v_i, which can clearly be done using only one hub, namely v_i. ◀

To finish the reduction for k-Clustering^q, we claim that there is a satisfying assignment for φ if and only if there is a solution for G_φ with cost at most $k + \sum_{i=1}^{\ell}(11c)^{iq}$. If there is a satisfying assignment for φ we open each facility t_x for variables x that are set to true, and we open each facility f_x for variables x that are set to false. This opens exactly k facilities and the cost of the solution is $k + \sum_{i=1}^{\ell}(11c)^{iq}$, since each of the k vertices u_x is assigned to either t_x or f_x at distance 1, and vertex v_i is assigned to a vertex t_x or f_x at distance $(11c)^i$ that corresponds to a literal of C_i that is true.

Conversely, assume there is a solution to k-Clustering^q of cost at most $k + \sum_{i=1}^{\ell}(11c)^{iq}$ in G_φ. Note that the minimum distance from any u_x to a facility is 1, while the minimum distance from any v_i to a facility is $(11c)^i$. Thus any solution must have cost at least $k + \sum_{i=1}^{\ell}(11c)^{iq}$, so that the assumed solution must open a facility at minimum distance for each client of G_φ. In particular, for each variable x, at least one of the facilities t_x and f_x is opened by the solution. Moreover, as only k facilities can be opened and there are k variables, exactly one of t_x and f_x is opened for each x. Thus the k-Clustering^q solution in G_φ can be interpreted as an assignment for φ, where we set a variable x to true if t_x is opened, and we set it to false if f_x is opened. Since also for each v_i the solution opens a facility at minimum distance, there must be a variable in C_i that is set so that its literal in C_i is true, i.e., the assignment satisfies φ. Thus due to the above lemma bounding the highway dimension of G_φ, we obtain the Theorem 3 for k-Clustering^q.

For Facility Location^q we claim that there is a satisfying assignment for φ if and only if there is a solution for G_φ of cost at most $2k + \sum_{i=1}^{\ell}(11c)^{iq}$. In fact the arguments are exactly the same as for k-Clustering^q above: if there is a satisfying assignment then a solution for Facility Location^q of cost $2k + \sum_{i=1}^{\ell}(11c)^{iq}$ exists, by opening the k facilities corresponding to the assignment of cost 1 each. Conversely, any solution has cost at least $k + \sum_{i=1}^{\ell}(11c)^{iq}$ due to the edge lengths, and at least k facilities need to be opened, one for each variable gadget. This gives a minimum cost of $2k + \sum_{i=1}^{\ell}(11c)^{iq}$, and any such solution corresponds to a satisfying assignment of φ. This proves Theorem 3 for uniform Facility Location^q.

Abstract

Given a training set P of *labeled* points, the *nearest-neighbor rule* predicts the class of an *unlabeled* query point as the label of its closest point in the set. To improve the time and space complexity of classification, a natural question is how to reduce the training set without significantly affecting the accuracy of the nearest-neighbor rule. *Nearest-neighbor condensation* deals with finding a subset $R \subseteq P$ such that for every point $p \in P$, p's nearest-neighbor in R has the same label as p. This relates to the concept of *coresets*, which can be broadly defined as subsets of the set, such that an exact result on the coreset corresponds to an approximate result on the original set. However, the guarantees of a coreset hold for any query point, and not only for the points of the training set.

This paper introduces the concept of coresets for nearest-neighbor classification. We extend existing criteria used for condensation, and prove sufficient conditions to correctly classify any query point when using these subsets. Additionally, we prove that finding such subsets of minimum cardinality is NP-hard, and propose quadratic-time approximation algorithms with provable upper-bounds on the size of their selected subsets. Moreover, we show how to improve one of these algorithms to have subquadratic runtime, being the first of this kind for condensation.

1 Introduction

In non-parametric classification, we are given a *training set* P consisting of n points in a metric space $(\mathcal{X}, \mathsf{d})$, with domain $\mathcal{X}$ and distance function $\mathsf{d} : \mathcal{X}^2 \to \mathbb{R}^+$. Additionally, P is partitioned into a finite set of *classes* by associating each point $p \in P$ with a *label* $l(p)$, indicating the class to which it belongs. Given an *unlabeled* query point $q \in \mathcal{X}$, the goal of a *classifier* is to predict q's label using the training set P.

The *nearest-neighbor rule* is among the best-known classification techniques [19]. It assigns a query point the label of its closest point in P, according to the metric d. The nearest-neighbor rule exhibits good classification accuracy both experimentally and theoretically [14, 15, 36], but it is often criticized due to its high space and time complexities. Clearly, the training set

P must be stored to answer nearest-neighbor queries, and the time required for such queries depends to a large degree on the size and dimensionality of the data. These drawbacks inspire the question of whether it is possible replace P with a significantly smaller subset, without significantly reducing the classification accuracy under the nearest-neighbor rule. This problem is called *nearest-neighbor condensation* [22, 25, 34, 37].

There are obvious parallels between condensation and the concept of *coresets* in geometric approximation [1, 17, 23, 33]. Intuitively, a *coreset* is small subset of the original data, that well approximates some statistical properties of the original set. Coresets have also been applied to many problems in machine learning, such as clustering and neural network compression [8, 11, 18, 29]. This includes recent results on coresets for the SVM classifier [38].

This paper presents the first approach to compute coresets for the nearest-neighbor rule, leveraging its resemblance to the problem of nearest-neighbor condensation. We also present one of the first results on practical condensation algorithms with theoretical guarantees.

Preliminaries. Given any point $q \in \mathcal{X}$ in the metric space, its nearest-neighbor, denoted $\mathrm{nn}(q)$, is the closest point of P according the the distance function d. The distance from q to its nearest-neighbor is denoted by $\mathsf{d}_{\mathrm{nn}}(q, P)$, or simply $\mathsf{d}_{\mathrm{nn}}(q)$ when P is clear. Given a point $p \in P$ from the training set, its nearest-neighbor in P is point p itself. Additionally, any point of P whose label differs from p's is called an *enemy* of p. The closest such point is called p's *nearest-enemy*, and the distance to this point is called p's *nearest-enemy distance*. These are denoted by $\mathrm{ne}(p)$ and $\mathsf{d}_{\mathrm{ne}}(p, P)$ (or simply $\mathsf{d}_{\mathrm{ne}}(p)$), respectively.

Clearly, the size of a coreset for nearest-neighbor classification depends on the spatial characteristics of the classes in the training set. For example, it is much easier to find a small coreset for two spatially well separated clusters than for two classes that have a high degree of overlap. To model the intrinsic complexity of nearest-neighbor classification, we define κ to be the number of nearest-enemy points of P, i.e., the cardinality of set $\{\mathrm{ne}(p) \mid p \in P\}$.

Through a suitable uniform scaling, we may assume that the *diameter* of P (that is, the maximum distance between any two points in the training set) is 1. The *spread* of P, denoted as Δ, is the ratio between the largest and smallest distances in P. Define the *margin* of P, denoted γ, to be the smallest nearest-enemy distance in P. Clearly, $1/\gamma \leq \Delta$.

A metric space $(\mathcal{X}, \mathsf{d})$ is said to be *doubling* [26] if there exist some bounded value λ such that any metric ball of radius r can be covered with at most λ metric balls of radius $r/2$. Its *doubling dimension* is the base-2 logarithm of λ, denoted as $\mathrm{ddim}(\mathcal{X}) = \log \lambda$. Throughout, we assume that $\mathrm{ddim}(\mathcal{X})$ is a constant, which means that multiplicative factors depending on $\mathrm{ddim}(\mathcal{X})$ may be hidden in our asymptotic notation. Many natural metric spaces of interest are doubling, including d-dimensional Euclidean space whose doubling dimension is $\Theta(d)$. It is well know that for any subset $R \subseteq \mathcal{X}$ with some spread Δ_R, the size of R is bounded by $|R| \leq \lceil \Delta_R \rceil^{\mathrm{ddim}(\mathcal{X})+1}$.

Related Work. A subset $R \subseteq P$ is said to be *consistent* [25] if and only if for every $p \in P$ its nearest-neighbor in R is of the same class as p. Intuitively, R is consistent if and only if all points of P are correctly classified using the nearest-neighbor rule over R. Formally, the problem of *nearest-neighbor condensation* consists of finding a consistent subset of P.

Another criterion used for condensation is known as *selectiveness* [34]. A subset $R \subseteq P$ is said to be *selective* if and only if for all $p \in P$ its nearest-neighbor in R is closer to p than its nearest-enemy in P. Clearly, any selective subset is also consistent. Observe that these condensation criteria ensure that every point in the training set will be correctly classified after condensation, but they do not imply the same for arbitrary points in the metric space.

Figure 1 An illustrative example of the subsets selected by different condensation algorithms from an initial training set P in $\mathbb{R}^2$ of 10^4 points. FCNN, VSS, and RSS, are known algorithms for this problem, while α-RSS is proposed in this paper, along with new condensation criteria. The subsets selected by α-RSS depend on the parameter $\alpha \geq 0$, here assigned to the values $\alpha = \{0.1, 0.5, 1, \sqrt{2}\}$.

It is known that the problems of computing consistent and selective subsets of minimum cardinality are both NP-hard [28, 39, 40]. An approximation algorithm called NET [22] was proposed for the problem of finding minimum cardinality consistent subsets, along with almost matching hardness lower-bounds. The algorithm simply computes a γ-net of P, where γ is the minimum nearest-enemy distance in P, which clearly results in a consistent subset of P (also selective). In practice, γ tends to be small, which results in subsets of much higher cardinality than needed. To overcome this issue, the authors proposed a post-processing pruning technique to further reduce the selected subset. Even with the extra pruning, NET is often outperformed on typical data sets by more practical heuristics with respect to runtime and selection size. More recently, a subexponential-time algorithm was proposed [10] for finding minimum cardinality consistent subsets of point sets $P \subset \mathbb{R}^2$ in the plane, along with other case-specific algorithms for special instances of the problem in $\mathbb{R}^2$. On the other hand, less is known about computing minimum cardinality selective subsets: there is only a worst-case exponential time algorithm called SNN [34] for computing such optimal subsets.

Most research has focused on proposing practical heuristics to find either consistent or selective subsets of P (for comprehensive surveys see [27, 37]). CNN (*Condensed Nearest-Neighbor*) [25] was the first algorithm proposed to compute consistent subsets. Even though it has been widely used in the literature, CNN suffers from several drawbacks: its running time is cubic in the worst-case, and the resulting subset is *order-dependent*, meaning that the result is determined by the order in which points are considered by the algorithm. Alternatives include FCNN (*Fast* CNN) [3] and MSS (*Modified Selective Subset*) [7], which compute consistent and selective subsets respectively. Both algorithms run in $\mathcal{O}(n^2)$ worst-case time, and are order-independent. While such heuristics have been extensively studied experimentally [21], theoretical results are scarce. Recently, it was shown [20] that the size of the subsets selected by MSS cannot be bounded, while for FCNN it is still unknown whether is possible to establish any bound. The same paper [20] proposes two new algorithms, namely

RSS (*Relaxed Selective Subset*) and VSS (*Voronoi Selective Subset*), to find selective subsets of P in $\mathcal{O}(n^2)$ worst-case time. Both algorithms provide some guarantees on its selection size in Euclidean space.

Contributions. As mentioned in the previous section, consistency and selectivity imply correct classification to points of the training set, but not to arbitrary points of the metric space (This is striking since this is the fundamental purpose of classification!). In this paper, we introduce the concept of a coreset for classification with the nearest-neighbor rule, which provides approximate guarantees on correct classification for all query points. We demonstrate their existence, analyze their size, and discuss their efficient computation.

We say that a subset $R \subseteq P$ is an *ε-coreset for the nearest-neighbor rule* on P, if and only if for every query point $q \in \mathcal{X}$, the class of its exact nearest-neighbor in R is the same as the class of some ε-approximate nearest-neighbor of q in P (see Section 2 for definitions). Recalling the concepts of κ and γ introduced in the preliminaries, here is our main result:

▶ **Theorem 1.** *Given a training set P in a doubling metric space $(\mathcal{X}, \mathsf{d})$, there exist an ε-coreset for the nearest-neighbor rule of size $\mathcal{O}(\kappa \log \frac{1}{\gamma} (1/\varepsilon)^{\mathrm{ddim}(\mathcal{X})+1})$, and this coreset can be computed in subquadratic worst-case time.*

Here is a summary of our principal results:

- We extend the criteria used for nearest-neighbor condensation, and identify sufficient conditions to guarantee the correct classification of any query point after condensation.
- We prove that finding minimum-cardinality subsets with this new criteria is NP-hard.
- We provide quadratic-time approximation algorithms with provable upper-bounds on the sizes of their selected subsets, and we show that the running time of one such algorithm can be improved to be subquadratic.

Our subquadratic-time algorithm is the first with such worst-case runtime for the problem of nearest-neighbor condensation.

2 Coreset Characterization

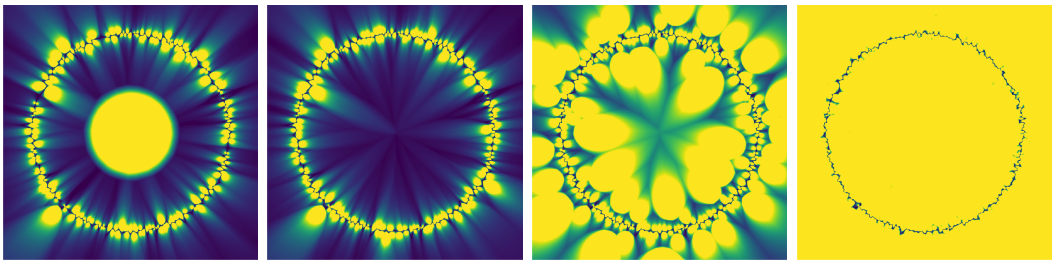
In practice, nearest-neighbors are usually not computed exactly, but rather approximately. Given an approximation parameter $\varepsilon \geq 0$, an *ε-approximate* nearest-neighbor or ε-ANN query returns any point whose distance from the query point is within a factor of $(1 + \varepsilon)$ times the true nearest-neighbor distance.

Intuitively, a query point should be easier to classify if its nearest-neighbor is significantly closer than its nearest-enemy. This intuition can be formalized through the concept of the *chromatic density* [31] of a query point $q \in \mathcal{X}$ with respect to a set $R \subseteq P$, defined as:

$$\delta(q, R) = \frac{\mathsf{d}_{\mathrm{ne}}(q, R)}{\mathsf{d}_{\mathrm{nn}}(q, R)} - 1. \tag{1}$$

Clearly, if $\delta(q, R) > \varepsilon$ then q will be correctly classified[1] by an ε-ANN query over R, as all possible candidates for the approximate nearest-neighbor belong to the same class as q's true nearest-neighbor. However, as evidenced in Figures 2a and 2b, one side effect of existing condensation algorithms is a significant reduction in the chromatic density of query points. Consequently, we propose new criteria and algorithms that maintain high chromatic densities after condensation, which are then leveraged to build coresets for the nearest-neighbor rule.

[1] By *correct classification*, we mean that the classification is the same as the classification that results from applying the nearest-neighbor rule exactly on the entire training set P.



(a) FCNN. **(b)** RSS. **(c)** 0.1-RSS. **(d)** 0.5-RSS.

Figure 2 Heatmap of *chromatic density* values of points in $\mathbb{R}^2$ w.r.t. the subsets computed by different condensation algorithms: FCNN, RSS, and α-RSS (see Figure 1). *Yellow* • corresponds to chromatic density values ≥ 0.5, while *blue* • corresponds to 0. Evidently, α-RSS helps maintaining high chromatic density values when compared to standard condensation algorithms.

2.1 Approximation-Sensitive Condensation

The decision boundaries of the nearest-neighbor rule (that is, points q such that $\mathsf{d}_{\text{ne}}(q, P) = \mathsf{d}_{\text{nn}}(q, P)$) are naturally characterized by points that separate clusters of points of different classes. As illustrated in Figures 1b-1d, condensation algorithms tend to select such points. However, this behavior implies a significant reduction of the chromatic density of query points that are far from such boundaries (see Figures 2a-2b).

A natural way to define an approximate notion of consistency is to ensure that all points in P are correctly classified by ANN queries over the condensed subset R. Given a condensation parameter $\alpha \geq 0$, we define a subset $R \subseteq P$ to be:

α-consistent if $\forall\ p \in P,\ \mathsf{d}_{\text{nn}}(p, R) < \mathsf{d}_{\text{ne}}(p, R)/(1+\alpha)$.

α-selective if $\forall\ p \in P,\ \mathsf{d}_{\text{nn}}(p, R) < \mathsf{d}_{\text{ne}}(p, P)/(1+\alpha)$.

It is easy to see that the standard forms arise as special cases when $\alpha = 0$. These new condensation criteria imply that $\delta(p, R) > \alpha$ for every $p \in P$, meaning that p is correctly classified using an α-ANN query on R. Note that any α-selective subset is also α-consistent. Such subsets always exist for any $\alpha \geq 0$ by taking $R = P$. Current condensation algorithms cannot guarantee either α-consistency or α-selectiveness unless α is equal to zero. Therefore, the central algorithmic challenge is how to efficiently compute such sets whose sizes are significantly smaller than P. We propose new algorithms to compute such subsets, which showcase how to maintain high chromatic density values after condensation, as evidenced in Figures 2c and 2d. This empirical evidence is matched with theoretical guarantees for α-consistent and α-selective subsets, described in the following section.

2.2 Guarantees on Classification Accuracy

These newly defined criteria for nearest-neighbor condensation enforce lower-bounds on the chromatic density of any point of P after condensation. However, this doesn't immediately imply having similar lower-bounds for unlabeled query points of $\mathcal{X}$. In this section, we prove useful bounds on the chromatic density of query points, and characterize sufficient conditions to correctly classify some of these query points after condensation.

Intuitively, the chromatic density determines how easy it is to correctly classify a query point $q \in \mathcal{X}$. We show that the "ease" of classification of q after condensation (i.e., $\delta(q, R)$) depends on both the condensation parameter α, and the chromatic density of q before condensation (i.e., $\delta(q, P)$). This result is formalized in the following lemma:

▶ **Lemma 2.** *Let $q \in \mathcal{X}$ be a query point, and R an α-consistent subset of P, for $\alpha \geq 0$. Then, q's chromatic density with respect to R is:*

$$\delta(q, R) > \frac{\alpha\,\delta(q, P) - 2}{\delta(q, P) + \alpha + 3}.$$

Proof. The proof follows by analyzing q's nearest-enemy distance in R. To this end, consider the point $p \in P$ that is q's nearest-neighbor in P. There are two possible cases:

Case 1: If $p \in R$, clearly $\mathsf{d}_{\mathrm{nn}}(q, R) = \mathsf{d}_{\mathrm{nn}}(q, P)$. Additionally, it is easy to show that after condensation, q's nearest-enemy distance can only increase: i.e., $\mathsf{d}_{\mathrm{ne}}(q, P) \leq \mathsf{d}_{\mathrm{ne}}(q, R)$. This implies that $\delta(q, R) \geq \delta(q, P)$.

Case 2: If $p \notin R$, we can upper-bound q's nearest-neighbor distance in R as follows:

Since R is an α-consistent subset of P, we know that there exists a point $r \in R$ such that $\mathsf{d}(p, r) < \mathsf{d}_{\mathrm{ne}}(p, R)/(1 + \alpha)$. By the triangle inequality and the definition of nearest-enemy, $\mathsf{d}_{\mathrm{ne}}(p, R) \leq \mathsf{d}(p, \mathrm{ne}(q, R)) \leq \mathsf{d}(q, p) + \mathsf{d}_{\mathrm{ne}}(q, R)$. Additionally, applying the definition of chromatic density on q and knowing that $\mathsf{d}_{\mathrm{ne}}(q, P) \leq \mathsf{d}_{\mathrm{ne}}(q, R)$, we have $\mathsf{d}(q, p) = \mathsf{d}_{\mathrm{nn}}(q, P) \leq \mathsf{d}_{\mathrm{nn}}(q, R) = \mathsf{d}_{\mathrm{ne}}(q, R)/(1 + \delta(q, P))$. Therefore:

$$\begin{aligned}\mathsf{d}_{\mathrm{nn}}(q, R) &\leq \mathsf{d}(q, r) \leq \mathsf{d}(q, p) + \mathsf{d}(p, r) \\ &< \mathsf{d}(q, p) + \frac{\mathsf{d}(q, p) + \mathsf{d}_{\mathrm{ne}}(q, R)}{1 + \alpha} \leq \left(\frac{\delta(q, P) + \alpha + 3}{(1 + \alpha)(1 + \delta(q, P))}\right) \mathsf{d}_{\mathrm{ne}}(q, R).\end{aligned}$$

Finally, from the definition of $\delta(q, R)$, we have:

$$\delta(q, R) = \frac{\mathsf{d}_{\mathrm{ne}}(q, R)}{\mathsf{d}_{\mathrm{nn}}(q, R)} - 1 > \frac{(1 + \alpha)(1 + \delta(q, P))}{\delta(q, P) + \alpha + 3} - 1 = \frac{\alpha\,\delta(q, P) - 2}{\delta(q, P) + \alpha + 3}.$$ ◀

The above result can be leveraged to define a coreset, in the sense that an exact result on the coreset corresponds to an approximate result on the original set. As previously defined, we say that a set $R \subseteq P$ is an *ε-coreset for the nearest-neighbor rule* on P, if and only if for every query point $q \in \mathcal{X}$, the class of q's exact nearest-neighbor in R is the same as the class of any of its ε-approximate nearest-neighbors in P.

▶ **Lemma 3.** *Any ε-coreset for the nearest-neighbor rule is an α-consistent subset, for $\alpha \geq 0$.*

Proof. Consider any ε-coreset $C \subseteq P$ for the nearest-neighbor rule on P. Since the approximation guarantee holds for any point in $\mathcal{X}$, it holds for any $p \in P \setminus C$. We know p's nearest-neighbor in the original set P is p itself, thus making $\mathsf{d}_{\mathrm{nn}}(p, P)$ zero. This implies that p must be correctly classified by a nearest-neighbor query on C, that is, $\mathsf{d}_{\mathrm{nn}}(p, C) < \mathsf{d}_{\mathrm{ne}}(p, C)$, which is the definition of α-consistency for any $\alpha \geq 0$. ◀

▶ **Theorem 4.** *Any $2/\varepsilon$-selective subset is an ε-coreset for the nearest-neighbor rule.*

Proof. Let R be an α-selective subset of P, where $\alpha = 2/\varepsilon$. Consider any query point $q \in \mathcal{X}$ in the metric space. It suffices to show that its nearest-neighbor in R is of the same class as any ε-approximate nearest-neighbor in P. To this end, consider q's chromatic density with respect to both P and R, denoted as $\delta(q, P)$ and $\delta(q, R)$, respectively. We identify two cases:

Case 1 (Correct-Classification guarantee): If $\delta(q, P) \geq \varepsilon$.

Consider the bound derived in Lemma 2. Since $\alpha \geq 0$, and by our assumption that $\delta(q, P) \geq \varepsilon > 0$, setting $\alpha = 2/\varepsilon$ implies that $\delta(q, R) > 0$. This means that the nearest-neighbor of q in R belongs to the same class as the nearest-neighbor of q in P. Intuitively, this guarantees that q is correctly classified by the nearest-neighbor rule in R.

Case 2 (ε-Approximation guarantee): If $\delta(q,P) < \varepsilon$.

Let $p \in P$ be q's nearest-neighbor in P, thus $\mathsf{d}(q,p) = \mathsf{d}_{\mathrm{nn}}(q,P)$. Since R is α-selective, there exists a point $r \in R$ such that $\mathsf{d}(p,r) = \mathsf{d}_{\mathrm{nn}}(p,R) < \mathsf{d}_{\mathrm{ne}}(p,P)/(1+\alpha)$. Additionally, by the triangle inequality and the definition of nearest-enemies, we have

$$\mathsf{d}_{\mathrm{ne}}(p,P) \leq \mathsf{d}(p,\mathrm{ne}(q,P)) \leq \mathsf{d}(p,q) + \mathsf{d}(q,\mathrm{ne}(q,P)) = \mathsf{d}_{\mathrm{nn}}(q,P) + \mathsf{d}_{\mathrm{ne}}(q,P).$$

From the definition of chromatic density, $\mathsf{d}_{\mathrm{ne}}(q,P) = (1+\delta(q,P))\,\mathsf{d}_{\mathrm{nn}}(q,P)$. Together, these inequalities imply that $(1+\alpha)\,\mathsf{d}(p,r) \leq (2+\delta(q,P))\,\mathsf{d}_{\mathrm{nn}}(q,P)$. Therefore:

$$\mathsf{d}_{\mathrm{nn}}(q,R) \leq \mathsf{d}(q,r) \leq \mathsf{d}(q,p) + \mathsf{d}(p,r) \leq \left(1 + \frac{2+\delta(q,P)}{1+\alpha}\right)\mathsf{d}_{\mathrm{nn}}(q,P).$$

Now, assuming $\delta(q,P) < \varepsilon$ and setting $\alpha = 2/\varepsilon$, imply that $\mathsf{d}_{\mathrm{nn}}(q,R) < (1+\varepsilon)\,\mathsf{d}_{\mathrm{nn}}(q,P)$. Therefore, the nearest-neighbor of q in R is an ε-approximate nearest-neighbor of q in P.

Cases 1 and 2 imply that setting $\alpha = 2/\varepsilon$ is sufficient to ensure that the nearest-neighbor rule classifies any query point $q \in \mathcal{X}$ with the class of one of its ε-approximate nearest-neighbors in P. Therefore, R is an ε-coreset for the nearest-neighbor rule on P. ◀

So far, we have assumed that nearest-neighbor queries over R are computed exactly, as this is the standard notion of coresets. However, it is reasonable to compute nearest-neighbors approximately even for R. How should the two approximations be combined to achieve a desired final degree of accuracy? Consider another approximation parameter ξ, where $0 \leq \xi < \varepsilon$. We say that a set $R \subseteq P$ is an (ξ,ε)-*coreset* for the approximate nearest-neighbor rule on P, if and only if for every query point $q \in \mathcal{X}$, the class of any of q's ξ-approximate nearest-neighbor in R is the same as the class of any of its ε-approximate nearest-neighbors in P. The following result generalizes Theorem 4 to accommodate for ξ-ANN queries after condensation.

▶ **Theorem 5.** *Any α-selective subset is an (ξ,ε)-coreset for the approximate nearest-neighbor rule when $\alpha = \Omega(1/(\varepsilon-\xi))$.*

Proof. This follows from similar arguments to the ones described in the proof of Theorem 4. Instead, here we set $\alpha = (\varepsilon\xi + 3\xi + 2)/(\varepsilon - \xi)$. Let R be an α-selective subset of P, and $q \in \mathcal{X}$ any query point in the metric space, consider the same two cases:

Case 1 (Correct-Classification guarantee): If $\delta(q,P) \geq \varepsilon$.

Consider the bound derived in Lemma 2. By our assumption that $\delta(q,P) \geq \varepsilon > 0$, and since $\alpha \geq 0$, the following inequality holds true:

$$\delta(q,R) > \frac{\alpha\,\delta(q,P) - 2}{\delta(q,P) + \alpha + 3} \geq \frac{\alpha\varepsilon - 2}{\varepsilon + \alpha + 3}$$

Based on this, it is easy to see that the assignment of $\alpha = (\varepsilon\xi + 3\xi + 2)/(\varepsilon - \xi)$ implies that $\delta(q,R) > \xi$, meaning that any of q's ξ-approximate nearest-neighbors in R belong to the same class as q's nearest-neighbor in P. Intuitively, this guarantees that q is correctly classified by the ξ-ANN rule in R.

Case 2 (ε-Approximation guarantee): If $\delta(q,P) < \varepsilon$.

The assignment of α implies that $\mathsf{d}_{\mathrm{nn}}(q,R) < \frac{1+\varepsilon}{1+\xi}\,\mathsf{d}_{\mathrm{nn}}(q,P)$. This means that an ξ-ANN query for q in R, will return one of q's ε-approximate nearest-neighbors in P.

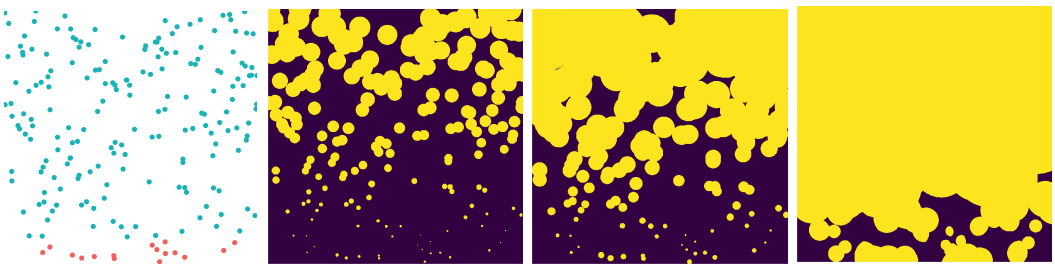
All together, this implies that R is an (ξ,ε)-coreset for the nearest-neighbor rule on P. ◀

In contrast with standard condensation criteria, these new results provide guarantees on either approximation or the correct classification, of any query point in the metric space. This is true even for query points that were "hard" to classify with the entire training set, formally defined as query points with low chromatic density. Consequently, Theorems 4 and 5 show that α must be set to large values if we hope to provide any sort of guarantees for these query points. However, better results can be achieved by restricting the set of points that are guaranteed to be correctly classified. This relates to the notion of *weak* coresets, which provide approximation guarantees only for a subset of the possible queries. Given $\beta \geq 0$, we define $\mathcal{Q}_\beta$ as the set of query points in $\mathcal{X}$ whose chromatic density with respect to P is at least β (i.e., $\mathcal{Q}_\beta = \{q \in \mathcal{X} \mid \delta(q, P) \geq \beta\}$). The following result describes the trade-off between α and β to guarantee the correct classification of query points in $\mathcal{Q}_\beta$ after condensation.

▶ **Theorem 6.** *Any α-consistent subset is a weak ε-coreset for the nearest-neighbor rule for queries in $\mathcal{Q}_\beta$, for $\beta = 2/\alpha$. Moreover, all query points in $\mathcal{Q}_\beta$ are correctly classified.*

The proof of this theorem is rather simple, and follows the same arguments outlined in Case 1 of the proof of Theorem 4. Basically, we use Lemma 2 to show that for any query point $q \in \mathcal{Q}_\beta$, q's chromatic density after condensation is greater than zero if $\alpha\beta \geq 2$. Note that ε plays no role in this result, as the guarantee on query points of $\mathcal{Q}_\beta$ is of correct classification (i.e., the class of its *exact* nearest-neighbor in P), rather than an approximation.

The trade-off between α and β is illustrated in Figure 3. From an initial training set $P \subset \mathbb{R}^2$ (Figure 3a), we show the regions of $\mathbb{R}^2$ that comprise the sets $\mathcal{Q}_\beta$ for $\beta = 2/\alpha$, using $\alpha = \{0.1, 0.2, \sqrt{2}\}$ (Figures 3b-3d). While evidently, increasing α guarantees that more query points will be correctly classified after condensation, this example demonstrates a phenomenon commonly observed experimentally: most query points lie far from enemy points, and thus have high chromatic density with respect to P. Therefore, while Theorem 4 states that α must be set to $2/\varepsilon$ to provide approximation guarantees on all query points, Theorem 6 shows that much smaller values of α are sufficient to provide guarantees on some query points, as evidenced in the example in Figure 3.



(a) Training set (200 pts). **(b)** $\mathcal{Q}_{2/\alpha}$ for $\alpha = 0.1$. **(c)** $\mathcal{Q}_{2/\alpha}$ for $\alpha = 0.2$. **(d)** $\mathcal{Q}_{2/\alpha}$ for $\alpha = \sqrt{2}$.

Figure 3 Depiction of the $\mathcal{Q}_\beta$ sets for which any α-consistent subset is weak coreset ($\beta = 2/\alpha$). Query points in the *yellow* • areas are inside $\mathcal{Q}_\beta$, and thus correctly classified after condensation. Query points in the *blue* • areas are not in $\mathcal{Q}_\beta$, and have no guarantee of correct classification.

These results establish a clear connection between the problem of condensation and that of finding coresets for the nearest-neighbor rule, and provides a roadmap to prove Theorem 1. This is the first characterization of sufficient conditions to correctly classify any query point in $\mathcal{X}$ after condensation, and not just the points in P (as the original consistency criteria implies). In the following section, these existential results are matched with algorithms to compute α-selective subsets of P of bounded cardinality.

3 Coreset Computation

3.1 Hardness Results

Define Min-α-CS to be the problem of computing an α-consistent subset of minimum cardinality for a given training set P. Similarly, let Min-α-SS be the corresponding optimization problem for α-selective subsets. Following known results from standard condensation [28, 39, 40], when α is set to zero, the Min-0-CS and Min-0-SS problems are both known to be NP-hard. Being special cases of the general problems just defined, this implies that both Min-α-CS and Min-α-SS are NP-hard.

In this section, we present results related to the hardness of approximation of both problems, along with simple algorithmic approaches with tight approximation factors.

▶ **Theorem 7.** *The Min-α-CS problem is* NP*-hard to approximate in polynomial time within a factor of* $2^{(\mathrm{ddim}(\mathcal{X})\log((1+\alpha)/\gamma))^{1-o(1)}}$.

The full proof is omitted, as it follows from a modification of the hardness bounds proof for the Min-0-CS problem described in [22], which is based on a reduction from the *Label Cover* problem. Proving Theorem 7 involves a careful adjustment of the distances in this reduction, so that all the points in the construction have chromatic density at least α. Consequently, this implies that the minimum nearest-enemy distance is reduced by a factor of $1/(1+\alpha)$, explaining the resulting bound for Min-α-CS.

The NET algorithm [22] can also be generalized to compute α-consistent subsets of P as follows. We define α-NET as the algorithm that computes a $\gamma/(1+\alpha)$-net of P, where γ is the smallest nearest-enemy distance in P. The covering property of nets [24] implies that the resulting subset is α-consistent, while the packing property suggests that its cardinality is $\mathcal{O}\left(((1+\alpha)/\gamma)^{\mathrm{ddim}(\mathcal{X})+1}\right)$, implying a tight approximation to the Min-α-CS problem.

▶ **Theorem 8.** *The Min-α-SS problem is* NP*-hard to approximate in polynomial time within a factor of* $(1-o(1))\ln n$ *unless* NP $\subseteq$ DTIME$(n^{\log\log n})$.

Proof. The result follows from the hardness of another related covering problem: the minimum *dominating set* [16, 30, 32]. We describe a simple L-reduction from any instance of this problem to an instance of Min-α-SS, which preserves the approximation ratio.

1. Consider any instance of minimum dominating set, consisting of the graph $G = (V, E)$.
2. Generate a new edge-weighted graph G' as follows:
   Create two copies of G, namely $G_{\mathsf{r}} = (V_{\mathsf{r}}, E_{\mathsf{r}})$ and $G_{\mathsf{b}} = (V_{\mathsf{b}}, E_{\mathsf{b}})$, of *red* and *blue* nodes respectively. Set all edge-weights of G_{r} and G_{b} to be 1. Finally, connect each red node v_{r} to its corresponding blue node v_{b} by an edge $\{v_{\mathsf{r}}, v_{\mathsf{b}}\}$ of weight $1+\alpha+\xi$ for a sufficiently small constant $\xi > 0$. Formally, G' is defined as the edge-weighted graph $G' = (V', E')$ where the set of nodes is $V' = V_{\mathsf{r}} \cup V_{\mathsf{b}}$, the set of edges is $E' = E_{\mathsf{r}} \cup E_{\mathsf{r}} \cup \{\{v_{\mathsf{r}}, v_{\mathsf{b}}\} \mid v \in V\}$, and an edge-weight function $w : E' \to \mathbb{R}^+$ where $w(e) = 1$ iff $e \in E_{\mathsf{r}} \cup E_{\mathsf{b}}$, and $w(e) = 1+\alpha+\xi$ otherwise.
3. A labeling function l where $l(v) = \textit{red}$ iff $v \in V_{\mathsf{r}}$, and $l(v) = \textit{blue}$ iff $v \in V_{\mathsf{b}}$.
4. Compute the shortest-path metric of G', denoted as $\mathsf{d}_{G'}$.
5. Solve the Min-α-SS problem for the set V', on metric $\mathsf{d}_{G'}$, and the labels defined by l.

A dominating set of G consists of a subset of nodes $D \subseteq V$, such that every node $v \in V \setminus D$ is adjacent to a node in D. Given any dominating set $D \subseteq V$ of G, it is easy to see that the subset $R = \{v_{\mathsf{r}}, v_{\mathsf{b}} \mid v \in D\}$ is an α-selective subset of V', where $|R| = 2|D|$.

Similarly, given an α-selective subset $R \subseteq V'$, there is a corresponding dominating set D of G, where $|D| \leq |R|/2$, as D can be either $R \cap V_{\mathsf{r}}$ or $R \cap V_{\mathsf{b}}$. Therefore, MIN-α-SS is as hard to approximate as the minimum dominating set problem. ◀

There is a clear connection between the MIN-α-SS problem and covering problems, in particular that of finding an optimal hitting set. Given a set of elements U and a family C of subsets of U, a *hitting set* of (U, C) is a subset $H \subseteq U$ such that every set in C contains at least one element of H. Therefore, let $N_{p,\alpha}$ be the set of points of P whose distance to p is less than $\mathsf{d}_{\mathrm{ne}}(p)/(1+\alpha)$, then any hitting set of $(P, \{N_{p,\alpha} \mid p \in P\})$ is also an α-selective subset of P, and vice versa. This simple reduction implies a $\mathcal{O}(n^3)$ worst-case time $\mathcal{O}(\log n)$-approximation algorithm for MIN-α-SS, based on the classic greedy algorithm for set cover [12, 35]. Call this approach α-HSS or *α-Hitting Selective Subset*. It follows from Theorem 8 that for training sets in general metric spaces, this is the best approximation possible under standard complexity assumptions.

While both α-NET and α-HSS compute tight approximations of their corresponding problems, their performance in practice does not compare to heuristic approaches for standard condensation (see Section 4 for experimental results). Therefore, in the next section, we consider one such heuristic and extend it to compute subsets with the newly defined criteria.

3.2 A Practical Algorithm

For standard condensation, the RSS algorithm was recently proposed [20] to compute selective subsets. It runs in quadratic worst-case time and exhibits good performance in practice. The selection process of this algorithm is heuristic in nature and can be described as follows: beginning with an empty set, the points in $p \in P$ are examined in increasing order with respect to their nearest-enemy distance $\mathsf{d}_{\mathrm{ne}}(p)$. The point p is added to the subset R if $\mathsf{d}_{\mathrm{nn}}(p, R) \geq \mathsf{d}_{\mathrm{ne}}(p)$. It is easy to see that the resulting subset is selective.

We define a generalization, called α-RSS, to compute α-selective subsets of P. The condition to add a point $p \in P$ to the selected subset checks if any previously selected point is closer to p than $\mathsf{d}_{\mathrm{ne}}(p)/(1+\alpha)$, instead of just $\mathsf{d}_{\mathrm{ne}}(p)$. See Algorithm 1 for a formal description, and Figure 4 for an illustration. It is easy to see that this algorithm computes an α-selective subset, while keeping the quadratic time complexity of the original RSS algorithm.

Algorithm 1 α-RSS.

Input: Initial training set P and parameter $\alpha \geq 0$
Output: α-selective subset $R \subseteq P$

```
R ← φ
Let {p_i}_{i=1}^n be the points of P sorted increasingly w.r.t. d_ne(p_i)
foreach p_i ∈ P, where i = 1...n do
    if d_nn(p_i, R) ≥ d_ne(p_i)/(1+α) then
        R ← R ∪ {p_i}
return R
```

Naturally, we want to analyze the number of points this algorithm selects. The remainder of this section establishes upper-bounds and approximation guarantees of the α-RSS algorithm for any doubling metric space, with improved results in the Euclidean space. This resolves the open problem posed in [20] of whether RSS computes an approximation of the MIN-0-CS and MIN-0-SS problems.

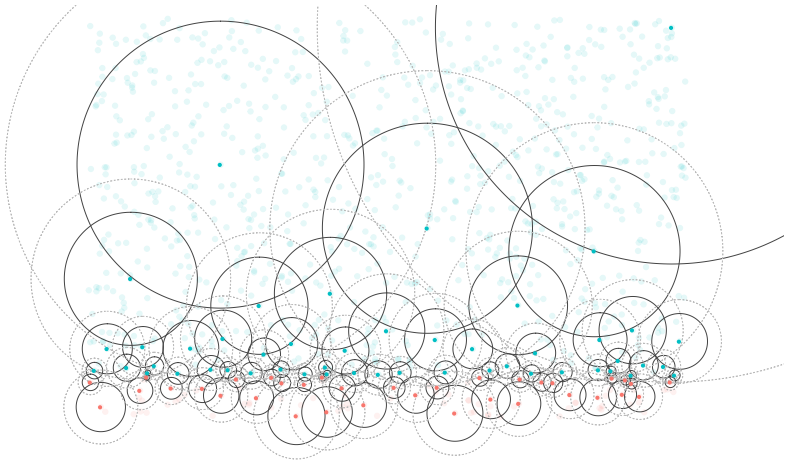


Figure 4 Selection of α-RSS for α=0.5. Faded points are not selected, while selected points are drawn along with a ball of radius $\mathsf{d}_{\mathrm{ne}}(p)$ (dotted outline) and a ball of radius $\mathsf{d}_{\mathrm{ne}}(p)/(1+\alpha)$ (solid outline). A point p is selected if no previously selected point is closer to p than $\mathsf{d}_{\mathrm{ne}}(p)/(1+\alpha)$.

Size in Doubling spaces. First, we consider the case where the underlying metric space $(\mathcal{X}, \mathsf{d})$ of P is doubling. The following results depend on the doubling dimension $\mathrm{ddim}(\mathcal{X})$ of the metric space (which is assumed to be constant), the margin γ (the smallest nearest-enemy distance of any point in P), and κ (the number of nearest-enemy points in P).

▶ **Theorem 9.** *α-RSS computes a tight approximation for the Min-α-CS problem.*

Proof. This follows from a direct comparison to the resulting subset of the α-NET algorithm from the previous section. For any point p selected by α-NET, let $B_{p,\alpha}$ be the set of points of P "covered" by p, that is, whose distance to p is at most $\gamma/(1+\alpha)$. By the covering property of ε-nets, this defines a partition on P when considering every point p selected by α-NET.

Let R be the set of points selected by α-RSS, we analyze the size of $B_{p,\alpha} \cap R$, that is, for any given $B_{p,\alpha}$ how many points could have been selected by the α-RSS algorithm. Let $a, b \in B_{p,\alpha} \cap R$ be any two such points, where without loss of generality, $\mathsf{d}_{\mathrm{ne}}(a) \leq \mathsf{d}_{\mathrm{ne}}(b)$. By the selection process of the algorithm, we know that $\mathsf{d}(a,b) \geq \mathsf{d}_{\mathrm{ne}}(b)/(1+\alpha) \geq \gamma/(1+\alpha)$. A simple packing argument in doubling metrics implies that $|B_{p,\alpha} \cap R| \leq 2^{\mathrm{ddim}(\mathcal{X})+1}$. Altogether, we have that the size of the subset selected by α-RSS is $\mathcal{O}\left((2(1+\alpha)/\gamma)^{\mathrm{ddim}(\mathcal{X})+1}\right)$. ◀

▶ **Theorem 10.** *α-RSS computes an $\mathcal{O}\left(\log\left(\min\left(1+2/\alpha, 1/\gamma\right)\right)\right)$-factor approximation for the Min-α-SS problem. For $\alpha = \Omega(1)$, this is a constant-factor approximation.*

Proof. Let OPT_α be the optimum solution to the Min-α-SS problem, i.e., the minimum cardinality α-selective subset of P. For every point $p \in \mathrm{OPT}_\alpha$ in such solution, define $S_{p,\alpha}$ to be the set of points in P "covered" by p, or simply $S_{p,\alpha} = \{r \in P \mid \mathsf{d}(r,p) < \mathsf{d}_{\mathrm{ne}}(r)/(1+\alpha)\}$. Additionally, let R be the set of points selected by α-RSS, define $R_{p,\sigma}$ to be the points selected by α-RSS which also belong to $S_{p,\alpha}$ and whose nearest-enemy distance is between σ and 2σ, for $\sigma \in [\gamma, 1]$. That is, $R_{p,\sigma} = \{r \in R \cap S_{p,\alpha} \mid \mathsf{d}_{\mathrm{ne}}(r) \in [\sigma, 2\sigma)\}$. Clearly, these subsets define a partitioning of R for all $p \in \mathrm{OPT}_\alpha$ and values of $\sigma = \gamma\, 2^i$ for $i = \{0, 1, 2, \ldots, \lceil \log \frac{1}{\gamma} \rceil\}$.

However, depending on α, some values of σ would yield empty $R_{p,\sigma}$ sets. Consider some point $q \in S_{p,\alpha}$, we can bound its nearest-enemy distance with respect to the nearest-enemy distance of point p. In particular, by leveraging simple triangle-inequality arguments, it is possible to prove that $\frac{1+\alpha}{2+\alpha}\,\mathsf{d}_{\mathrm{ne}}(p) \leq \mathsf{d}_{\mathrm{ne}}(q) \leq \frac{1+\alpha}{\alpha}\,\mathsf{d}_{\mathrm{ne}}(p)$. Therefore, the values of σ for which $R_{p,\sigma}$ sets are not empty, are $\sigma = 2^j\,\frac{1+\alpha}{2+\alpha}\,\mathsf{d}_{\mathrm{ne}}(p)$ for $j = \{0, \ldots, \lceil \log(1 + 2/\alpha) \rceil\}$.

The proof now follows by bounding the size of $R_{p,\sigma}$ which can be achieved by bounding its spread. Thus, lets consider the smallest and largest pairwise distances among points in $R_{p,\sigma}$. Take any two points $a, b \in R_{p,\sigma}$ where without loss of generality, $\mathsf{d}_{\mathrm{ne}}(a) \leq \mathsf{d}_{\mathrm{ne}}(b)$. Note that points selected by α-RSS cannot be "too close" to each other; that is, as a and b were selected by the algorithm, we know that $(1+\alpha)\,\mathsf{d}(a,b) \geq \mathsf{d}_{\mathrm{ne}}(b) \geq \sigma$. Therefore, the smallest pairwise distance in $R_{p,\sigma}$ is at least $\sigma/(1+\alpha)$. Additionally, by the triangle inequality, we can bound the maximum pairwise distance using their distance to p as $\mathsf{d}(a,b) \leq \mathsf{d}(a,p) + \mathsf{d}(p,b) \leq 4\sigma/(1+\alpha)$. Then, by the packing properties of doubling spaces, the size of $R_{p,\sigma}$ is at most $4^{\mathrm{ddim}(\mathcal{X})+1}$.

Altogether, for every $p \in \mathrm{OPT}_\alpha$ there are up to $\lceil \log(\min(1 + 2/\alpha, 1/\gamma)) \rceil$ non-empty $R_{p,\sigma}$ subsets, each containing at most $4^{\mathrm{ddim}(\mathcal{X})+1}$ points. In doubling spaces with constant doubling dimension, the size of these subsets is also constant. ◀

While these results are meaningful from a theoretical perspective, it is also useful to establishing bounds in terms of the geometry of the learning space, which is characterized by the boundaries between points of different classes. Thus, using similar packing arguments as above, we bound the selection size of the algorithm with respect to κ.

▶ **Theorem 11.** α-RSS *selects* $\mathcal{O}\left(\kappa \log \frac{1}{\gamma}\ (1+\alpha)^{\mathrm{ddim}(\mathcal{X})+1}\right)$ *points.*

Proof. This follows from similar arguments to the ones used to prove Theorem 10, using an alternative charging scheme for each nearest-enemy point in the training set. Consider one such point $p \in \{\mathrm{ne}(r) \mid r \in P\}$ and a value $\sigma \in [\gamma, 1]$, we define $R'_{p,\sigma}$ to be the subset of points from α-RSS whose nearest-enemy is p, and their nearest-enemy distance is between σ and 2σ. That is, $R'_{p,\sigma} = \{r \in R \mid \mathrm{ne}(r) = p \wedge \mathsf{d}_{\mathrm{ne}}(r) \in [\sigma, 2\sigma)\}$. These subsets partition R for all nearest-enemy points of P, and values of $\sigma = \gamma\, 2^i$ for $i = \{0, 1, 2, \ldots, \lceil \log \frac{1}{\gamma} \rceil\}$.

For any two points $a, b \in R'_{p,\sigma}$, the selection criteria of α-RSS implies some separation between selected points, which can be used to prove that $\mathsf{d}(a,b) \geq \sigma/(1+\alpha)$. Additionally, we know that $\mathsf{d}(a,b) \leq \mathsf{d}(a,p) + \mathsf{d}(p,b) = \mathsf{d}_{\mathrm{ne}}(a) + \mathsf{d}_{\mathrm{ne}}(b) \leq 4\sigma$. Using a simple packing argument, we have that $|R'_{p,\sigma}| \leq \lceil 4(1+\alpha) \rceil^{\mathrm{ddim}(\mathcal{X})+1}$.

Altogether, by counting all sets $R'_{p,\sigma}$ for each nearest-enemy in the training set and values of σ, the size of R is upper-bounded by $|R| \leq \kappa \lceil \log 1/\gamma \rceil \lceil 4(1+\alpha) \rceil^{\mathrm{ddim}(\mathcal{X})+1}$. Based on the assumption that $\mathrm{ddim}(\mathcal{X})$ is constant, this completes the proof. ◀

As a corollary, this result implies that when $\alpha = 2/\varepsilon$, the α-selective subset computed by α-RSS contains $\mathcal{O}\left(\kappa \log 1/\gamma\ (1/\varepsilon)^{\mathrm{ddim}(\mathcal{X})+1}\right)$ points. This establishes the size bound on the ε-coreset given in Theorem 1, which can be computed using the α-RSS algorithm.

Size in Euclidean space. In the case where $P \subset \mathbb{R}^d$ lies in d-dimensional Euclidean space, the analysis of α-RSS can be further improved, leading to a constant-factor approximation of Min-α-SS for any value of $\alpha \geq 0$, and reduced dependency on the dimensionality of P.

▶ **Theorem 12.** α-RSS *computes an* $\mathcal{O}(1)$*-approximation for the* Min-α*-SS problem in* $\mathbb{R}^d$.

Proof. Similar to the proof of Theorem 10, define $R_p = S_{p,\alpha} \cap R$ as the points selected by α-RSS that are "covered" by p in the optimum solution OPT_α. Consider two such points $a, b \in R_p$ where without loss of generality, $\mathsf{d}_{\mathrm{ne}}(a) \leq \mathsf{d}_{\mathrm{ne}}(b)$. By the definition of $S_{p,\alpha}$ we know that $\mathsf{d}(a,p) < \mathsf{d}_{\mathrm{ne}}(a)/(1+\alpha)$, and similarly with b. Additionally, from the selection of the algorithm we know that $\mathsf{d}(a,b) \geq \mathsf{d}_{\mathrm{ne}}(b)/(1+\alpha)$. Overall, these inequalities imply that the angle $\angle apb \geq \pi/3$. By a simple packing argument, the size of R_p is bounded by the *kissing number* in d-dimensional Euclidean space, or simply $\mathcal{O}((3/\pi)^{d-1})$. Therefore, we have that $|R| \leq \sum_p |R_p| = |\mathrm{OPT}_\alpha|\ \mathcal{O}((3/\pi)^{d-1})$. Assuming d is constant, this completes the proof. ◀

Furthermore, a similar constant-factor approximation can be achieved for any training set P in ℓ_p space for $p \geq 3$. This follows analogously to the proof of Theorem 12, exploiting the bounds between ℓ_p and ℓ_2 metrics, where $1/\sqrt{d}\ \|v\|_p \leq \|v\|_2 \leq \sqrt{d}\ \|v\|_p$. This would imply that the angle between any two points in α-RSS_p is $\Omega(1/d)$. Therefore, it shows that α-RSS achieves an approximation factor of $\mathcal{O}(d^{d-1})$, or simply $\mathcal{O}(1)$ for constant dimension.

Similarly to the case of doubling spaces, we also establish upper-bounds in terms of κ for the selection size of the algorithm in Euclidean space. The following result improves the exponential dependence on the dimensionality of P (from $\mathsf{ddim}(\mathbb{R}^d) = \Theta(d)$ to $d-1$), while keeping the dependency on the margin γ, which contrast with the approximation factor results.

▶ **Theorem 13.** *In Euclidean space $\mathbb{R}^d$, α-RSS selects $\mathcal{O}\left(\kappa \log \frac{1}{\gamma}\ (1+\alpha)^{d-1}\right)$ points.*

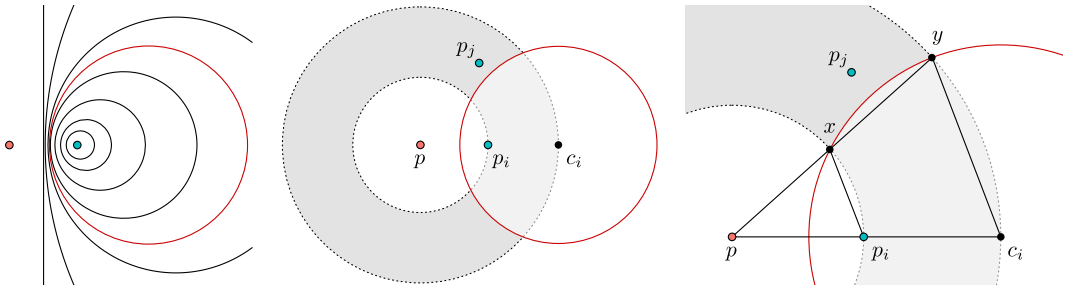
Proof. Let p be any nearest-enemy point of P and $\sigma \in [\gamma, 1]$, similarly define $R'_{p,\sigma}$ to be the set of points selected by α-RSS whose nearest-enemy is p and their nearest-enemy distance is between σ and $b\sigma$, for $b = \frac{(1+\alpha)^2}{\alpha(2+\alpha)}$. Equivalently, these subsets define a partitioning of R for all nearest-enemy points p and values of $\sigma = \gamma\, b^k$ for $k = \{0, 1, 2, \ldots, \lceil \log_b \frac{1}{\gamma} \rceil\}$. Thus, the proof follows from bounding the minimum angle between points in these subsets. For any two such points $p_i, p_j \in R'_{p,\sigma}$, we lower bound the angle $\angle p_i p p_j$. Assume without loss of generality that $\mathsf{d}_{\mathrm{ne}}(p_i) \leq \mathsf{d}_{\mathrm{ne}}(p_j)$. By definition of the partitioning, we also know that $\mathsf{d}_{\mathrm{ne}}(p_j) \leq b\sigma \leq b\, \mathsf{d}_{\mathrm{ne}}(p_i)$. Therefore, altogether we have that $\mathsf{d}_{\mathrm{ne}}(p_i) \leq \mathsf{d}_{\mathrm{ne}}(p_j) \leq b\, \mathsf{d}_{\mathrm{ne}}(p_i)$.

First, consider the set of points whose distance to p_i is $(1+\alpha)$ times their distance to p, which defines a multiplicative weighted bisector [6] between points p and p_i, with weights equal to 1 and $1/(1+\alpha)$ respectively. This is characterized as a d-dimensional ball (see Figure 5a) with center $c_i = (p_i - p)\, b + p$ and radius $\mathsf{d}_{\mathrm{ne}}(p_i)\, b/(1+\alpha)$. Thus p, p_i and c_i are collinear, and the distance between p and c_i is $\mathsf{d}(p, c_i) = b\, \mathsf{d}_{\mathrm{ne}}(p_i)$. In particular, let's consider the relation between p_j and such bisector. As p_j was selected by the algorithm after p_i, we know that $(1+\alpha)\, \mathsf{d}(p_j, p_i) \geq \mathsf{d}_{\mathrm{ne}}(p_j)$ where $\mathsf{d}_{\mathrm{ne}}(p_j) = \mathsf{d}(p_j, p)$. Therefore, clearly p_j lies either outside or in the surface of the weighted bisector between p and p_i (see Figure 5b).

For angle $\angle p_i p p_j$, we can frame the analysis to the plane defined by p, p_i and p_j. Let x and y be two points in this plane, such that they are the intersection points between the weighted bisector and the balls centered at p of radii $\mathsf{d}_{\mathrm{ne}}(p_i)$ and $b\, \mathsf{d}_{\mathrm{ne}}(p_i)$ respectively (see Figure 5c). By the convexity of the weighted bisector between p and p_i, we can say that $\angle p_i p p_j \geq \min(\angle xpp_i, \angle ypc_j)$. Now, consider the triangles $\triangle pxp_i$ and $\triangle pyc_i$. By the careful selection of b, these triangles are both isosceles and similar. In particular, for $\triangle pxp_i$ the two sides incident to p have length equal to $\mathsf{d}_{\mathrm{ne}}(p_i)$, and the side opposite to p has length equal to $\mathsf{d}_{\mathrm{ne}}(p_i)/(1+\alpha)$. For $\triangle pyc_i$, the side lengths are $b\, \mathsf{d}_{\mathrm{ne}}(p_i)$ and $\mathsf{d}_{\mathrm{ne}}(p_i)\, b/(1+\alpha)$. Therefore, the angle $\angle p_i p p_j \geq \angle xpp_i \geq 1/(1+\alpha)$.

By a simple packing argument based on this minimum angle, we have that the size of $R'_{p,\sigma}$ is $\mathcal{O}((1+\alpha)^{d-1})$. All together, following the defined partitioning, we have that:

$$|R| = \sum_p \sum_{k=0}^{\lceil \log_b \frac{1}{\gamma} \rceil} |R'_{p,b^k}| \leq \kappa \left\lceil \log_b \frac{1}{\gamma} \right\rceil \mathcal{O}\left((1+\alpha)^{d-1}\right)$$



(a) Multiplicatively weighted bisectors for different weights.

(b) Position of point p_j w.r.t. the weighted bisector between points p and p_i.

(c) The intersection points x and y between the weighted bisector and the limit balls of $R_{p,\sigma}$.

Figure 5 Construction for the analysis of the minimum angle between two points in $R'_{p,\sigma}$ w.r.t. some nearest-enemy point $p \in P$. Let points $p_i, p_j \in R'_{p,\sigma}$, we analyze the angle $\angle p_i p p_j$.

For constant α and d, the size of α-RSS is $\mathcal{O}(\kappa \log \frac{1}{\gamma})$. Moreover, when α is zero α-RSS selects $\mathcal{O}(\kappa\ c^{d-1})$, matching the previously known bound for RSS in Euclidean space. ◀

3.3 Subquadratic Algorithm

In this section we present a subquadratic implementation for the α-RSS algorithm, which completes the proof of our main result, Theorem 1. Among algorithms for nearest-neighbor condensation, FCNN achieves the best worst-case time complexity, running in $\mathcal{O}(nm)$ time, where $m = |R|$ is the size of the selected subset.

The α-RSS algorithm consists of two main stages: computing the nearest-enemy distances of all points in P (and sorting the points based on these), and the selection process itself. The first stage requires a total of n nearest-enemy queries, plus additional $\mathcal{O}(n \log n)$ time for sorting. The second stage performs n nearest-neighbor queries on the current selected subset R, which needs to be updated m times. In both cases, using exact nearest-neighbor search would degenerate into linear search due to the *curse of dimensionality*. Thus, the first and second stage of the algorithm would need $\mathcal{O}(n^2)$ and $\mathcal{O}(nm)$ worst-case time respectively.

These bottlenecks can be overcome by leveraging approximate nearest-neighbor techniques. Clearly, the first stage of the algorithm can be improved by computing nearest-enemy distances approximately, using as many ANN structures as classes there are in P, which is considered to be a small constant. Therefore, by also applying a simple brute-force search for nearest-neighbors in the second stage, result (i) of the next theorem follows immediately. Moreover, by combining this with standard techniques for static-to-dynamic conversions [9], we have result (ii) below. Denote this variant of α-RSS as (α, ξ)-RSS, for a parameter $\xi \geq 0$.

▶ **Theorem 14.** *Given a data structure for ξ-ANN searching with construction time t_c and query time t_q (which potentially depend on n and ξ), the (α, ξ)-RSS variant can be implemented with the following worst-case time complexities, where m is the size of the selected subset.*

(i) $\mathcal{O}\left(t_c + n\left(t_q + m + \log n\right)\right)$

(ii) $\mathcal{O}\left(\left(t_c + n\, t_q\right) \log n\right)$

More generally, if we are given an additional data structure for dynamic ξ-ANN searching with construction time t'_c, query time t'_q, and insertion time t'_i, the overall running time will be $\mathcal{O}\left(t_c + t'_c + n\left(t_q + t'_q + \log n\right) + m\, t'_i\right)$. Indeed, this can be used to obtain (ii) from the static-to-dynamic conversions [9], which propose an approach to convert static search

structures into dynamic ones. These results directly imply implementations of (α, ξ)-RSS with subquadratic worst-case time complexities, based on ANN techniques [4, 5] for low-dimensional Euclidean space, and using techniques like LSH [2] that are suitable for ANN in high-dimensional Hamming and Euclidean spaces. More generally, subquadratic runtimes can be achieved by leveraging techniques [13] for dynamic ANN search in doubling spaces.

Dealing with uncertainty. Such implementation schemes for α-RSS would incur an approximation error (of up to $1+\xi$) on the computed distances: either only during the first stage if (i) is implemented, or during both stages if (ii) or the dynamic-structure scheme are implemented. The uncertainty introduced by these approximate queries, imply that in order to guarantee finding α-selective subsets, we must modify the condition for adding point during the second stage of the algorithm. Let $\mathsf{d}_{\mathrm{ne}}(p, \xi)$ denote the ξ-approximate nearest-enemy distance of p computed in the first stage, and let $\mathsf{d}_{\mathrm{nn}}(p, R, \xi)$ denote the ξ-approximate nearest-neighbor distance of p over points of the current subset (computed in the second stage). Then, (α, ξ)-RSS adds a point p into the subset if $(1+\xi)(1+\alpha)\,\mathsf{d}_{\mathrm{nn}}(p, R, \xi) \geq \mathsf{d}_{\mathrm{ne}}(p, \xi)$.

By similar arguments to the ones described in Section 3.2, size guarantees can be extended to (α, ξ)-RSS. First, the size of the subset selected by (α, ξ)-RSS, in terms of the number of nearest-enemy points in the set, would be bounded by the size of the subset selected by $\hat{\alpha}$-RSS with $\hat{\alpha} = (1+\alpha)(1+\xi)^2 - 1$. Additionally, the approximation factor of (α, ξ)-RSS in both doubling and Euclidean metric spaces would increase by a factor of $\mathcal{O}((1+\xi)^{2(\mathrm{ddim}(\mathcal{X})+1)})$.

This completes the proof of Theorem 1.

4 Experimental Evaluation

In order to get a clearer impression of the relevance of these results in practice, we performed experimental trials on several training sets, both synthetically generated and widely used benchmarks. First, we consider 21 training sets from the UCI *Machine Learning Repository*[2] which are commonly used in the literature to evaluate condensation algorithms [21]. These consist of a number of points ranging from 150 to 58000, in d-dimensional Euclidean space with d between 2 and 64, and 2 to 26 classes. We also generated some synthetic training sets, containing 10^5 uniformly distributed points, in 2 to 3 dimensions, and 3 classes. All training sets used in these experimental trials are summarized in Table 1. The implementation of the algorithms, training sets used, and raw results, are publicly available[3].

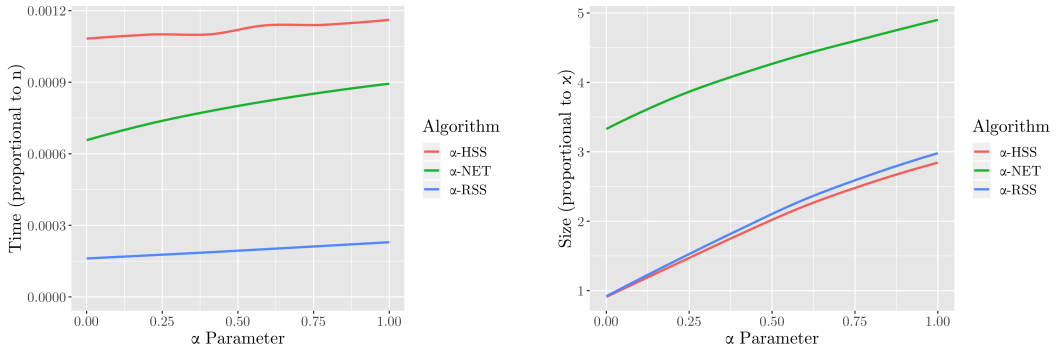
These experimental trials compare the performance of different condensation algorithms when applied to vastly different training sets. We use two measures of comparison on these algorithms: their runtime in the different training sets, and the size of the subset selected. Clearly, these values might differ greatly on training sets whose size are too distinct. Therefore, before comparing the raw results, these are normalized. The runtime of an algorithm for a given training set is normalized by dividing it by n, the size of the training set. The size of the selected subset is normalized by dividing it by κ, the number of nearest-enemy points in the training set, which characterizes the complexity of the boundaries between classes.

Algorithm Comparison. The first experiment evaluates the performance of the three algorithms proposed in this paper: α-RSS, α-HSS, and α-NET. The evaluation is carried out by varying the value of the α parameter from 0 to 1, to understand the impact of increasing

[2] `https://archive.ics.uci.edu/ml/index.php`
[3] `https://github.com/afloresv/nnc/`

this parameter. The implementation of α-HSS uses the well-known greedy algorithm for set cover [12], and solves the problem using the reduction described in Section 3.1. In the other hand, recall that the original NET algorithm (for $\alpha = 0$) implements an extra pruning technique to further reduce the training set after computing the γ-net. To do a fair comparison between the techniques, we implemented the α-NET algorithm with a modified version of this pruning techinque that guarantees that the selected subset is still α-selective.

The results show that α-RSS outperforms the other algorithms in terms of running time by a big margin, and irrespective of the value of α (see Figure 6a). Additionally, the number of points selected by α-RSS is comparable to α-HSS, which guarantees the best possible approximation factor in general metrics, while α-NET is significantly outperformed.



(a) Running time.

(b) Size of the selected subsets.

Figure 6 Comparison α-RSS, α-NET, and α-HSS, for different values of α.

Subquadratic Approach. Using the same experimental framework, we evaluate performance of the subquadratic implementation (α, ξ)-RSS described in Section 3.3. In this case, we change the value of parameter ξ to assess its effect on the running time and selection size over the algorithm, for two different values of α (see Figure 7). The results show an expected increase of the number of selected points, while significantly improving its running time.

Abstract

A fundamental theorem of Whitney from 1933 asserts that 2-connected graphs G and H are 2-isomorphic, or equivalently, their cycle matroids are isomorphic, if and only if G can be transformed into H by a series of operations called Whitney switches. In this paper we consider the quantitative question arising from Whitney's theorem: Given 2-isomorphic graphs, can we transform one into another by applying at most k Whitney switches? This problem is already NP-complete for cycles, and we investigate its parameterized complexity. We show that the problem admits a kernel of size $\mathcal{O}(k)$, and thus, is fixed-parameter tractable when parameterized by k.

Acknowledgements We are grateful to Erlend Raa Vågset for fruitful discussions that initiated the research resulted in the paper.

1 Introduction

A fundamental result of Whitney from 1933 [35], asserts that every 2-connected graph is completely characterized, up to a series of Whitney switches (also known as 2-switches), by its edge set and cycles. This theorem is one of the cornerstones of Matroid Theory, since it provides an exact characterization of two graphs having isomorphic cycle matroids [32]. In graph drawing and graph embeddings, this theorem (applied to dual graphs) is used to characterize all drawings of a planar graph [8].

A *Whitney switch* is an operation, that from a 2-connected graph G, constructs graph G' as follows. Let $\{u, v\}$ be two vertices of G, whose removal separates G into two disjoint subgraphs G_1 and G_2. The graph G' is obtained by flipping the neighbors of u and v in the set of vertices of G_2. In other words, for every vertex $w \in V(G_2)$, if w was adjacent to u in G, in graph G' edge uw is replaced by vw. Similarly, if w was adjacent to v in G, we replace vw by uw. See Figure 1 for an example.

If we view the graph G as a graph with labelled edges, then a Whitney switch transforms G into a graph G' with the same set of labelled edges, however graphs G and G' are not necessarily isomorphic. On the other hand, graphs G and G' have the same set of cycles in the following sense: a set of (labelled) edges forms a cycle in G if and only if it forms a cycle in G'. (In other words, the cycle matroids of G and G' are isomorphic.) Whitney's

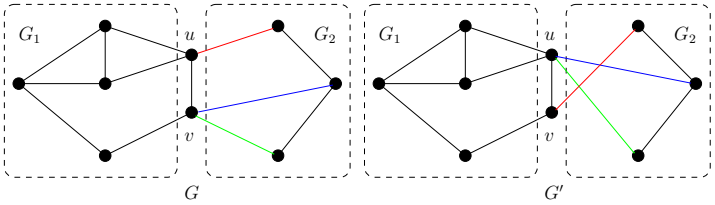

Figure 1 G' is obtained from G by the Whitney switch with respect to the partition of $G - \{u, v\}$ into G_1 and G_2.

theorem claims that the opposite is also true: if there is a cycle-preserving mapping between graphs G and G' then one graph can be transformed into another by a sequence of Whitney switches. To state the theorem of Whitney more precisely, we need to define 2-isomorphisms.

We say that 2-connected graphs G and H are 2-*isomorphic* if there is a bijection $\varphi\colon E(G) \to E(H)$ such that φ and φ^{-1} preserve cycles, that is, for every cycle C of G, C is mapped to a cycle of H by φ and, symmetrically, every cycle of H is mapped to a cycle of G by φ^{-1}. We refer to φ as to 2-*isomorphism* from G to H. An isomorphism $\psi\colon V(G) \to V(H)$ is a φ-*isomorphism* if for every edge $uv \in E(G)$, $\varphi(uv) = \psi(u)\psi(v)$, and G and H are φ-isomorphic if there is an isomorphism G to H that is a φ-isomorphism. Let us note that if G is 3-connected and 2-isomorphic to H under φ then G and H are φ-isomorphic [29, Lemma 1]. But for 2-connected graphs this is not true. For example, the graphs in Fig. 1 are not isomorphic but are 2-isomorphic. Moreover, even isomorphic graphs with 2-isomorphism φ not always have a φ-isomorphism. For example, for the 2-isomorphism φ in Fig. 2 mapping a cycle G into another cycle H (we view these cycles as labelled graphs), there is no φ-isomorphism. (For every φ-isomorphism edges $\varphi(a)$ and $\varphi(b)$ should have an endpoint in common.) On the other hand, graph G' obtained from G by Whitney switch (for vertices u and v) is φ-isomorphic to H.

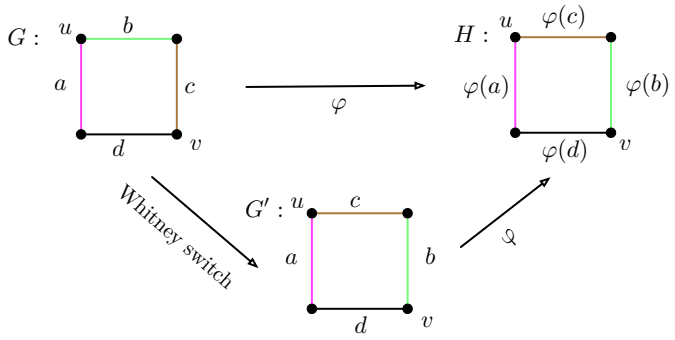

Figure 2 Graph G is not φ-isomorphic to H but its Whitney switch G' is.

▶ **Theorem 1** (Whitney's theorem [35]). *If there is a* 2*-isomorphism* φ *from graph* G *to graph* H*, then* G *can be transformed by a sequence of Whitney switches to a graph* G' *which is* φ*-isomorphic to* H*.*

However, Whitney's theorem does not provide an answer to the following question: Given a 2-isomorphism φ from graph G to graph H, *what is the minimum number of Whitney switches required to transform* G *to a graph* φ*-isomorphic to* H*?* Truemper in [29] proved that $n - 2$ switches always suffices, where n is the number of vertices in G. He also proved

that this upper bound it tight, that is, there are graphs G and H for which $n-2$ switches are necessary. In this paper we study the algorithmic complexity of the following problem about Whitney switches.

WHITNEY SWITCHES

Input:	2-Isomorphic n-vertex graphs G and H with a 2-isomorphism $\varphi\colon E(G) \to E(H)$, and a nonnegative integer k.
Task:	Decide whether it is possible to obtain from G a graph G' that φ-isomorphic to H by at most k Whitney switches.

The departure point for our study is an easy reduction (Theorem 4) from SORTING BY REVERSALS that establishes NP-completeness of WHITNEY SWITCHES even when input graphs G and H are cycles. Our main algorithmic result is the following theorem (we postpone the definition of a kernel till Section 2). Informally, it means that the instance of the problem can be compressed in polynomial time to an equivalent instance with two graphs on $\mathcal{O}(k)$ vertices. It also implies that WHITNEY SWITCHES is fixed-parameter tractable parameterized by k.

▶ **Theorem 2.** *WHITNEY SWITCHES admits a kernel with $\mathcal{O}(k)$ vertices and is solvable in $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ time.*

While Theorem 2 is not restricted to planar graphs, pipelined with the well-known connection of planar embeddings and Whitney switches, it can be used to obtain interesting algorithmic consequences about distance between planar embeddings of a graph. Recall that graphs G and G^* are called abstractly dual if there is a bijection $\pi\colon E(G) \to E(G^*)$ such that edge set $E \subseteq E(G)$ forms a cycle in G if and only if $\pi(E)$ is a minimal edge-cut in G^*. By another classical theorem of Whitney [34], a graph G has a dual graph if and only if G is planar. Moreover, an embedding of a planar graph into a sphere is uniquely defined by the planar graph G and edges of the faces, or equivalently, its dual graph G^*. While every 3-connected planar graph has a unique embedding into the sphere, a 2-connected graph can have several non-equivalent embeddings, and hence several non-isomorphic dual graphs. If G_1^* and G_2^* are dual graphs of graph G, then G_1^* is 2-isomorphic to G_2^*. Then by Theorem 1, by a sequence of Whitney switches G_1^* can be transformed into G_2^*, or equivalently, the embedding of G corresponding to G_1^* can be transformed to embedding of G corresponding to G_2^*. We refer to the survey of Carsten Thomassen [28, Section 2.2] for more details. By Theorem 2, we have that given two planar embeddings of a (labelled) 2-connected graph G, deciding whether one embedding can be transformed into another by making use of at most k Whitney switches, admits a kernel of size $\mathcal{O}(k)$ and is fixed-parameter tractable.

Related work. Whitney's theorem had a strong impact on the development of modern graph and matroid theories. While the original proof is long, a number of simpler proofs are known in the literature. In particular, the work of Truemper in [29], whose proof of Whitney's theorem is based on applications of Tutte decomposition [30, 31]. This is also the approach we adapt in our work.

The well-studied problem similar in spirit to WHITNEY SWITCHES is the problem of computing the flip distance for triangulations of a set of points. The parameterized complexity of this problem was studied in [10, 23]. As we already have mentioned, WHITNEY SWITCHES for planar graphs is equivalent to the problem of computing the Whitney switch distance between planar embeddings. We refer to the survey of Bose and Hurtado [4] for the discussion of the relations between geometric and graph variants. The problem is known to be NP-complete [22] and FPT parameterized by the number of flips [19]. For the special case when

the set of points defines a convex polygon, the problem of computing the flip distance between triangulations is equivalent to computing the rotation distance between two binary trees. For that case linear kernels are known [10, 23] but for the general case the existence of a polynomial kernel is open.

Whitney Switches also can be seen as a reconfiguration problem, study of reconfiguration problems is a popular trend in parameterized complexity, see e.g. [24, 21].

Overview of the proof of Theorem 2. The main tool in the construction of the kernel is the classical Tutte decompositions [30, 31] We postpone the formal definition till Section 2. Informally, the Tutte decomposition of a 2-connected graph represents the vertex separators of size two in a tree-like structure. Each node of this tree represents a part of the graph (or *bag*) that is either a 3-connected graph or a cycle, and each edge corresponds to a separator of size two. Then a 2-isomorphism of G and H allows to establish an isomorphism of the trees representing the Tutte decompositions of the input graphs. After that, potential Whitney switches can be divided into two types: the switches with respect to separators corresponding to the edges of the trees and the switches with respect to separators formed by nonadjacent vertices of a cycle-bag. The switches of the first type are relatively easy to analyze and we can identify necessary switches of this type. The "troublemakers" that make the problem hard are switches of the second type. To deal with them, we use the structural results about sorting of permutations by reversals of Hannenhalli and Pevzner [17] adapted for our purposes. This allows us to identify a set of vertices of size $\mathcal{O}(k)$ that potentially can be used for Whitney switches transforming G to H. Given such a set of crucial vertices, we simplify the structure of the input graphs and then reduce their size.

Organization of the paper. In Section 2, we give basic definitions. In Section 3, we discuss the Sorting by Reversals problem for permutations that is closely related to Whitney Switches. Section 4 contains structural results used by our kernelization algorithm, and in Section 5, we give the algorithm itself. We conclude in Section 6 by discussing further directions of research. Due to space constraints, the proofs are either omitted or just sketched. The details are given in the full version of the paper [15].

2 Preliminaries

Graphs. All graphs considered in this paper are finite undirected graphs without loops or multiple edges, unless it is specified explicitly that we consider directed graphs (in Section 6 we deal with tournaments). We follow the standard graph theoretic notation and terminology (see, e.g., [13]). For each of the graph problems considered in this paper, we let $n = |V(G)|$ and $m = |E(G)|$ denote the number of vertices and edges, respectively, of the input graph G if it does not create confusion. A pair (A, B), where $A, B \subseteq V(G)$, is a *separation* of G if $A \cup B = V(G)$, $A \setminus B \neq \emptyset$, $B \setminus A \neq \emptyset$ and G has no edge uv with $u \in A \setminus B$ and $v \in B \setminus A$; $|A \cap B|$ is the *order* of the separation. If the order is 2, then we say that (A, B) is a *Whitney separation*. A set $S \subseteq V(G)$ is a *separator* of G if there is a separation (A, B) of G with $S = A \cap B$.

Whitney switches. It is convenient to define Whitney switches using separations. Let G be a 2-connected graph. Let also (A, B) be a Whitney separation of G with $A \cap B = \{u, v\}$. The *Whitney switch* operation with respect to (A, B) transforms G as follows: take $G[A]$ and $G[B]$ and identify the vertex u of $G[A]$ with the vertex v of $G[B]$ and, symmetrically, v of $G[A]$ with

u of $G[B]$; if u and v are adjacent in G, then the edges uv of $G[A]$ and $G[B]$ are identified as well. Let G' be the obtained graph. We define the mapping $\sigma_{(A,B)}\colon E(G) \to E(G')$ that maps the edges of $G[A]$ and $G[B]$, respectively, to themselves. It is easy to see that $\sigma_{(A,B)}$ is a 2-isomorphism of G to G'. Therefore, if φ is a 2-isomorphism of G to a graph H, then $\varphi \circ \sigma^{-1}_{(A,B)}$ is a 2-isomorphism of G' to H. To simplify notation, we assume, if it does not create confusion, that the sets of edges of G and G' are identical and we only change incidences by switching. In particular, under this assumption, we have that $\varphi \circ \sigma^{-1}_{(A,B)} = \varphi$. We also assume that the graphs G and G' have the same sets of vertices.

Tutte decomposition. Our kernelization algorithm for Whitney Switches is based on the classical result of Tutte [30, 31] about decomposing of 2-connected graphs via separators of size two. Following Courcelle [11], we define Tutte decompositions in the terms of tree decompositions.

A *tree decomposition* of a graph G is a pair $\mathcal{T} = (T, \{X_t\}_{t\in V(T)})$, where T is a tree whose every node t is assigned a vertex subset $X_t \subseteq V(G)$, called a bag, such that the following three conditions hold:

(T1) $\bigcup_{t\in V(T)} X_t = V(G)$, that is, every vertex of G is in at least one bag,

(T2) for every $uv \in E(G)$, there exists a node t of T such that the bag X_t contains both u and v,

(T3) for every $v \in V(G)$, the set $T_v = \{t \in V(T) \mid v \in X_t\}$, i.e., the set of nodes whose corresponding bags contain v, induces a connected subtree of T.

To distinguish between the vertices of the decomposition tree T and the vertices of the graph G, we will refer to the vertices of T as *nodes*.

Let $\mathcal{T} = (T, \{X_t\}_{t\in V(T)})$ be a tree decomposition of G. The *torso* of X_t for $t \in V(T)$ is the graph obtained from $G[X_t]$ by additionally making adjacent every two distinct vertices $u, v \in X_t$ such that there is $t' \in V(T)$ adjacent to t with $u, v \in X_t \cap X_{t'}$. For adjacent $t, t' \in V(T)$, $X_t \cap X_{t'}$ is the *adhesion set* of the bags X_t and $X_{t'}$ and $|X_t \cap X_{t'}|$ is the *adhesion* of the bags. The maximum adhesion of adjacent bags is called the *adhesion* of the tree decomposition.

Let G be a 2-connected graph. A tree decomposition $\mathcal{T} = (T, \{X_t\}_{t\in V(T)})$ is said to be a *Tutte decomposition* if $\mathcal{T}$ is a tree decomposition of adhesion 2 such that there is a partition $(W_2, W_{\geq 3})$ of $V(T)$ such that the following holds:

(T4) $|X_t| = 2$ for $t \in W_2$ and $|X_t| \geq 3$ for $t \in W_{\geq 3}$,

(T5) the torso of X_t is either a 3-connected graph or a cycle for every $t \in W_{\geq 3}$,

(T6) for every $t \in W_2$, $d_T(t) \geq 2$ and $t' \in W_{\geq 3}$ for each neighbor t' of t,

(T7) for every $t \in W_{\geq 3}$, $t' \in W_2$ for each neighbor t' of t,

(T8) if $t \in W_2$ and $d_T(t) = 2$, then for the neighbors t' and t'' of t, either the torso of t' or the torso of t'' is a 3-connected graph or the vertices of X_t are adjacent in G.

Notice that the bags X_t for $t \in W_2$ are distinct separators of G of size two, and $X_t \subseteq X_{t'}$ for $t \in W_2$ and $t' \in N_T(t)$. Observe also that if $\{u, v\}$ is a separator of G of size two, then either $\{u, v\} = X_t$ for some $t \in W_2$ or $u, v \in X_t$ for $t \in W_{\geq 3}$ such that the torso of X_t is a cycle and u and v are nonadjacent vertices of the torso.

Combining the results of Tutte [30, 31] and of Hopcroft and Tarjan [18], we state the following proposition.

▶ **Proposition 3** ([30, 31, 18]). *A 2-connected graph G has a unique Tutte decomposition that can be constructed in linear time.*

Parameterized Complexity and Kernelization. We refer to the books [12, 14, 16] for the detailed introduction to the field. Here we only give the most basic definitions. In the Parameterized Complexity theorey, the computational complexity is measured as a function of the input size n of a problem and an integer *parameter* k associated with the input. A parameterized problem is said to be *fixed parameter tractable* (or FPT) if it can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ for some function f. A *kernelization* algorithm for a parameterized problem Π is a polynomial algorithm that maps each instance (I, k) of Π to an instance (I', k') of Π such that (i) (I, k) is a yes-instance of Π if and only if (I', k') is a yes-instance of Π, and (ii) $|I'| + k'$ is bounded by $f(k)$ for a computable function f. Respectively, (I', k') is a *kernel* and f is its *size*. A kernel is *polynomial* if f is polynomial. It is common to present a kernelization algorithm as a series of *reduction rules*. A reduction rule for a parameterized problem is an algorithm that takes an instance of the problem and computes in polynomial time another instance that is more "simple" in a certain way. A reduction rule is *safe* if the computed instance is equivalent to the input instance.

3 Sorting by reversals

Sorting by reversals is the classical problem with many applications including bioinformatics. We refer to the book of Pevzner [25] for the detailed survey of results and applications of this problem. This problem is also strongly related to Whitney Switches– solving the problem for two cycles is basically the same as sorting circular permutations by reversals. First we use this relation to observe the NP-completeness. But we also need to establish some structural properties of sorting by reversals which will be used in kernelization algorithm.

Let $\pi = (\pi_1, \ldots, \pi_n)$ be a permutation of $\{1, \ldots, n\}$, that is, a bijective mapping of $\{1, \ldots, n\}$ to itself. Throughout this section, all considered permutations are permutations of $\{1, \ldots, n\}$. For $1 \leq i \leq j \leq n$, the *reversal* $\rho(i, j)$ reverse the order of elements $\pi_i, \ldots, \pi_j$ and transforms π into

$$\rho(i, j) \circ \pi = (\pi_1, \ldots, \pi_{i-1}, \pi_j, \pi_{j-1}, \ldots, \pi_i, \pi_{j+1}, \ldots, \pi_n).$$

The *reversal distance* $d(\pi, \sigma)$ between two permutations π and σ is the minimum number of reversals needed to transform π to σ. For a permutation π, $d(\pi) = d(\pi, \iota)$, where ι is the identity permutation; note that $d(\pi, \sigma) = d(\sigma^{-1} \circ \pi, \iota)$ and this means that computing the reversal distance can be reduced to sorting a permutation by the minimum number of reversals.

These definitions can be extended for circular permutations (further, we may refer to usual permutations as *linear* to avoid confusion). We say that $\pi^c = (\pi_1, \ldots, \pi_n)$ is a *circular* permutation if π^c is the class of the permutations that can be obtained from the linear permutation $(\pi_1, \ldots, \pi_n)$ by *rotations* and *reflections*, that is, all the permutations

$$(\pi_1, \ldots, \pi_n), (\pi_n, \pi_1, \ldots, \pi_{n-1}), \ldots, (\pi_2, \ldots, \pi_n, \pi_1),$$

and

$$(\pi_n, \ldots, \pi_1), (\pi_1, \pi_n, \ldots, \pi_2), \ldots, (\pi_{n-1}, \ldots, \pi_1, \pi_n)$$

composing one class are identified, meaning that we do not distinguish them when discussing circular permutations. The *circular reversals* $\rho^c(i, j)$ and *circular reversal distance* $d^c(\pi^c, \sigma^c)$ and $d^c(\pi^c)$ are defined in the same way as for linear permutations.

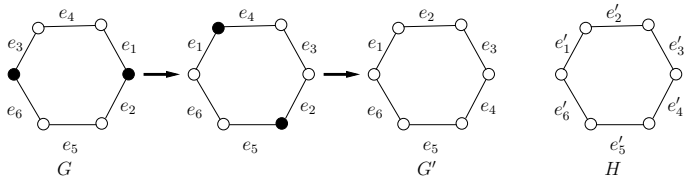

Figure 3 The construction of G' that is φ-isomorphic to H by the Whitney switches corresponding to the sorting by reversals $(3,4,1,2,5,6) \to (1,4,3,2,5,6) \to (1,2,3,4,5,6)$; $\varphi(e_i) = e'_i$ for $i \in \{1,\ldots,6\}$, the vertices of the separators for the switches are shown in black.

To see the connection between Whitney switches and circular reversals of permutations, consider a cycle G with the vertices $v_1,\ldots,v_n$ for $n \geq 4$ taken in the cycle order and the edges $e_i = v_{i-1}v_i$ for $i \in \{1,\ldots,r\}$ assuming that $v_0 = v_n$. Let $1 \leq i < j \leq n$ be such that v_i and v_j are not adjacent. Then the Whitney switch with respect to (A,B), where $A = \{v_1,\ldots,v_i\} \cup \{v_j,\ldots,v_n\}$ and $B = \{v_i,\ldots,v_j\}$ is equivalent to applying the reversal $\rho^c(i+1,j)$ to the circular permutation $(e_1,\ldots,e_n)$ of the edges of G. Moreover, let H be a cycle with n vertices and denote by $e'_1,\ldots,e'_n$ its edges in the cycle order. Notice that every bijection $\varphi\colon E(G) \to E(H)$ is a 2-isomorphism of G to H, and G and H are φ-isomorphic if and only if the circular permutation $\pi^c = (\varphi^{-1}(e'_1),\ldots,\varphi^{-1}(e'_n))$ is the same as $\sigma^c = (e_1,\ldots,e_n)$. Clearly, we can assume that π^c is a permutation of $\{1,\ldots,n\}$ and σ^c is the identity permutation. Then G can be transformed to a graph G' φ-isomorphic to H by at most k Whitney switches if and only if $d^c(\pi^c) \leq k$. An example is shown in Fig. 3.

In particular, the above observation implies the hardness of Whitney Switches, because the computing of the reversal distances is known to be NP-hard. For linear permutations, this was shown by Caprara in [7]. Then Solomon, Sutcliffe, and Lister [27] proved that it is NP-complete to decide, given a circular permutation π^c and a nonnegative integer k, whether $d^c(\pi^c) \leq k$. This brings us to the following result.

▶ **Theorem 4.** *Whitney Switches is NP-complete even when restricted to cycles.*

For our kernelization algorithm, we need some further structural results about reversals in an optimal sorting sequence.

Let $\pi = (\pi_1,\ldots,\pi_n)$ be a linear permutation. For $1 \leq i \leq j \leq n$, we say that $(\pi_i,\ldots,\pi_j)$ is an *interval* of π. An interval $(\pi_i,\ldots,\pi_j)$ is called a *block* if either $i = j$ or $i < j$ and for every $h \in \{i+1,\ldots,j\}$, $|\pi_{h-1} - \pi_h| = 1$, that is, a block is formed by consecutive integers in π in either the ascending or descending order. An inclusion maximal block is called a *strip*. In other words, a strip is an inclusion maximal interval that has no *breakpoint*, that is, a pair of elements π_{h-1},π_h with $|\pi_{h-1} - \pi_h| \geq 2$. It is said that a reversal $\rho(p,q)$ *cuts* a strip $(\pi_i,\ldots,\pi_j)$ if either $i < p \leq j$ or $i \leq q < j$, that is, the reversals separates elements that are consecutive in the identity permutation.

It is known that there are cases when every optimal sorting by reversal requires a reversal that cuts a strip. For example, as was pointed by Hannenhalli and Pevzner in [17], the permutation $(3,4,1,2)$ requires three reversals that do not cut strips, but the sorting can be done by two reversals: [1]

$$(3,4,1,2) \to (1,4,3,2) \to (1,2,3,4).$$

[1] This example can be extended for circular permutations: $(3,4,1,2,5,6) \to (1,4,3,2,5,6) \to (1,2,3,4,5,6)$.

However, it was conjectured by Kececioglu and Sankoff [20] that there is an optimal sorting that does not cut strips other than at their first or last elements. This conjecture was proved by Hannenhalli and Pevzner in [17]. More precisely, they proved that there is an optimal sorting that does not cut strips of length at least three.

It is common for bioinformatics applications, to consider *signed permutations* (see, e.g., [25]). In a signed permutation $\overrightarrow{\pi} = (\pi_1, \ldots, \pi_n)$, each element π_i has its *sign* "$-$" or "$+$". Then for $i, j \in \{1, \ldots, n\}$, the reversal reverse the sign of each element $\pi_i, \ldots, \pi_j$ besides reversing their order. We generalize this notion and define *partially signed circular permutations*, where each element has one of the sings: "$-$", "$+$" or "no sign". Formally, a *partially signed circular permutation* $\overrightarrow{\pi}^c = (\langle \pi_1, s_1 \rangle, \ldots, \langle \pi_n, s_n \rangle)$, where $(\pi_1, \ldots, \pi_n)$ is a linear permutation and $s_i \in \{-1, +1, 0\}$ for $i \in \{1, \ldots, m\}$, as the class of the linear permutations that can be obtained from $(\langle \pi_1, s_1 \rangle, \ldots, \langle \pi_n, s_n \rangle)$ by rotations and reflections such that every reflection reverse signs. For $i, j \in \{1, \ldots, n\}$, the reversal

$$\overrightarrow{\rho}^c(i,j) \circ \overrightarrow{\pi}^c = (\langle \pi_1, s_1 \rangle, \ldots, \langle \pi_{i-1}, s_{i-1} \rangle, \langle \pi_j, -s_j \rangle, \ldots, \langle \pi_i, -s_i \rangle, \langle \pi_{j+1}, s_{j+1} \rangle \ldots, \langle \pi_n, s_n \rangle)$$

if $i \leq j$, and

$$\overrightarrow{\rho}^c(i,j) \circ \overrightarrow{\pi}^c = (\langle \pi_n, -s_n \rangle, \ldots, \langle \pi_i, -s_i \rangle, \langle \pi_{j+1}, s_{j+1} \rangle, \ldots, \langle \pi_{i-1}, s_{i-1} \rangle, \langle \pi_j, -s_j \rangle \ldots, \langle \pi_1, -s_1 \rangle)$$

otherwise.

We say that $\overrightarrow{\pi}^c$ is *signed* if each s_i is either -1 or $+1$ and the *signed circular identity permutation* is $\overrightarrow{\iota}^c = (\langle 1, +1 \rangle, \ldots, \langle n, +1 \rangle)$. Also a partially signed circular permutation $\overrightarrow{\pi}^c = (\langle \pi_1, s_1 \rangle, \ldots, \langle \pi_n, s_n \rangle)$ *agrees in signs* with a signed circular permutation $\overrightarrow{\pi}'^c = (\langle \pi_1, s'_1 \rangle, \ldots, \langle \pi_n, s'_n \rangle)$ if $s_i = s'_i$ for $i \in \{1, \ldots, n\}$ such that $s_i \neq 0$, that is, the zero signs are replaced by either -1 or $+1$ in the signed permutation, and $\Sigma(\overrightarrow{\pi}^c)$ is used to denote the set of all signed circular permutations $\overrightarrow{\pi}'^c$ that agree in signs with $\overrightarrow{\pi}^c$. Then *reversal distance* $\overrightarrow{d}^c(\overrightarrow{\pi}^c, \sigma^c)$, where $\overrightarrow{\sigma}^c$ is a signed circular permutation, is the minimum number or reversal needed to obtain from $\overrightarrow{\pi}^c$ a partially signed circular permutation $\overrightarrow{\pi}'^c$ that agrees in signs with $\overrightarrow{\sigma}^c$, and $\overrightarrow{d}^c(\overrightarrow{\pi}^c) = \overrightarrow{d}^c(\overrightarrow{\pi}^c, \overrightarrow{\iota}^c)$. A a sequence of reversals of minimum length that result in a partially signed circular permutation that agrees in signs with $\overrightarrow{\iota}^c$ is an *optimal sorting* sequence.

Let $\overrightarrow{\pi}^c = (\langle \pi_1, s_1 \rangle, \ldots, \langle \pi_n, s_n \rangle)$ be a partially signed circular permutation. For $1 \leq i \leq j \leq n$, we say that $(\langle \pi_i, s_i \rangle, \ldots, \langle \pi_j, s_j \rangle)$ and $(\langle \pi_{j+1}, s_{j+1} \rangle, \ldots, \langle \pi_n, s_n \rangle, \langle \pi_1, s_1 \rangle, \ldots, \langle \pi_i, s_i \rangle)$ are *intervals* of $\overrightarrow{\pi}^c$. An interval is a *signed block* if it either has size one or for every two consecutive elements $\langle \pi_{i-1}, s_{i-1} \rangle, \langle \pi_i, s_i \rangle$, $|\pi_{i-1} - \pi_i| \leq 1$ and, moreover, if the elements of the interval are in the increasing order, then all the signs $s_i \in \{0, +1\}$, and if they are in the the decreasing order, then all the signs $s_i \in \{0, -1\}$. A *signed strip* is an inclusion maximal signed block. A reversal $\overrightarrow{\rho}^c(p, q)$ *cuts* an interval if the reversed part includes at least one element of the interval and excludes at least one element of the interval. We use the result of Hannenhalli and Pevzner [17] to show the following lemma.

▶ **Lemma 5.** *For a signed circular permutation $\overrightarrow{\pi}^c$, there is an optimal sorting sequence such that no reversal in the sequence cuts the interval formed by a signed strip of $\overrightarrow{\pi}^c$ of length at least* 5*.*

Notice that we do not claim that no reversal cuts a strip of length at least 5 that is obtained by performing the previous reversals; only the long strips of the initial permutation $\overrightarrow{\pi}^c$ are not cut by any reversal in the sorting sequence.

4 Tutte decomposition and 2-isomorphisms

In this section we provide a number of auxiliary results about 2-isomorphisms and Tutte decompositions.

We need the following folklore observation about φ-isomorphisms that we prove for completeness. For this, we extend φ on sets of edges in standard way, that is, $\varphi(A) = \{\varphi(e) \mid e \in A\}$ and $\varphi(\emptyset) = \emptyset$.

▶ **Lemma 6.** *Let G and H be n-vertex 2-connected 2-isomorphic graphs with a 2-isomorphism φ. Then G and H are φ-isomorphic if and only if there is a bijective mapping $\psi\colon V(G) \to V(H)$ such that for every $v \in V(G)$, $\varphi(E_G(v)) = E_H(\psi(v))$. Moreover, G and H are φ-isomorphic if and only if φ bijectively maps the family of the sets of edges $\{E_G(v) \mid v \in V(G)\}$ to the family $\{E_H(v) \mid v \in V(H)\}$, and this property can be checked in polynomial time.*

By Lemma 6, we can restate the task of Whitney Switches and ask whether it is possible to obtain a graph G' by performing at most k Whitney switches starting from G with the property that the extension of φ to the family of sets $\{E_{G'}(v) \mid v \in V(G')\}$ bijectively maps this family to $\{E_H(v) \mid v \in V(H)\}$.

We use Whitney's theorem [35](see also [29]).

▶ **Proposition 7** ([35]). *Let G and H be n-vertex graphs and let φ be a 2-isomorphism of G to H. Then there is a finite sequence of Whitney switches such that the graph G' obtained from G by these switches is φ-isomorphic to H.*

We also use the property of 3-connected graphs explicitly given by Truemper [29]. It also can be derived from Proposition 7.

▶ **Proposition 8** ([29]). *Let G and H be 3-connected n-vertex graphs and let φ be a 2-isomorphism of G to H. Then G and H are φ-isomorphic.*

Throughout this section we assume that G and H are n-vertex 2-connected graphs and let φ be a 2-isomorphism of G to H. Let also $\mathcal{T}^{(1)} = (T^{(1)}, \{X_t^{(1)}\}_{t\in V(T^{(1)})})$ and $\mathcal{T}^{(2)} = (T^{(2)}, \{X_t^{(2)}\}_{t\in V(T^{(2)})})$ be the Tutte decompositions of G and H, respectively, and denote by $(W_2^{(h)}, W_{\geq 3}^{(h)})$ the partition of $V(T^{(h)})$ satisfying (T4)–(T8) for $h = 1, 2$. We use Lemma 6 and Propositions 7 and 8 to show the following lemmata.

▶ **Lemma 9.** *There is an isomorphism α of $T^{(1)}$ to $T^{(2)}$ such that*

- **(i)** *for every $t \in V(T^{(1)})$, $|X_t^{(1)}| = |X_{\alpha(t)}^{(2)}|$, in particular, $t \in W_2^{(1)}$ ($t \in W_{\geq 3}^{(1)}$, respectively) if and only if $\alpha(t) \in W_2^{(2)}$ ($\alpha(t) \in W_{\geq 3}^{(2)}$, respectively),*
- **(ii)** *for every $t \in W_{\geq 3}^{(1)}$, the torso of $X_t^{(1)}$ is a 3-connected graph (a cycle, respectively) if and only if the torso of $X_{\alpha(t)}^{(2)}$ is a 3-connected graph (a cycle, respectively),*
- **(iii)** *for every $t \in V(T^{(1)})$, $\varphi(E(G[X_t^{(1)}]) = E(H[X_{\alpha(t)}^{(2)}])$.*

Let F be a 2-connected graph. Let also $\mathcal{T} = (T, \{X_t\}_{t\in V(T)})$ be the Tutte decomposition of F and let $(W_2, W_{\geq 3})$ be the partition of $V(T)$ satisfying (T4)–(T8). We denote by $\widehat{F}$ the graph obtained from F by making the vertices of X_t adjacent for every $t \in W_2$. We say that $\widehat{F}$ is the *enhancement* of F. Note that $\mathcal{T}$ is the Tutte decomposition of $\widehat{F}$ and the torso of each bag X_t is $\widehat{F}[X_t]$. Notice also that (A, B) is a Whitney separation of F if and only if (A, B) is a Whitney separation of $\widehat{F}$. We also say that F is *enhanced* if $F = \widehat{F}$.

To simplify the arguments in our proofs, it is convenient for us to switch from 2-isomorphisms of graphs to 2-isomorphisms of their enhancements. By Lemma 9, there is an isomorphism α of $T^{(1)}$ to $T^{(2)}$ satisfying conditions (i) – (ii) of the lemma. We define

the *enhanced* mapping $\widehat{\varphi}\colon E(\widehat{G}) \to E(\widehat{H})$ such that $\widehat{\varphi}(e) = \varphi(e)$ for $e \in E(G)$, and for each $e \in E(\widehat{G}) \setminus E(G)$ with its end-vertices in $X_t^{(1)}$ for some $t \in W_2^{(1)}$, we define $\widehat{\varphi}(e)$ be the edge with the end-vertices in $X_{\alpha(t)}^{(2)}$.

▶ **Lemma 10.** *The mapping $\widehat{\varphi}$ is a 2-isomorphism of $\widehat{G}$ to $\widehat{H}$. Moreover, a sequence of Whitney switches makes G φ-isomorphic to H if and only if the same sequence makes $\widehat{G}$ $\widehat{\varphi}$-isomorphic to $\widehat{H}$.*

Lemma 10 allows us to consider enhanced graph and this is useful, because we can strengthen the claim of Lemma 9.

▶ **Lemma 11.** *Let G and H be enhanced graphs. Then there is an isomorphism α of $T^{(1)}$ to $T^{(2)}$ such that conditions (i)–(iii) of Lemma 9 are fulfilled and, moreover,*

(iv) *for every $t \in V(T^{(1)})$, $G[X_t^{(1)}]$ is isomorphic to $H[X_{\alpha(t)}^{(2)}]$.*

Moreover, if $G[X_t^{(1)}]$ is 3-connected, then $G[X_t^{(1)}]$ is φ-isomorphic to $H[X_{\alpha(t)}^{(2)}]$.

For the remaining part of the sections, we assume that G and H are enhanced graphs and α is the isomorphism of $T^{(1)}$ to $T^{(2)}$ satisfying conditions (i)–(iv) of Lemmas 9 and 11.

Our next aim is to investigate properties of the sequences of Whitney switches that are used in solutions for Whitney Switches. For a sequence $\mathcal{S}$ of Whitney switches such that the graph G' obtained from G by applying this sequence is ϕ-isomorphic to H, we say that $\mathcal{S}$ is an *H-sequence*. We also say that $\mathcal{S}$ is *minimum* if $\mathcal{S}$ has minimum length.

For $t \in W_{\geq 3}^{(1)}$, we say that $X_t^{(1)}$ is *φ-good* if $G[X_t^{(1)}]$ is φ-isomorphic to $H[X_{\alpha(t)}^{(2)}]$, and $X_t^{(1)}$ is *φ-bad* otherwise. Notice that if $G[X_t^{(1)}]$ is 3-connected, then $X_t^{(1)}$ is φ-good but this not always so if $G[X_t^{(1)}]$ is a cycle.

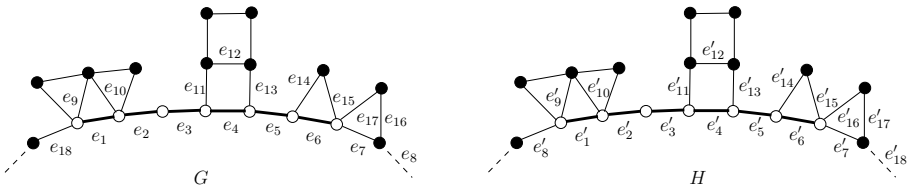

Figure 4 An example of a φ-good segment; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 18\}$, the vertices of the segment are white.

Let $t \in W_{\geq 3}^{(1)}$ such that $X_t^{(1)}$ is φ-bad. Clearly, $G[X_t^{(1)}]$ is a cycle. Let $\{t_1, \ldots, t_s\} = N^2_{T^{(1)}}(t)$ and denote $G_t = G[X_t^{(1)} \cup \bigcup_{i=1}^s X_{t_i}^{(1)}]$ and $H_{\alpha(t)} = H[X_{\alpha(t)}^{(2)} \cup \bigcup_{i=1}^s X_{\alpha(t_i)}^{(2)}]$. Let $P = v_0 \cdots v_r$ be a path in $G[X_t^{(1)}]$ and $e_i = v_{i-1}v_i$ for $i \in \{1, \ldots, r\}$. We say that P a *φ-good segment* of $X_t^{(1)}$ if the following holds (see Fig. 4 for an example):

(i) the length of P is at least 5,

(ii) there is a path $P' = u_0 \cdots u_r$ in $H[X_{\alpha(t)}^{(2)}]$ such that $u_{i-1}u_i = \varphi(e_i)$ for all $i \in \{1, \ldots, r\}$,

(iii) for every $i \in \{1, \ldots, r\}$ and for every $t' \in W_{\geq 3}^{(1)}$ such that $X_t^{(1)} \cap X_{t'}^{(1)} = \{v_{i-1}, v_i\}$, $X_{t'}^{(1)}$ is φ-good,

(iv) for every $i \in \{1, \ldots, r-1\}$, $\varphi(E_{G_t}(v_i)) = E_{H_{\alpha(t)}}(u_i)$.

For distinct $t_1, t_2 \in W_{\geq 3}^{(1)}$ with a common neighbor in $T^{(1)}$, we say that $X_{t_1}^{(1)}$ and $X_{t_2}^{(1)}$ are *mutually φ-good* (see Fig. 5) if they are φ-good and $G[X_{t_1}^{(1)} \cup X_{t_2}^{(1)}]$ is φ-isomorphic to $H[X_{\alpha(t_1)}^{(2)} \cup X_{\alpha(t_2)}^{(2)}]$.

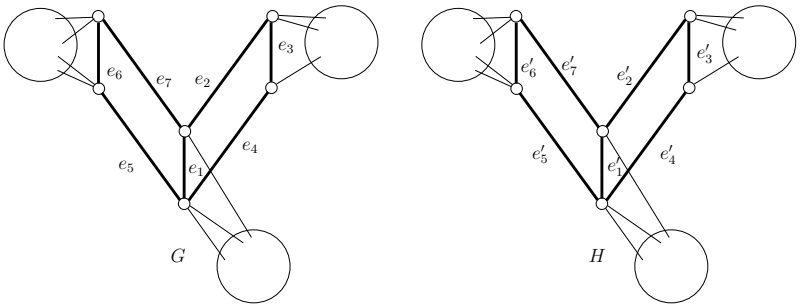

Figure 5 Mutually φ-good bags; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 7\}$, the vertices of the mutually φ-good bags of G and the corresponding bags of H are white.

We say that an H-sequence is *φ-good* if no Whitney switch of $\mathcal{S}$ splits (mutually) φ-good bags and segments. Formally, for every switch with respect to some Whitney separation (A, B) in $\mathcal{S}$,

- **(i)** $X_t^{(1)} \subseteq A$ or $X_t^{(1)} \subseteq B$ for every φ-good bag $X_t^{(1)}$,
- **(ii)** $V(P) \subseteq A$ or $V(P) \subseteq B$ for every φ-good segment P,
- **(iii)** $X_{t_1}^{(1)} \cup X_{t_2}^{(1)} \subseteq A$ or $X_{t_1}^{(1)} \cup X_{t_2}^{(1)} \subseteq B$ for every two distinct mutually φ-good bags $X_{t_1}^{(1)}$ and $X_{t_2}^{(1)}$.

We prove that it is sufficient to consider φ-good H-sequences. The crucial tool for our kernelization algorithm is the following lemma that is proved by using Lemmata 5 and 11. In particular, Lemma 5 is crucial for showing that we can avoid splitting φ-good segments.

▶ **Lemma 12.** *There is a minimum H-sequence of Whitney switches $\mathcal{S}$ that is φ-good.*

Let $t \in W_{\geq 3}^{(1)}$ be such that $X_t^{(1)}$ is φ-bad. Denote by $t_1, \ldots, t_s \neq t$ the nodes of $N^2_{T^{(1)}}(t)$. Let $G_t = G[X_t^{(1)} \cup \bigcup_{i=1}^s X_{t_i}^{(1)}]$ and $H_{\alpha(t)} = G[X_{\alpha(t)}^{(2)} \cup \bigcup_{i=1}^s X_{\alpha(t_i)}^{(2)}]$. In words, G_t is the subgraphs of G induced by the vertices of $X_t^{(1)}$ and the vertices of the bags at distance two in $T^{(1)}$ from t, and $H_{\alpha(t)}$ the subgraph of H induced by the vertices of the bags that are images of the bags composing G_t according to α.

We say that a vertex $v \in X_t^{(1)}$ is a *crucial breakpoint* if $\varphi(E_{G_t}(v)) \neq E_{H_{\alpha(t)}}(u)$ for every $u \in V(H_{\alpha(t)})$. We denote by $b(G)$ the total number of crucial breakpoints in the φ-bad bags and say that $b(G)$ is the *breakpoint number* of G. Recall that by our convention, G and H are enhanced graphs, but we extend this definition for the general case needed in the next section. For (not necessarily enhanced) 2-isomorphic graphs G and H, and a 2-isomorphism φ, we construct their enhancements $\widehat{G}$ and $\widehat{H}$, and consider the enhanced mapping $\widehat{\varphi}$. Then $b(G)$ is defined as $b(\widehat{G})$.

Observe that if G and H are φ-isomorphic, then $b(t) = 0$ by Lemma 6, but not the other way around.

We conclude the section by giving a lower bound for the length of an H-sequence.

▶ **Lemma 13.** *Let $\mathcal{S}$ be an H-sequence of Whitney switches. Then $b(G)/2 \leq |\mathcal{S}|$.*

5 Kernelization for Whitney Switches

In this section, we show that Whitney Switches parameterized by k admits a polynomial kernel. To do it, we obtain a more general result by proving that the problem has a polynomial kernel when parameterized by the breakpoint number of the first input graph.

▶ **Theorem 14.** *Whitney Switches has a kernel such that each graph in the obtained instance has at most* $\max\{52 \cdot b - 36, 3\}$ *vertices, where* b *is the breakpoint number of the input graph.*

Proof sketch. Let (G, H, φ, k) be an instance of Whitney Switches, where G and H are n-vertex 2-connected 2-isomorphic graphs, $\varphi\colon E(G) \to E(H)$ is a 2-isomorphism, and k is a nonnegative integer.

First, we use Proposition 3 to construct the Tutte decompositions of G and H. Denote by $\mathcal{T}^{(1)} = (T^{(1)}, \{X_t^{(1)}\}_{t \in V(T^{(1)})})$ and $\mathcal{T}^{(2)} = (T^{(2)}, \{X_t^{(2)}\}_{t \in V(T^{(2)})})$ the constructed Tutte decompositions of G and H respectively, and let $(W_2^{(h)}, W_{\geq 3}^{(h)})$ be the partition of $V(T^{(h)})$ satisfying (T4)–(T8) for $h = 1, 2$.

In the next step, we construct the isomorphism $\alpha\colon V(T^{(1)}) \to V(T^{(2)})$ satisfying conditions (i)–(iii) of Lemma 9. Recall that Lemma 9 claims that such an isomorphism always exists.

Given α, we compute the enhancements $\widehat{G}$ and $\widehat{H}$ of G and H respectively, and then define the enhanced mapping $\widehat{\varphi}\colon E(\widehat{G}) \to E(\widehat{H})$. Note that α satisfies the conditions of Lemma 11. Observe also that we can verify in polynomial time whether a bag $X_t^{(1)}$ for $t \in W_{\geq 3}^{(1)}$ is φ-good or not.

To simplify notation, let $G := \widehat{G}$, $H := \widehat{H}$ and $\varphi := \widehat{\varphi}$.

Now we apply a series of reduction rules that are applied for G, H, φ, and the Tutte decompositions of G and H.

The aim of the first rule is to decrease the total size of bags that are φ-bad (see Fig. 6 for an example).

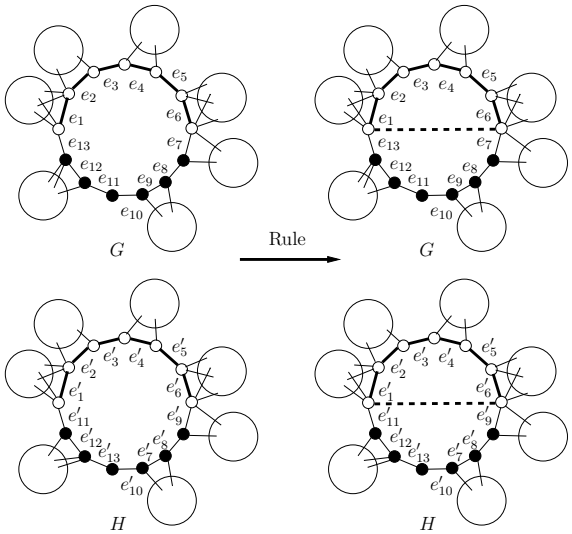

Figure 6 An example of an application of Reduction Rule 1; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 13\}$, the vertices of the φ-good segment in G and the corresponding segment in H are white, and the added edges are shown by dashed lines.

▶ **Reduction Rule 1.** *If for* $t \in W_{\geq 3}^{(1)}$ *such that* $X_t^{(1)}$ *is* φ*-bad, there is an inclusion maximal* φ*-good segment* $P = v_0 \cdots v_r$*, then do the following:*

- *find the path* $P' = u_0 \cdots u_r$ *in* $H[X_{\alpha(t)}^{(2)}]$ *composed by the edges* $u_{i-1}u_i = \varphi(v_{i-1}v_i)$ *for* $i \in \{1, \ldots, r\}$*,*
- *add the edge* v_0v_r *to* G *and* u_0u_r *to* H*,*
- *extend* φ *by setting* $\varphi(v_0u_r) = u_0u_r$*,*
- *recompute the Tutte decompositions of the obtained graphs and the isomorphism* α*.*

The safeness of the rule is proved by using Lemma 12. The crucial observation is that there is an optimal sequence of Whitney switches such that every φ-good segment remains in one part of every Whitney separation in the sequence, i.e., they are not split. Reduction Rule 1 is applied exhaustively while we are able to find φ-good segments. To simplify notation, we use G, H and φ to denote the obtained graphs and the obtained 2-isomorphism. We also keep the notation used for the Tutte decompositions.

Our next reduction rule is used to simplify the structure of φ-good bags by turning them into cliques (see Fig. 7 for an example).

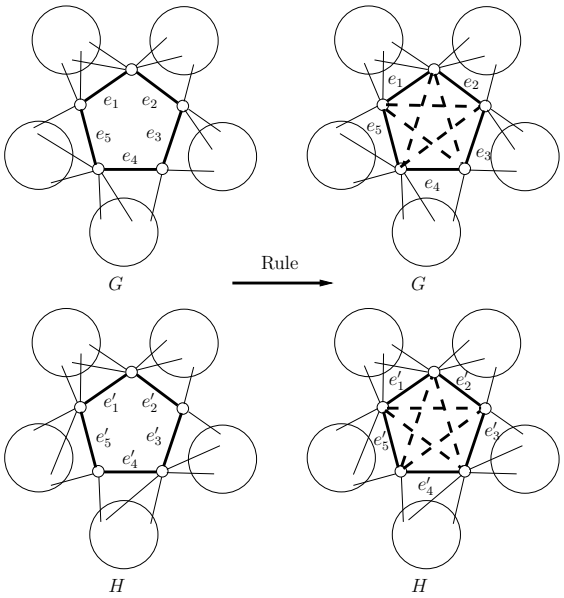

Figure 7 An example of an application of Reduction Rule 2; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 5\}$, the vertices of the φ-good bag of G and the corresponding bag of H are white, and the added edges are shown by dashed lines.

▶ **Reduction Rule 2.** *If for $t \in W^{(1)}_{\geq 3}$ such that $X^{(1)}_t$ is a φ-good, there are nonadjacent vertices in $X^{(1)}_t$, then compute the φ-isomorphism ψ of $G[X^{(1)}_t]$ to $H[X^{(2)}_{\alpha(t)}]$ and for every nonadjacent $u, v \in X^{(1)}_t$, do the following:*

- *add the edge uv to G and $\psi(u)\psi(v)$ to H,*
- *extend φ by setting $\varphi(uv) = \psi(u)\psi(v)$.*

The safeness of the rule follows from Lemma 12. We use that there is an optimal sequence of Whitney switches such that no Whitney separation splits φ-good bags. We apply Reduction Rule 2 for all bags of G that are not cliques. We use the same convention as for the first rule, and keep the old notation for the obtained graphs, their Tutte decompositions, and the obtained 2-isomorphism.

The next aim is to reduce the number of mutually φ-good bags by "gluing" them into cliques (see Fig. 8 for an example).

▶ **Reduction Rule 3.** *For distinct $t_1, t_2 \in W^{(1)}_{\geq 3}$ such that $X^{(1)}_{t_1}$ and $X^{(1)}_{t_2}$ are mutually φ-good,*

- *compute the φ-isomorphism ψ of $G[X^{(1)}_{t_1} \cup X^{(1)}_{t_2}]$ to $H[X^{(2)}_{\alpha(t_1)} \cup X^{(2)}_{\alpha(t_2)}]$,*
- *for every $u \in X^{(1)}_{t_1} \setminus X^{(1)}_{t_2}$ and every $v \in X^{(1)}_{t_2} \setminus X^{(1)}_{t_1}$, do the following:*
  - *add the edge uv to G and $\psi(u)\psi(v)$ to H,*
  - *extend φ by setting $\varphi(uv) = \psi(u)\psi(v)$,*
- *recompute the Tutte decompositions of the obtained graphs and the isomorphism α.*

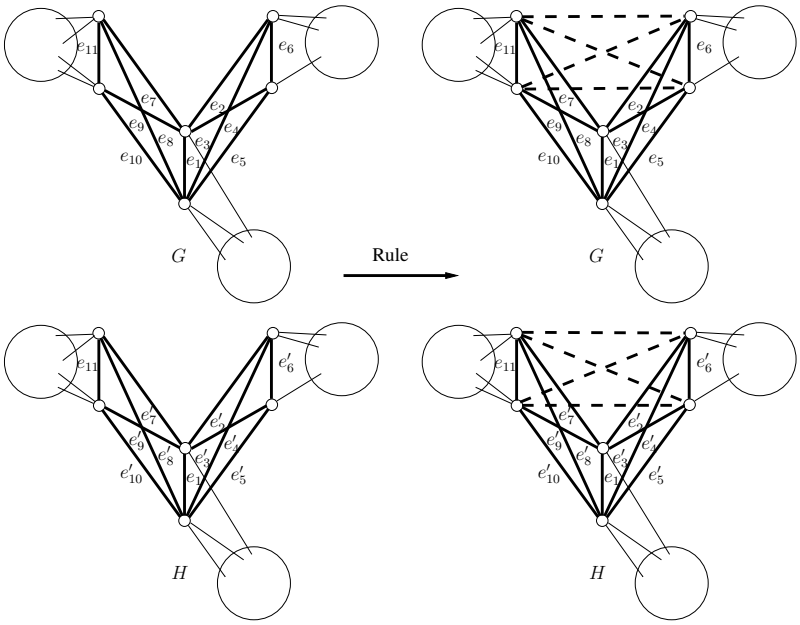

Figure 8 An example of an application of Reduction Rule 3; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 11\}$, the vertices of the mutually φ-good bags of G and the corresponding bags of H are white, and the added edges are shown by dashed lines.

To show the safeness, we use that, by Lemma 12, we can find an optimal sequence of Whitney switches such that the corresponding Whitney separations do not split mutually φ-good bags. Reduction Rule 3 is applied exhaustively whenever it is possible. As before, we do not change the notation for the obtained graphs, their Tutte decompositions, and the obtained 2-isomorphism.

Our next rule is used to perform the Whitney switches that are unavoidable (see Fig. 9 for an example).

▶ **Reduction Rule 4.** *If there is $t \in W_2^{(1)}$ such that $d_{T^{(1)}}(t) = 2$ and for the neighbors t_1 and t_2 of t, it holds that $X_{t_1}^{(1)}$ and $X_{t_2}^{(2)}$ are φ-good but not mutually φ-good, then do the following:*

- *find the connected components T_1 and T_2 of $T^{(1)} - t$, and construct $A = \bigcup_{t' \in V(T_1)} X_{t'}^{(1)}$ and $B = \bigcup_{t' \in V(T_2)} X_{t'}^{(1)}$,*
- *perform the Whitney switch with respect to the separation (A, B),*
- *set $k := k - 1$, and if $k < 0$, then return the trivial no-instance and stop.*

Reduction Rule 4 is applied exhaustively whenever it is possible. Note that after applying this rule, we are able to apply Reduction Rule 3 and we do it.

Suppose that the algorithm did not stop while executing Reduction Rule 4. In the same way as with previous rules, we maintain the initial notation for the obtained graphs, their Tutte decompositions, and the obtained 2-isomorphism.

Our final rule deletes simplicial vertices of degree at least 3.

▶ **Reduction Rule 5.** *If there is a simplicial vertex $v \in V(G)$ with $d_G(v) \geq 3$, then do the following:*

- *find the vertex $u \in V(H)$ such that $E_H(u) = \varphi(E_G(v))$,*
- *set $G := G - v$ and $H := H - u$,*
- *set $\varphi := \varphi|_{E(G) \setminus E_G(v)}$.*

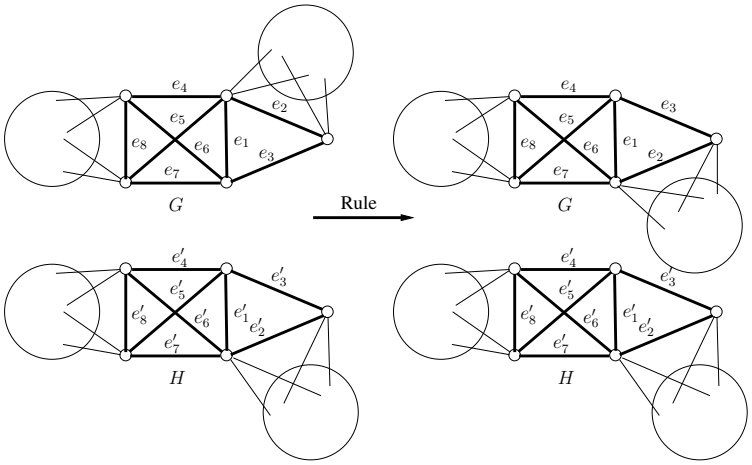

Figure 9 An example of an application of Reduction Rule 4; $\varphi(e_i) = e'_i$ for $i \in \{1, \ldots, 8\}$, the vertices of the switched φ-good bags of G and the corresponding bags of H are white.

Reduction Rule 5 is applied exhaustively. Let G, H and φ be the resulting graphs. We also keep the same notation for the Tutte decompositions of G and H and the isomorphism α following the previous convention. This completes the description of our kernelization algorithm as the graphs G and H have bounded size. We show that $|V(G)| = |V(H)| \leq \max\{52 \cdot b(G) - 36, 3\}$.

It can be shown that Reduction Rules 1–5 do not increase the breakpoint number. Therefore, for the the obtained instance (G, H, φ, k) of Whitney Switches, $|V(G)| = |V(H)| \leq \min\{52 \cdot b - 36, 3\}$, where b is the breakpoint number of the initial input graph G. ◀

Theorem 14 together with Lemma 13 imply that Whitney Switches has a polynomial kernel when parameterized by k. Thus, we can show Theorem 2 that we restate.

▶ **Theorem 2.** *Whitney Switches admits a kernel with $\mathcal{O}(k)$ vertices and is solvable in $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ time.*

In Corollary 4, we proved that Whitney Switches is NP-hard when the input graphs are constrained to be cycles. Theorem 14 indicates that it is the presence of bags in the Tutte decompositions that are cycles of length at least 4 that makes Whitney Switches difficult, because only such cycles may contain crucial breakpoint. In particular, we can derive the following straightforward corollary.

▶ **Corollary 15.** *Let (G, H, φ, k) be an instance of Whitney Switches such that $b(G) = 0$. Then Whitney Switches for this instance can be solved in polynomial time.*

For example, the condition that $b(G) = 0$ holds when G and H have no induced cycles of length at least 4, that is, when G and H are chordal graphs.

▶ **Corollary 16.** *Whitney Switches can be solved in polynomial time on chordal graphs.*

6 Conclusion

We proved that Whitney Switches admits a polynomial kernel when parameterized by the breakpoint number of the input graphs and this implies that the problem has a polynomial kernel when parameterized by k. More precisely, we obtain a kernel, where the graphs have $\mathcal{O}(k)$ vertices. Using this kernel, we can solve Whitney Switches in $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$ time. It is natural to ask whether the problem can be solved in a single-exponential in k time.

Another interesting direction of research is to investigate approximability for Whitney Switches. In [3], Berman and Karpinski proved that for every $\varepsilon > 0$, it is NP-hard to approximate the reversal distance $d(\pi)$ for a linear permutation π within factor $\frac{1237}{1236} - \varepsilon$. This result can be translated for circular permutations and this allows to obtain inapproximability lower bound for Whitney Switches on cycles similarly to Corollary 4. From the positive side, the currently best 1.375-approximation for $d(\pi)$ was given by Berman, Hannenhalli, and Karpinski [2]. Due to the close relations between Whitney Switches and the sorting by reversal problem, it is interesting to check whether the same approximation ratio can be achieved for Whitney Switches.

In Whitney Switches, we are given two graphs G and H together with a 2-isomorphism and the task is to decide whether we can apply at most k Whitney switches to obtain a graph G' from G such that G' is φ-isomorphic to H. We can relax the task and ask whether we can obtain G' that is isomorphic to H, that is, we do not require an isomorphism of G to H be a φ-isomorphism. Formally, we define the following problem.

Unlabeled Whitney Switches

Input:	2-Isomorphic graphs G and H, and a nonnegative integer k.
Task:	Decide whether it is possible to obtain a graph G' from G by at most k Whitney switches such that G' is isomorphic to H.

Note that if φ is a 2-isomorphism of G to H, then the minimum number of Whitney switches needed to obtain G' that is φ-isomorphic to H gives an upper bound for the number of Whitney switches required to obtain from G a graph that isomorphic to G. However, these values can be arbitrary far apart. Consider two cycles G and H with the same number of vertices. Clearly, G and H are isomorphic but for a given 2-isomorphism φ of G to H, we may need many Whitney switches to obtain G' that is φ-isomorphic to H and the number of switches is not bounded by any constant.

Using the result of Solomon, Sutcliffe, and Lister [27], we can show that Unlabeled Whitney Switches is NP-hard for very restricted instances.

▶ **Proposition 17.** *Unlabeled Whitney Switches is NP-complete when restricted to 2-connected series-parallel graphs even if the input graphs are given together with their* 2*-isomorphism.*

Proposition 17 lead to the question about the parameterized complexity of Unlabeled Whitney Switches. In particular, does the problem admit a polynomial kernel when parameterized by k?

Notice that to deal with Unlabeled Whitney Switches, we should be able to check whether the input graphs G and H are isomorphic. If we are given a 2-isomorphism φ of G to H, then checking whether G and H are φ-isomorphic can be done in polynomial time by Lemma 6. However, checking whether G and H are isomorphic, even if a 2-isomorphism φ is given, is a complicated task. For example, it can be observed that this is at least as difficult as solving Graph Isomorphism on tournaments (recall that a *tournament* is a directed graph such that for every two distinct vertices u and v, either uv or vu is an arc). While Graph Isomorphism on tournaments may be easier than the general problem (we refer to [26, 33] for the details), still it is unknown whether this special case can be solved in polynomial time and the best known algorithm is the quasi-polynomial algorithm of Babai [1]. Given this observation, it is natural to consider Unlabeled Whitney Switches on graph classes for which Graph Isomorphism is polynomially solvable. For example, what can be said about Unlabeled Whitney Switches on planar graphs?

The relation between Whitney switches and sorting by reversals together with the reduction in the proof of Proposition 17 indicates that as the first step, it could be reasonable to investigate the following problem for sequences that generalizes Sorting by Reversals for permutations. Let $\pi = (\pi_1, \ldots, \pi_n)$ be a sequence of positive integers; note that now some elements of π may be the same. For $1 \leq i < j \leq n$, we define the *reversal* $\rho(i, j)$ in exactly the same way as for permutations. Then we can define the *reversal distance* between two n-element sequences such that the multisets of their elements are the same; we assume that the distance is $+\infty$ if the multisets of elements are distinct.

Sequence Reversal Distance

Input:	Two n-element sequences π and σ of positive integers and a nonnegative integer k.
Task:	Decide whether the reversal distance between π and σ is at most k.

By the result of Caprara in [7], this problem is NP-complete even if the input sequences are permutations. It is also known that the problem is NP–complete if the input sequences contain only two distinct elements [9]. The question, whether Sequence Reversal Distance is FPT when parameterized by k, was explicitly stated in the survey of Bulteau et. al [6] (in terms of strings) and is open and only some partial results are known [5]. We also can define the version of Sequence Reversal Distance for circular sequences and ask the same question about parameterized complexity. Using the idea behind the reduction in the proof of Proposition 17, it is easy to observe that Unlabeled Whitney Switches on 2-connected series-parallel graphs is at least as hard as the circular variant of Sequence Reversal Distance.

Abstract

We study algorithmic properties of the graph class Chordal $-$ ke, that is, graphs that can be turned into a chordal graph by adding at most k edges or, equivalently, the class of graphs of fill-in at most k. We discover that a number of fundamental intractable optimization problems being parameterized by k admit *subexponential* algorithms on graphs from Chordal $-$ ke. While various parameterized algorithms on graphs for many structural parameters like vertex cover or treewidth can be found in the literature, up to the Exponential Time Hypothesis (ETH), the existence of subexponential parameterized algorithms for most of the structural parameters and optimization problems is highly unlikely. This is why we find the algorithmic behavior of the "fill-in parameterization" very unusual.

Being intrigued by this behaviour, we identify a large class of optimization problems on Chordal $-$ ke that admit algorithms with the typical running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$. Examples of the problems from this class are finding an independent set of maximum weight, finding a feedback vertex set or an odd cycle transversal of minimum weight, or the problem of finding a maximum induced planar subgraph. On the other hand, we show that for some fundamental optimization problems, like finding an optimal graph coloring or finding a maximum clique, are FPT on Chordal $-$ ke when parameterized by k but do not admit subexponential in k algorithms unless ETH fails.

Besides subexponential time algorithms, the class of Chordal $-$ ke graphs appears to be appealing from the perspective of kernelization (with parameter k). While it is possible to show that most of the weighted variants of optimization problems do not admit polynomial in k kernels on Chordal $-$ ke graphs, this does not exclude the existence of Turing kernelization and kernelization for unweighted graphs. In particular, we construct a polynomial Turing kernel for Weighted Clique on Chordal $-$ ke graphs. For (unweighted) Independent Set we design polynomial kernels on two interesting subclasses of Chordal $-$ ke, namely, Interval $-$ ke and Split $-$ ke graphs.

1 Introduction

Many NP-hard graph optimization problems are solvable in polynomial or even linear time when the input of the problem is restricted to a special graph class. For example, the chromatic number of a perfect graph can be computed in polynomial time [34], the Feedback Vertex Set problem is solvable in polynomial time on chordal graphs [31], and Hamiltonicity on interval graphs [44]. From the perspective of parameterized complexity, the natural question here is how stable are these nice algorithmic properties of graph classes subject to some perturbations. For example, if an input n-vertex graph G is not chordal, but can be turned into a chordal graph by adding at most k edges, how fast can we solve Feedback Vertex Set on G? Can we solve the problem in polynomial time for constant k? Or maybe for $k = \log n$ or even for $k = poly(\log n)$? A word of warning is on order here. Since an algorithm for Feedback Vertex Set of running time $2^{o(n)}$ will refute the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi and Zane [37, 38], and because $k \leq \binom{n}{2}$, the existence of an algorithm of running time $2^{k^{1/2-\varepsilon}} \cdot n^{\mathcal{O}(1)}$ for some $\varepsilon > 0$ (which is polynomial for $k = (\log n)^{2/(1-2\varepsilon)}$) is unlikely. Interestingly, as we shall see, Feedback Vertex Set (and many other problems) are solvable in time $2^{k^{1/2}\log k} \cdot n^{\mathcal{O}(1)}$.

Leizhen Cai in [11] introduced a convenient notation for "perturbed" graph classes. Let $\mathcal{F}$ be a class of graphs, then $\mathcal{F} - ke$ (respectively $\mathcal{F} - ve$) is the class of those graphs that can be obtained from a member of $\mathcal{F}$ by deleting at most k edges (respectively vertices). Similarly one can define classes $\mathcal{F} + ke$ and $\mathcal{F} + ve$. Then for any class $\mathcal{F}$ and optimization problem $\mathcal{P}$ that can be solved in polynomial time on $\mathcal{F}$, the natural question is whether $\mathcal{P}$ is fixed-parameter tractable parameterized by k, the "distance" to $\mathcal{F}$.

In this paper we obtain several algorithmic results on the parameterized complexity of optimization problems on $\mathcal{F} - ke$, where $\mathcal{F}$ is the class of chordal graphs. Let us remind that a graph H is *chordal* (or *triangulated*) if every cycle of length at least four has a chord, i.e., an edge between two nonconsecutive vertices of the cycle. We denote by Chordal $- ke$ the class of graphs that can be made chordal graph by adding at most k edges. While parameterized algorithms for some optimization problems on the class of Chordal $- ke$ graphs were studied (see the section on previous work), our work introduces the first subexponential parameterized algorithms in this graph class. We prove the following.

Subexponential parameterized algorithms. We discover a large class of optimization problems on graph class Chordal $- ke$ that are solvable in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$. Examples of such optimization problems are: the problem of finding an induced d-colorable subgraph of maximum weight (which generalizes Weighted Independent Set for $d = 1$ and Weighted Bipartite Subgraph for $d = 2$); the problem of finding a maximum weight induced subgraph admitting a homomorphism into a fixed graph H; the problem of finding an induced d-degenerate subgraph of maximum weight and its variants like Weighted Induced Forest (or, equivalently, Weighted Feedback Vertex Set), Weighted Induced Tree, Induced Planar Graph, Weighted Induced Path (Cycle) or Weighted Induced Cycle Packing; as well as various connectivity variants of these problems like Weighted Connected Vertex Cover and Weighted Connected Feedback Vertex Set. This implies that all these problems are solvable in polynomial time for $k = (\frac{\log n}{\log\log n})^2$. On the other hand, we refute (subject to ETH) existence of a subexponential time $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ algorithms on graphs in Chordal $- ke$ for Coloring and Clique. Moreover, our lower bounds hold for way more restrictive graph class Complete $- ke$, the graphs within k edges from a complete graph. We also show that both problems are fixed-parameter tractable (FPT) (parameterized by k) on Chordal $- ke$ graphs.

Kernelization. It follows almost directly from the previous work [39, 8] that Weighted Independent Set, Weighted Vertex Cover, Weighted Bipartite Subgraph, Weighted Odd Cycle Transversal, Weighted Feedback Vertex Set and Weighted Clique do not admit a polynomial in k kernel (unless coNP $\not\subseteq$ NP/poly) on Complete $-$ ke and hence on Chordal $-$ ke. Interestingly, these lower bounds do not refute the possibility of polynomial Turing kernelization or kernelization for unweighted variants of the problems. Indeed, we show that Weighted Clique on Chordal $-$ ke parameterized by k admits a Turing kernel. For unweighted Independent Set we show that the problem admits polynomial in k kernel on graph classes Interval $-$ ke and Split $-$ ke (graphs that can be turned into an interval or split graphs, corrspondingly, by adding at most k edges).

Previous work. Chordal graphs form an important subclass of perfect graphs. These graphs were also intensively studied from the algorithmic perspective. We refer to books [9, 33, 58] for introduction to chordal graphs and their algorithmic properties.

The problem of determining whether a graph G belongs to Chordal$-ke$, that is checking whether G can be turned into a chordal graph by adding at most k edges, is known in the literature as the Minimum Fill-in problem. The name fill-in is due to the fundamental problem arising in sparse matrix computations which was studied intensively in the past [52, 55]. The survey of Heggernes [36] gives an overview of techniques and applications of minimum and minimal triangulations.

Minimum Fill-in (under the name Chordal Graph Completion) was one of the 12 open problems presented at the end of the first edition of Garey and Johnson's book [30] and it was proved to be NP-complete by Yannakakis [60]. Kaplan et al. proved that Minimum Fill-in is fixed parameter tractable by giving an algorithm of running time $16^k \cdot n^{\mathcal{O}(1)}$ in [43]. There was a chain of algorithmic improvements resulting in decreasing the constant in the base of the exponents [42, 10, 7] resulting with a subexponential algorithm of running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ [28]. A significant amount of work in parameterized algorithms is devoted to recognition problems of classes $\mathcal{F} - ke$, $\mathcal{F} + ke$, $\mathcal{F} - kv$, and $\mathcal{F} + kv$ for chordal graphs and various subclasses of chordal graphs [1, 2, 4, 5, 14, 12, 13, 26, 40, 48, 59].

Parameterized algorithms, mostly for graph coloring problems, were studied on perturbed chordal graphs and subclasses of this graph class [11, 56]. Among other results, Cai [11] proved that Coloring (the problem of computing the chromatic number of a graph) is FPT (parameterized by k) on Split $-$ ke graphs. Marx [47] proved that Coloring is FPT on Chordal $+$ ke and Interval $+$ ke graphs but is W[1]-hard on Chordal $+$ kv and Interval $+$ kv graphs. Jansen and Kratsch [41] proved that for every fixed integer d, the problems d-Coloring and d-List Coloring admit polynomial kernels on the parameterized graph classes Split $+$ kv, Cochordal $+$ kv, and Cograph $+$ kv.

Liedloff, Montealegre, and Todinca [46] gave a general theorem establishing fixed-parameter tractability for a large class of optimization problems. Let $\mathcal{C}_{poly}$ be a class of graphs having at most $poly(n)$ minimal separators. (Since every chordal graph has at most n minimal separators, the class of chordal graphs is a subclass of $\mathcal{C}_{poly}$.) Let φ be a Counting Monadic Second Order Logic (CMSO) formula, G be a graph, and $t \geq 0$ be an integer. Liedloff, Montealegre, and Todinca proved that on graph class $\mathcal{C}_{poly} + kv$, the generic problem, whose task is to maximize $|X|$ subject to the following constraints: (i) there is a set $F \subseteq V(G)$ such that $X \subseteq F$, (ii) the treewidth of $G[F]$ is at most t, and (iii) $(G[F], X) \models \varphi$, is solvable in time $\mathcal{O}(n^{\mathcal{O}(t)} \cdot f(t, \varphi, k))$, and thus is fixed-parameter tractable parameterized by k. The problem generalizes many classical algorithmic problems like Independent Set, Longest Induced Path, Induced Forest, and different packing problems, see [27].

Since the class $\mathcal{C}_{poly} + kv$ contains Chordal $- ke$, the work of Liedloff et al. [46] yields that all these problems are fixed-parameter tractable on Chordal $- ke$ graphs parameterized by $k + t + |\varphi|$. However, the theorem of Liedloff et al. cannot be used to derive our results. First, this theorem provides FPT algorithm only for problems of finding an induced subgraph of constant treewidth, which is not the case in our situation. Second, even for graphs of treewidth 0, their technique does not derive parameterized algorithms with subexponential running times.

Organization of the paper. In Section 2, we introduce basic notation. In Section 3, we discuss subexponential algorithms on Chordal $- ke$. Section 4 contains conditional lower bounds (assuming ETH) for Coloring and Clique on Chordal$-ke$. Section 5 is devoted to kernelization. We give lower bounds and construct a polynomial Turing kernel for Weighted Clique on Chordal $- ke$, and construct polynomial kernels for Independent Set on Interval $- ke$ and Split $- ke$. We conclude in Section 6 with some open problems. Due to space constraints, we either omit or just sketch the proofs. The details can be found in the full version of the paper [22].

2 Preliminaries

Graphs. All graphs considered in this paper are assumed to be simple, that is, finite undirected graphs without loops or multiple edges. We follow the standard graph theoretic notation and terminology (see, e.g., [19]). For each of the graph problems considered in this paper, we let $n = |V(G)|$ and $m = |E(G)|$ denote the number of vertices and edges, respectively, of the input graph G if it does not create confusion.

A *tree decomposition* of a graph G is a pair $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$, where T is a tree whose every node t is assigned a vertex subset $X_t \subseteq V(G)$, called a bag, such that the following three conditions hold: (i) $\bigcup_{t \in V(T)} X_t = V(G)$, (ii) for every $uv \in E(G)$, there exists a node t of T such that bag X_t contains both u and v, and (iii) for every $u \in V(G)$, the set $T_u = \{t \in V(T) | u \in X_t\}$, i.e., the set of nodes whose corresponding bags contain u, induces a connected subtree of T.

A graph G is *chordal* (or *triangulated*) if it does not contain an induced cycle of length at least four. The intersection graph of a family of intervals of the real line is called an *interval* graph; it is also said that G is an interval graph if there is a family of intervals (called *interval model* or *representation*) such that G is isomorphic to the intersection graph of this family. A graph G is said to be *split* if its vertex set can be partition into independent set and a clique. We refer to [9, 33] for detailed introduction to these graph classes. Notice that interval and split graphs are chordal.

A *triangulation* (or a *chordal complementation*) of a graph G is a chordal supergraph H with $V(H) = V(G)$. The *size* of the triangulation is $|E(H)| - |E(G)|$. The *fill-in* of a graph G, denoted $\mathsf{fill\text{-}in}(G)$, is the minimum integer k such that $G \in$ Chordal $- ke$ or, in other words, fill-in is the minimum number of edges whose addition makes the graph chordal. An *interval complementation* of a graph G is an interval supergraph H with $V(H) = V(G)$. Similarly, a *split complementation* of G is a split supergraph H and a *clique complementation* is a complete supergraph with $V(H) = V(G)$. The *size of interval (split, clique) completion* is $|E(H)|-|E(G)|$ and we denote the minimum size of an interval (split, clique) complementation by $\mathsf{int\text{-}comp}(G)$ ($\mathsf{split\text{-}comp}(G)$, $\mathsf{c\text{-}comp}(G)$ respectively). Clearly, G has an interval (split, clique) complementation of size at most k if and only if $G \in$ Interval $- ke$ (Split $- ke$, Complete $- ke$). It is easy to see that $\mathsf{c\text{-}comp}(G) = \binom{|V(G)|}{2} - |E(G)|$, and it is known that it is NP-hard to compute $\mathsf{fill\text{-}in}(G)$ [60] and $\mathsf{int\text{-}comp}(G)$ [30] and the same holds for $\mathsf{split\text{-}comp}(G)$ [50]. We will make use of the following observation.

▶ **Observation 1.** *For every graph G, c-comp$(G) \geq$ int-comp$(G) \geq$ fill-in(G) and c-comp$(G) \geq$ split-comp$(G) \geq$ fill-in(G).*

In particular, this observation implies that complexity lower bounds obtained for graph problems parameterized by the clique completion size hold for the same problems when they are parmeterized by the interval or split completion or by the fill-in, and the hardness for the interval or split completion parameterization implies the hardness for the fill-in parameterization.

Parameterized Complexity and Kernelization. We refer to the books [16, 20, 25] for the detailed introduction to the field. In the Parameterized Complexity theorey, the computational complexity is measured as a function of the input size n of a problem and an integer *parameter* k associated with the input. A parameterized problem is said to be *fixed parameter tractable* (or FPT) if it can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ for some function f. Parameterized complexity theory also provides tools for obtaining complexity lower bounds. Here we use lower bounds based on *Exponential Time Hypothesis (ETH)* formulated by Impagliazzo, Paturi and Zane [37, 38]. In particular, ETH implies that k-Satisfiability with n variables cannot be solved in time $2^{o(n)}n^{\mathcal{O}(1)}$.

A *compression* of a parameterized problem Π_1 into a (non-parameterized) problem Π_2 is a polynomial algorithm that maps each instance (I, k) of Π_1 with the input I and the parameter k to an instance I' of Π_2 such that (i) (I, k) is a yes-instance of Π_1 if and only if I' is a yes-instance of Π_2, and (ii) $|I'|$ is bounded by $f(k)$ for a computable function f. The output I' is also called a *compression*. The function f is said to be the *size* of the compression. A compression is *polynomial* if f is polynomial. A *kernelization* algorithm for a parameterized problem Π is a polynomial algorithm that maps each instance (I, k) of Π to an instance (I', k') of Π such that (i) (I, k) is a yes-instance of Π if and only if (I', k') is a yes-instance of Π, and (ii) $|I'| + k'$ is bounded by $f(k)$ for a computable function f. Respectively, (I', k') is a *kernel* and f is its *size*. A kernel is *polynomial* if f is polynomial.

Even if a paramterized problem admits no polynomial kernel up to some complexity conjectures, sometimes we can reduce it to solving of a polynomial number of instances of the same problem such that the size of each instance is bounded by a polynomial of the parameter. Let Π be a parameterized problem and let $f\colon \mathbb{Z}^+ \to \mathbb{Z}^+$ be a computable function. A *Turing kernelization* or *Turing kernel* for Π of size f is an algorithm that decides whether an instance (I, k) of Π is a yes-instance in time polynomial in $|I| + k$, when given access to an oracle that decides whether (I', k') is a yes-instance of Π in a single step if $|I'| + k \leq f(k)$.

3 Subexponential algorithms for induced d-colorable subgraphs

To construct subexponential algorithms on Chordal $-$ ke, we consider tree decompositions such that each bag is "almost" a clique.

▶ **Definition 2.** *Let k be a nonnegative integer. A tree decomposition $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ of a graph G is* k-almost chordal *if for every $t \in V(T)$, c-comp$(G[X_t]) \leq k$, that is, every bag can be converted to a clique by adding at most k edges.*

Note that every chordal graph has 0-almost chordal tree decomposition. Given a k-almost chordal tree decomposition, we are able to construct dynamic programming algorithms that are subexponential in k for various problems. The crucial property of the graphs in Chordal $-$ ke is that we are able to construct k-almost chordal tree decompositions for them in subexponential in k time by making use of the following result of Fomin and Villanger [28].

▶ **Proposition 3** ([28]). *Deciding whether graph G is in $\textsc{Chordal} - ke$ can be done in time $2^{\mathcal{O}(\sqrt{k}\log k)} + \mathcal{O}(k^2nm)$. Moreover, if $G \in \textsc{Chordal} - ke$, then the corresponding triangulation can be found in time $2^{\mathcal{O}(\sqrt{k}\log k)} + \mathcal{O}(k^2nm)$.*

Using Proposition 3 we obtain the following lemma.

▶ **Lemma 4.** *A k-almost chordal decomposition of a graph $G \in \textsc{Chordal} - ke$ with at most n bags can be constructed in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$.*

The crux of our subexponential algorithms is in the following combinatorial lemma.

▶ **Lemma 5.** *Let $d \geq 1$ be an integer. Let G be a graph and let $\mathcal{F}$ be a set of induced d-colorable subgraphs of G. Let $U \subseteq V(G)$ be a set of vertices of G such that $\mathsf{c\text{-}comp}(G[U]) \leq k$, that is, U can be made a clique by adding at most k edges. Then*

- *for every $F \in \mathcal{F}$,*

$$|U \cap V(F)| \leq \frac{3d + \sqrt{d^2 + 8dk}}{2},$$

and

- *the size of the projection of $\mathcal{F}$ on U, that is, the size of the family*

$$\mathcal{S} = \{S \mid S = U \cap V(F) \text{ for some } F \in \mathcal{F}\}$$

is at most $(1 + 2^{(\sqrt{1+8k}-1)/2} \cdot |U|)^d$.

Moreover, there is an algorithm that in time $2^{\mathcal{O}(d\sqrt{k})} \cdot n^{\mathcal{O}(d)}$ outputs a family of sets $\mathcal{S}' \supseteq \mathcal{S}$ such that each set from $\mathcal{S}'$ has at most $\frac{3d+\sqrt{d^2+8dk}}{2}$ vertices, the number of sets in $\mathcal{S}'$ is $(1 + 2^{(\sqrt{1+8k}-1)/2} \cdot n)^d$ and $G[S]$ is d-colorable for $S \in \mathcal{S}'$.

Proof sketch. We partition U into sets X and Y as follows. Let X be the vertices of U that have at least one non-neighbor in U. In other words, for every $v \in X$ there is $u \in U$ that is not adjacent to v. Two observations about set X will be useful. First, because U, and hence X, can be turned into a clique by adding at most k edges, we have that $|X| \leq 2k$. Second, the remaining vertices of U, namely, $Y = U \setminus X$, form a clique. For every set $S \in \mathcal{S}$, we define $S_X = X \cap S$ and $S_Y = Y \cap S$. Note that $S = S_X \cup S_Y$.

Because Y is a clique in G, no d-colorable subgraph from $\mathcal{F}$ can contain more than d vertices from Y. Hence, $|S_Y| \leq d$.

Let $x = |S_X|$. Because $G[S_X]$ is an induced subgraph of some d-colorable graph $F \in \mathcal{F}$, we have that $G[S_X]$ is d-colorable. On the other hand, since $\mathsf{c\text{-}comp}(G[U]) \leq k$, $G[S_X]$ can be turned into complete graph by adding at most k edges. These two conditions are used to estimate x. Let us remind that *Turán graph* is the complete d-partite graph on x vertices whose partition sets differ in size by at most 1. According to Turán's theorem, see e.g. [19], Turán graph has the maximum possible number of edges among all d-colorable graphs. The number of edges in Turán's graph is at most $\frac{1}{2}x^2\frac{d-1}{d}$. Thus,

$$\binom{x}{2} - k \leq |E(G[S_X])| \leq \frac{1}{2}x^2\frac{d-1}{d} \text{ and } k \geq \binom{x}{2} - \frac{1}{2}x^2\frac{d-1}{d} = \frac{x^2 - dx}{2d}.$$

Therefore, $x \leq \frac{d+\sqrt{d^2+8dk}}{2}$. We obtain that $|S| = |S_X| + |S_Y| \leq x + d \leq \frac{3d+\sqrt{d^2+8dk}}{2}$, which implies the first claim of the lemma.

To prove the second claim, let $H = G[U]$. Observe that the complement $\overline{H}$ has at most k edges. Consider $Z \subseteq V(H)$. If $|Z| \leq \frac{\sqrt{1+8k}+1}{2}$, then the minimum degree $\delta(\overline{H}[Z]) \leq \frac{\sqrt{1+8k}-1}{2}$. If $|Z| > \frac{\sqrt{1+8k}+1}{2}$, then

$$\delta(\overline{H}[Z]) \leq \frac{2|E(\overline{H}[Z])|}{|Z|} \leq \frac{4k}{\sqrt{1+8k}+1} = \frac{\sqrt{8k+1}-1}{2},$$

that is, the minimum degree of every induced subgraph of $\overline{H}$ is at most $\frac{\sqrt{8k+1}-1}{2}$. Therefore, $\overline{H}$ is $\frac{\sqrt{1+8k}-1}{2}$-degenerate. This implies that U has at most $2^{(\sqrt{1+8k}-1)/2} \cdot |U|$ independent in G subsets. Therefore, U has at most $(1+2^{(\sqrt{1+8k}-1)/2} \cdot |U|)^d$ subsets inducing d-colorable subgraphs. The same observations also allow to construct $\mathcal{S}'$ in $2^{\mathcal{O}(d\sqrt{k})} \cdot n^{\mathcal{O}(d)}$ time. ◀

Let G be a graph and let F be an induced d-colorable subgraph of G. Informally, Lemma 5 says that for a given a k-almost chordal tree decomposition, every bag of this tree decomposition contains roughly $\mathcal{O}(d+\sqrt{dk})$ vertices of F. This statement combined with dynamic programming over the tree decomposition could easily bring us to the algorithm computing a maximum d-colored subgraph of G in time $n^{\mathcal{O}(d+\sqrt{dk})}$. However, this is not what we are shooting for; such an algorithm is not fixed-parameter tractable with parameter k. This is where the second part of the lemma becomes extremely helpful. Let us look at the family of all d-colorable induced subgraphs of G. Then the number of different intersections of the graphs from this family with a single bag of the tree decomposition is bounded by $2^{\mathcal{O}(d\sqrt{k})}n^{\mathcal{O}(d)}$. This allows us to bound the number of "partial solutions" in the dynamic programming, which in turn brings us to a parameterized subexponential algorithm. As an example of the applicability of Lemma 5, we give an algorithm for the following generic problem.

Weighted d-colorable Subgraph

Input:	Graph G with weight function $w\colon V(G) \to \mathbb{R}$.
Task:	Find a properly d-colorable induced subgraph H of G of maximum weight $\sum_{v \in V(H)} w(v)$.

For $d = 1$, this is the problem of finding an independent set of maximum weight, the Weighted Independent Set problem. For $d = 2$, this is the problem of finding an induced bipartite subgraph of maximum weight, Weighted Bipartite Subgraph.

▶ **Theorem 6.** *Let $d \geq 1$ be an integer. For a given graph G with a nice k-almost chordal tree decomposition with $n^{\mathcal{O}(1)}$ bags, the Weighted d-colorable Subgraph problem is solvable in time $2^{\mathcal{O}(\sqrt{k} \cdot d \log d)} \cdot n^{\mathcal{O}(d)}$.*

Proof sketch. Let $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ be a k-almost chordal tree decomposition of G with $|V(T)| = n^{\mathcal{O}(1)}$. We perform dynamic programming over $\mathcal{T}$. Let us note that the width of the decomposition can be of order of n. As it is standard, we assume that T is rooted at some node r. For a node t of T, let V_t be the union of all the bags present in the subtree of T rooted at t, including X_t. For vertex sets $X \subset X'$ of graph G, we say that a coloring c of $G[X]$ is *extendible* to a coloring c' of $G[X']$, if for every $x \in X$, $c(v) = c'(v)$.

For every node t, every $S \subseteq X_t$ such that $G[S]$ is d-colorable, every mapping $c\colon S \to \{1, \ldots, d\}$ of $G[S]$, we define the following value:

$$\begin{aligned} \mathrm{cost}[t, S, c] \quad = \quad & \text{maximum possible weight of a set } \widehat{S} \text{ such that} \\ & S \subseteq \widehat{S} \subseteq V_t,\ \widehat{S} \cap X_t = S, \text{ and } c \text{ is a proper coloring of } G[S] \text{ extendible} \\ & \text{to a proper } d\text{-coloring of } G[\widehat{S}]. \end{aligned} \tag{1}$$

If c is not a proper coloring of $G[S]$ or if no such set $\widehat{S}$ exists, then we put $\mathrm{cost}[t, S, c] = -\infty$. We also put $\mathrm{cost}[t, \emptyset, c]$ be the maximum possible weight of a set $\widehat{S}$ such that $\widehat{S} \subseteq V_t$, $\widehat{S} \cap X_t = \emptyset$, and $G[\widehat{S}]$ is d-colorable. Our algorithm computes the tables of values of $\mathrm{cost}[t, S, c]$ bottom-up for $t \in V(T)$ from the leaves of T. Given the table for the root, it is straightforward to compute the maximum weight of a d-colorable induced subgraph of G. The corresponding optimal subgraph can be found by the standard backtracking arguments.

The proof of the correctness for this dynamic programming is very similar to the one provided normally for graphs of bounded treewidth. However, the running time analysis is based on Lemma 5. The crucial observation that allows us to obtain a subexponential running time is that the running time of our dynamic programming algorithm, up to some polynomial multiplicative factor, is dominated by the number of triples $[t, S, c]$. The number t is in $n^{\mathcal{O}(1)}$. Every set S should induce a d-colorable subgraph, so we can restrict our attention only to sets of the form $X_t \cap V(F)$ for some d-colorable graph F. By Lemma 5, each of these sets is of size at most $d + \frac{d+\sqrt{d^2+8dk}}{2}$ and the total number of such sets S for each bag X_t is is $2^{\mathcal{O}(d\sqrt{k})} \cdot n^{\mathcal{O}(d)}$ and they can be listed in time $2^{\mathcal{O}(d\sqrt{k})} \cdot n^{\mathcal{O}(d)}$. Thus, the number of d-colorings c of each of the sets S is $d^{\mathcal{O}(|S|)} = d^{\mathcal{O}(d+\sqrt{dk})}$. Hence the total running time of the dynamic programming is $2^{\mathcal{O}(\sqrt{k} \cdot d \log d)} \cdot n^{\mathcal{O}(d)}$. ◀

Combining Lemma 4 and Theorem 6, we immediately obtain the following corollary. We say that $A \subseteq \binom{V(G)}{2} \setminus E(G)$ is a *chordal modulator* if the graph obtained from G by adding the edges A is chordal.

▶ **Corollary 7.** *Weighted d-colorable Subgraph on a graph $G \in$ Chordal $- ke$ is solvable in time $2^{\mathcal{O}(\sqrt{k}(\log k + d \log d))} \cdot n^{\mathcal{O}(d)}$. Moreover, the problem can be solved in $2^{\mathcal{O}(\sqrt{k} \cdot d \log d)} \cdot n^{\mathcal{O}(d)}$ time if a chordal modulator of size at most k is given.*

In particular, we derive the following corollary for Weighted Independent Set and Weighted Bipartite Subgraph and the dual minimization problems. In the Weighted Vertex Cover, we are given a weighted graph G and the task is to find a vertex cover of minimum weight, that is, a set of vertices X such that every edge of G has at least one endpoint in G. Similarly, in the Weighted Odd Cycle Transversal, we are asked to find a set of vertices of minimum weight such that every cycle of odd length contains at least one vertex from the set. Clearly the complement of every independent set is a vertex cover, and the complement of every induced bipartite subgraph is an odd cycle transversal.

▶ **Corollary 8.** *Weighted Independent Set (Weighted Vertex Cover) and Weighted Bipartite Subgraph (Weighted Odd Cycle Transversal) on $G \in$ Chordal $- ke$ are solvable in time $2^{\mathcal{O}(\sqrt{k} \log k)} \cdot n^{\mathcal{O}(1)}$. Moreover, the problems can be solved in $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ time if a chordal modulator of size at most k is given.*

The technique developed to prove Theorem 6 could be used to obtain subexponential algorithms for other problems beyond Weighted d-colorable Subgraph. These algorithms are very similar to the one from Theorem 6 and we mention here only few problems.

A *homomorphism* $G \to H$ from a graph G to a graph H is a mapping from the vertex set of G to that of H such that the image of every edge of G is an edge of H. In other words, a homomorphism $G \to H$ exists if and only if there is a mapping $g : V(G) \to V(H)$, such that for every edge $uv \in E(G)$, we have $g(u)g(v) \in E(H)$. Since there is a homomorphism from G to a complete graph K_d on d vertices if and only if G is d-colorable, the deciding whether there is a homomorphism from G to H is often referred as the H-coloring. Note that if G admits an H-coloring, then G is $|V(H)|$-colorable. The only difference between solving Weighted H-colorable Subgraph, the problem of finding the maximum weight induced subgraph admitting a homomorphism to H, with Theorem 6 is that the value $\mathrm{cost}[t, S, c]$ in (1) should be redefined by setting c be a homomorphism to H.

Similar running times could be derived for the variants of Weighted d-colorable Subgraph where some additional constrains on the properties of the d-colorable induced subgraph of minimum weight are imposed by some property $\mathcal{C}$. For example, property $\mathcal{C}$ could be that the required subgraph is connected, acyclic, regular, degenerate, etc. As far as the

information of the partial solution required for property $\mathcal{C}$ is characterized by set $S \subseteq V_t$ and all possible subsets of S or all permutations of S, we can solve the corresponding problem in time $2^{\mathcal{O}((d\sqrt{k})\log(dk))} \cdot n^{\mathcal{O}(d)}$. We summarize these observations within the following theorem.

▶ **Theorem 9.** *Let $d \geq 1$ be an integer and G be a graph from* Chordal $-$ ke. *Then*

- *Weighted H-colorable Subgraph can be solved in $2^{\mathcal{O}(\sqrt{k}(\log k + |V(H)| \log |V(H)|))} \cdot n^{\mathcal{O}(|V(H)|)}$ time,*
- *Weighted d-degenerate Subgraph is solvable in time $2^{\mathcal{O}((d\sqrt{k})\log(dk))} \cdot n^{\mathcal{O}(d)}$,*
- *Weighted Induced Forest (Weighted Feedback Vertex Set), Weighted Induced Tree, Weighted Induced Path (Cycle), and Weighted Induced Cycle Packing are solvable in $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ time.*

In some cases, we can obtain a better running time if a chordal modulator of size at most k is given. For Weighted H-colorable Subgraph, this is done in the same way as for Weighted d-colorable Subgraph. For some other problems, like Weighted Induced Forest (Weighted Feedback Vertex Set), this would demand using recent techniques for dynamic programming on graphs of bounded treewidth for problems with connectivity contstraints (see [18, 6, 23, 53]) but this goes beyond the scope of our paper.

Another extension of Theorem 6 can be derived from the very recent results of Baste, Sau and Thilikos [3] about the $\mathcal{F}$-Minor Deletion problem on graphs of bounded treewidth. Recall that a graph F is a *minor* of G if a graph isomorphic to F can be obtained from G by vertex and edge deletions and edge contractions. Respectively, G is said to be *F-minor free* if G does not contain F as a minor. For a family of graphs $\mathcal{F}$, G is $\mathcal{F}$-minor free if G is F-minor free for every $F \in \mathcal{F}$. For a family $\mathcal{F}$, the task of $\mathcal{F}$-Minor Deletion is, given a graph G, to find a minimum set of vertices X such that $G - X$ is $\mathcal{F}$-minor free. Then $\mathcal{F}$-Minor Deletion is equivalent to $\mathcal{F}$-Minor Free Induced Subgraph, whose task is to find a maximum $\mathcal{F}$-minor free induced subgraph of G. A family of graphs $\mathcal{F}$ is *connected* if every $F \in \mathcal{F}$ is a connected graph. Baste et al. [3] obtained, in particular, the following result.

▶ **Proposition 10** ([3]). *Let $\mathcal{F}$ be a finite connected family of graphs. Then $\mathcal{F}$-Minor Deletion can be solved in time $2^{\mathcal{O}(w \log w)} \cdot n^{\mathcal{O}(1)}$ on graphs of treewidth at most w.*[1]

It is well-known (see, e.g., the book [51] for the inclusion relations between the classes of sparse graphs) that if $\mathcal{F}$ is a finite family, then there is a positive integer d such that every $\mathcal{F}$-minor free graph is d-degenerate. This means that for a finite family $\mathcal{F}$, $\mathcal{F}$-minor free graphs are d-colorable for some constant d that depends on $\mathcal{F}$ only. This allows us to use Lemma 5 and then combine our approach from Theorem 6 with the techniques of Baste et al. [3]. Using Lemma 10, we obtain the following theorem.

▶ **Theorem 11.** *Let $\mathcal{F}$ be a finite connected family of graphs. Let also G be a from* Chordal$-$ ke. *Then $\mathcal{F}$-Minor Deletion (or, equivalently, $\mathcal{F}$-Minor Free Induced Subgraph) can be solved in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$.*

For example, this framework encompasses such problems as Induced Planar Subgraph or Induced Outerplanar Subgraph whose task is to find a subgraph of maximum size that is planar or outerplanar, respectively.

With a small adjustment the dynamic programming could be applied to the problems with specific requirements on the complement of the maximum induced d-colored subgraph. For example, consider the following problem. A set of vertices $S \subseteq V(G)$ is a *connected vertex*

[1] the constants hidden in the big-$\mathcal{O}$ notation depend on $\mathcal{F}$.

cover if S is a vertex cover and $G[S]$ is connected. Then in the Weighted Connected Vertex Cover problem, we are given a graph G with a weight function $w\colon V(G) \to \mathbb{Z}^+$ and the task is to find a connected vertex cover in G of minimum weight. Similarly, Weighted Connected Feedback Vertex Set is the problem of finding a connected feedback vertex set of minimum weight. The complement of every vertex cover is an independent set, that is a 1-colorable subgraph, and the complement of every feedback vertex set is a forest, hence 2-colorable subgraph. While now the connectivity constraints are not on the maximum induced subgraph but on its complement our previous arguments can be adapted to handle these problems.

▶ **Theorem 12.** *Weighted Connected Vertex Cover and Weighted Connected Feedback Vertex Set are solvable in time* $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ *on* Chordal $- ke$.

In this section, we discussed optimization problems but, in many cases, similar dynamic programming can be applied for counting problems. For example, we can compute the number of (inclusion) maximal independent sets, maximal bipartite subgraphs, minimal (connected) feedback vertex sets, minimal connected vertex covers in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ on Chordal $- ke$.

4 Beyond induced d-colorable subgraphs

In Section 3, among other algorithms, we gave a subexponential (in k) algorithm on Chordal $- ke$ graphs that finds a maximum d-colorable subgraph. In particular, this also implies that for every fixed d, deciding whether a graph from Chordal $- ke$ is d-colorable, can be done in time subexponential in k. In this section we show that two fundamental problems, namely, Coloring and Clique, while still being FPT, are unlikely to be solvable in subexponential parameterized time.

First, we consider the Coloring problem, where the task is for a given graph G and positive integer ℓ, to decide whether the chromatic number of G is at most ℓ, that is, if G is ℓ-colorable. Note that ℓ here is not a fixed constant as in Section 3. Cai [11] proved that Coloring is FPT (parameterized by k) on Split $- ke$ graphs. The following theorem generalizes his result by showing that Coloring is FPT on a larger class Chordal $- ke$. Our approach is based on the dynamic programming which is similar to the one we used in Section 3.

▶ **Theorem 13.** *Coloring can be solved in time* $2^{\mathcal{O}(k\log k)} \cdot n^{\mathcal{O}(1)}$ *on* Chordal $- ke$ *graphs.*

On the other hand, it is unlikely that Coloring can be solved in subexponential in k time. For this, we show the complexity lower bound based on ETH. In fact, we prove a stronger claim.

▶ **Theorem 14.** *Coloring cannot be solved in time* $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ *on* Complete $- ke$ *graphs unless ETH fails.*

Next, we consider the Clique problem that asks, given a graph G and a positive integer ℓ, whether G has a clique of size at least ℓ. We show that Clique is FPT on Chordal $- ke$ when parameterized by k even for the weighted variant of the problem in Section 5 by demonstrating that the problem admits a Turing kernel. Here, we give a lower bound.

▶ **Theorem 15.** *Clique cannot be solved in time* $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ *on graphs in* Complete $- ke$ *unless ETH fails.*

We established that Coloring and Clique do not admit subexponential algorithms on Complete $-$ ke, when parameterized by k, unless ETH fails. By Observation 1, this yields that these problems do not admit subexponential algorithms on Chordal $-$ ke as well.

5 Kernelization on Chordal-ke

In this section we discuss kernelization of the problems considered in the previous section.

Jansen and Bodlaender in [39] and Bodlaender, Jansen and Kratsch in [8] proved that Weighted Independent Set, Weighted Vertex Cover, Weighted Bipartite Subgraph, Weighted Odd Cycle Transversal, Weighted Feedback Vertex Set and Clique do not admit a polynomial kernel parameterized by the size of the minimum vertex cover of a graph unless coNP $\subseteq$ NP/ poly. It is easy to observe that if G has a vertex cover of size at most k, then $\mathsf{split\text{-}comp}(G) \leq \binom{k}{2}$. Thus, by the results of [8, 39], we obtain the following proposition.

▶ **Proposition 16.** *Weighted Independent Set, Weighted Vertex Cover, Weighted Bipartite Subgraph, Weighted Odd Cycle Transversal, Weighted Feedback Vertex Set and Clique do not admit a polynomial in k kernel on Split $-$ ke graphs unless* coNP $\subseteq$ NP/ poly.

By Observation 1, these problems parameterized by k have no polynomial kernel on Chordal $-$ ke as well unless coNP $\subseteq$ NP/ poly.

These results do not refute the existence of polynomial Turing kernels. To demonstrate this, we show that Weighted Clique has such a kernel. The input of Weighted Clique contains a graph G together with a weight function $w\colon V(G) \to \mathbb{Z}^+$ and a nonnegative integer W, and the task is to decide whether G has a clique C of weight at least W.

▶ **Theorem 17.** *Weighted Clique on Chordal $-$ ke parameterized by k admits a Turing kernel with at most $16k^2$ vertices with size $\mathcal{O}(k^8)$.*

Proof sketch. Let (G, w, W) be an instance of Weighted Clique. We use the result of Natanzon, Shamir and Sharan [49] that fill-in admits a polyopt approximation. The approximation algorithm either correctly reports that $\mathsf{fill\text{-}in}(G) > k$ or returns a set of nonedges $A \subseteq \binom{V(G)}{2} \setminus E(G)$ of size at most $8k^2$ such that the graph G' obtained by adding the edges of A is a chordal graph. In the first case, we have that $G \notin$ Chordal $-$ ke. Assume that this is not the case. Then we use the well-known property of chordal graphs (see [32, 57]) that G' has at most n inclusion-maximal cliques $C_1, \ldots, C_r$ and they can be listed in linear time. Now we observe that K is a maximal clique of G if and only if K is a clique of $G[C_i]$ for some $i \in \{1, \ldots, r\}$. Moreover, every such K contains all the vertices of C_i that are not vertices of the pairs $\{u, v\} \in A$ with $u, v \in C_i$. Then the problem is reduced to finding solutions for $G[C'_i]$ for $i \in \{1, \ldots, r\}$, where each C'_i is the subset of C_i containing the vertices of pairs $\{u, v\} \in A$ with $u, v \in C_i$. Since $|C'_i| \leq 2|A| \leq 16k^2$, we obtain the upper bound on the number of vertices. To compress the weights and obtain the upper bound on the size, we use the the technique of Frank and Tardos [29], see also [21] for applications of this technique for kernelization. ◀

While Proposition 16 rules out the existence of a polynomial kernel for Weighted Independent Set on Chordal $-$ ke graphs, for unweighted Independent Set the existence of a polynomial kernel remains open. In what follows, we obtain polynomial kernels for Independent Set on two interesting subclasses of Chordal $-$ ke, namely Interval $-$ ke and Split $-$ ke. Let us note that again, by Proposition 16, the Weighted Independent Set problem admits no polynomial kernel on Split $-$ ke.

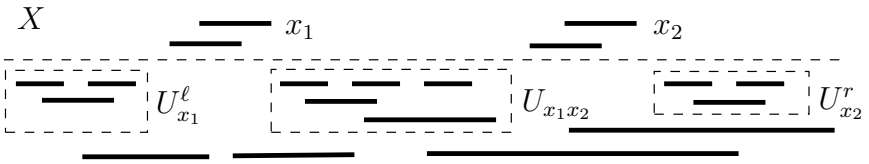

Figure 1 Structure of a maximum independent set in G.

We start with the kernel on Interval $-$ ke graphs. This kernel is the most technical part of the paper. In order to obtain the required kernel, we show that Independent Set parameterized by the size of interval completion of the input graph admits a polynomial compression into the Weighted Independent Set problem. (We state Weighted Independent Set as a decision problem, whose input contains a graph G with a weight function $w\colon V(G) \to \mathbb{Z}^+$ and a nonnegative integer W, and the task is to decide whether G has an independent set S with $w(S) \geq W$.) Then the standard arguments about polynomial compression of NP-complete problems, see e.g. [24, Theorem 1.6], yield the polynomial kernel for Independent Set on Interval $-$ ke graphs.

▶ **Theorem 18.** *Independent Set on $G \in$ Interval $-$ ke admits a compression of size $\mathcal{O}(k^{56})$ into Weighted Independent Set.*

Proof sketch. The proof is long and here we only sketch briefly the main ideas behind the algorithm. Let G be a graph and let $A \subseteq \binom{V(G)}{2} \setminus E(G)$ be a set of pairs of nonadjacent vertices such that the graph G' obtained from G by adding the edges from A becomes interval. Denote by X the set of end-vertices of the edges of A in G'.

Consider an interval model of G'. For each vertex $v \in V(G')$, let ℓ_v and r_v be, respectively, the left and right endpoint of the interval representing v. For each $v \in V(G')$, denote by G^{ℓ}_v and G^r_v the subgraphs of G' induced by the sets of vertices $U^{\ell}_v = \{u \in V(G') \mid r_u < \ell_v\}$ and $U^r_v = \{u \in V(G') \mid r_v < \ell_u\}$ respectively, and for every two distinct $u, v \in V(G')$, let G_{uv} be the subgraph induced by $U_{uv} = \{w \in V(G') \mid r_u < \ell_w \leq r_w < \ell_v\}$ (see Figure 1). For a graph H, denote by $I(H)$ a maximum independent set of H. Suppose that I is a maximum independent set of G and let $I \cap X = \{x_1, \ldots, x_s\}$ with $r_{v_{i-1}} < \ell_{v_i}$ for $i \in 2, \ldots, s$. Then it is possible to prove that

$$I' = I(G^{\ell}_{x_1}) \cup \Big(\bigcup_{i=2}^{s} I(G_{x_{i-1}x_i})\Big) \cup I(G^r_{x_s})$$

is a maximum independent set of G.

This allows us to create the following compression of the initial problem to an instance of Weighted Independent Set. Let $\mathcal{F}$ be the set of all induced subgraphs G^{ℓ}_v, G^r_v and G_{uv} for all $u, v \in X$. Consider the graph $\mathcal{G}$ with the set of vertices $X \cup \mathcal{F}$ with the following adjacencies: for distinct $u, v \in V(\mathcal{G})$, u and v are adjacent if and only if one of the following holds:

- $u, v \in X$ and $xy \in E(G)$,
- $u \in X$, $v \in \mathcal{F}$ and u is adjacent to a vertex of v in G,
- $u, v \in \mathcal{F}$ and the subgraphs u and v have either common or adjacent vertices in G.

We define the weight $w(v)$ for $v \in V(\mathcal{G})$ be one if $v \in X$ and set $w(v) = |I(v)|$ for $v \in \mathcal{F}$. It can be shown that G has an independent set of size at least W if and only if $\mathcal{G}$ has an independent set of weight at least W.

Unfortunately, the above arguments *do not work* for the following reason. We based our construction on the assumption that we know the resulting interval model. But computing such a model is an NP-hard task. Of course it would suffice even if we had a poly(OPT)

approximation algorithm for interval completion. That is, an algorithm producing in polynomial time an edge set A of polynomial in k size whose addition turns the input graph G into an interval graph. However the existence of such an approximation is a long-standing open problem. The best known result is the $\mathcal{O}(\log n)$ approximation algorithm of Rao and Richa [54] for the minimum number of edges of an interval supergraph of an n-vertex graphs. While at the end we were able to implement the above idea and obtain the required compression, the absence of a good approximation makes the proof way more difficult.

Given a graph G, we construct a vertex set X and a set of induced subgraphs $\mathcal{F}$ of $G - X$ such that the graph $\mathcal{G}$ defined above have the desired property: G has an independent set of size at least W if and only if $\mathcal{G}$ has an independent set of weight at least W. We start the construction of X using the algorithm of Natanzon, Shamir and Sharan [49] to approximate $\mathsf{fill\text{-}in}(G) \leq \mathsf{int\text{-}comp}(G)$. Initially, we set X be the set of vertices that are in the pairs of nonadjacent vertices returned by the algorithm. Then we apply a series of reduction rules that either solve the problem, or enhance X by adding vertices, or delete vertices of the graph. The reduction rules are based on the forbidden induced subgraph characterization of interval graphs given by Lekkerkerker and Boland [45]. This way we construct X of size $\mathcal{O}(k^3)$. Then we construct $\mathcal{F}$ of size $\mathcal{O}(k^{14})$ and define $\mathcal{G}$. Here again we use the technique of Frank and Tardos [29] to compress the weights. ◀

Since Weighted Independent Set is in NP and, consecutively, has a polynomial reduction to Independent Set that is NP-complete [30], by applying a standard trick, see e.g. [24, Theorem 1.6], we obtain the following corollary.

▶ **Corollary 19.** *Independent Set on $G \in$ Interval $-$ ke admits a polynomial kernel when parameterized by k.*

Finally, we show that Independent Set admits a polynomial kernel when parameterized by the split completion size. For this result, we exploit the result of Hammer and Simeone in [35] that Split Editing can be solved in polynomial time.

▶ **Theorem 20.** *Independent Set on Split $-$ ke admits a polynomial kernel with at most $2k^2(k+2)$ vertices when parameterized by k.*

6 Conclusion

In this paper, we initiated the study of parameterized subexponential and kernelization algorithms on Chordal $-$ ke graphs. The existence of such algorithms makes this graph class a very interesting object for studies. For other structural parameters, like treewidth or vertex cover, we have quite good understanding about the complexity of various optimization problems derived from general meta-theorems like Courcelle's or Pilipczuk's theorems [15, 53] and advanced algorithmic techniques [18, 17, 23]. We believe that further exploration of the complexity landscape of fill-in parameterization is an interesting research direction. If an optimization problem is NP-complete on chordal graphs, like Dominating Set, then on Chordal $-$ ke this problem is in Para-NP. On the other hand, even if a problem is solvable in polynomial time on chordal graphs, in theory, there is nothing preventing it from being Para-NP on Chordal $-$ ke. Is there a natural graph problem with this property? For many problems that are solvable in polynomial time on chordal graphs, we also established FPT algorithms on Chordal $-$ ke class. This does not exclude a possibility that there are problems that are not FPT parameterized by k but solvable in polynomial time for every fixed k. We do not know any such problem (in other words, the problem in class XP) yet. It will

be interesting to see, if there is any natural graph problem of such complexity. In addition, we proved that there are problems that are FPT on Chordal $-$ ke when parameterized by k and which cannot be solved in subexponential time unless ETH fails. We believe it would be exciting to obtain a logical characterization of problems that can be solved in subexponential time on Chordal $-$ ke when parameterized by k, similar to the classical Courcelle's theorem [15].

Some concrete open problems. Observe that for our subexponential dynamic programming algorithms, we only need a k-almost chordal tree decomposition of the input graph, that is, a decomposition where each bag can be made a clique by adding at most k edges. (Recall Definition 2.) The maximum of numbers $\mathsf{c\text{-}comp}(G[X_t]) \leq k$ can be significantly smaller than the minimum fill-in of a graph. For graphs in Chordal $-$ ke, we can find fill-in in a subexponential in k time by the algorithm of Fomin and Villanger [28]. However, we do not know if it is FPT in k to decide, whether a graph admits a k-almost chordal tree decomposition. And if yes, can it be done in subexponential time?

By the results of Natanzon, Shamir and Sharan [49], $\mathsf{fill\text{-}in}(G)$ can be approximated in polynomial time within a polyopt factor $8 \cdot \mathsf{fill\text{-}in}(G)$. Deciding whether $\mathsf{fill\text{-}in}(G) \leq k$ can be done in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ by the results of Fomin and Villanger [28] (Proposition 3). Is there a constant-factor approximation FPT algorithm with running time $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$? The existence of such an algorithm would speed-up our algorithms for several problems. For example, we would be able to solve Weighted Independent Set in $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ time on Chordal-ke.

Finally, we proved that Independent Set on Interval $-$ ke and Split $-$ ke admit polynomial kernels when parameterized by k. We leave open the question whether or not this problem has a polynomial (Turing) kernel on Chordal $-$ ke.

Abstract

The incidence matrix of a graph is a fundamental object naturally appearing in many applications, involving graphs such as social networks, communication networks, or transportation networks. Often, the data collected about the incidence relations can have some slight noise. In this paper, we initiate the study of the computational complexity of recovering incidence matrices of graphs from a binary matrix: given a binary matrix M which can be written as the superposition of two binary matrices L and S, where S is the incidence matrix of a graph from a specified graph class, and L is a matrix (i) of small rank or, (ii) of small (Hamming) weight. Further, identify all those graphs whose incidence matrices form part of such a superposition. Here, L represents the noise in the input matrix M. Another motivation for this problem comes from the Matroid Minors project of Geelen, Gerards and Whittle, where perturbed graphic and co-graphic matroids play a prominent role. There, it is expected that a perturbed binary matroid (or its dual) is presented as $L + S$ where L is a low rank matrix and S is the incidence matrix of a graph. Here, we address the complexity of constructing such a decomposition.

When L is of small rank, we show that the problem is NP-complete, but it can be decided in time $(mn)^{O(r)}$, where m, n are dimensions of M and r is an upper-bound on the rank of L. When L is of small weight, then the problem is solvable in polynomial time $(mn)^{O(1)}$. Furthermore, in many applications it is desirable to have the list of all possible solutions for further analysis. We show that our algorithms naturally extend to enumeration algorithms for the above two problems with delay $(mn)^{O(r)}$ and $(mn)^{O(1)}$, respectively, between consecutive outputs.

1 Introduction

Suppose that we are given a large binary data matrix M, and we know that this matrix is of the form $M = L + S$, where S is the incidence matrix of an undirected graph and L is a sparse binary matrix. We assume that the sums are taken over GF(2) and thus $1 + 1 = 0$. See Section 2 for a formal definition of incidence matrices. Now, consider the following two computational questions.

Question 1: How efficiently can we recover *some* incidence matrix S such that $M = L + S$ as described above?

Question 2: How efficiently can we recover *all* possible graphs whose incidence matrices form part of such a superposition $M = L + S$?

Our main motivation for studying these questions comes from the study of perturbed graphic matroids, which naturally arise in many settings. A prominent example is the emerging Matroid Minors Project of Geelen, Gerards, and Whittle [5], mirroring the Graph Minors project. Let us recall that binary matroids are represented by a matrix over $\mathsf{GF}(2)$, and graphic matroids are a sub-class of binary matroids defined by the incidence matrices of graphs. Then, for each proper minor-closed class $\mathcal{M}$ of binary matroids, there exists a non-negative integer r such that every well-connected matroid $M \in \mathcal{M}$ is either a perturbation of a graphic matroid or a co-graphic matroid [5]. In other words, either M or $M^\star$ (the dual matroid) can be decomposed as $L + S$ where S is the incidence matrix of a graph and L is a matrix of rank at most r. Matroid Minors and perturbed matroids are expected to have important applications in matroid algorithms, similar to the applications of Graph Minors and H-minor free decompositions in graph algorithms. In the applications of perturbed binary matroids [6, 4], it is expected that a decomposition of the perturbed matroid M into $L + S$ is given as a part of the input. A natural computational question that arises here is the construction of such a decomposition for a given matroid.

Such a problem can be seen as the problem of the recovery of incidence matrices, which is a fundamental representation of graphs. Often the data collected about the network incidence relations contains some slight noise or errors. Our objective is to decompose the data matrix M into two sparse matrices L and S, where L is a low weight matrix, that is matrix with a small number of ones, representing the error or noise, and S is the incidence matrix of some graph from a specified graph class.

Besides applications in matroid minors theory, the problem of superposing binary matrix M in $L+S$ has strong connections to robust Principal Component Analysis (PCA), a popular approach to robust subspace learning by the decomposition of the data matrix into low rank and sparse components. Here we have as data a matrix M, which is the superposition of a low rank component L and a sparse component S. In particular, this approach to robust PCA was popularized by Candès et al. [1], Wright et al. [11], and Chandrasekaran et al. [2]. Thus our problem can be seen as a variant of robust PCA for binary matrices, with additional constraint on sparse component S of being incidence matrix of some graph. Other variants of robust PCA when the structure of the sparse matrix S is imposed from the structure of some graph were studied in [10, 12].

In this paper, we initiate the study of the computational complexity of graph recovering problems and identify several settings which imply efficient algorithms for the questions stated above. Moreover, we also provide complexity theoretic lower bounds for certain other settings that preclude polynomial-time solvability of either question. Let us formally describe our contributions and state our results.

Our contributions. Our first contribution is the formulation of a pair of generic Graph Recovering problems dealing with two common notions of sparsity for L. Let $\mathcal{C}$ be a fixed class of simple graphs.

(MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY
Input: An $n \times m$ binary matrix M and $r \in \mathbb{N}$.
Question: Decide whether $M = L + S$, where L is a binary matrix of $\mathsf{GF}(2)$-rank at most r, S is the incidence matrix of a graph in $\mathcal{C}$ and the sums are taken over $\mathsf{GF}(2)$.

Let $\|L\|$ denote the *(Hamming) weight* of a matrix L, i.e. the number of non-zero entries in L.

(MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY
Input: An $n \times m$ binary matrix M and $r \in \mathbb{N}$.
Question: Decide whether $M = L + S$, where L is a binary matrix of weight at most r, S is the incidence matrix of a graph in $\mathcal{C}$ and the sums are taken over $\mathsf{GF}(2)$.

Our second contribution is establishing the computational complexity of (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY and (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY for some fundamental graph classes and obtain the following upper and lower bounds.

(a) We show that if $\mathcal{C}$ is one of {simple graphs, acyclic graphs, trees, arboricity-d graphs, connected graphs}, then (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY can be solved in time $(mn)^{\mathcal{O}(r)}$.
(b) We show that if $\mathcal{C}$ is one of {simple graphs, acyclic graphs, trees, connected graphs}, then (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY is polynomial-time solvable, i.e., in time $(mn)^{\mathcal{O}(1)}$.
(c) We show that the running time in Result (a) cannot be improved to a purely polynomial dependence on m and n (as in Result (b)) unless $\mathsf{P}{=}\mathsf{NP}$. Specifically, we show that if $\mathcal{C}$ is any of {simple graphs, acyclic graphs, trees, arboricity-d graphs, connected graphs}, then the (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY problem is NP-complete.

A key feature of the methodology we introduce to obtain our algorithms is that it not only answers Question 1 (i.e., the decision problem) for the settings above, it also naturally extends to an algorithm that addresses the significantly harder Question 2 (i.e., the enumeration of all solutions) in these settings. Specifically, we show that in the case of Result (a) above, we can also *enumerate* all possible solution matrices S (if any exist) with a delay of time $(mn)^{\mathcal{O}(r)}$ between consecutive outputs. Similarly, we show that in the case of Result (b), we can also enumerate all possible solution matrices S (and equivalently, the corresponding graphs) with polynomial delay, i.e., a delay of time $(mn)^{\mathcal{O}(1)}$ between consecutive outputs. The importance of enumeration lies in the fact that a solution $M = S + L$ may not be unique, and further analysis of the list of all solutions is required.

Roadmap of the paper

Following the introduction of the requisite notation, we first describe the methodology behind our enumeration algorithms, where we reduce the problem of enumerating all solutions to one of *deciding* whether a solution exists for appropriate annotated variants of (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY and (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY. We then present our decision algorithms for the aforementioned annotated problems. The precise formulation of these problems involves some notation and we do not go into more details here. The algorithms for the annotated variant of (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY are centred around a novel application of Matroid Intersection involving carefully chosen matroids. On the other hand, the algorithms for (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY are designed through an

intricate analysis of the structure of bridges (or cut edges) in graphs and appropriate repeated reassignments of these to columns of our input matrix in a manner reminiscent of the "augmenting path" step in maximum matching algorithms. Finally, we give our NP-completeness result for (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY.

2 Preliminaries

Matrices and Linear Algebra

For $\ell \in \mathbb{N}$, we use $[\ell]$ to denote the set $\{1, \ldots, \ell\}$. For a matrix M, we denote the set of rows of M by $\text{rows}(M)$ and the set of column of M by $\text{cols}(M)$. For a set $P \subseteq \text{cols}(M)$, we denote by $M[P]$ the submatrix of M induced by the columns in P. Consider the set $V = \{v_1, v_2, \ldots, v_k\}$ of vectors over $\mathbb{F}$. The vectors in V are said to be *linearly dependent* if there exist elements $a_1, a_2, \ldots, a_k \in \mathbb{F}$, not all zero, such that $\sum_{i=1}^{k} a_i v_i = 0$. Otherwise these vectors are said to be *linearly independent*. The *rank* of a matrix is the cardinality of a maximum sized set of columns which are linearly independent. The vector space *spanned by* V is the set of all linear combinations of vectors in V and is denoted by $\text{span}(V)$. The vector space spanned by the set of columns of a matrix M over the field $\mathbb{F}$ is defined as $\text{span}(\text{cols}(M))$ and is denoted by $\text{col-span}(M)$. We say a matrix A has dimension $n \times m$ (or is an $n \times m$ matrix) if A has n rows and m columns. In this paper we always view the elements of a binary matrix as elements of $\mathsf{GF}(2)$, the Galois field of two elements. Then the $\mathsf{GF}(2)$-rank of a binary $n \times m$ matrix A is the minimum r such that $A = U \cdot V$, where U and V are $n \times r$ and $r \times m$ binary matrices respectively, and arithmetic operations are over $\mathsf{GF}(2)$.

Graphs

For standard graph theoretic terminology and notation, we refer to [3]. For an undirected graph G, we denote by $\text{inc}(G)$, the *incidence matrix* of G which is the $|V(G)| \times |E(G)|$ binary matrix M with a row for each vertex and a column for each edge such that for every $v \in V(G)$ and $e \in E(G)$, $M[v, e] = 1$ if and only if v is an endpoint of e. When considering the incidence matrix M of an unspecified graph, we denote by $\text{inc}^{-1}(M)$ the graph G where $V(G) = \text{rows}(M)$, $E(G) = \text{cols}(M)$ and whose incidence matrix is precisely M. For $\ell \in \mathbb{N}$, we denote by K_ℓ the complete graph on ℓ vertices. We assume without loss of generality that the vertices of K_ℓ are labelled 1 to ℓ and unless otherwise specified, the columns in $\text{inc}(K_n)$ are assumed to be arranged in lexicographically increasing order based on the endpoints of the corresponding edges.

Matroids

We recall relevant definitions related to matroids. For a broader overview on matroids, we refer to [9].

▶ **Definition 1.** *A matroid M is a pair $(E, \mathcal{I})$, where E is a set called the universe or ground set, and $\mathcal{I}$ is a family of subsets of E, called independent sets, with the following three properties : (i) $\emptyset \in \mathcal{I}$, (ii) if $I \in \mathcal{I}$ and $I' \subseteq I$, then $I' \in \mathcal{I}$, and (iii) if $I, J \in \mathcal{I}$ and $|I| < |J|$, then there is $e \in J \setminus I$ such that $I \cup \{e\} \in \mathcal{I}$.*

Any set $F \subseteq E$, $F \notin \mathcal{I}$, is called a *dependent set* and an inclusion-wise maximal set B such that $B \in \mathcal{I}$ is called a *basis*. The cardinality of a basis in a matroid M is called the *rank* of M and is denoted by $\mathsf{rank}(M)$. The rank function of M, denoted by $\text{rank}_M()$ (with the reference to M omitted when clear from the context), is a function from 2^E to $\mathbb{N} \cup \{0\}$ and is defined as, $\text{rank}(S) = \max_{S' \subseteq S, S' \in \mathcal{I}} |S'|$ for every $S \subseteq E$.

▶ **Definition 2.** *Let A be a matrix over a field $\mathbb{F}$ and E be the set of columns of A. The pair $(E, \mathcal{I})$, where $\mathcal{I}$ defined as follows, is a matroid. For every $X \subseteq E$, $X \in \mathcal{I}$ if and only if the columns of A corresponding to X are linearly independent over $\mathbb{F}$. Such matroids are called* linear matroids. *If a matroid M can be defined by a matrix A over a field $\mathbb{F}$, then we say that the matroid is* representable over $\mathbb{F}$ *and A is a linear representation of M.*

▶ **Definition 3** (Elongation of matroids)**.** *Let $M = (E, \mathcal{I})$ be a matroid and $k \in \mathbb{N}$. Suppose that $\text{rank}(M) \leq k \leq |E|$. A k-elongation matroid M_k of M is a matroid with the universe as E and $S \subseteq E$ is a basis of M_k if and only if, it contains a basis of M and $|S| = k$.*

Observe that the rank of the matroid M_k in the definition above is k.

▶ **Definition 4** (Direct-sum of matroids)**.** *Consider a set of ℓ matroids $\{M_i = (E_i, \mathcal{I}_i) \mid i \in [\ell]\}$, where $E_i \cap E_j = \emptyset$ for every $i \neq j$. The* direct-sum *of these matroids is the matroid $M = (\bigcup_{i \in [\ell]} E_i, \mathcal{I})$ where $I \in \mathcal{I}$ if and only if $I = \bigcup_{i \in [\ell]} I_i$ where $I_i \in \mathcal{I}_i$ for every $i \in [\ell]$.*

Given the representations of ℓ linear matroids over $\mathbb{F}$, it is straightforward to obtain a representation for their direct-sum over $\mathbb{F}$ and this can be done in polynomial time.

For a finite field $\mathbb{F}$, $\mathbb{F}[X]$ denotes the *ring of polynomials in X over $\mathbb{F}$* and $\mathbb{F}(X)$ denotes the *field of fractions* of $\mathbb{F}[X]$. A vector v over a field $\mathbb{F}$ is a tuple of elements from $\mathbb{F}$.

The next two propositions follow from [8].

▶ **Proposition 5** ([8])**.** *Let M be a linear matroid of rank r, over a ground set of size n, which is representable over a field $\mathbb{F}$. Given $k \geq r$, we can compute a representation of the k-elongation of M, over the field $\mathbb{F}(X)$ in $\mathcal{O}(nrk)$ field operations over $\mathbb{F}$.*

▶ **Proposition 6** ([8])**.** *Given a linear representation of the k-elongation of M over the field $\mathbb{F}(X)$ and a set of columns in the representation matrix, one can test for linear dependence of this set in polynomial time.*

In the Weighted Matroid Intersection problem, the input is a pair of matroids $M_1 = (E, \mathcal{I}_1), M_2 = (E, \mathcal{I}_2)$ and a weight function $w : E \to \mathbb{N} \cup \{0\}$ and the objective is to find a maximum-weight common independent set in the two matroids. That is, the goal is to compute $I \in \mathcal{I}_1 \cap \mathcal{I}_2$ such that $\Sigma_{e \in I} w(e)$ is maximized. We will use the polynomial-time algorithm for this problem stated in Proposition 7.

▶ **Proposition 7** ([7])**.** *Given two general matroids M_1 and M_2 over the element set E, one can solve Weighted Matroid Intersection in time $O(\tau W n r^{1.5})$, where W is the largest weight assigned to an element, $n = |E|$, $r = min\{\text{rank}(M_1), \text{rank}(M_2)\}$ and τ is the time required to test whether a given subset of E is independent in M_1 and M_2.*

Graphic Matroids. These are matroids that arise from graphs in the following way. The graphic matroid $M(G)$ of an undirected graph G has universe $E(G)$ and a set $S \subseteq E(G)$ is independent if the subgraph with vertex set $V(G)$ and edge set S is acyclic. Graphic matroids are representable over every field and a representation of $M(G)$ over $\mathsf{GF}(2)$ can be computed in time polynomial in the size of G [9]. Observe that testing whether a set is independent in the matroid $M(G)$ can be done in polynomial time if one is given either the linear representation of the matroid or the graph G.

Transversal Matroids. For a bipartite graph $G = (X, Y, E)$, we can define a matroid M with universe X, where a set $S \subseteq X$ is independent if there exists a matching in G such that every vertex in S is an endpoint of a matching edge. We denote this matroid by $\text{Tr}(G, X)$.

Observe that if G is given, then one can use a *Maximum Matching* algorithm as a subroutine to determine in polynomial time (in the size of G) whether a given set is independent in $\mathrm{Tr}(G, X)$.

Gammoids. Let D be a digraph and $S, T \subseteq V(D)$. Then a *gammoid* with respect to D and S on ground set T is a matroid $(T, \mathcal{I})$, where $\mathcal{I}$ is defined as follows. For any $T' \subseteq T$, $T' \in \mathcal{I}$, if and only if there are $|T'|$ vertex disjoint paths which originate in S and end in T'. Observe that if D, S are given, then one can use a *Maximum Flow* algorithm as a subroutine to determine in polynomial time (in the size of D) whether a given set is independent in this gammoid.

▶ **Definition 8.** *A pair of matroids $M_1 = (E_1, \mathcal{I}_1), M_2 = (E_2, \mathcal{I}_2)$ are said to be* isomorphic *if there is a bijection $\phi : E_1 \to E_2$ such that for every $S \subseteq E_1$, $S \in \mathcal{I}_1$ if and only if $\phi(S) \in \mathcal{I}_2$ where the function ϕ is extended in the natural way to subsets of E_1. Equivalently, we say that M_1 and M_2 are isomorphic under the bijection ϕ.*

3 The enumeration algorithms for (min-rank, $\mathcal{C}$)-Graph Recovery and (min-weight, $\mathcal{C}$)-Graph Recovery

This section is devoted to our enumeration algorithms. We begin by reducing the enumeration task to one of deciding an annotated version of the problem at hand.

3.1 Reducing enumeration to decision

Our enumeration strategy is based on first designing an algorithm for the decision version of an "annotated" version of these problems. In this version, certain columns of the input matrix M already have their corresponding columns in the hypothetical solution matrix S (equivalently, in the matrix L) identified and the goal is to check whether this partial mapping can be extended to a full solution. We now formally define the annotated versions of these problems.

In the Extended (min-rank, $\mathcal{C}$)-Graph Recovery problem, we are given an $n \times m$ binary matrix M, number $r \in \mathbb{N}$, a set $C_M \subseteq \mathrm{cols}(M)$ and an injective mapping $\tau : C_M \to \mathsf{GF}(2)^n$ and the task is to *decide whether there exist* binary matrices L and S such that $M = L + S$, S is an incidence matrix of a simple graph belonging to the class $\mathcal{C}$, $\mathrm{rank}(L) \leq r$ and moreover, for every $x \in C_M$, $S[\{x\}] = \tau(x)$. Similarly in the Extended (min-weight, $\mathcal{C}$)-Graph Recovery problem, the input is the same and the the goal is to decide whether there exist binary matrices L and S such that $M = L + S$, S is an incidence matrix of a simple graph belonging to the class $\mathcal{C}$, $\|L\| \leq r$ and for every $x \in C_M$, $S[\{x\}] = \tau(x)$.

We remark that if, in an instance (M, r, C_M, τ) of either problem, it holds that $C_M = \emptyset$, then the corresponding mapping $\tau : C_M \to \mathsf{GF}(2)^n$ is denoted by $\tau_\emptyset$. Moreover, notice that by setting $C_M = \emptyset$ and $\tau = \tau_\emptyset$, we have that (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY ((MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY) is a special case of Extended (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY (respectively, Extended (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY).

Our enumeration algorithms are based on the following pair of algorithms for Extended (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY and Extended (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY.

▶ **Lemma 9.** *For every $\mathcal{C} \in \{$simple graph, forest, connected graph, arboricity-d graph$\}$, there is an algorithm $\mathcal{C}$-$\mathcal{D}$ that runs in time $(mn)^{\mathcal{O}(r)}$ and correctly decides whether or not the given input (M, r, C_M, τ) is a yes-instance of Extended (min-rank, $\mathcal{C}$)-Graph Recovery.*

Algorithm 1 Algorithm $\mathcal{C}$-$\mathcal{E}$.

```
if C_M = [m] then
    Define the matrix S as S[{x}] = τ(x) for every x ∈ [m].
    if inc^{-1}(S) ∈ C and rank(M + S) ≤ r then
        Output S
    end
end
return
x ← min_{p∈[m]}{p ∉ C_M}
for each y ∈ cols(inc(K_n)) such that τ^{-1}(y) is undefined do
    if C-D((M, r, C_M ∪ {x}, τ ∪ {x ⟼ y})) returns Yes then
        C-E((M, r, C_M ∪ {x}, τ ∪ {x ⟼ y}))
    end
end
return
```

▶ **Lemma 10.** *For every $\mathcal{C} \in \{$simple graph, forest, connected graph$\}$, there is an algorithm $\mathcal{C}$-$\mathcal{D}'$ that runs in time $(mn)^{\mathcal{O}(1)}$ and correctly decides whether or not the given input (M, r, C_M, τ) is a yes-instance of Extended $(\mathsf{min\text{-}weight}, \mathcal{C})$-Graph Recovery.*

We first assume Lemma 9 and Lemma 10, and present our enumeration algorithms (Theorem 11 and Theorem 12).

▶ **Theorem 11.** *For every $\mathcal{C} \in \{$simple graph, forest, connected graph, arboricity-d graph$\}$, there is an algorithm $\mathcal{C}$-$\mathcal{E}$ that, on input (M, r, C_M, τ), outputs precisely those matrices S such that $M = S + L$ for some binary matrix L of $\mathsf{GF}(2)$-rank at most r, S is an incidence matrix of a simple graph in $\mathcal{C}$ such that for every $x \in C_M$, $S[\{x\}] = \tau(x)$. Moreover, the delay between successive outputs is $(mn)^{O(r)}$ and each such matrix S is output exactly once.*

Proof. The algorithm $\mathcal{C}$-$\mathcal{E}$ is described in Algorithm 1. The **for** loop is executed at most $\binom{n}{2}$ times in any single call to the algorithm and the recursive call to $\mathcal{C}$-$\mathcal{E}$ is made precisely when there is at least one solution to be output for a specific extension of C_M and τ. This is witnessed by the positive answer returned by the execution of the decision algorithm $\mathcal{C}$-$\mathcal{D}$. Finally, since the depth of the recursion is bounded by m, the first part of the lemma follows. The fact that this algorithm outputs precisely the required matrices (exactly once each) with delay bounded by $(mn)^{O(r)}$ follows from the correctness and running time bound of the algorithm $\mathcal{C}$-$\mathcal{D}$ in Lemma 9. ◀

The enumeration algorithm for (MIN-WEIGHT, $\mathcal{C}$)-GRAPH RECOVERY is analogous to that for (MIN-RANK, $\mathcal{C}$)-GRAPH RECOVERY (building on Lemma 10 instead of Lemma 9) and so we only state the theorem, omitting the proof.

▶ **Theorem 12.** *For every $\mathcal{C} \in \{$simple graph, forest, connected graph, arboricity-d graph$\}$, there is an algorithm $\mathcal{C}$-$\mathcal{E}'$ that, on input (M, r, C_M, τ), outputs precisely those matrices S such that $M = S + L$ for some binary matrix L such that $\|L\| \leq r$, S is an incidence matrix of a simple graph in $\mathcal{C}$ such that for every $x \in C_M$, $S[\{x\}] = \tau(x)$. Moreover, the delay between successive outputs is $(mn)^{O(1)}$ and each such matrix S is output exactly once.*

Notice that in order to enumerate all possible solutions for an instance (M, r) of (min-rank, $\mathcal{C}$)-Graph Recovery ((min-weight, $\mathcal{C}$)-Graph Recovery), it is sufficient to execute the enumeration algorithm $\mathcal{C}$-$\mathcal{E}$ (respectively, $\mathcal{C}$-$\mathcal{E}'$) on input $(M, r, \emptyset, \tau_\emptyset)$. We next prove Lemma 9.

3.2 Decision algorithms for Extended (min-rank, $\mathcal{C}$)-Graph Recovery

The goal of this subsection is to prove Lemma 9. We always assume that without loss of generality, the input M satisfies: $m, n \geq r$. Note that since we require that for every $x \in C_M$, $S[\{x\}] = \tau(x)$, the range of τ can be assumed to be $\text{cols}(\text{inc}(K_n))$.

Our algorithms for deciding the Extended (min-rank, $\mathcal{C}$)-Graph Recovery problem comprise the following two steps, the first of which only relies on S being an incidence matrix and L being a matrix of rank at most r. The second step depends on the class $\mathcal{C}$ under consideration and we will describe it in detail for each application separately.

1. We show that given M, one can enumerate in time $(mn)^{\mathcal{O}(r)}$, a set $\mathcal{Q}_M^r$ of sufficiently few sets, each of which contains at most r n-dimensional binary vectors such that for every L, S such that $M = L + S$, $\text{rank}(L) \leq r$ and S is an incidence matrix, there is a $Q \in \mathcal{Q}_M^r$ whose elements form a basis for col-span(L).
2. We then show that for each class $\mathcal{C}$ that we consider, if one is *given* a basis for the vector space spanned by the columns of the hypothetical solution matrix L of rank $\leq r$, then it is possible to determine the existence of the required matrix S in polynomial time (in the size of M) using an appropriate Weighted Matroid Intersection algorithm as a subroutine.

We begin by formalizing Step 1 of our algorithms.

▶ **Lemma 13.** *Given M and r, one can enumerate in time $(mn)^{O(r)}$, a set $\mathcal{Q}_M^r = \{Q_1, \ldots, Q_\ell\}$ satisfying the following properties: (a) $\ell = (mn)^{O(r)}$, (b) each Q_i is a set of r n-dimensional vectors over $\mathsf{GF}(2)$, (c) for every pair of matrices L, S such that $M = L + S$, S is an incidence matrix and $\text{rank}(L) \leq r$, there is an $i \in [\ell]$ such that Q_i is a basis for col-span(L).*

In the rest of this section, for given r and M, we denote by $\mathcal{Q}_M^r$ the set described in Lemma 13.

▶ **Definition 14.** *For an $n \times m$ binary matrix M and a set $Q \in \binom{\mathsf{GF}(2)^n}{\leq r}$, we denote by G_M^Q the bipartite graph $(X_M^Q = [m], Y_M^Q = \text{cols}(\text{inc}(K_n)), E_M^Q)$ where the edge set E_M^Q is defined as all those pairs (x, y) such that $x \in [m], y \in \text{cols}(\text{inc}(K_n))$ and satisfying $\exists q \in \text{span}(Q)$ such that $M[\{x\}] = y + q$.*

Note that in the graph G_M^Q, the set Y_M^Q contains all columns of the incidence matrix of *every* simple graph on n vertices.

▶ **Observation 15.** *Given M, r and Q, the graph G_M^Q can be computed in time $2^r \cdot (m+n)^{O(1)}$ and has $m + \binom{n}{2}$ vertices.*

The time bound in the above observation comes from the fact that for each $x \in X_M^Q$ and $y \in Y_M^Q$, deciding whether $(x, y) \in E_M^Q$ can be done by iterating over all the at most 2^r vectors in $\text{span}(Q)$.

▶ **Definition 16.** *Consider an $n \times m$ binary matrix M, $Q \in \binom{\mathsf{GF}(2)^n}{\leq r}$, $C_M \subseteq \text{cols}(M)$ and an injective mapping $\tau : C_M \to \mathsf{GF}(2)^n$. If $Z = \{(x, \tau(x)) \mid x \in C_M\}$ is a matching in the graph G_M^Q, then we denote by $\widetilde{G}_M^Q$ the graph obtained from G_M^Q by deleting all edges incident*

on the set $V(Z)$ except the edges in Z. Otherwise, we denote by $\widetilde{G}^Q_M$ the graph obtained from G^Q_M by deleting every edge. Then, $\mathrm{Tr}(G^Q_M, Y^Q_M, \langle C_M, \tau\rangle)$ denotes the transversal matroid $\mathrm{Tr}(\widetilde{G}^Q_M, Y^Q_M)$.

▶ **Definition 17.** *Let $\phi : Y^Q_M \to E(K_n)$ be the trivial bijection which maps $y \in Y^Q_M$ to the corresponding edge of K_n (recall that Y^Q_M is precisely the set of columns of the incidence matrix of K_n). We denote by $\mathcal{M}(K_n, Y^Q_M)$ the matroid over the element set Y^Q_M which is isomorphic to the graphic matroid $M(K_n)$ under the bijection ϕ. We assume that ϕ is extended in the natural way to subsets of vertices. That is, for every $Y \subseteq Y^Q_M$, $\phi(Y) = \bigcup_{y\in Y} \phi(y)$.*

▶ **Observation 18.** *Let ϕ and $\mathcal{M}(K_n, Y^Q_M)$ be as in Definition 17. For every $n \times m$ incidence matrix S, the graph $\mathrm{inc}^{-1}(S)$ is isomorphic to the subgraph of K_n with edge set $\phi(\mathrm{cols}(S))$.*

We are now ready to give our algorithms for each choice of $\mathcal{C}$.

3.2.1 Recovering simple graphs

▶ **Lemma 19.** *(M, r, C_M, τ) is a yes-instance of Extended-(min-rank, simple)-Graph Recovery if and only if there is a $Q \in \mathcal{Q}^r_M$ such that the graph G^Q_M has a matching saturating X^Q_M and containing the edges $\{(x, \tau(x)) \mid x \in C_M\}$.*

Proof. In the forward direction, suppose that $M = S + L$ where $\mathrm{inc}^{-1}(S)$ is a simple graph, $\mathrm{rank}(L) \leq r$ and for every $x \in C_M$, $S[\{x\}] = \tau(x)$. By Lemma 13, we know that some $Q \in \mathcal{Q}^r_M$ is a basis for col-span(L). Consequently, by Definition 14, for each $x \in [m]$, there is an edge in G^Q_M between x and $S[\{x\}]$. Since no 2 columns in S are identical ($\mathrm{inc}^{-1}(S)$ is a simple graph), this implies a matching saturating X^Q_M in G^Q_M and extending the set $\{(x, \tau(x)) \mid x \in C_M\}$ as required.

Conversely, suppose that there is a matching C saturating X^Q_M in G^Q_M and extending the set $\{(x, \tau(x)) \mid x \in C_M\}$. For each $x \in X^Q_M = [m]$, we denote by x_C the partner of x in C. By definition, for every $x \in C_M$, $x_C = \tau(x)$. We define S and L as follows. For each $x \in [m]$, set $S[\{x\}] = x_C$ and $L[\{x\}] = M[\{x\}] + x_C$. Since S contains only distinct columns and these are all contained in $\mathrm{cols}(\mathrm{inc}(K_n))$, it follows that S is the incidence matrix of a simple graph. On the other hand, Definition 14 implies that for every $x \in [m]$, since $(x, x_C) \in E^Q_M$, it must be the case that $L[\{x\}] = M[\{x\}] + x_C \in \mathrm{span}(Q)$. Consequently we have that col-span$(L) \subseteq \mathrm{span}(Q)$ and since $|Q| \leq r$, the lemma follows. ◀

Lemma 13 and Lemma 19 imply our algorithm for Extended-(min-rank, simple)-Graph Recovery.

▶ **Lemma 20.** *Extended-(min-rank, simple)-Graph Recovery can be solved in time $(mn)^{O(r)}$.*

Observe that based on Lemma 19, we may conclude that if the given instance is positive, then there is a solution $M = S + L$ where the columns of S form an independent set of size m in the transversal matroid $\mathrm{Tr}(G^Q_M, Y^Q_M)$ for some $Q \in \mathcal{Q}^r_M$. Moreover, there must be such an independent set saturated by a matching extending $\{(x, \tau(x)) \mid x \in C_M\}$. Consequently, we have the following observation which forms a critical part of all our algorithms.

▶ **Observation 21.** *(M, r, C_M, τ) is a yes-instance of Extended-(min-rank, simple)-Graph Recovery if and only if there is a $Q \in \mathcal{Q}^r_M$ such that there is an independent set of size m in the transversal matroid $\mathrm{Tr}(G^Q_M, Y^Q_M, \langle C_M, \tau\rangle)$.*

3.2.2 Recovering acyclic graphs

▶ **Lemma 22.** *(M, r, C_M, τ) is a yes-instance of* Extended (min-rank, acyclic)-Graph Recovery *if and only if there is a $Q \in \mathcal{Q}_M^r$ such that there is a common independent set of size m in the transversal matroid $\mathrm{Tr}(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ and the matroid $\mathcal{M}(K_n, Y_M^Q)$.*

Proof. In the forward direction, suppose that $M = S + L$ where $\mathrm{inc}^{-1}(S)$ is a forest, for every $x \in C_M$, $S[\{x\}] = \tau(x)$ and $\mathrm{rank}(L) \leq r$. By Lemma 13, we know that some $Q \in \mathcal{Q}_M^r$ is a basis for col-span(L). Moreover, we know that the columns of S form an independent set in $\mathrm{Tr}(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ (by Observation 21). Hence, it is sufficient to show that the set of columns of S form an independent set of the matroid $\mathcal{M}(K_n, Y_M^Q)$. But this follows from the fact that $\mathrm{inc}^{-1}(S)$ is a forest and $\mathcal{M}(K_n, Y_M^Q)$ is isomorphic to $M(K_n)$ under ϕ (see Definition 17 and Observation 18).

In the converse direction, suppose that for some $Q \in \mathcal{Q}_M^r$, there is a common independent set I of size m in the transversal matroid $\mathrm{Tr}(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ and the matroid $\mathcal{M}(K_n, Y_M^Q)$. We construct S and L as follows. Pick a matching C in $\widetilde{G}_M^Q$ (see Definition 16) saturating I and X_M^Q. Since $|I| = m$, such a matching exists. For each $x \in X_M^Q = [m]$, we denote by x_C the partner of x in C. Notice that by the definition of $\widetilde{G}_M^Q$, every vertex $x \in C_M$ has a unique neighbor, which must be $\tau(x)$.

We now define S and L as follows. For each $x \in [m]$, set $S[\{x\}] = x_C$ and $L[\{x\}] = M[\{x\}] + x_C$. Since S contains only distinct columns and these are all contained in $\mathrm{cols}(\mathrm{inc}(K_n))$, it follows that S is the incidence matrix of a simple graph. In addition, for every $x \in C_M$, $S[\{x\}] = \tau(x)$ by the definition of S. Moreover, from Observation 18 and the fact that the set $I = \{x_C | x \in [m]\}$ is an independent set in $\mathcal{M}(K_n, Y_M^Q)$, we have that $\mathrm{inc}^{-1}(S)$ is isomorphic to the subgraph of K_n induced by the edge set $\phi(I)$, which is a forest.

Finally, by the definition of G_M^Q, we have that for every $x \in [m]$, $M[\{x\}] + x_C \in \mathrm{span}(Q)$. Consequently we have that col-span$(L) \subseteq$ span(Q) and since $|Q| \leq r$, and the lemma follows. ◀

▶ **Lemma 23.** *Extended* (min-rank, acyclic)-Graph Recovery *can be solved in time $(mn)^{O(r)}$.*

3.2.3 Recovering Graphs of Fixed Arboricity

In the Arboricity-d Graph Recovery problem, the input is the pair (M, r) and the goal is to decide whether $M = S + L$, where $H = \mathrm{inc}^{-1}(S)$ has arboricity at most d and $\mathrm{rank}(L) \leq r$. Observe that Extended Arboricity-d Graph Recovery is a generalization of Extended Acyclic Graph Recovery (set $d = 1$).

▶ **Definition 24.** *For every $d \in \mathbb{N}$, we define the gammoid $\mathrm{Gam}^d(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ as follows. Consider the digraph D_1 obtained from $\widetilde{G}_M^Q$ by orienting all edges from X_M^Q to Y_M^Q. For each $y \in Y_M^Q$, construct a directed path $D_2^y = (y, 1), \ldots, (y, d)$. We define the digraph D_3 as the graph obtained by identifying each $y \in Y_M^Q$ in D_1 with $(y, 1)$ in D_2^y. The vertex set of D_3 is now $X_M^Q \cup (Y_M^Q \times [d])$. Then, $\mathrm{Gam}^d(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ is defined as the gammoid with respect to D_3 and X_M^Q on ground set $Y_M^Q \times [d]$.*

▶ **Definition 25.** *For each $i \in [d]$, define the matroid $\mathcal{J}^i(K_n, Y_M^Q)$ as the matroid over element set $Y_M^Q \times \{i\}$ which is isomorphic to $\mathcal{M}(K_n, Y_M^Q)$ under the bijection ψ_i where $\psi_i(y, i) = y$, for each $y \in Y_M^Q$. We denote by $\mathcal{M}^d(K_n, Y_M^Q)$ the direct-sum of the d matroids $\{\mathcal{J}^i(K_n, Y_M^Q) \mid i \in [d]\}$. We also extend each ψ_i to sets in the following way: for every $Z_1 \subseteq Y_M^Q$, and $Z_2 = Z_1 \times \{i\}$, $\psi_i(Z_2) = Z_1$.*

The following lemma generalizes Lemma 22.

▶ **Lemma 26.** *(M, r, C_M, τ) is a yes-instance of* Extended Arboricity-d Graph Recovery *if and only if there is a $Q \in \mathcal{Q}_M^r$ such that there is a common independent set of size m in the gammoid $\mathrm{Gam}^d(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ and the matroid $\mathcal{M}^d(K_n, Y_M^Q)$.*

▶ **Lemma 27.** *For every fixed constant d,* Extended (min-rank, d-arboricity)-Graph Recovery *can be solved in time $(mn)^{O(r)}$ on input (M, r, C_M, τ).*

Proof. (Sketch) The crux of this lemma is a proof that (M, r, C_M, τ) is a yes-instance of Extended (min-rank, d-arboricity)-Graph Recovery if and only if there is a $Q \in \mathcal{Q}_M^r$ such that there is a common independent set of size m in an appropriate defined gammoid and the matroid $\mathcal{M}^d(K_n, Y_M^Q)$. ◀

3.2.4 Recovering connected graphs

Here, we prove an analogous version of Lemma 23 for Extended (min-rank, connected)-Graph Recovery.

▶ **Lemma 28.** *Extended (min-rank, connected)-Graph Recovery can be solved in time $(mn)^{O(r)}$.*

Proof. (Sketch) The crux of this lemma is a proof that (M, r, C_M, τ) is a yes-instance of Extended (min-rank, connected)-Graph Recovery if and only if there is a $Q \in \mathcal{Q}_M^r$ such that there is a common independent set of size m in the transversal matroid $\mathrm{Tr}(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$ and the m-elongation of the matroid $\mathcal{M}(K_n, Y_M^Q)$ (assuming that $m \geq n-1$, otherwise we have a no-instance). The details of this argument follow along the same lines as the proof of Lemma 22. The crucial part of this lemma is the choice of the m-elongation of $\mathcal{M}(K_n, Y_M^Q)$ as the matroid that we intersect with $\mathrm{Tr}(G_M^Q, Y_M^Q, \langle C_M, \tau\rangle)$. ◀

Lemma 9 is now a straightforward consequence of Lemma 20, Lemma 23, Lemma 28, and Lemma 27.

3.3 Decision algorithms for Extended (min-weight, $\mathcal{C}$)-Graph Recovery

The goal of this subsection is to prove Lemma 10. The proof is involved and has several stages. In the following, we provide a high level overview of our proof strategy.

Recall that an instance of (min-weight, $\mathcal{C}$)-Graph Recovery is of the form (M, k, C_M, τ) where $C_M \subseteq \mathrm{cols}(M)$ and τ fixes the mapping of the columns in C_M in the solution. When we just want G to be a simple graph (i.e., $\mathcal{C}$ is the class of all simple graphs), a solution $M = L + S$ minimizing the cost, $\|L\|$, can be computed in polynomial time using an algorithm for Minimum Weight Bipartite Matching, in an auxiliary bipartite graph which represents the costs of mapping each column of M to a specific edge. The design of this bipartite graph is similar in spirit to that of the graph in Definition 14. We refer to a solution $M = L + S$ minimizing the cost $\|L\|$, as a *minimum cost solution*.

To obtain connected graphs and forests, we build upon this algorithm. We first describe an algorithm that computes a minimum cost solution $M = L_0 + S_0$ along with the graph G_0 and try to reassign columns of M associated with non-bridge edges in G_0 to reduce the number of connected components without increasing the cost of the solution at hand. That is, we move from one solution to another without increasing the cost but while decreasing the number of connected components in the graph corresponding to the incidence matrix in the solution. Note that, we may need to perform a number of reassignments in a sequence

before the number of connected components is reduced. To determine this sequence of reassignments, we associate them with paths in an auxiliary digraph, where the nodes are the edges and non-edges of the current graph, and directed edges indicate feasible reassignments, or reassignments that convert a bridge in the current graph to a non-bridge. We show that the current solution minimizes the number of connected components if and only if the auxiliary digraph has no paths starting from a non-bridge edge and ending at a non-edge. This requires an intricate analysis of the structure of a solution and how reassignments affect them. This leads to an iterative algorithm that "remaps" the edges in the graph associated with the current solution using paths in the auxiliary digraph. When this algorithm terminates, we obtain a minimum cost solution that minimizes the number of connected components in the corresponding graph. We then use this algorithm as the starting point for the algorithms to recover connected graphs and forests. To recover a connected graph, we observe that any further reassignments to reduce the number of connected components must increase the cost of the solution. Therefore, we design an iterative algorithm that reassigns non-bridge edges until every edge is a bridge, or the graph becomes connected. This algorithm can be used to recover a connected graph, or a forest satisfying the required properties.

3.4 NP-completeness of (min-rank, $\mathcal{C}$)-Graph Recovery

▶ **Theorem 29.** (min-rank, $\mathcal{C}$)-*Graph Recovery is NP-complete for* $\mathcal{C} \in \{$*simple graphs, acyclic graphs, connected graphs, arboricity-d graphs*$\}$.

4 Concluding remarks and future work

In this paper, we have initiated the study of a family of graph recovery problems. In these problems, the aim is to recover the incidence matrix of a graph (contained in a specific graph class) from a given binary matrix. The input matrix is assumed to be a perturbation of an incidence matrix by either a small rank or low weight matrix. We have demonstrated the rich combinatorial structure possessed by these problems by designing decision and enumeration algorithms using classic concepts such as matchings and matroids. We leave open the following concrete questions.

1. Is (min-rank, $\mathcal{C}$)-Graph Recovery fixed-parameter tractable parameterized by r for the classes we consider? That is, can it be solved in time $f(r)(mn)^{\mathcal{O}(1)}$ for some computable function f?
2. Identify classes $\mathcal{C}$ for which (min-rank, $\mathcal{C}$)-Graph Recovery is polynomial-time solvable.
3. Characterize those $\mathcal{C}$ for which (min-weight, $\mathcal{C}$)-Graph Recovery is polynomial-time solvable.

Abstract

In general, a *graph modification problem* is defined by a graph modification operation $\boxtimes$ and a target graph property $\mathcal{P}$. Typically, the modification operation $\boxtimes$ may be vertex removal, edge removal, edge contraction, or edge addition and the question is, given a graph G and an integer k, whether it is possible to transform G to a graph in $\mathcal{P}$ after applying k times the operation $\boxtimes$ on G. This problem has been extensively studied for particilar instantiations of $\boxtimes$ and $\mathcal{P}$. In this paper we consider the general property $\mathcal{P}_\phi$ of being planar and, moreover, being a model of some First-Order Logic sentence ϕ (an FOL-sentence). We call the corresponding meta-problem Graph $\boxtimes$-Modification to Planarity and ϕ and prove the following algorithmic meta-theorem: there exists a function $f : \mathbb{N}^2 \to \mathbb{N}$ such that, for every $\boxtimes$ and every FOL sentence ϕ, the Graph $\boxtimes$-Modification to Planarity and ϕ is solvable in $f(k, |\phi|) \cdot n^2$ time. The proof constitutes a hybrid of two different classic techniques in graph algorithms. The first is the *irrelevant vertex technique* that is typically used in the context of Graph Minors and deals with properties such as planarity or surface-embeddability (that are *not* FOL-expressible) and the second is the use of *Gaifman's Locality Theorem* that is the theoretical base for the meta-algorithmic study of FOL-expressible problems.

1 Introduction

The term *algorithmic meta-theorems* was coined by Grohe in his seminal exposition in [20] in order to describe results providing general conditions, typically of logical and/or combinatorial nature, that automatically guarantee the existence of certain types of algorithms for wide families of problems. Algorithmic meta-theorems reveal deep relations between logic and combinatorial structures, which is a fundamental issue of computational complexity. Such theorems not only yield a better understanding of the scope of general algorithmic techniques and the limits of tractability but often provide (or induce) a variety of new algorithmic results. The archetype of algorithmic meta-theorems is Courcelle's theorem [5,6] stating that all graph properties expressible in Monadic Second-Order Logic (in short, *MSOL-expressible properties*) are fixed-parameter tractable when parameterized by the size of the sentence and the treewidth of the graph.

Our meta-theorem belongs to the intersection of two algorithmic research directions: Deciding First-Order Logic properties of sparse graphs and graph planarization algorithms.

FOL-expressible properties on sparse graphs. For graph properties expressible in first-order logic (in short *FOL-expressible properties*), a rich family of algorithmic meta-theorems, were developed within the last decades. Each of these meta-theorems can be stated in the following form: for a graph class $\mathcal{C}$, deciding FOL-expressible properties is fixed-parameter tractable on $\mathcal{C}$, i.e. there is an algorithm running in $f(|\phi|) \cdot n^{\mathcal{O}(1)}$ time where $|\phi|$ is the size of the the input FOL-sentence ϕ and n is the number of vertices of the input graph. The starting point in the chain of such meta-theorems is the work of Seese [33] for $\mathcal{C}$ being the class of graphs of bounded degree [33]. The first significant extension of Seese's theorem was obtained by Frick and Grohe [16] for the class $\mathcal{C}$ of graphs of bounded local treewidth [16]. The class of graphs of bounded local treewidth contains graphs of bounded degree, planar graphs, graphs of bounded genus, and apex-minor-free graphs. The next step was done by Flum and Grohe [12], who extended these results up to graph classes excluding some minor. Dawar, Grohe, and Kreutzer [9] pushed the tractability border up to graphs locally excluding a minor. Further extension was due to Dvořák, Král, and Thomas, who proved tractability for the class $\mathcal{C}$ of being locally bounded expansion [11]. Finally, Grohe, Kreutzer, and Siebertz [22] established fixed-parameter tractability for classes that are effectively nowhere dense. In some sense, the result of Grohe et al. is the culmination of this long line of meta-theorems, because for somewhere dense graph classes closed under taking subgraphs deciding first-order properties is unlikely to be fixed-parameter tractable [11, 26].

Notice that the above line of results also sheds some light on graph modification problems. In particular, since many modification operations are FOL-expressible, in some situations when the target property $\mathcal{P}$ is FOL-expressible, the above meta-algorithmic results can be extended to graph modification problems. As a concrete example, consider the problem of removing at most k vertices to obtain a graph of degree at most 3. All vertices of the input graph of degree at least $4 + k$ should be deleted, so we delete them and adapt the parameter k accordingly. In the remaining graph all vertices are of degree at most $3 + k$ and the property of removing at most k vertices from such a graph to obtain a graph of degree at most 3 is FOL-expressible. Hence the Seese's theorem implies that there is an algorithm of running time $f(k) \cdot n^{\mathcal{O}(1)}$ solving this problem. However these theories are not applicable with instantiations of $\mathcal{P}$, like planarity, that are not FOL-expressible.

Another island of tractability for graph modification problems is provided by Courcelle's theorem and similar theorems on graphs of bounded widths. For example, graph modification problems are fixed-parameter tractable in cases where the target property $\mathcal{P}$ is MSOL-expressible under the additional assumption that the graphs in $\mathcal{P}$ have fixed treewidth (or bounded rankwidth, for MSOL_1-properties, see e.g., [7]).

To conclude, according to the current state of the art, all known algorithmic meta-theorems concerning fixed-parameter tractability of graph modification problems are attainable either when the target property $\mathcal{P}$ is FOL-expressible and the structure is sparse or when $\mathcal{P}$ is $\mathrm{MSOL}/\mathrm{MSO}_1$-expressible and the structure has bounded tree/rank-width. Interestingly, *planarity* is the typical property that escapes the above pattern: it is *not* FOL-expressible and it has *unbounded* treewidth.

Graph planarization. The Planar Vertex Deletion problem is a generalization of planarity testing. For a given graph G the goal is to find a vertex set of size at most k whose removal makes the resulting graph planar. Planarity is a nontrivial and hereditary graph property, hence by the result of Lewis and Yannakakis [27], the decision version of Planar Vertex Deletion is NP-complete. The parameterized complexity of this problem has been extensively studied.

The non-uniform fixed-parameter tractability of Planar Vertex Deletion (parameterized by k) follows from the deep result of Robertson and Seymour in Graph Minors theory [32], that every minor-closed graph class can be recognized in polynomial time. Since the class of graphs that can be made planar by removing at most k vertices is minor-closed, the result of Robertson and Seymour implies that for Planar Vertex Deletion, for each k, there exists a (non-uniform) algorithm that in time $\mathcal{O}(n^3)$ solves Planar Vertex Deletion. Significant amount of work was involved to improve the enormous constants hidden in the big-Oh and the polynomial dependence in n. Marx and Schlotter [29] gave an algorithm that solves the problem in time $f(k) \cdot n^2$, where f is some function of k only. Kawarabayashi [24] obtained the first linear time algorithm of running time $f(k) \cdot n$ and Jansen, Lokshtanov, and Saurabh [23] obtained an algorithm of running time $\mathcal{O}(2^{\mathcal{O}(k \log k)} \cdot n)$. For the related problem of contracting at most k edges to obtain a planar graph, Planar Edge Contraction, an $f(k) \cdot n^{\mathcal{O}(1)}$ time algorithm was obtained by Golovach, van 't Hof and Paulusma [19]. Approximation algorithms for Planar Vertex Deletion and for Planar Edge Deletion were studied in [2–4].

Our results. Let $\boxtimes$ be one of the following operations on graphs: Vertex removal, edge removal, edge contraction, or edge addition. We are interested whether, for a given graph G and an FOL-sentence ϕ, it is possible to transform G by applying at most k $\boxtimes$-operations, into a planar graph with the property defined by ϕ. We refer to this problem as the Graph $\boxtimes$-Modification to Planarity and ϕ problem. For example, when $\boxtimes$ is the vertex removal operation and ϕ is a tautology, then the problem is Planar Vertex Deletion. Similarly, Graph $\boxtimes$-Modification to Planarity and ϕ generalizes Planar Edge Deletion and Planar Edge Contraction. On the other hand, for the special case of $k = 0$ this is the problem of deciding FOL-expressible properties on planar graphs.

Examples of first-order expressible properties are deciding whether the input graph G contains a fixed graph H as a subgraph (H-Subgraph Isomorphism), deciding whether there is a homomorphism from a fixed graph H to G to (H-Homomorphism), satisfying degree constraints (the degree of every vertex of the graph should be between a and b for some constants a and b), excluding a subgraph of constant size or having a dominating

set of constant size. Thus Graph $\boxtimes$-Modification to Planarity and ϕ encompasses the variety of graph modification problems to planar graphs with specific properties. For example, can we delete k vertices (or edges) such that the obtained graph is planar and each vertex belongs to a triangle? Reversely, can we delete at most k vertices (or edges) from a graph such that the resulting graph is a triangle-free planar graph? Can we add (or contract) at most k edges to such that the resulting graph is 4-regular and planar? Or can we delete at most k edges resulting in a square-free or claw-free planar graph?

Informally, our main result can be stated as follows.

▶ **Theorem** (Informal). *Graph $\boxtimes$-Modification to Planarity and ϕ is solvable in time $f(k,\phi)\cdot n^2$, for some function f depending on k and ϕ only. Thus the problem is fixed-parameter tractable, when parameterized by $k+|\phi|$.*

Our theorem not only implies that Planar Vertex Deletion is fixed-parameter tractable parameterized by k (proved in [23, 29]) and that deciding whether a planar graph has a first-order logic property ϕ is fixed-parameter tractable parameterized by $|\phi|$ (that follows from [9, 11, 16, 22]). It also implies a variety of new algorithmic results about graph modification problems to planar graphs with some specific properties that cannot be obtained by applying the known results directly. Of course, for some formulas ϕ, Graph $\boxtimes$-Modification to Planarity and ϕ can be solved by more simple techniques. For example, if ϕ defines a hereditary property characterized by a finite family of forbidden induced subgraphs $\mathcal{F}$, then deciding, whether it is possible to delete at most k vertices to obtain a planar $\mathcal{F}$-free graph, can be done by combining the straightforward branching algorithm and, say, the algorithm of Jansen, Lokshtanov, and Saurabh [23] for Planar Vertex Deletion. For this, we iteratively find a copy of each $F\in\mathcal{F}$ and if such a copy exists we branch on all the possibilities to destroy this copy of F by deleting a vertex. By this procedure, we obtain a search tree of depth at most k, whose leaves are all $\mathcal{F}$-free induced subgraphs of the input graph that could be obtained by at most k vertex deletions. Then for each leaf, we use the planarization algorithm limited by the remaining budget. However, this does not work for edge modifications, because deleting an edge in order to ensure planarity may result in creating a copy of a forbidden subgraph. For such type of problems, even for very "simple" ones, like deleting k edges to obtain a claw-free planar graph, or planar graph without induced cycles of length 4, our theorem establishes the first fixed-parameter algorithms. Also our theorem is applicable to the situation when ϕ defines a hereditary property that requires an infinite family of forbidden subgraphs for its characterization and for non-hereditary properties expressible in FOL.

In our paper, we show the result for Graph $\boxtimes$-Modification to Planarity and ϕ, but further we argue that it can be extended for modification problems to graphs embeddable to a surface of a given Euler genus.

The price we pay for such generality is the running time. While the polynomial factor in the running time of our algorithm is comparable with the running time of the algorithm of Marx and Schlotter [29] for Planar Vertex Deletion, it is worse than the more advanced algorithms of Kawarabayashi [24] and Jansen et al. [23]. Similarly, the algorithms for deciding first-order logic properties on graph classes [11, 16, 22] are faster than our algorithm.

The proof of the main theorem is based on a non-trivial combination of the *irrelevant vertex* technique of Robertson and Seymour [30,31] with the *Gaifman's Locality Theorem* [17]. While both techniques were widely used, see [1, 8, 19, 21, 23, 28] and [9, 12, 16], the combination of the two techniques requires novel ideas. Following the popular trend in Theoretical Computer Science, an alternative title for our paper could be *"Robertson and Seymour meet Gaifman"*.

Organization of the paper. In Section 2 we give the formal definition of the general Graph $\boxtimes$-Modification to Planarity and ϕ problem, present the theoretical background around Gaifman's Locality Theorem, and give some preliminary definitions and results. In Section 3 we highlight the main ideas behind the proof explain how our arguments can be extended in cases where the target property is having bounded Euler genus and being a model of an FOL-sentence ϕ. Finally, in Section 4 we provide some directions for further research.

2 Problem definition and preliminaries

Before we explain our techniques, we give some necessary definitions. We denote by $\mathbb{N}$ the set of all non-negative integers. Given an $n \in \mathbb{N}$, we denote by $\mathbb{N}_{\geq n}$ the set containing all integers equal or greater than n. Given two integers x and y we define by $[x, y] = \{x, x+1, \ldots, y-1, y\}$. Given an $n \in \mathbb{N}_{\geq 1}$, we also define $[n] = [1, n]$.

All graphs in this paper are undirected, finite, and they do not have loops or multiple edges. Given a graph G, we denote by $V(G)$ and $E(G)$ the set of its vertices and edges, respectively. If $S \subseteq V(G)$, then we denote by $G \setminus S$ the graph obtained by G after removing from it all vertices in S, together with their incident edges. Also, we denote by $G \setminus v$ the graph $G \setminus \{v\}$, for some $v \in V(G)$. We also denote by $G[S]$ the graph $G \setminus (V(G) \setminus S)$.

2.1 Modifications on graphs

We define $\mathsf{OP} := \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$, that is the set of graph operations of removing a vertex, removing an edge, contracting an edge, and adding an edge, respectively. Given an operation $\boxtimes \in \mathsf{OP}$, a graph G, and a vertex set $R \subseteq V(G)$, we define the *application domain* of the operation $\boxtimes$ as

$$\boxtimes\langle G, R\rangle = \begin{cases} R, & \text{if } \boxtimes = \mathsf{vr}, \\ E(G) \cap \binom{R}{2}, & \text{if } \boxtimes = \mathsf{er}, \mathsf{ec}, \text{and} \\ \binom{R}{2} \setminus E(G), & \text{if } \boxtimes = \mathsf{ea}. \end{cases}$$

Notice that $\boxtimes\langle G, R\rangle$ is either a vertex set or a set of subsets of vertices each of size two.

Given a set $S \subseteq \boxtimes\langle G, R\rangle$, we define $G \boxtimes S$ as the graph obtained after applying the operation $\boxtimes$ on the elements of S. The vertices of G that are *affected* by the modification of G to $G \boxtimes S$, denoted by $A(S)$, are the vertices in S, in case $\boxtimes = \mathsf{vr}$ or the endpoints of the edges of S, in case $\boxtimes \in \{\mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$.

Given an FOL-sentence ϕ and some $\boxtimes \in \mathsf{OP}$, we define the following meta-problem:

Graph $\boxtimes$-Modification to Planarity and ϕ (In short: G$\boxtimes$MPϕ)
Input: A graph G and a non-negative integer k.
Question: Is there a set $S \subseteq \boxtimes\langle G, V(G)\rangle$ of size k such that $G \boxtimes S$ is a planar graph and $G \boxtimes S \models \phi$?

Let $(x_1, \ldots, x_\ell) \in \mathbb{N}^\ell$ and $f, g : \mathbb{N} \to \mathbb{N}$. We use notation $f(n) = \mathcal{O}_{x_1,\ldots,x_\ell}(g(n))$ to denote that there exists a computable function $h : \mathbb{N}^\ell \to \mathbb{N}$ such that $f(n) = h(x_1, \ldots, x_\ell) \cdot g(n)$. We are ready to give the formal statement of the main theorem of this paper.

▶ **Theorem 1.** *There exists a function $f : \mathbb{N}^2 \to \mathbb{N}$ such that, for every FOL-sentence ϕ and for every $\boxtimes \in \mathsf{OP}$, G$\boxtimes$MP$\phi$ is solvable in $\mathcal{O}_{k,|\phi|}(n^2)$ time.*

2.2 Gaifman's theorem

For vertices u, v of graph G, we use $d_G(u, v)$ to denote the distance between u and v in G. We also use $N_G^{(\leq r)}(v)$ to denote the set of vertices of G at distance at most r from v.

Formulas. In this paper we deal with logic formulas on graphs. In particular we deal with formulas of first-order logic (FOL) and monadic second-order logic (MSO_2). The syntax of FOL-formulas includes the logical connectives $\vee, \wedge, \neg$, a set of variables for vertices, the quantifiers $\forall, \exists$ that are applied to these variables, the predicate $u \sim v$, where u and v are vertex variables and whose interpretation is that u and v are adjacent, and the equality of variables representing vertices. An MSO_2-formula, in addition to the variables for vertices of FOL-formulas, may also contain variables for subsets of vertices or subsets of edges. The syntax of MSO_2-formulas is obtained after enhancing the syntax of FOL-formulas so to further allow quantification on subsets of vertices or subsets of edges and introduce the predicates $v \in S$ (resp. $e \in F$) whose interpretation is that the vertex v belongs in the vertex set S (resp. the edge e belongs in the edge set F).

An FOL-formula ϕ is in *prenex normal form* if it is written as $\phi = Q_1 x_1 \dots Q_n x_n \psi$ such that for every $i \in [n]$, $Q_i \in \{\forall, \exists\}$ and ψ is a quantifier-free formula on the variables $x_1, \dots, x_n$. Then $Q_1 x_1 \dots Q_n x_n$ is referred as the *prefix* of ϕ. For the rest of the paper, when we mention the term "FOL-formula", we mean an FOL-formula on graphs that is in prenex normal form. Given an FOL-formula ϕ, we say that a variable x is a *free variable* in ϕ if it does not occur in the prefix of ϕ. We write $\phi(x_1, \dots, x_r)$ to denote that ϕ is a formula with free variables $x_1, \dots, x_r$. We call a formula without free variables a *sentence*. For a sentence ϕ and a graph G, we write $G \models \phi$ to denote that ϕ evaluates to *true* on G. Also, for a sentence ϕ we denote its length by $|\phi|$.

Gaifman sentences. Given an FOL-formula $\psi(x)$ with one free variable x, we say that $\psi(x)$ is *r-local* if the validity of $\psi(x)$ depends only on the r-neighborhood of x, that is for every graph G and $v \in V(G)$ we have

$$G \models \psi(v) \iff N_G^{(\leq r)}(v) \models \psi(v).$$

Observe that there exists an FOL-formula $\delta_r(x, y)$ such that for every graph G and $v, u \in V(G)$, we have $d_G(u, v) \leq r \iff G \models \delta_r(v, u)$ (see [13, Lemma 12.26]).

We say that an FOL-sentence ϕ is a *Gaifman sentence* when it is a Boolean combination of sentences $\phi_1, \dots, \phi_m$ such that, for every $h \in [m]$,

$$\phi_h = \exists x_1 \dots \exists x_{\ell_h} \Big(\bigwedge_{1 \leq i < j \leq \ell_h} d(x_i, x_j) > 2r_h \wedge \bigwedge_{i \in [\ell_h]} \psi_h(x_i) \Big), \tag{1}$$

where $\ell_h, r_h \geq 1$ and ψ_h is an r_h-local formula with one free variable. We refer to the variables $x_1, \dots, x_{\ell_h}$ for each $h \in [m]$ as the *basic variables* of ϕ. Moreover, for every $h \in [m]$ we call ϕ_h a *basic local sentence* of ϕ and the formula ψ_h a *local formula* of ϕ.

▶ **Proposition 2** (Gaifman's Theorem [17]). *Every FOL-sentence ϕ is equivalent to a Gaifman sentence ϕ'. Furthermore, ϕ' can be computed effectively.*

2.3 Equivalent formulations

Given a Gaifman sentence ϕ combined from sentences $\phi_1, \ldots, \phi_m$ and a unary relation symbol R, we define $\phi\|_R$ as the sentence that is the same Boolean combination of sentences $\phi_1\|_R, \ldots, \phi_m\|_R$ such that, for every $h \in [m]$,

$$\phi_h\|_R = \exists x_1 \ldots \exists x_{\ell_h} \Big(\bigwedge_{i\in[\ell_h]} x_i \in R \wedge \bigwedge_{1\leq i<j\leq \ell_h} d(x_i,x_j) > 2r_h \wedge \bigwedge_{i\in[\ell_h]} \psi_h(x_i)\Big), \tag{2}$$

where $\ell_h, r_h \geq 1$ and ψ_h is an r_h-local formula with one free variable.

Let (G,k) be an instance of the G$\boxtimes$MPϕ problem. We may assume, because of Proposition 2, that ϕ is a Gaifman sentence. We consider an enhanced version of the G$\boxtimes$MPϕ problem as follows. Let (G,R,k) be a triple, where G is a graph, $R \subseteq V(G)$, and $k \in \mathbb{N}$. We say that (G,R,k) is a $(\phi,\boxtimes)$-*triple* if there exists a set $S \subseteq \boxtimes\langle G,R\rangle$ such that $|S| \leq k$, $G \boxtimes S$ is a planar graph, and $G \boxtimes S \models \phi\|_R$. Also, we say that a set $S \subseteq \boxtimes\langle G, V(G)\rangle$ is a $\boxtimes$-*planarizer* of G if $G \boxtimes S$ is planar. It is easy to observe that the property that (G,R,k) is a $(\phi,\boxtimes)$-triple can be expressed in MSO_2. This is easy in case $\boxtimes \in \{\mathsf{vr},\mathsf{er},\mathsf{ec}\}$. In the case where $\boxtimes = \mathsf{ea}$, we observe the following:

▶ **Observation 3.** *Let $\boxtimes = \mathsf{ea}$, G be a graph, and $S \subseteq \langle G, V(G)\rangle$ where $S = \{\{v_1,u_1\},\ldots,\{v_r,u_r\}\}$. Then there exists an MSO_2-formula $\phi_{\mathcal{P},\mathcal{S}}$ on structures of the type $(G,v_1,u_1,\ldots,v_r,u_r)$ such that*

$$G \boxtimes S \text{ is a planar graph} \iff (G,v_1,u_1,\ldots,v_r,u_r) \models \phi_{\mathcal{P},S}.$$

Treewidth. A *tree decomposition* of a graph G is a pair (T,χ) where T is a tree and $\chi : V(T) \to 2^{V(G)}$ such that

1. $\bigcup_{t\in V(T)} \chi(t) = V(G)$;
2. for every edge e of G there is a $t \in V(T)$ such that $\chi(t)$ contains both endpoints of e and
3. for every $v \in V(G)$, the subgraph of T induced by $\{t \in V(T) \mid v \in \chi(t)\}$ is connected.

The *width* of (T,χ) is defined as $\mathbf{w}(T,\chi) := \max\big\{\, |\chi(t)| - 1 \;\big|\; t \in V(T)\big\}$. The *treewidth of* G is defined as

$$\mathbf{tw}(G) := \min\big\{\, \mathbf{w}(T,\chi) \;\big|\; (T,\chi) \text{ is a tree decomposition of } G\big\}.$$

Theorem 1 is a consequence of the following lemma.

▶ **Lemma 4.** *Given a Gaifman sentence ϕ and a $\boxtimes \in \mathsf{OP}$, there exists a function $f_1 : \mathbb{N}^2 \to \mathbb{N}$, and an algorithm with the following specifications:*

Reduce_Instance(k,G,S,R)

Input: an integer $k \in \mathbb{N}$, a graph G, a set $R \subseteq V(G)$, and a set $S \subseteq R$ that is a vr*-planarizer of G of size at most k.*

Output: One of the following:

1. - *if $\boxtimes \in \{\mathsf{er},\mathsf{ec},\mathsf{ea}\}$: a report that (G,k) is a* no*-instance of* G$\boxtimes$MPϕ.
   - *if $\boxtimes = \mathsf{vr}$: a vertex $u \in S$ such that $S \setminus \{u\}$ is a* vr*-planarizer of $G \setminus u$ of size at most $k-1$ and (G,k) and $(G \setminus u, k-1)$ are equivalent instances of* G$\boxtimes$MPϕ.
2. *a vertex set $X \subseteq V(G)$ and a vertex $v \in X$ such that $S \subseteq R \setminus X$ and (G,R,k) is a $(\phi,\boxtimes)$-triple iff $(G \setminus v, R \setminus X, k)$ is a $(\phi,\boxtimes)$-triple.*
3. *a tree decomposition of G of width at most $f_1(k,|\phi|)$.*

Moreover, this algorithm runs in $\mathcal{O}_{k,|\phi|}(n)$ steps.

Given Lemma 4, Theorem 1 can be proved as follows.

Proof of Theorem 1. Let ϕ be an FOL-formula. By Proposition 2, ϕ is equivalent to a Gaifman sentence ϕ'. Using the planarization algorithm from [23], we compute, in $\mathcal{O}_k(n)$ steps, a vr-planarizer S of G of size at most k. If $\boxtimes = \mathsf{ea}$, then $S := \emptyset$, while if $\boxtimes \in \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$, then if such a set does not exist the we safely return a negative answer (for the case of $\boxtimes = \mathsf{er}, \mathsf{ec}$, this is due to the fact that if there exists a ec- or an er-planarizer of G of size at most k then also a vr-planarizer of G of size at most k exists (see [19, Lemma 1])). We are now in position to apply recursively the algorithm **Reduce_Instance**(k, G, S, R) of Lemma 4 until either an answer or the third case appears. In the first case, we either return a negative answer, if $\boxtimes \in \{\mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$, or set $(k, G, S, R) := (k-1, G \setminus v, S \setminus v, R)$ if $\boxtimes = \mathsf{vr}$, while in the second case we set $(k, G, S, R) := (k, G \setminus v, S, R \setminus X)$. In the third case we have that $\mathbf{tw}(G) \leq f_1(k, |\phi'|)$. Recall that the property that (G, R, k) is a $(\phi, \boxtimes)$-triple can be expressed in MSO_2, thus the status of the final equivalent instance (G, R, k) can be evaluated in $\mathcal{O}_{k,|\phi|}(n)$ steps by applying Courcelle's theorem. As the recursion takes at most n steps, we obtain the claimed running time. ◀

3 The algorithm

3.1 Two main lemmata

We now give two lemmata, whose combination gives the proof of Lemma 4. Before we state them, we give a series of definitions.

Let $\boxtimes \in \mathsf{OP}$, G be a graph, $k \in \mathbb{N}$, and let S be a $\boxtimes$-planarizer of G. We say that S is an *inclusion-minimal* $\boxtimes$*-planarizer* of G if none of its proper subsets is a $\boxtimes$-planarizer of G. Notice that, in the special case where $\boxtimes = \mathsf{ea}$, the unique inclusion-minimal $\boxtimes$-planarizer of G is the empty set of edges. We say that a set $Q \subseteq V(G)$ is $\boxtimes$*-planarization irrelevant* if for every inclusion-minimal $\boxtimes$-planarizer S of G that has size at most k, it holds that $A(S) \cap Q = \emptyset$.

Partially disk-embedded graphs. We define a *closed disk* Δ to be a subset of the plane homeomorphic to the set $\{(x, y) \mid x^2 + y^2 \leq 1\}$ and we use $\mathbf{bor}(\Delta)$ to denote its boundary. We say that a graph G is *partially disk-embedded in some closed disk* Δ, if there is some subgraph K of G that is embedded in Δ such that $\mathbf{bor}(\Delta)$ is a cycle of K and no vertex in $\Delta \setminus \mathbf{bor}(\Delta)$ is adjacent to a vertex not in Δ. We use the term *partially* Δ*-embedded graph* G to denote that a graph G is partially disk-embedded in some closed disk Δ. We also call the graph K *compass* of the partially Δ-embedded graph G and we always assume that we accompany a partially Δ-embedded graph G together with an embedding of its compass in Δ that is the set $G \cap \Delta$.

Grids and walls. Let $k, r \in \mathbb{N}$. The $(k \times r)$*-grid* is the Cartesian product of two paths on k and r vertices respectively. An *elementary* r*-wall*, for some odd $r \geq 3$, is the graph obtained from a $(2r \times r)$-grid with vertices (x, y), $x \in [2r] \times [r]$, after the removal of the "vertical" edges $\{(x, y), (x, y+1)\}$ for odd $x + y$, and then the removal of all vertices of degree one. Notice that, as $r \geq 3$, an elementary r-wall is a planar graph that has a unique (up to topological isomorphism) embedding in the plane such that all its finite faces are incident to exactly six edges. The *perimeter* of an elementary r-wall is the cycle bounding its infinite face, while the cycles bounding its finite faces are called *bricks*. Given an elementary wall $\overline{W}$, a *vertical path* of $\overline{W}$ is one whose vertices, in ordering of appearance, are $(i, 1), (i, 2), (i+1, 2), (i+1, 3), (i, 3), (i, 4), (i+1, 4), (i+1, 5), (i, 5), \ldots, (i, r-2), (i, r-1), (i+1, r-1), (i+1, r)$, for

some $i \in \{1, 3, \ldots, 2r-1\}$. Also an *horizontal path* of $\overline{W}$ is the one whose vertices, in ordering of appearance, are $(1, j), (2, j), \ldots, (2r, j)$, for some $j \in [2, r-1]$, or $(1, 1), (2, 1), \ldots, (2r-1, 1)$ or $(2, r), (2, r), \ldots, (2r, r)$.

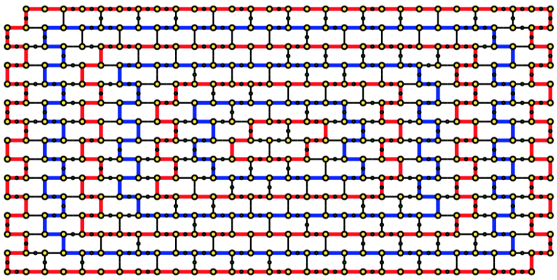

Figure 1 An 15-wall and its 7 layers.

An *r-wall* is any graph W obtained from an elementary r-wall $\overline{W}$ after subdividing edges (see Figure 1). We call the vertices that where added after the subdivision operations *subdivision vertices*, while we call the rest of the vertices (i.e., those of $\overline{W}$) *branch vertices*. The *perimeter* of W, denoted by $\mathsf{perim}(W)$, is the cycle of W whose non-subdivision vertices are the vertices of the perimeter of $\overline{W}$. Also, a vertical (resp. horizontal) path of W is a subdivided vertical (resp. horizontal) path of $\overline{W}$.

A subgraph W of a graph G is called a *wall* of G if W is an r-wall for some odd $r \geq 3$ and we refer to r as the *height* of the wall W.

Let W be a wall of a graph G and K' be the connected component of $G \setminus \mathsf{perim}(W)$ that contains $W \setminus \mathsf{perim}(W)$. The *compass* of W, denoted by $\mathsf{comp}(W)$, is the graph $G[V(K') \cup V(\mathsf{perim}(W))]$. Observe that W is a subgraph of $\mathsf{comp}(W)$ and $\mathsf{comp}(W)$ is connected.

The *layers* of an r-wall W are recursively defined as follows. The first layer of W is its perimeter. For $i = 2, \ldots, (r-1)/2$, the i-th layer of W is the $(i-1)$-th layer of the subwall W' obtained from W after removing from W its perimeter and all occurring vertices of degree one. Notice that each $(2r+1)$-wall has r layers (see Figure 1). The *central vertices* of W, denoted by $\mathsf{center}(W)$, are the two branch vertices of W that do not belong to any of its layers.

We are now in position to state the following two lemmata.

▶ **Lemma 5.** *Given a $\boxtimes \in \mathsf{OP}$, there exist two functions $f_1, f_2 : \mathbb{N}^2 \to \mathbb{N}$, and an algorithm with the following specifications:*

Find_Area(k, q, G, S)

Input: a $k \in \mathbb{N}$, an odd $q \in \mathbb{N}_{\geq 1}$, a graph G, and a set $S \subseteq V(G)$ that is a vr-planarizer of G of size at most k.

Output: One of the following:

1. *if $\boxtimes \in \{\mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$: a report that (G, k) is a no-instance of $\mathrm{G}\boxtimes\mathrm{MP}\phi$.*
   - *if $\boxtimes = \mathsf{vr}$: a vertex $u \in S$ such that $S \setminus u$ is a vr-planarizer of $G \setminus u$ of size at most $k-1$ and (G, k) and $(G \setminus u, k-1)$ are equivalent instances of $\mathrm{G}\boxtimes\mathrm{MP}\phi$.*
2. *a q-wall W of G and a closed disk Δ such that*
   - *the compass of W has treewidth at most $f_2(k, q)$,*
   - *G is partially Δ-embedded, where $G \cap \Delta = \mathsf{comp}(W)$, $\mathsf{bor}(\Delta) = \mathsf{perim}(W)$,*

- $V(\mathsf{comp}(W))$ *is* $\boxtimes$*-planarization irrelevant, and*
- $N_G(S) \cap V(\mathsf{comp}(W)) = \emptyset$*, or*

3. *a tree decomposition of* G *of width at most* $f_1(k, q)$*.*

Moreover, this algorithm runs in $\mathcal{O}_{k,q}(n)$ *steps.*

By $N_G(S)$ we denote the vertices not in S adjacent in G with vertices in S. In the first possible output of the algorithm of Lemma 5 we have either a negative answer to the G$\boxtimes$MPϕ problem or an equivalent instance of G$\boxtimes$MPϕ with reduced value of k.

The main steps of the proof of Lemma 5 are the following. In case, $\boxtimes = \mathsf{ea}$ we first check whether G is planar. If not, we report a negative answer, otherwise we find a wall W in G whose size is a "big-enough" function of k and whose compass has "small-enough" treewidth using [18, Lemma 4.2]. This wall contains an (also "big-enough") subwall of W whose compass is not affected by S. In case $\boxtimes \in \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$, we consider the neighbors of S in the planar graph G', that is the set $N := N_G(S)$. Moreover, we consider a big enough triangulated grid Γ as a contraction of G' (using [14, Theorem 3]) and the set N_Γ of the "contraction-heirs" of the vertices of N in Γ. If $|N_\Gamma|$ is "big-enough", then we prove, using the main technical result of [10], that some of the vertices of S should be affected by every possible solution, in case $\boxtimes = \mathsf{vr}$, or that we have a no-instance, in case $\boxtimes \in \{\mathsf{er}, \mathsf{ec}\}$. If $|N_\Gamma|$ is "small-enough", then we can find a "big-enough" wall W in G whose compass is not affected by S (again using the previously mentioned result of [18]). The proof is completed by proving that this wall contains some "big-enough" subwall that is not affected by any inclusion-minimal $\boxtimes$-planarizer.

The next lemma deals with the second possible output of the algorithm of Lemma 5 and contains the "core arguments" of this paper.

▶ **Lemma 6.** *Given a Gaifman sentence* ϕ *and a* $\boxtimes \in \mathsf{OP}$*, there exists a function* $f_3 : \mathbb{N}^2 \to \mathbb{N}$ *and an algorithm with the following specifications:*

Find_Vertex$(k, \Delta, G, R, \tilde{W})$

Input: a $k \in \mathbb{N}$*, a partially* Δ*-embedded graph* G*, a set of annotated vertices* $R \subseteq V(G)$*, and a* q*-wall* $\tilde{W}$ *of* G *such that*

- $q = f_3(k, |\phi|)$*.*
- *the compass of* $\tilde{W}$ *has treewidth at most* $f_2(k, q)$*,*
- $G \cap \Delta = \mathsf{comp}(\tilde{W})$*,* $\mathsf{bor}(\Delta) = \mathsf{perim}(\tilde{W})$*,*
- $V(\mathsf{comp}(\tilde{W}))$ *is* $\boxtimes$*-planarization irrelevant, and*

Output: a vertex set $X \subsetneq V(\mathsf{comp}(\tilde{W}))$ *and a vertex* $v \in X$ *such that* (G, R, k) *is a* $(\phi, \boxtimes)$*-triple iff* $(G \setminus v, R \setminus X, k)$ *is a* $(\phi, \boxtimes)$*-triple.*

Moreover, this algorithm runs in $\mathcal{O}_{k,|\phi|}(n)$ *steps.*

Notice that the above algorithm produces a $(\phi, \boxtimes)$-triple where both R and G are reduced. To see why Lemma 4 follows from Lemma 5 and Lemma 6, observe that in the second possible output of the algorithm **Find_Area**(k, q, G, S) we can call the algorithm **Find_Vertex**$(k, \Delta, G, R, \tilde{W})$, where $\tilde{W} := W$, which outputs a vertex set $X \subsetneq V(\mathsf{comp}(\tilde{W}))$ and a vertex $v \in X$ such that (G, R, k) is a $(\phi, \boxtimes)$-triple iff $(G \setminus v, R \setminus X, k)$ is a $(\phi, \boxtimes)$-triple. Observe that since $N_G(S) \cap V(\mathsf{comp}(\tilde{W})) = \emptyset$, then $S \subseteq R \setminus X$. We insist that the algorithm **Find_Vertex**$(k, \Delta, G, R, \tilde{W})$ does not use the fact that $N_G(S) \cap V(\mathsf{comp}(\tilde{W})) = \emptyset$ but we use the latter to guarantee that $S \subseteq R \setminus X$. For the running time of Lemma 4, recall that the two algorithms of Lemma 5 and Lemma 6 run in $\mathcal{O}_{k,|\phi|}(n)$ steps.

3.2 Sketch of the proof of Lemma 6

In order to prove Lemma 6, we first find a collection $\mathcal{W}$ of "sufficiently many" subwalls of $\tilde{W}$ each with ρ layers (where ρ is "big-enough"), whose compasses are pairwise vertex-disjoint.

The key idea is to define a "characteristic" of each wall $W \in \mathcal{W}$ that encodes all possible ways that a $\boxtimes$-planarizer S of G affects $\mathsf{comp}(W)$ along with the ways that the fact that $G \boxtimes S \models \phi$ is certified by a vertex assignment to the basic variables of the Gaifman formula ϕ in $\mathsf{comp}(W)$. Recall that $\phi\|_R$ is a Boolean combination of sentences $\phi_1\|_R, \ldots, \phi_m\|_R$ so that for every $h \in [m]$,

$$\phi_h\|_R = \exists x_1 \ldots \exists x_{\ell_h} \Big(\bigwedge_{i\in[\ell_h]} x_i \in R \wedge \bigwedge_{1\le i<j\le \ell_h} d(x_i,x_j) > 2r_h \wedge \bigwedge_{i\in[\ell_h]} \psi_h(x_i)\Big),$$

where $\ell_h, r_h \geq 1$ and ψ_h is an r_h-local formula with one free variable. Notice that $\phi\|_R$ is evaluated on annotated graphs of the form (G, R). Clearly, $\phi\|_R$ is a sentence in Monadic Second Order Logic, in short, a MSO_2-sentence.

As a first step, for every $h \in [m]$, $W \in \mathcal{W}$, $S \subseteq \boxtimes\langle G, R\rangle$ of size at most k, $I_h \subseteq [\ell_h]$, and $t \in [\rho]$, we define:

$$\mathsf{sig}^{(S,I_h,t)}_{\phi_h,\boxtimes}(W) := \begin{cases} 1, & \text{if } \exists \tilde{X} = \{x_i \mid i \in I_h\} \subseteq V(\mathsf{comp}(W^{(t)}) \boxtimes S) \cap R \text{ such that } \tilde{X} \\ & \text{is } (|I_h|, r_h)\text{-scattered in } \mathsf{comp}(W^{(t)}) \boxtimes S \text{ and } G \boxtimes S \models \bigwedge_{x\in\tilde{X}} \psi_h(x), \\ 0, & \text{otherwise.} \end{cases}$$

In the above definition, $W^{(t)}$ is the subwall of W that has t layers (which are the last t layers of W) and the same center as W. Also, a set X of vertices is (α, β)-*scattered*, if $|X| = \alpha$ and there are no two vertices in X within distance $\leq 2\beta$. Intuitively, $\mathsf{sig}^{(S,I_h,t)}_{\phi_h,\boxtimes}(W) = 1$ if the application of the operation $\boxtimes$ on G as defined by S gives rise to the existence of a scattered set $\tilde{X}$ in the compass of $W^{(t)}$ so that when the vertices of $\tilde{X}$ are assigned to the basic variables of ϕ_h corresponding to I_h, the local formula ψ_h is satisfied for each $x_i \in \tilde{X}$ in the modified graph.

Next, for every $W \in \mathcal{W}$ and every $S \subseteq \boxtimes\langle G, R\rangle$ of size at most k we define:

$$\mathsf{msig}^{(S)}_{\phi,\boxtimes}(W) = \Big((\mathsf{sig}^{(S,I_1,t)}_{\phi_1,\boxtimes}(W), \ldots, \mathsf{sig}^{(S,I_m,t)}_{\phi_m,\boxtimes}(W)) \mid (I_1, \ldots, I_m, t) \in 2^{[\ell_1]} \times \cdots \times 2^{[\ell_m]} \times [\rho] \Big).$$

Clearly, $\mathsf{msig}^{(S)}_{\phi,\boxtimes}(W)$ can be seen as a $(2^\ell \cdot \rho)$-tuple of binary m-tuples, given that $\ell := \sum_{h\in[m]} \ell_h$. Let SIG be the set of all such tuples and notice that $|\mathsf{SIG}|$ is bounded by some function of k and $|\phi|$ and $\Big\{ \mathsf{msig}^{(S)}_{\phi,\boxtimes}(W) \;\Big|\; W \in \mathcal{W}, S \subseteq \boxtimes\langle G, R\rangle \text{ of size at most } k \Big\} \subseteq \mathsf{SIG}$.

It is now time to define the characteristic of a wall $W \in \mathcal{W}$. We set $r := \max_{h\in[m]}\{r_h\}$ and $d := 2(r + (\ell+1)r + r)$. We define the $(\phi, \boxtimes)$-*characteristic* of W as follows:

$$\begin{aligned} (\phi,\boxtimes)\text{-}\mathsf{char}(W) \quad = \quad \{(s,\sigma,t) \in [0,k] \times \mathsf{SIG} \times [d+1,\rho] \mid \exists S \subseteq \boxtimes\langle G,R\rangle,& \\ |S| = s,& \\ A(S) \subseteq V(\mathsf{comp}(W^{(t-d)})) \cap R,& \\ \mathsf{comp}(W) \boxtimes S \text{ is planar, and}& \\ \mathsf{msig}^{(S)}_{\phi,\boxtimes}(W) = \sigma\}.& \end{aligned}$$

Notice that all queries in the definition of $(\phi, \boxtimes)$-char(W) can be expressed in MSO_2. Indeed, this is easy to see when $\boxtimes \in \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$, as in this case the query "$\mathsf{comp}(W) \boxtimes S$ is planar" is trivially true, since $V(\mathsf{comp}(\tilde{W}))$ is $\boxtimes$-planarization irrelevant. In the case where $\boxtimes = \mathsf{ea}$, the MSO_2 expressibility follows from Theorem 3. As each $W \in \mathcal{W}$ has treewidth bounded by a function of k and $|\phi|$, it follows by the theorem of Courcelle that $(\phi, \boxtimes)$-char(W) can be computed in $\mathcal{O}_{k,|\phi|}(n)$ time.

We say that two walls are $(\phi, \boxtimes)$-*equivalent* if they have the same $(\phi, \boxtimes)$-characteristic. Since the collection $\mathcal{W}$ contains "sufficiently many" walls, then we can find a collection $\mathcal{W}' \subseteq \mathcal{W}$ of also "sufficiently many" walls that are pairwise equivalent. We fix a wall $W_1 \in \mathcal{W}'$ and we set $X := \mathsf{comp}(W_1^{(r)})$, where $r = \max_{h\in[m]}\{r_h\}$, and $v \in \mathsf{center}(W_1)$.

In what follows, we highlight the ideas of the proof of the fact that if (G, R, k) is a $(\phi, \boxtimes)$-triple, then $(G \setminus v, R \setminus X, k)$ is a $(\phi, \boxtimes)$-triple. We first consider a set $S \subseteq \boxtimes\langle G, R\rangle$ of size at most k that certifies that (G, R, k) is a $(\phi, \boxtimes)$-triple. Then, we pick a wall $W_2 \in \mathcal{W}' \setminus \{W_1\}$ whose compass is not affected by S. We are allowed to pick this wall since there are "sufficiently many" walls equivalent to W_1 in $\mathcal{W}'$. Our strategy is to use the fact that W_1 and W_2 are $(\phi, \boxtimes)$-equivalent in order to state a "replacement argument": we can find a $t \in [\rho]$, such that the subset S_{in} of S that affects $\mathsf{comp}(W_1^{(t)})$ and the set X of vertices of $\mathsf{comp}(W_1^{(t)})$ that are assigned to the basic variables of ϕ in order to certify that $G \boxtimes S \models \phi$, can be replaced by their "equivalent" sets $\tilde{S}$ and $\tilde{X}$ in $\mathsf{comp}(W_2^{(t)})$. As a consequence of this, for every possible solution S and vertex assignment to the basic variables of ϕ, we can find both a new solution and a new vertex assignment that "avoid" the "inner part" of W_1. This implies that the validity of any local formula of ϕ does not depend on the central vertices of W_1. Thus, we can declare one of them "irrelevant" and safely remove it from G, while storing (by reducing R to $R \setminus X$) the fact that every possible solution S and vertex assignment to the basic variables of ϕ can "avoid" the "inner part" of W_1.

To further inspect how this "replacement" is achieved, we need to dive deeper into the technicalities of the proof (through an intuitive perspective). Given a wall W, we refer to a *wall-annulus* of W as the subgraph of W that is obtained from W after removing from W all its layers, except a fixed number of consecutive layers. We think of every wall $W \in \mathcal{W}$ as divided in consecutive wall-annuli of fixed size. Since ρ is "big-enough", then we can find also "many enough" such wall-annuli. We denote each one of them by $A_i(W)$. Given a $W \in \mathcal{W}$, every wall-annulus $A_i(W)$ is divided in some regions as depicted in Figure 2.

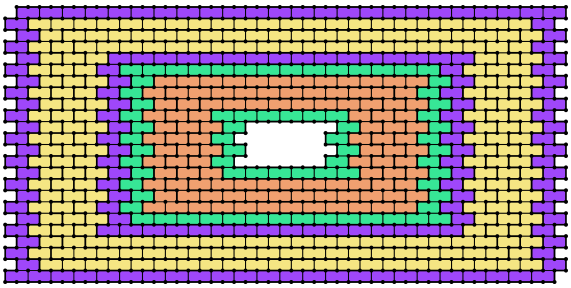

Figure 2 An example of a wall-annulus $A_i(W)$ of a wall $W \in \mathcal{W}$, together with its regions refered in the proof of Lemma 6.

The regions depicted in purple and green are consisting of r layers of the wall W (recall that $r = \max_{h\in[m]}\{r_h\}$). The regions depicted in yellow and orange are "big-enough" so as to be able to find an also "big-enough" wall-annulus that "avoids" a given vertex assignment to the basic variables of ϕ.

Since ρ is "big-enough", then we can find a wall-annulus $A_i(W_1)$ that is not affected by S. This allows us to partition S in two sets, S_{in} and S_{out} in the obvious way. The fact that W_1 and W_2 are $(\phi, \boxtimes)$-equivalent implies the existence of a set $\tilde{S}$ in W_2 certifying that $(\phi, \boxtimes)\text{-}\mathsf{char}(W_2) = (\phi, \boxtimes)\text{-}\mathsf{char}(W_1)$. Thus, by setting $S' := \tilde{S} \cup S_{\mathsf{out}}$, we have that $S' \subseteq \boxtimes\langle G, R'\rangle$, $|S'| = |S|$, and $G \boxtimes S'$ is planar. The latter is guaranteed by the fact that $V(\mathsf{comp}(\tilde{W}))$ is $\boxtimes$-planarization irrelevant, in the case $\boxtimes \in \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$, while in the case that

$\boxtimes = \mathsf{ea}$, the existence of the outer purple buffer of $A_i(W_1)$ (resp. $A_i(W_2)$) allows us to treat S_{in} (resp. $\tilde{S}$) and S_{out} separately, while not spoiling planarity. The last part of the proof requires to prove that $G \boxtimes S \models \phi\|_R \iff G \boxtimes S' \models \phi\|_{R'}$.

For simplicity, here we only argue why $G \boxtimes S \models \phi_h\|_R \implies G \boxtimes S' \models \phi_h\|_{R'}$ holds, as the arguments in the proof of the inverse direction are completely symmetrical. Therefore, given an (ℓ_h, r_h)-scattered set X such that ϕ_h is satisfied if the vertices of X are assigned to the basic variables of ϕ_h, we aim to find a $t \in [\rho]$ in order to "replace" the vertices in $X \cap V(\mathsf{comp}(W_1^{(t)}))$ with a set $\tilde{X}$ of vertices in $\mathsf{comp}(W_2^{(t)})$ such that the resulting vertex set X' is (ℓ_h, r_h)-scattered and ϕ_h is satisfied if the vertices of X' are assigned to the basic variables of ϕ_h. Notice that for every $h \in [m]$ such that $G \boxtimes S \models \phi_h\|_R$, these "replacement arguments" are pairwise independent.

We first deal with the possibility that the given scattered set X intersects some "inner part" of $\mathsf{comp}(W_2)$. Thus, in order to "clean" the "inner part" of $\mathsf{comp}(W_2)$, we find a wall $W_3 \in \mathcal{W}' \setminus \{W_1, W_2\}$ that "avoids" both S and X (for different $h \in [m]$, the choice of W_3 may coincide). Also, we consider a $\tilde{t} \in [\rho]$ corresponding to a layer in the yellow region of the wall-annulus $A_i(W_2)$ such that the annulus of the wall-annulus of $A_i(W_2)$ bounded by the $(t-r+1)$-th and t-th layer of W_2 is not intersected by X. Then, we "replace" the vertices of X in $\mathsf{comp}(W_2^{(\tilde{t})})$, call it X_{in} with an "equivalent" vertex set $\tilde{X}$ in $\mathsf{comp}(W_3^{(\tilde{t})})$ (notice that this is achieved by arguing for $S := \emptyset$ in the notion of $(\phi, \boxtimes)$-characteristic). This results to an (ℓ_h, r_h)-scattered set Y such that Y does not intersect $\mathsf{comp}(W_2^{(\tilde{t})})$ and $G \boxtimes S \models \bigwedge_{x \in Y} \psi_h(x)$ (see Figure 3).

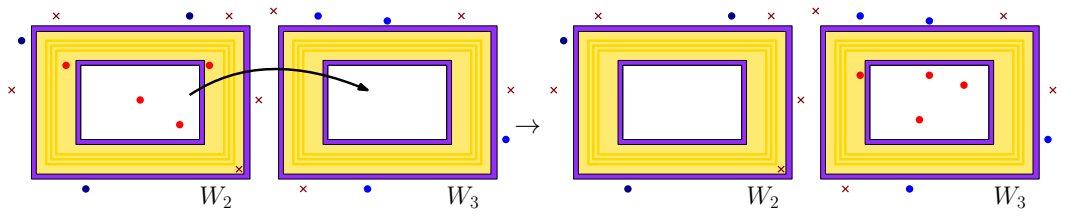

Figure 3 The "cleaning" of the "inner part" of $\mathsf{comp}(W_2)$. Left: The set $A(S)$ is depicted in cross vertices, the set $X \setminus X_{\mathsf{in}}$ is depicted in blue, and the set X_{in} is depicted in red. Right: The set $A(S)$ is depicted in cross vertices, the set $Y \setminus X_{\mathsf{in}}$ is depicted in blue, and the set $\tilde{X}$ is depicted in red.

Now, we are allowed to pick a $t \in [\rho]$ corresponding to an "orange" layer of $A_i(W_1)$ such that the annulus of the wall-annulus of $A_i(W_1)$ bounded by the $(t'-r)$-th and t'-th layer of W_1 is not intersected by X. If we set Y_{in} to be the set of vertices of Y in $\mathsf{comp}(W_1^{(t')})$, then since $\mathsf{msig}^{(S_{\mathsf{in}})}_{\phi,\boxtimes}(W_1) = \mathsf{msig}^{(\tilde{S})}_{\phi,\boxtimes}(W_2)$, then there exists a set $\tilde{Y}$ in $\mathsf{comp}(W_2^{(t')})$ that is "equivalent" to Y_{in} (see Figure 4).

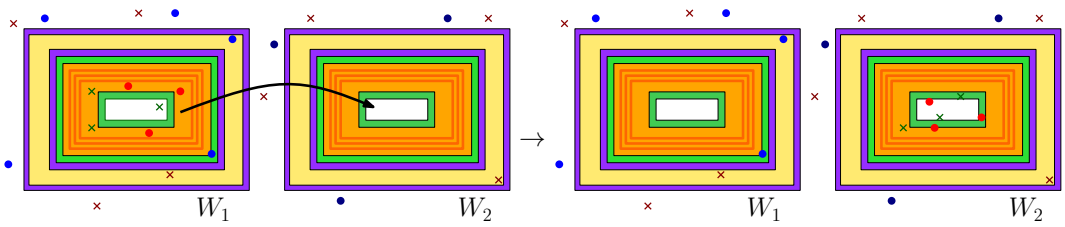

Figure 4 The last part of the proof. Left: The set $A(S_{\mathsf{out}})$ is depicted in red cross vertices, the set $A(S_{\mathsf{in}})$ is depicted in green cross vertices, the set $Y \setminus Y_{\mathsf{in}}$ is depicted in blue, and the set Y_{in} is depicted in red. Right: The set $A(S_{\mathsf{out}})$ is depicted in red cross vertices, the set $A(\tilde{S})$ is depicted in green cross vertices, the set $Y \setminus Y_{\mathsf{in}}$ is depicted in blue, and the set $\tilde{Y}$ is depicted in red.

Therefore, since $\tilde{Y}$ is in the orange region of $\mathsf{comp}(W_2)$ and Y is "avoiding" $\mathsf{comp}(W_2^{(\tilde{t})})$, then we can derive that Y and $\tilde{Y}$ are "separated" by a green and a purple region of $A_i(W_2)$. Thus, $X' := (Y \setminus Y_{\mathsf{in}}) \cup \tilde{Y}$ is an (ℓ_h, r_h)-scattered set of $G \boxtimes S'$ that "avoids" $\mathsf{comp}(W_1^{(r)})$. Moreover, ϕ_h is satisfied given that the vertices of X' of $G \boxtimes S'$ are assigned to the basic variables of ϕ_h. The proof is concluded.

3.3 Extension on graphs of bounded genus

The immediate question is whether our results can be extended to target properties that are more general than planarity (and still not FOL-expressible). The first candidate is the $\boxtimes$-Modification to g-Euler Genus and ϕ, where we ask for a set $S \subseteq \boxtimes\langle G, V(G)\rangle$ of size k such that $G \boxtimes S$ has Euler genus at most g. Notice that the property of having Euler genus at most g is not FOL-expressible. On the positive side, this property is MSO_2-expressible as there is a set $\mathcal{B}_g$ of graphs such that G has Euler genus at most g iff none of the graphs in $\mathcal{B}_g$ is a minor of G and minor containment is MSO_2-expressible. We next argue about how to adapt the techniques of this paper in order to prove that this problem can be solved in $\mathcal{O}_{k,|\phi|,g}(n^2)$ when $\boxtimes \in \{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$. For this we first straightforwardly extend the notions of $\boxtimes$-planarization irrelevant vertex set and $\boxtimes$-planarizer to the respective notions of $\boxtimes$-*g-Euler Genus irrelevant* vertex set $\boxtimes$-*g-euler genus enforcer*. Our aim is to prove a more general version of Lemma 4 where $\boxtimes$-planarizer is replaced by $\boxtimes$-g-euler genus enforcer. The $\mathcal{O}_{k,|\phi|,g}(n^2)$ time algorithm for $\boxtimes$-Modification to g-Euler Genus and ϕ follows directly from this extended version of Lemma 4 with the same arguments as its planarization counterpart. The extended version of Lemma 4 in turn is a consequence of the generalized versions of Lemma 5 and Lemma 6 where $\boxtimes$-planarizer is replaced by $\boxtimes$-g-euler genus enforcer and $\boxtimes$-planarization irrelevant is replaced by $\boxtimes$-g-Euler Genus irrelevant. The generalized version of Lemma 5 follows as the same arguments also hold on bounded-genus graphs: the result we use from [18] has a bounded-genus analogue, the results from [14] and [10] hold for the more general graph class of apex-minor-free graphs. Also the fact that the "big-enough" q-wall that we find is $\boxtimes$-g-Euler Genus irrelevant can be proven using arguments from [25]. Having the extended version of Lemma 5, the proof of the extended version of Lemma 6 is almost identical as we still work inside a disk Δ where G is partially embedded, so that local modifications should locally respect planarity. To be precise, the main difference is that in the definition of d, we now demand that d is also lower bounded by some big-enough function of the genus which guarantees that local modifications in the disk Δ do not alter the genus of the whole graph.

4 Further research directions

In this paper we provide an algorithmic-meta theorem for the graph modifiction problem where the modification operation is in $\{\mathsf{vr}, \mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$ and the target property is planarity plus being a model of some FOL-sentence ϕ. We also argued how to extend this result for modification operations in $\{\mathsf{vr}, \mathsf{er}, \mathsf{ec}\}$ for the case where instead of planarity we consider the class of graphs embeddable in a surface of Euler genus g, for fixed g. The two general challenges that we distinguish are the following.

- Pick a (non-empty) subset $\mathfrak{O}$ of $\{\mathsf{vr}, \mathsf{er}, \mathsf{ec}, \mathsf{ea}\}$ and define Graph $\mathfrak{O}$-Modification to Planarity and ϕ in the obvious way, by permitting any modification operation from $\mathfrak{O}$. It is possible (however more technical) to adapt our results for this problem in the case where $\mathsf{ea} \notin \mathfrak{O}$. However, in the case where $\mathsf{ea} \in \mathfrak{O}$ (while $|\mathfrak{O}| > 1$) the

problem becomes considerably more complicated as parts of the graph may be relocated during the modification operation (in fact, from a more general perspective, the same issue appears for the EA-MODIFICATION TO g-EULER GENUS AND ϕ problem that we avoided to consider in Subsection 3.3). We believe that this issue can be tackled using the techniques of [15]. However, the technical details of such an enterprise seem to be quite involved.

- Consider other target properties, alternative to planarity, that are not FOL-expressible. A natural challenge in this direction is to consider some finite set of graphs $\mathcal{H}$ and define the $\boxtimes$-MODIFICATION TO EXCLUDING $\mathcal{H}$-MINORS AND ϕ problem where the target property, apart from being a model of ϕ, is to exclude every graph in $\mathcal{H}$ as a minor. Notice that if $\mathcal{H}$ contains some planar graph, then the yes-instance of the problem has bounded treewidth, therefore the problem is fixed-parameter tractable due to Courcelle's Theorem. The result of this paper can be seen as $\boxtimes$-MODIFICATION TO EXCLUDING $\{K_5, K_{3,3}\}$-MINORS AND ϕ that is the simplest, however essential, version of the general problem. We conjecture that the same results can be achieved for every $\mathcal{H}$ and we believe that the techniques introduced in this paper can be the starting point of such a project.

Abstract

We consider the *directed minimum latency problem* (DirLat), wherein we seek a path P visiting all points (or clients) in a given asymmetric metric starting at a given root node r, so as to minimize the sum of the client waiting times, where the waiting time of a client v is the length of the r-v portion of P. We give the *first constant-factor approximation* guarantee for DirLat, but in quasi-polynomial time. Previously, a polynomial-time $O(\log n)$-approximation was known [12], and no better approximation guarantees were known even in quasi-polynomial time.

A key ingredient of our result, and our chief technical contribution, is an extension of a recent result of [17] showing that the integrality gap of the natural Held-Karp relaxation for *asymmetric TSP-Path* (ATSPP) is at most a constant, which itself builds on the breakthrough similar result established for *asymmetric TSP* (ATSP) by Svensson et al. [25]. We show that the integrality gap of the Held-Karp relaxation for ATSPP is bounded by a constant even if the cut requirements of the LP relaxation are relaxed from $x(\delta^{\text{in}}(S)) \geq 1$ to $x(\delta^{\text{in}}(S)) \geq \rho$ for some constant $1/2 < \rho \leq 1$.

We also give a better approximation guarantee for the *minimum total-regret problem*, where the goal is to find a path P that minimizes the total time that nodes spend in excess of their shortest-path distances from r, which can be cast as a special case of DirLat involving so-called regret metrics.

1 Introduction

Vehicle-routing problems form a rich class of combinatorial-optimization problems that find applications in a wide variety of settings, and have been extensively studied in the Operations Research and Computer Science communities (see, e.g., [26]). These problems typically involve designing routes for vehicles to service a given underlying set of clients in the most time- and/or cost-effective fashion. A fundamental problem in this genre is the *minimum latency problem* (MLP), also known as the *traveling repairman problem* or the *delivery man problem* [1, 19, 10, 5], wherein, adopting a client-oriented perspective, we seek a route starting at a given root node and visiting all client nodes that minimizes the sum of client waiting times (or equivalently, the average client waiting time).[1]

[1] In contrast, the path-version of TSP can be seen as minimizing the *maximum* client waiting time.

We investigate *directed* MLP (DirLat), i.e., MLP in directed (or asymmetric) metrics. Formally, we are given an asymmetric metric space $(V \cup \{r\}, c)$, where V is a set of client nodes, r is a root or depot node, and $c = \{c_{u,v}\}_{u,v \in V \cup \{r\}}$ specifies the asymmetric metric: in particular, for any $u, v, w \in V \cup \{r\}$, we have $c_{u,u} = 0$, $c_{u,v} \geq 0$, and $c_{u,v} \leq c_{u,w} + c_{w,v}$. The goal is to find a Hamiltonian path P starting at the depot r to minimize $\sum_{v \in V} c_P(v)$, where $c_P(v)$ is the cost of the $r \rightsquigarrow v$ subpath of P and is interpreted as the waiting time or *latency* of node v. Throughout, we let n denote $|V|$.

Whereas we have a reasonably good understanding of MLP in undirected (i.e., symmetric) metrics – a constant-factor approximation is known (see [9] and the references therein) and recent work has also led to LP-based approaches [7, 22] for the problem – there are significant gaps in our understanding of directed MLP: the approximation factor has remained stagnant at $O(\log n)$ [12] for close to a decade, and it is not known if $\log n$ (or any super-constant function of n) constitutes a real inapproximability barrier for the problem.

2 Our contributions

Our main contribution is to provide the *first constant-factor approximation* guarantee for DirLat, albeit in quasi-polynomial time, i.e., $O\left(n^{O(\log n)}\right)$ time. This provides the first concrete indication that $\log n$ is unlikely to be an inapproximability barrier for DirLat (unless $NP \subseteq DTIME\left[n^{O(\log n)}\right]$).

▶ **Theorem 1.** *There is an $O(1)$-approximation for* DirLat *running in $O\left(n^{O(\log n)}\right)$ time.*

Our algorithm is based on a natural time-indexed linear programming (LP) relaxation that is similar to, and inspired by, the approach taken in [22] for undirected MLP. Roughly speaking, our LP (LP-Lat) utilizes variables for (v, t) pairs where $v \in V$ is a node to be visited and t is the time they should be visited, and other variables indicating the edges present on various prefixes of the optimal path. As is typical for minimum-latency problems, we utilize the LP to find rooted paths of geometrically increasing lengths and stitch them together. However, with asymmetric metrics, *both* steps present significant challenges. A key technical contribution underlying our result is a procedure for achieving the former step, namely a way of rounding the fractional prefix of the optimal path of length t to obtain a rooted path of length $O(t)$. We achieve this by generalizing some recent work by [17] on the integrality gap for *asymmetric s-t TSP-path* (ATSPP). We show that the integrality gap of a weakening of the standard LP-relaxation, where we require non-s-t cuts to only be covered to some extent strictly larger than 1 still remains a constant (see Theorem 2 below).

An interesting special case of DirLat, involves the notion of *regret* of a client: the regret of a client v lying on a rooted path P is defined as $c_P(v) - c_{r,v}$; that is, regret measures the time that node v spends waiting *in excess* of its its least possible waiting time. The notion of regret can be seen as a nuanced and better way of measuring the (dis)satisfaction of a client than the standard measure of simply considering the waiting time of a client. The latter does not differentiate between clients located at different distances from the depot and their varying expectations, and fails to take into account that a client closer to the depot that incurs a larger delay than further-away clients may face a greater level of dissatisfaction. A natural problem that arises is to find a path that minimizes the total regret of clients, i.e., to minimize $\sum_{v \in V}(c_P(v) - c_{r,v})$ (or equivalently, minimize average client regret). [2] This can be cast as a special case of DirLat by defining the regret distances,

[2] Minimizing total regret is harder than MLP in the metric (V, c). While an optimal MLP-solution for the metric (V, c) clearly yields an optimal solution to the minimum total-regret problem, this translation does not apply to near-optimal MLP-solutions. However, it is easy to see that an α-approximate solution to the minimum-total-regret problem is also an α-approximate MLP solution for the metric (V, c).

$c^{\mathsf{reg}}_{u,v} := c_{r,u} + c_{u,v} - c_{r,v}$, which form an asymmetric metric that we call the *regret metric* of (V, c). We have not attempted to optimize the constant in Theorem 1, but it is rather large; we provide a substantially improved (and explicit) guarantee for the minimum-total-regret problem (Theorem 5) when (V, c) is a *symmetric* metric (i.e. $c_{u,v} = c_{v,u}$).

Our techniques. As noted above, our algorithm utilizes a natural time-indexed LP-relaxation for DirLat. Using standard scaling techniques, one may assume all $c_{u,v}$ distances are integers that are bounded by a polynomial in n (see Appendix A). Let $T = n \cdot \max_{u,v} c_{uv}$ and notice that T is bounded by a polynomial in n. Any Hamiltonian path in the metric $(V \cup \{r\}, c)$ has length at most T, so all nodes in the optimum solution are visited by time T.

For a directed graph $G = (N, E)$, and set $S \subseteq N$, let $\delta^{\text{in}}_G(S) := \{(u, v) \in E : u \in N - S, v \in S\}$ and $\delta^{\text{out}}_G(S) := \{(u, v) \in E : u \in S, v \in N - S\}$ denote respectively the edges entering and leaving S. Define $\delta_G(S) := \delta^{\text{in}}_G(S) \cup \delta^{\text{out}}_G(S)$. If the graph is clear from the context, we may omit the subscript G. We often identify an asymmetric metric $(V \cup \{r\}, c)$ with the complete directed graph over nodes $V \cup \{r\}$, with edge costs $c_{u,v}$ for distinct $u, v \in V \cup \{r\}$. For a path P and a node v on P, recall that $c_P(v)$ is the cost of the $r \rightsquigarrow v$ subpath of P. We begin with essentially the same time-indexed LP relaxation used in [22] for the undirected MLP, specifically (LP3) in their work. For $v \in V \cup \{r\}$ and $t \in [T]$, let $x_{v,t}$ be a variable indicating that we visit v at time *exactly* t, and let $z_{uv,t}$ indicate that we finish traversing edge (u, v) at time *exactly* t. Define $[T] := \{0, 1, \ldots, T\}$.

$$\textbf{minimize}: \quad \sum_{v \in V, t \in [T]} t \cdot x_{v,t} \qquad \text{(LP-Lat)}$$

$$\textbf{subject to}: \quad \sum_{t \in [T]} x_{v,t} = 1 \qquad \forall\, v \in V \qquad (1)$$

$$\sum_{e \in \delta^{\text{in}}(S)} \sum_{t' \le t} z_{e,t'} \ge \sum_{t' \le t} x_{v,t'} \qquad \forall\, v \in V,\ \{v\} \subseteq S \subseteq V, t \in [T] \qquad (2)$$

$$x_{v,t} = \sum_{e \in \delta^{\text{in}}(v)} z_{e,t} \ge \sum_{e \in \delta^{\text{out}}(v)} z_{e,t+c_e} \qquad \forall\, v \in V, t \in [T] \qquad (3)$$

$$x, z \ge 0.$$

(We remark that the $z_{uv,t}$ variables above have a slightly different meaning from [22], wherein $z_{uv,t}$ indicated that t was traversed *by* time t. Also, we omit constraints (14) from [22], which encode that the length-t prefix of the optimal path has length at most t, as one can easily show they are implied by our slightly different approach.)

It is easy to check that an optimal solution P^* naturally corresponds to an integral solution to (LP-Lat) with the same cost as the latency of P^*. Constraints (2) admit an efficient separation oracle simply by checking for each $v \in V$ and $t \in T$ if the minimum $r - v$ cut has capacity at least $\sum_{t' \le t} x_{v,t'}$ when using a capacity of $\sum_{t' \le t} z_{e,t'}$ for each edge e.

Our proof of Theorem 1 proceeds by bucketing clients based on their fractional latencies, finding low-cost paths for these buckets, and stitching these paths together to form our final path. Our advantage over [12] comes from the fact that we guess the $O(\log T) = O(\log n)$ nodes v^*_i appearing at distances roughly 2^i along the optimum path P^*, plus their exact visiting times, ℓ^*_i, along P^*. We add constraints to (LP-Lat) to reflect these guesses. For each v^*_i, consider the nodes v that are at least, say, 2/3-visited before v^*_i but not 2/3-visited before v^*_{i-1} is visited: call this the *bucket* B_i for v^*_i. With a bit of modification, the restriction of (LP-Lat) to the times before ℓ^*_i is visited induces an LP solution with cost $O(2^i)$ for the natural ATSPP LP relaxation that covers all $v \in B_i$ to an extent of at least 2/3. That is, we get a solution to the following LP relaxation for ATSPP for $\rho = 2/3$.

$$\textbf{minimize}: \quad \sum_{u,v} c_{u,v} \cdot x_{u,v} \qquad \text{(LP-ATSPP}_\rho\text{)}$$

$$\textbf{subject to}: \quad x(\delta^{\text{out}}(v)) - x(\delta^{\text{in}}(v)) = \begin{cases} +1 & v = s \\ -1 & v = t \\ 0 & v \neq s,t \end{cases} \qquad \forall\, v \in V$$

$$x(\delta(U)) \geq 2 \cdot \rho \qquad \forall\, \emptyset \subsetneq U \subseteq V - \{s,t\}$$

$$x \geq 0.$$

The integrality gap when $\rho = 1$ was shown to be constant in [17]. We prove the following more-general result establishing a constant integrality gap for (LP-ATSPP$_\rho$) for all $1/2 < \rho \leq 1$, which is one of our chief technical results. By an *LP-relative α-approximation algorithm for* (LP-ATSPP$_\rho$) (or simply LP-relative approximation algorithm), we mean a polytime algorithm that returns an ATSPP solution of cost at most $\alpha \cdot OPT_{\text{LP-ATSPP}_\rho}$.

▶ **Theorem 2.** *There is an LP-relative $\frac{\psi}{2\rho-1}$-approximation algorithm for* (LP-ATSPP$_\rho$)*, where ψ is some absolute constant (i.e., independent of the instance).*

We do not compute the exact value of ψ, or attempt to optimize it (favoring simplicity of presentation instead). It's precise value depends on the integrality gap for ATSP, which is known to be bounded by a constant [25, 28].

Using Theorem 2, we can obtain a path P_i for each bucket B_i, of cost $O(2^i)$ spanning the nodes of $\{r\} \cup B_i$. Our final path Q will be the concatenation of these P_i paths. To obtain Theorem 1, it suffices to show that the latency under Q of each node in B_i is $O(2^i)$. For the latter, while $c(P_i) = O(2^i)$, we also need a bound of $O(2^i)$ on the cost of stitching the last node of P_{i-1} to the first node after r on P_i. This is where guessing plays the most prominent role: we show that strengthening the LP with our guess ultimately implies the new edge used to stitch P_{i-1} to P_i also has cost $O(2^i)$, as required.

As an aside, complementing Theorem 2, we show that the dependence of the integrality gap on ρ stated in Theorem 2 is asymptotically correct, and this holds even if we strengthen (LP-ATSPP$_\rho$) to require an in-flow of 1 for each $v \in V - \{s,t\}$ (but still have the relaxed cut constraints). This generalizes a similar result in [12] showing that the integrality gap of (LP-ATSPP$_\rho$) is unbounded when $\rho = 1/2$.

▶ **Theorem 3.** *The integrality gap of* (LP-ATSPP$_\rho$) *is at least $\frac{1}{2\rho-1}$, for every $1/2 < \rho \leq 1$, and this holds even if we strengthen the LP with the constraints $x(\delta^{\text{in}}(v)) = 1$ for each $v \in V - \{s,t\}$.*

Our final result pertains to the minimum total-regret problem, for which we obtain a much-improved approximation guarantee (compared to Theorem 1). Recall that this is the special case of DirLat, where the metric is the regret metric of an *undirected* metric; in the sequel, we refer to this simply as a regret metric. Our improvement stems from the following improved and explicit integrality gap for (LP-ATSPP$_\rho$) in regret metrics.

▶ **Theorem 4.** *There is an LP-relative α_ρ^{reg}-approximation algorithm for* (LP-ATSPP$_\rho$) *in regret metrics, where $\alpha_\rho^{\text{reg}} := \frac{300}{42-12\sqrt{6}} \cdot \frac{1}{2\rho-1} \approx \frac{23.8}{2\rho-1}$.*

The proof of the above result is quite different from that of Theorem 2. It exploits the structure of regret metrics, and leverages and builds upon the insights and machinery developed in [13, 14] for this class of metrics. Theorem 4 leads to the following explicit approximation factor for DirLat in regret metrics.

▶ **Theorem 5.** *There is a quasi-polynomial time 397-approximation for* DirLat *in regret metrics.*

2.1 Related Work

Nagarajan and Ravi first studied DirLat and obtained an approximation guarantee of $n^{1/2+\epsilon}$ in time $n^{O(1/\epsilon)}$ for any constant $\epsilon > 0$ [20], which extends easily to an $O(\alpha' \cdot \log^{O(1)}(n))$-approximation in quasi-polynomial time where (roughly speaking) α' is an upper bound on the integrality gap of the natural Held-Karp LP relaxation for ATSPP. They also showed α' is bounded by $O(\sqrt{n})$. Friggstad, Salavatipour, and Svitkina improved the approximation guarantee for DirLat and the upper bound on the integrality gap for ATSPP to $O(\log n)$ [12]. This is currently the best polynomial-time approximation for DirLat and no better quasi-polynomial time approximation was known before our work. If the metric is symmetric, constant-factor approximations are know. The first was given by Blum et al. [5], the best guarantee so far is a 3.59-approximation by Chaudhuri et al. [9].

Chakrabarty and Swamy [7], and Post and Swamy [22] studied LP relaxations for the undirected minimum latency problem. Using time-indexed LP relaxations, [22] obtain improved approximations for the multi-depot variant and also recover the 3.59-approximation for the single-vehicle version using an LP relaxation. Our work builds upon the ideas behind one of their LP relaxations.

The integrality-gap upper bound for ATSPP has seen various improvements since [12], which have followed analogous improvements on the integrality gap, denoted α_{ATSP}, of the Held-Karp relaxation for ATSP, its more well-studied cousin. Friggstad et al. [11] show that the integrality gap is $O(\log n/\log\log n)$ by building upon ideas introduced in [3] who proved a similar bound for α_{ATSP}. Recently, [17] shows the integrality gap is in fact $O(1)$. Specifically, they show the gap is at most $4 \cdot \alpha_{\mathsf{ATSP}} - 3$; combined with a breakthrough result of Svensson, Tarnawski, and Vegh [25], who showed $\alpha_{\mathsf{ATSP}} = O(1)$, this yields an $O(1)$ upper bound on the integrality gap for ATSPP. An even more recent development by Traub and Vygen shows that $\alpha_{\mathsf{ATSP}} \leq 22$ [28], and Traub [27] has shown the integrality gap for ATSPP is at most 43. The best lower bound known on α_{ATSP} is 2 [8].

The notion of regret has been proposed in the vehicle-routing literature (see, e.g., [24, 21]) as a more refined way of measuring client dissatisfaction than simply considering its waiting time. The underlying motivation is that since the shortest-path distance of a client from the depot is an inherent lower bound on its waiting time, it is more meaningful to measure the waiting time of a client *relative* to this lower bound. In symmetric metrics, two main regret-related problems have been investigated: finding a path (or a fixed number of paths) that minimizes maximum client regret; and finding the fewest number of bounded-regret paths to visit all clients. Constant-factor approximation algorithms are known for both problems (see [13] and the references therein). To our knowledge there is no prior work on finding provably near-optimal solutions for the total-regret (or equivalently average-regret) objective.

Outline of the paper. Section 3 presents the proofs of Theorems 1 and 5, assuming the LP-relative approximation algorithms provided by Theorems 2 and 4. Section 4 proves Theorem 2 and is concluded with the proof of Theorem 3. Finally, the proof of Theorem 4 is presented in Section 5.

3 An $O(1)$-Approximation in Quasi-Polynomial Time

In this section, we assume Theorems 2 and 4 and use them to prove Theorems 1 and 5. By scaling (see Theorem 26 in Appendix A), we may assume distances are integers bounded by a polynomial in n and that $c_{u,v} \geq 1$ for distinct nodes u, v. We also let $T = n \cdot \max_{u,v \in V \cup \{r\}} c_{u,v}$,

which is an upper bound on the cost of any Hamiltonian path. We focus on a fixed optimal path P^*. Our algorithm starts by guessing the last node v_i^* visited by P^* at some time in the interval $[2^i, 2^{i+1})$ (if any) and its exact distance $\ell_i^* \in [T]$ for each $0 \le i \le \log_2 T = O(\log n)$. Let $v_i^* = \perp$ if no such node exists for this interval. For any i, we then know that no node is visited at any time in $[2^i, 2^{i+1})$ if $v_i^* = \perp$ and, if $v_i^* \neq \perp$, we also know no node is visited at a time in the interval $(\ell_i^*, 2^{i+1})$ so we mark these times as **forbidden**. Let $A = \{i : v_i^* \neq \perp\}$ be **admissible** buckets corresponding to intervals where the optimum visits at least one node. Let $1/2 < \rho \le 1$ be a parameter we optimize later.

Algorithm 1 Directed Latency: $\boldsymbol{O(1)}$-approximation in $\boldsymbol{n^{O(\log n)}}$ time.

Input: asymmetric metric $(V \cup \{r\}, c)$ with integer distances at most T/n; parameter $\rho \in (1/2, 1]$; an LP-relative α_ρ-approximation algorithm Alg for (LP-ATSPP$_\rho$).
Output: an r-rooted path P

D1. For every choice (guess) of $v_i^* \in V \cup \{\perp\}$ for each $0 \le i \le \log_2 T$ and $\ell_i^* \in [T]$ for each such i where $v_i^* \neq \perp$, perform the following steps. Let $F = \{t \in [T] : t \in [2^i, 2^{i+1})$ where $v_i^* = \perp$ or $t \in (\ell_i^*, 2^{i+1})$ where $v_i^* \neq \perp\}$ be the forbidden times for this guess (v^*, ℓ^*) and $A = \{i \in [0, \log_2 T] : v_i^* \neq \perp\}$ the admissible buckets.

- **D1.1.** Obtain an optimal extreme point solution (x, z) to (LP-Lat) strengthened with the following additional constraints: 1) $x_{v_i^*, \ell_i^*} = 1$ for each $i \in A$ and 2) $x_{v,t} = 0$ for each $v \in V$ and $t \in F$. If the LP is infeasible, abort this guess of (v^*, ℓ^*).
- **D1.2.** For each $v \in V$, let $t(v) = t_\rho(v)$ be the minimum time such that $\sum_{t \le t(v)} x_{v,t} \ge \rho$. For $i \in A$, let $B_i = \{v \in V : t(v) \in [2^i, 2^{i+1})\}$.
- **D1.3.** For each $i \in A$, use algorithm Alg to obtain an $r - v_i^*$ path P_i spanning $\{r\} \cup B_i$.
- **D1.4.** Let P^{v^*, ℓ^*} be the path obtained by concatenating the paths $\{P_i\}_{i \in A}$ in increasing order of i, and shortcutting past repeat occurrences of r.

D2. Return the best path P^{v^*, ℓ^*} found over all guesses where the strengthening of (LP-Lat) was feasible.

Let P^* be an optimum solution and consider the iteration where (v^*, ℓ^*) is consistent with P^*. Let (x, z) be an optimum LP solution for the strengthening of (LP-Lat) by the constraints in Step (11). Clearly this strengthened LP is feasible and the value of the solution (x, z) is at most OPT, the latency of P^*.

For each $v \in V$, note that $t(v)$ is well-defined by Constraints (1). Ultimately, we will show the path P^{v^*, ℓ^*} visits each $v \in V$ by time $O(t(v))$. We begin by showing this suffices to get a constant-factor approximation.

▶ **Lemma 6.** *Let P be a path and $c \ge 1$ be such that $c_P(v) \le c \cdot t(v)$ for each $v \in V$. Then the latency of P is at most $\frac{c}{1-\rho} \cdot OPT$.*

Proof. Fix some $v \in V$. By definition of $t(v)$, we have $\sum_{t(v) \le t \le T} x_{v,t} \ge 1 - \rho$ which yields $t(v) \le \frac{1}{1-\rho} \cdot \sum_{t(v) \le t \le T} t(v) \cdot x_{v,t} \le \frac{1}{1-\rho} \cdot \sum_{t \in [T]} t \cdot x_{v,t}$. It follows that $\sum_v c_P(v) \le \frac{c}{1-\rho} \cdot OPT$. ◀

3.1 Bounding the Latency of P^{v^*, ℓ^*}

In the remainder of the proof it is convenient to view a "time-expanded" graph G_T. The nodes are pairs (v, t) with $v \in V \cup \{r\}$ and $t \in [T]$ and an edge connects (u, t) to (v, t') if $c_{u,v} = t' - t$. Observe G_T is acyclic. We can then view $z_{e,t}$ as assigning values to edges of G_T: the edge $(u, t - c_{u,v}), (v, t)$ has value $z_{(u,v),t}$ and cost $c_{u,v}$.

We begin with some observations. The constraints of (LP-Lat) mean z constitutes one unit of $(r,0)$-preflow[3] in G_T (i.e. a preflow with source vertex $(r,0)$). Namely, Constraints (3) ensure preflow is satisfied at every vertex (v,t) of G_T apart from the "source" vertex $(r,0)$. Let i' be the greatest index in A. Considering the LP constraints added in Step (11), we see $x_{v^*_{i'},\ell^*_{i'}} = 1$ and $x_{v,t} = 0$ for all $t > \ell^*_{i'}$. Thus, z must be a flow with value 1 in G_T ending at $(v^*_{i'}, \ell^*_{i'})$. Since the support of the flow z is acyclic in G_T and since one unit of flow passes through *every* (v^*_i, ℓ^*_i) node in G_T for each $i \in A$, no flow skips past node (v^*_i, ℓ^*_i). That is, no edge $((u,t),(v,t'))$ in G_T supports any z-flow if $t < \ell^*_i < t'$ for some $i \in A$, nor does any edge $((u,t),(v,t'))$ support any z-flow if $t = \ell^*_i$ yet $u \neq v^*_i$ or $t' = \ell^*_i$ yet $v \neq v^*_i$ for some $i \in A$.

Next, we recall a famous splitting-off result by Mader. The following is a slight specialization of one such result.

▶ **Theorem 7** (Mader [18]). *Let $D = (V \cup \{s\}, A)$ be a directed, Eulerian multigraph such that the $u - v$ connectivity for every $u, v \in V$ is at least k. Then for every $(u,s) \in A$ there is some $(s,v) \in A$ such that in the graph $D' = (V \cup \{s\}, A - \{(u,s),(s,v)\} \cup \{(u,v)\})$, the $u - v$ connectivity for every $u, v \in V$ is still at least k.*

Using this, we show how to compute low-cost paths covering each bucket. Roughly speaking, we show that (LP-ATSPP$_\rho$) restricted to $\{r\} \cup B_i$ with start node r and end node v^*_i has cost at most 2^{i+1}. Thus, step 13 would find a path starting at r and covering all B_i with cost at most $\alpha_\rho \cdot 2^{i+1}$ where we recall α_ρ denotes the approximation factor of the LP-relative approximation Alg.

▶ **Lemma 8.** *For each $i \in A$, we can compute a Hamiltonian $r - v^*_i$ path P_i in $G[\{r\} \cup B_i]$ with cost $\alpha_\rho \cdot 2^{i+1}$ in polynomial time.*

Proof. Let x' be a vector over edges of the metric given by $x'_{u,v} = \sum_{t<2^{i+1}} z_{(u,v),t}$ for $u, v \in V \cup \{r\}$. From the observations above, the restriction of z to edges $((u,t),(v,t'))$ where $t < 2^{i+1}$ constitutes one unit of flow from $(r,0)$ to (v^*_i, ℓ^*_i) in G_T, so x'_{uv} is then one unit of $r - v^*_i$ flow in the metric. Further, since the cost of an edge $((u, t - c_{u,v}),(v,t))$ is $c_{u,v}$ in G_T, the cost of this flow x' is exactly ℓ^*_i, which is at most 2^{i+1}.

Next we verify $x'(\delta(S)) \geq 2 \cdot \rho$ for each $S \subseteq V - \{v^*_i\}$ with $S \cap B_i \neq \emptyset$. Consider some $v \in S \cap B_i$. Constraint (2), the fact that $v \in B_i$, and the fact that $x_{v,t} = 0$ for $\ell^*_i < t < 2^{i+1}$ shows $x'(\delta^{\text{in}}(S)) = \sum_{e \in \delta(S)} \sum_{t<2^{i+1}} z_{e,t} \geq \rho$. Since x' is an $r - v^*_i$ flow and $r, v^*_i \notin S$, then flow conservation shows $x'(\delta(S)) \geq 2 \cdot \rho$.

Much like in [2] for the Prize-Collecting TSP-Path problem, one can use Theorem 7 to shortcut x' past nodes not in $B_i \cup \{r\}$ to get solution for (LP-ATSPP$_\rho$) for in the graph $G[\{r\} \cup B_i]$ (with start node $s = r$ and end node $t = v^*_i$), also with cost at most 2^{i+1}. That is, we may assume x' is rational as z is a rational vector since it is part of an extreme point of an LP with rational coefficients. Let Δ be an integer such that the vector $\Delta \cdot x'$ is integral. Consider the graph G' with nodes $V \cup \{r\} \cup \{r'\}$ where r' is a new node. The edges of G' consist of $\Delta \cdot x'_{uv}$ copies of edge uv for each $u, v \in V \cup \{r\}$, and Δ edges from v^*_i to r' and also from r' to r (each having cost 0). Note the $r - u$ connectivity for each $u \in V$ is at least $\Delta \cdot \rho$. Note, the cost of all edges in G' is at most $\Delta \cdot 2^{i+1}$.

For each $v \in V - B_i$, we iteratively perform the splitting off procedure from Theorem 7 for $s = v$. The total cost of the edges does not increase by the triangle inequality (note the edges that are removed and added all lie in the metric over $V \cup \{r\}$), and the $r - u$

[3] An s-preflow in a digraph (V,E) where $s \in V$ is an assignment $f : E \to \mathbb{R}_{\geq 0}$ such that $f(\delta^{in}(v)) \geq f(\delta^{out}(v))$ for each $v \in V - \{s\}$. The value of the preflow f is $f(\delta^{out}(s)) - f(\delta^{in}(s))$.

connectivity remains at least $\Delta \cdot \rho$ for each $u \in B_i$. After doing this for each $v \in V - B_i$, we are left with a multigraph of total edge cost cost no more than the total cost of all edges in G'. Further, if we remove all $v_i^* r'$ and $r' r$ edges, we still get the connectivity from r to any other $v \in B_i$ is at least $\Delta \cdot \rho$. If $k_{u,v}$ denotes the number of copies of uv in this new graph, setting $x''_{u,v} = k_{u,v}/\Delta$ for each $(u,v) \in G[\{r\} \cup B_i]$ yields a feasible LP solution for (LP-ATSPP$_\rho$) in the metric graph over $B_i \cup \{r\}$ (with start node r and end node v_i^*) with cost at most 2^{i+1}.

From this, the optimal solution to (LP-ATSPP$_\rho$) in $G[\{r\} \cup B_i]$ (starting at r and ending at v_i^*) has value at most 2^{i+1}. So Alg returns a Hamiltonian $r - v_i^*$ path P_i in $G[\{r\} \cup B_i]$ with cost at most $\alpha_\rho \cdot 2^{i+1}$. ◀

Next we bound the cost of stitching together the paths for the admissible buckets.

▶ **Lemma 9.** *Let P_i and $P_{i'}$ be two paths constructed in Step* (13) *for consecutive indices $i, i' \in A$. Let $u_{i'}$ be the first node on $P_{i'}$ after r and recall v_i^* is the last node of P_i. Then $c_{v_i^*, u_{i'}} \le 2^{i'+1}$.*

Proof. Note that $u_{i'} \in B_{i'}$ means $t(u_{i'}) \in [2^{i'}, 2^{i'+1})$. Also, $x_{u_{i'}, t(u_{i'})} > 0$ by definition of $t(u_{i'})$. All units of z-flow in the acyclic graph G_T pass through (v_i^*, ℓ_i^*) and also through $(v_{i'}^*, \ell_{i'}^*)$. So the restriction of z to edges $((u,t),(v,t'))$ in G_T with $\ell_i^* \le t \le t' \le \ell_{i'}^*$ constitutes one unit of $(v_i^*, \ell_i^*) - (v_{i'}^*, \ell_{i'}^*)$ flow that supports $(u_{i'}, t(u_{i'}))$. Therefore, a path decomposition of this restriction of z includes $(u_{i'}, t(u_{i'}))$ on some path. Any such path has cost exactly $\ell_{i'}^* - \ell_i^* \le 2^{i'+1}$. By the triangle inequality, $c_{v_i^*, u_{i'}} + c_{u_{i'}, v_{i'}^*} \le 2^{i'+1}$. ◀

Next, we bound the latency of each $v \in V$ along the final path P^{v^*, ℓ^*} obtained by concatenating the P_i paths for increasing indices $i \in A$ and shortcutting past all but the first occurrence of r.

▶ **Lemma 10.** $c_{P^{v^*,\ell^*}}(v) \le 4(\alpha_\rho + 1) \cdot t(v)$ *for any $v \in V$.*

Proof. Consider any $v \in V$ and say it lies on P_i. To reach v along P^{v^*,ℓ^*}, we traverse paths $P_{i'}$ for $i' < i$ plus the "stitching" edges $v_{i'}^* u_{i''}^*$ for consecutive indices $i', i'' \in A$, $i'' \le i$. By Lemma 8 and Lemma 9, the latency of v along P^{v^*,ℓ^*} can be bounded by $\sum_{i' \in A, i' \le i} \alpha_\rho \cdot 2^{i'+1} + \sum_{i' \in A, i' \le i} 2^{i'+1} \le (\alpha_\rho + 1) \cdot \sum_{i'=0}^{i} \cdot 2^{i'+1} \le 4(\alpha_\rho + 1) \cdot 2^i \le 4(\alpha_\rho + 1) \cdot t(v)$. ◀

Proof of Theorem 1. We set $\rho = 2/3$, and note that Theorem 2 yields an LP-relative $\alpha_{2/3}$-approximation algorithm, where $\alpha_{2/3} = O(1)$. The proof of Theorem 1 then follows readily from Lemmas 6 and 10 and the fact that T is bounded by a polynomial in n. ◀

We remark that even with the improved bound of $\alpha \le 22$ from [28], our approach yields an approximation ratio in the thousands. As noted earlier, we obtain a much-better guarantee for the special case of regret metrics, i.e., the minimum-total-regret problem.

Proof of Theorem 5. First, we note that a worse approximation ratio follows by choosing $\rho = 0.75$: this yields an approximation ratio α_ρ of at most 47.6 for the LP-relative algorithm in Theorem 4 for regret metrics, which combined with Lemmas 10 and 6 (and choosing ϵ sufficiently small in Theorem 26) yields a 778-approximation.

The better guarantee stated in the theorem follows by choosing the best ρ *tailored for the given instance.* (Note that there are only polynomially many combinatorially-distinct choices of ρ, and we can simply try all of these to pick the best ρ.) We analyze this by choosing a random ρ and bounding the expected latency incurred; this is similar to the use of random α-points in scheduling algorithms (see, e.g., [23]).

For $v \in V$, recall that $t_\rho(v)$ is the minimum time for $\sum_{t \le t(v)} x_{v,t} \ge \rho$. Define $\mathsf{LP}_v := \sum_{t \in [T]} t x_{v,t}$. The key is to realize that $\int_0^1 t_\rho(v) d\rho = \mathsf{LP}_v$, and leverage this in place of the coarse bound $t_\rho(v) \le \frac{\mathsf{LP}_v}{1-\rho}$ used earlier (in Lemma 6). The approximation factor α_ρ given by Theorem 4 is of the form $\frac{c}{2\rho - 1}$, where $c = 23.8$. We choose a random ρ from $(1/2, 1]$ according to the density function $8(x - 1/2)$. The expected latency incurred by a node v is then at most

$$\int_{1/2}^1 4\Big(\frac{c}{2\rho-1}+1\Big) t_\rho(v) \cdot 8(\rho - 1/2) d\rho \le 16c \cdot \int_{1/2}^1 t_\rho(v) d\rho + 16 \int_{1/2}^1 t_\rho(v) d\rho \le 16(c+1) \cdot \mathsf{LP}_v.$$

Thus, the expected total latency is at most $16(23.8 + 1) \cdot OPT \le 397 \cdot OPT$. ◀

4 Bounding the Integrality Gap of (LP-ATSPP$_\rho$)

Consider nodes V with two distinguished $s, t \in V$ ($s \ne t$) and asymmetric metric distances $c_{u,v}$ between points of V. We consider (LP-ATSPP$_\rho$) for the Asymmetric TSP Path problem where the goal is to find the cheapest Hamiltonian $s - t$ path. As mentioned earlier, the integrality gap is unbounded if $\rho \le 1/2$ [12], so we focus on the case $1/2 < \rho \le 1$. As in [17], we start with the dual of (LP-ATSPP$_\rho$).

$$\begin{aligned} \textbf{maximize}: \quad & z_t - z_s + \sum_U 2\rho \cdot y_U && && (\text{DUAL}_\rho) \\ \textbf{subject to}: \quad & z_v - z_u + \sum_{U : uv \in \delta(U)} y_U \;\le\; c_{u,v} && \forall\, u, v \\ & y \;\ge\; 0. \end{aligned}$$

Naturally, our proof borrows many steps from Köhne, Traub, and Vygen [17] but there are additional challenges we have to work through in this more general setting.

For a vector x over the edges E of the directed metric (when viewed as a complete, directed graph), let $\text{supp}(x) = \{uv \in E : x_{u,v} > 0\}$. Similarly, for a vector y over cuts of the metric let $\text{supp}(y) = \{\emptyset \subsetneq S \subseteq V - \{s,t\} : y_S > 0\}$. From now on, we focus on the graph $G = (V, \text{supp}(x))$. The proofs of Propositions 11, 12, and 14 are very similar to proofs in [17] and are omitted or just sketched in this paper.

▶ **Proposition 11.** *Given any optimal dual solution (y, z), one can find an optimal dual solution (y', z) with $\text{supp}(y')$ being laminar in polynomial time.*

In other words, we can modify y to be laminar without changing z using efficient uncrossing techniques. The proof is exactly the same as the proof in [17] essentially because the set of feasible solutions to (DUAL$_\rho$) does not change if we select different values for ρ.

The next proposition is almost identical to one in [17], but we omit the case $U = V$ in the statement. In fact, the result may not be true for this case $U = V$, we handle that separately below.

▶ **Proposition 12.** *Let x be an optimum primal solution and let and $G = (V, \text{supp}(x))$. For any $U \subseteq V - \{s,t\}$ with $x(\delta(U)) = 2\rho$, any topological ordering $U_1, \ldots, U_\ell$ of the strongly connected components of $G[U]$ satisfies:*

- $\delta^{\text{in}}(U_1) = \delta^{\text{in}}(U)$,
- $\delta^{\text{out}}(U_\ell) = \delta^{\text{out}}(U)$, *and*
- $x(\delta^{\text{out}}(U_i)) = x(\delta^{\text{in}}(U_{i+1}))$ *for any* $1 \le i < \ell$.

We sketch the proof of Proposition 12 so the reader is assured it holds, though the proof is essentially the same.

Proof sketch. Because U is a tight set, $x(\delta^{\text{in}}(U)) = \rho$. Further, $x(\delta^{\text{in}}(U_1)) \geq \rho$. All edges in $\text{supp}(x)$ entering $\delta(U_1)$ must lie in $\delta^{\text{in}}(U)$ because U_1 is the first node in the topological ordering. Thus, $\rho = x(\delta^{\text{in}}(U)) \geq x(\delta^{\text{in}}(U_1)) \geq \rho$, so equality must hold throughout and $\delta^{\text{in}}(U) = \delta^{\text{in}}(U_1)$ as we are working in the support of x. A similar statement shows $\delta^{\text{out}}(U_\ell) = \delta^{\text{out}}(U)$.

For $i > 1$ we note $\delta^{\text{in}}(U_i) \subseteq \delta^{\text{in}}(U) \cup \bigcup_{j<i} \delta^{\text{out}}(U_j)$ simply because the U_j are topologically ordered. Inductively, we have $x(\delta^{\text{out}}(U_{i-1})) = \rho$ and each edge in $\delta^{\text{in}}(U) \cup \bigcup_{j<i-1} \delta^{\text{out}}(U_j)$ is already proven to lie in $\delta^{\text{in}}(U_{j'})$ for some $j' < i$. So we see $\delta^{\text{in}}(U_i) \subseteq \delta^{\text{out}}(U_{i-1})$ and, thus,

$$\rho = x(\delta^{\text{in}}(U_{i-1})) = x(\delta^{\text{out}}(U_{i-1})) \geq x(\delta^{\text{in}}(U_i)) \geq \rho.$$

So, again, equality must hold throughout. ◀

We use a different observation to address the case $U = V$ that was omitted from Proposition 12. Intuitively, we show that it is still possible to buy a cheap set of edges to chain the strongly-connected components of G in sequence but the cost of these edges does increase relative to OPT_{LP} as $\rho \to 1/2$.

▶ **Proposition 13.** *In any topological ordering $U_1, \ldots, U_\ell$ of the strongly connected components of G, for each $1 \leq i < \ell$ there is some edge $(u, v) \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})$ with $c_{u,v} \leq \frac{1}{2\rho-1} \cdot \sum_{u',v' \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})} c_{u',v'} x_{u',v'}$.*

Proof. This is easy for $i = 1$ and $i = \ell - 1$. For example, we have $x(\delta^{\text{in}}(U_2) \geq \rho$ and all edges from $\delta^{\text{in}}(U_2)$ lie in $\delta^{\text{out}}(U_1)$. Thus, $x(\delta^{\text{out}}(U_1) \cap \delta^{\text{in}}(U_2)) \geq \rho$ so the cheapest edge in $\delta^{\text{out}}(U_1) \cap \delta^{\text{in}}(U_2)$ has cost at most $\frac{1}{\rho} \cdot \sum_{uv \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1}))} c_{u,v} x_{u,v}$. We finish by observing $1/\rho \leq 1/(2\rho - 1)$ as $\rho \leq 1$. A similar argument works for $i = \ell - 1$, so we now assume $1 < i < \ell - 1$.

We quickly introduce notation. For an index $1 \leq j \leq \ell$ let $U_{\leq j} = \cup_{1 \leq j' \leq j} U_{j'}$ and $U_{\geq j} = \cup_{j \leq j' \leq \ell} U_{j'}$. Let $\delta(X; Y)$ denote $\{uv \in \text{supp}(x) : u \in X, v \in Y\}$ for $X, Y \subseteq V$. With this notation, let $a = x(\delta(U_i; U_{i+1})), b = x(\delta(U_i; U_{\geq i+2})), c = x(\delta(U_{\leq i-1}; U_{i+1}))$, and $d = x(\delta(U_{\leq i-1}; U_{\geq i+1}))$. We have $a + b + c + d = x(\delta^{\text{out}}(U_{\leq i})) = 1$ as $\delta^{\text{out}}(U_{\leq i})$ is the disjoint union of the sets defining a, b, c, d. On the other hand, $\rho \leq x(\delta^{\text{out}}(U_i)) = a + b$ and $\rho \leq x(\delta^{\text{in}}(U_{i+1})) = a + c$. Therefore, $2\rho - 1 \leq (a + b) + (a + c) - (a + b + c + d) \leq a$ so $x(\delta^{\text{out}}(U_i) \cap x(\delta^{\text{in}}(U_i)) \geq 2\rho - 1$. So the cheapest edge $(u, v) \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})$ has $c_{u,v} \leq \frac{1}{2\rho-1} \cdot \sum_{(u',v') \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1}))} c_{u',v'} x_{u',v'}$. ◀

▶ **Proposition 14.** *Let G be the support graph of an optimum solution x to* (LP-ATSPP$_\rho$) *and (y, z) an optimum dual with* $\text{supp}(y)$ *laminar. For any $U \in \text{supp}(y) \cup \{V\}$ and any $u, w \in U$ with w being reachable from u in $G[U]$, there is a $v - w$ path in $G[U]$ that crosses each set $U' \in \text{supp}(y)$ at most twice for $U' \subsetneq U$.*

Again, the proof is the same as that in [17] which only relies on Proposition 12 for $U \in \text{supp}(y)$ (i.e. not on the case $U = V$ that we omitted from the proposition in our setting). We sketch the argument briefly to ensure the reader this still holds with the omission of $U = V$ from Proposition 12.

Proof. Consider any $u - w$ path P contained in $G[U]$. Suppose $U' \in \text{supp}(y)$ is maximal among all such sets where P re-enters U' after it exits U'. Let a be the first node of P in U' and b the last node of P in U' (it could be $a = u$ or $b = v$). Inductively, replace the $a - b$ portion of P with an $a - b$ path in $G[U']$ that enters and leaves every set $U'' \in \text{supp}(y)$ at most once for $U'' \subsetneq U'$. Repeat for all such maximal $U' \in \text{supp}(y)$. ◀

4.1 Constructing the Path

Let OPT_{LP} denote the optimum solution value to (LP-ATSPP$_\rho$). Recall we let α denote an upper bound on the integrality gap of the standard Held-Karp relaxation for ATSP. We will prove the following lemma later.

▶ **Lemma 15.** *An optimal dual solution (y, z) with $\text{supp}(y)$ being laminar and $z_s - z_t \leq \frac{1}{2\rho-1} \cdot OPT_{LP}$ can be computed in polynomial time.*

Using this, we now turn to the main result of this section. Note, we are choosing simplicity in presentation over optimizing the constants in the guarantee.

Proof of Theorem 2. Complementary slackness ensures $x(\delta(U)) = 2\rho$ for each $U \in \text{supp}(y)$ Consider the edge support graph $G = (V, \text{supp}(x))$. Modify G to get an ATSP instance H by adding a new node $\overline{v}$ and edges $(t, \overline{v})$ with cost OPT_{LP} and $(\overline{v}, s)$ with cost 0.

It is easy to check that setting

$$x'_{u,v} = \begin{cases} \frac{1}{\rho} & \text{if } (u,v) \in \{(t,\overline{v}), (\overline{v}, s)\} \\ \frac{x_{u,v}}{\rho} & \text{otherwise} \end{cases}$$

yields a feasible solution for the ATSP-Circuit relaxation from [25] in instance H with cost $\frac{2}{\rho} OPT_{LP}$. Using [25], we can find a circuit W spanning all nodes in H with cost at most $\frac{2\alpha}{\rho} OPT_{LP}$ in polynomial time. This circuit must use the $(t, \overline{v})$ edge at least once as it visits $\overline{v}$. By deleting occurrences of $(t, \overline{v})$ and $(\overline{v}, s)$, we get $s - t$ walks $W_1, \ldots, W_k$ in G that collectively span all nodes in V with $\sum_j c(W_j) \leq \frac{2\alpha}{\rho} \cdot OPT_{LP} \leq 4\alpha \cdot OPT_{LP}$. We also point out $k \leq 4\alpha$ because in removing the k edges incident to $\overline{v}$ to get the walks W_i, we removed a total edge cost of $k \cdot OPT_{LP}$ from a circuit whose cost is at most $4\alpha \cdot OPT_{LP}$, so $k \leq 4\alpha$. The walks $W_1, \ldots, W_\ell$ are depicted in the top of Figure 1.

Let $U_1, \ldots, U_\ell$ be the strongly connected components of the support graph G. For each U_i, let $\mathcal{W}_i = \{j : W_j \text{ visits a node in } U_i\}$ and note $|\mathcal{W}_i| \leq k$. Unlike the case $\rho = 1$ in [17], it could be that $j \notin \mathcal{W}_i$ for some U_i and W_j. For each $1 \leq i \leq \ell$ and each $j \in \mathcal{W}_i$, let $R_{i,j}$ denote the restriction of W_j to U_i. Now, if some W_j enters U_i, then once it leaves it cannot re-enter because U_i is a strongly connected component of G. So $R_{i,j}$ is a single walk for each $j \in \mathcal{W}_i$. For such (i, j), let u^i_j and v^i_j be the first and last nodes of W_j in U_i.

Order $\mathcal{W}_i$ as $j_1 < j_2 < \ldots < j_{|\mathcal{W}_i|}$. By Proposition 14 and the fact each U_i is a strongly connected component, we can find paths P_{i,j_m} for $j_m \in \mathcal{W}_i$ from $v^i_{j_m}$ to $u^i_{j_{m+1}}$ (or u^i_1 if $m = |\mathcal{W}_i|$) where $P_{i,j}$ enters and exits each $U' \in \text{supp}(y)$ with $U' \subsetneq U_i$ at most once and does not cross any other set in $\text{supp}(y)$. Then, for each i we get a circuit C_i spanning all nodes of U_i by adding the paths $P_{i,j}$ for $j \in \mathcal{W}_i$ to the walks $R_{i,j}$.

By Proposition 13, for each $1 \leq i < \ell$ there are edges $u'_i v'_{i+1} \in \delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})$ with cost at most $\frac{1}{2\rho-1}$ times the fractional cost of edges in $\delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})$. Also, say $v'_1 = s$ and $u'_\ell = t$. By fully traversing each C_i starting at v'_i and then continuing to follow it again to reach u'_i, we get $v'_i - u'_i$ walks W'_i spanning U_i. The final path P we output is the concatenation of the walks $W'_1, W'_2, \ldots, W'_\ell$. Let $S = \{v'_i u'_{i+1} : 1 \leq i < \ell\}$ be the edges used to "stitch" these walks W'_i together. The bottom of Figure 1 depicts the final construction of P.

To bound the cost of P, first observe $c(S) \leq \frac{1}{2\rho-1} OPT_{LP}$ as the sets $\delta^{\text{out}}(U_i) \cap \delta^{\text{in}}(U_{i+1})$ are disjoint for $1 \leq i < \ell$. To bound the cost of the cycles C_i, we define a modified cost $c^y_{uv} = \sum_{U : uv \in \delta(U)}$ and observe $c(Q) = z_v - z_u + c^y(Q)$ for any $u - v$ path Q (the z-values for internal nodes of Q cancel).

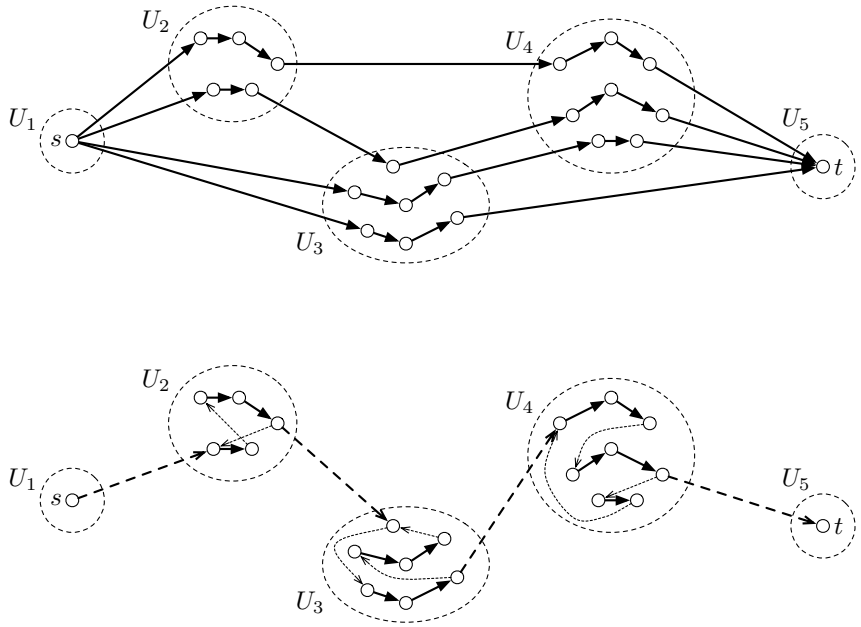

Figure 1

Top: A depiction of $s-t$ walks $W_1, \ldots, W_k$ with $k = 4$ and the strongly-connected components $U_1, \ldots, U_\ell$ with $\ell = 5$.

Bottom: The solid edges are the restrictions of the walks W_i to the strongly-connected components: these are the $R_{i,j}$ walks. The thin dashed edges in each component are the paths $P_{i,j}$ that stitch these $R_{i,j}$ to form a circuit C_i over the strongly connected component U_i. Finally, the dashed edges between components are the edges in S obtained from Proposition 13. The final path P is obtained by visiting the U_i consecutively using these dashed edges, where each visit traverses C_i fully and then travels to the start of the edge exiting U_i.

By complementary slackness, $c_{u,v} = z_v - z_u + c^y_{uv}$ for each $uv \in \text{supp}(x)$. Each C_i was formed by stitching together endpoints of $R_{i,j}$ using paths $P_{i,j}$. Each $P_{i,j}$ crosses each $U' \in \text{supp}(y), U \subsetneq U_i$ at most twice and does not cross any set in $\text{supp}(y)$ not contained in U_i. Further, no two $P_{i,j}, P_{i',j'}$ paths for $i \neq i'$ can cross the same $U' \in \text{supp}(y)$ because the two paths are contained in different components of G.

Each $U' \in \text{supp}(y)$ is crossed by at most k paths of the form $P_{i,j}$ meaning $\sum_{i,j} c^y(P_{i,j}) \leq \sum_{i,j} z_{v^i_j} - z_{u^i_j} + 2k \cdot \sum_U y_U$. We also have $c^y(R_{i,j}) = z_{u^i_j} - z_{v^i_j} + c(R_{i,j})$. Therefore, $\sum_i c^y(C_i) = \sum_i \sum_{j \in \mathcal{W}_{i,j}} c^y(P_{i,j}) + c^y(R_{i,j}) \leq 2k \sum_U y_U + \sum_{i,j \in \mathcal{W}_i} c(R_{i,j}) \leq 2k \sum_U y_U + \sum_j c(W_j)$ (the z terms for the endpoints of the $R_{i,j}$ cancel out in the first inequality).

But $c(C) = c^y(C)$ for any cycle C because, again, the z-terms cancel out. So

$$\begin{array}{rcl} c(P) \leq c(S) + 2 \cdot \sum_i c(C_i) & \leq & \frac{OPT_{LP}}{2\rho - 1} + 2 \sum_{i=1}^k c(W_i) + 2k \sum_U y_U \\ \leq \frac{OPT_{LP}}{2\rho-1} + 4\alpha \cdot OPT_{LP} + 2k \sum_U y_U & \leq & O(1) \cdot \frac{1}{2\rho-1} \cdot OPT_{LP} + \frac{k}{\rho} \left(OPT_{LP} + z_s - z_t \right) \\ \leq \frac{O(1)}{2\rho-1} \cdot OPT_{LP} + \frac{k}{\rho} \cdot (z_s - z_t). & & \end{array}$$

Here, $O(1)$ refers to some constant that is independent of ρ where we also recall k is bounded by a constant as well. Using Lemma 15 to bound $z_s - z_t$ finishes the proof. ◀

4.2 Bounding $z_s - z_t$: Proof of Lemma 15

We prove Lemma 15 to finish the proof of Theorem 2. Our approach is more direct than [17], they used an argument that shifts LP weight around to show that $y_U > 0$ implies U is not an $s-t$ separator in the support graph $G = (V, \text{supp}(x))$. We establish this fact using complementary slackness applied to the LP used to find the optimal solution to DUAL_ρ with minimum possible $z_s - z_t$. We comment that their proof could also be adapted to show what we want, we are presenting this alternative proof because we feel it is more naturally motivated: we already want to minimize $z_s - z_t$ among all optimal duals so it is natural to ask what complementary slackness gives for $y_U > 0$.

Let x be an optimal primal solution to LP-ATSPP$_\rho$. Note that if we restricted the variables of (LP-ATSPP$_\rho$) and the constraints of (DUAL_ρ) to supp(x) then x and (y,z) remains optimal. For any feasible solution (y,z) to (DUAL_ρ), we know $z_t - z_s \le OPT_{LP}$ because $y \ge 0$. So the following LP is bounded. Note, we first solved (LP-ATSPP$_\rho$) to compute OPT_{LP} which is then a fixed value (not a variable) in DUAL_ρ-Z below.

$$\textbf{maximize}: \quad z_t - z_s \qquad (\text{DUAL}_\rho\text{-Z})$$

$$\textbf{subject to}: \quad z_t - z_s + \sum_{\emptyset \subsetneq U \subseteq V - \{s,t\}} 2\rho \cdot y_U \ \ge \ OPT_{LP} \qquad (4)$$

$$z_v - z_u + \sum_{U : uv \in \delta(U)} y_U \ \le \ c_{u,v} \qquad \forall\, u,v \in \text{supp}(x) \qquad (5)$$

$$y \ \ge \ 0.$$

The second constraint asserts (y,z) is a feasible solution for (DUAL_ρ), so the first constraint then asserts it is an optimal solution for DUAL_ρ In fact, in any feasible solution the first constraint must hold with equality. We prove $z_s - z_t \le \frac{1}{2\rho - 1} \cdot OPT_{LP}$ for an optimal solution (y,z) to (DUAL_ρ-Z). With this, we finish the proof of Lemma 15 by simply noting that Proposition 11 shows we can uncross the support of y while leaving z unchanged.

The LP that is dual to (DUAL_ρ-Z) has a variable κ for Constraint (4) of (DUAL_ρ-Z) and new variables x'_{uv} for each instance uv of Constraint (5).

$$\textbf{minimize}: \quad \sum_{uv \in \text{supp}(x)} c_{u,v} \cdot x'_{uv} - OPT_{LP} \cdot \kappa$$

$$\textbf{subject to}: \quad x'(\delta^{\text{out}}(v)) - x'(\delta^{\text{in}}(v)) \ = \ \begin{cases} 1+\kappa & v = s \\ -1-\kappa & v = t \\ 0 & v \ne s,t \end{cases} \qquad \forall\, v \in V$$

$$x'(\delta(U)) \ \ge \ 2\rho \cdot \kappa \qquad \forall\, \emptyset \subsetneq U \subseteq V - \{s,t\}$$

$$x', \kappa \ \ge \ 0.$$

▶ **Lemma 16.** *In an optimal solution (y,z) to $DUAL_\rho$-Z, if $y_U > 0$ then there is an $s-t$ path in the graph $G[V-U]$.*

Proof. Let x' be an optimal solution to the dual of (DUAL_ρ-Z). Then $y_U > 0$ implies $x'(\delta(U)) = 2\rho \cdot \kappa$ so, by flow conservation, $x'(\delta^{\text{in}}(U)) = \rho \cdot \kappa$.

On the other hand, x' constitutes an $s-t$ flow of value $1+\kappa$. Consider a decomposition of x' into paths and cycles. The total weight of paths that do not enter U is at least $1 + \kappa - \rho \cdot \kappa = 1 + (1-\rho) \cdot \kappa > 0$. Thus, there is an $s-t$ path in G that does not pass through U. ◀

Continuing as in [17], let $U_1, \ldots, U_k$ be the maximal sets in $\text{supp}(y)$. In the graph G' obtained by contracting each U_i, we have by Lemma 16 that for each contracted node U_i there is an $s-t$ path in G' that avoids U_i. By a variant of Menger's Theorem (Lemma 9 in [17]), there are node-disjoint $s-t$ paths P_1, P_2 in G'. Consider the edges of P_1 and P_2 in G. For any U_i, at most one of P_1 or P_2 enters (and exits) U_i. Suppose it is the case that one of them $\overline{P} \in \{P_1, P_2\}$ enters U_i. Let u, v be the first and last nodes of $\overline{P}$ as it passes through U_i. By Proposition 14, we can find a $u-v$ path in $G[U_i]$ that crosses each $U' \in \text{supp}(y)$ contained in U at most twice, and does not cross any other set in $\text{supp}(y)$. Add these edges to $\overline{P}$.

Do this for each U_i that is entered by some $\overline{P} \in \{P_1, P_2\}$. We get paths P_1', P_2' using only edges in $\text{supp}(x)$ that, collectively, cross each set in $\text{supp}(y)$ at most twice. Thus, $0 \leq c(P_1) + c(P_2) = c^y(P_1) + c^y(P_2) + 2 \cdot (z_t - z_s) \leq 2 \cdot \sum_{U \in \text{supp}(y)} y_U + 2 \cdot (z_t - z_s)$. Multiplying the terms in this bound by ρ and then subtracting $(2\rho - 1) \cdot (z_t - z_s)$ from both sides, we see $(2\rho - 1) \cdot (z_s - z_t) \leq \sum_{U \in \text{supp}(y)} 2\rho \cdot y_U + z_t - z_s = OPT_{LP}$. ◀

4.3 A Bad Example for (LP-ATSPP$_\rho$)

We show that the dependence on the factor $\frac{1}{2\rho-1}$ in our analysis of the integrality gap of (LP-ATSPP$_\rho$) is asymptotically tight.

Proof of Theorem 3. Consider the following metric depicted in Figure (2), which is inspired from the example showing the integrality gap is unbounded if $\rho = 1/2$ from [12]. The solid edges have cost 0 and the dashed edges have cost 1. The cost of all other edges not depicted is the shortest path distance in this graph (using a cost of 1 if there is no path in this graph). The number beside each edge uv indicates the value of $x_{u,v}$. It can be easily check that this is a feasible solution for (LP-ATSPP$_\rho$) even if we added the constraints $x(\delta^{\text{in}}(v)) = 1$ for each $v \in V - \{s, t\}$. An optimal integral solution must use an edge with cost 1, yet this LP solution only has cost $2\rho - 1$ so the integrality gap of (LP-ATSPP$_\rho$) is at least $\frac{1}{2\rho-1}$. ◀

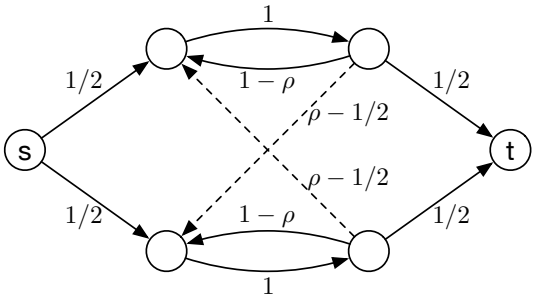

Figure 2 The bad integrality gap example for LP-ATSPP$_\rho$.

5 An Improved Integrality Gap Bound for (LP-ATSPP$_\rho$) in Regret Metrics

Let V be nodes and $s, t \in V$ be the start and end points. Let c be *symmetric* metric distances $c_{u,v} \geq 0$. For each $u, v \in V$, let $c^{\text{reg}}_{u,v} = c_{r,u} + c_{u,v} - c_{r,v}$ be the *regret* metric induced by c. It is convenient to consider a complete directed graph over V where for distinct $u, v \in V$ we have $c_{u,v} = c_{v,u}$ yet (u, v) and (v, u) are themselves distinct edges: the *bidirected* variant of the natural undirected graph associated with (V, c). The following observations about regret metrics can be found in [13].

▶ **Observation 17.** *If c is a metric (asymmetric or symmetric) then c^{reg} is an asymmetric metric. For any $u, v \in V$ and any $u - v$ path P, $c(P) = c^{reg}(P) + c_{u,v}$. For any cycle C, $c(C) = c^{reg}(C)$.*

We consider integrality gap bounds for (LP-ATSPP$_\rho$) when the metric is a regret metric. In [14], it was shown the integrality gap bound is 2 in the standard case $\rho = 1$ and that this is tight. For the purpose of getting better approximations for DirLat in regret metrics (i.e. the problem of minimizing the average time a node v waits *in excess* of their shortest path distance $c_{r,v}$ from the depot), we give explicit integrality gap bounds for the more general case $1/2 < \rho \leq 1$.

Note, in the case $\rho = 1$ that the analysis from [14] produces a stronger result. But the analysis does not extend in any clear way to the case $\rho < 1$. We begin by recalling the following structural result by Bang-Jensen et al about decomposing preflows into branchings [4], which was made efficient by Gabow [15] (see also [22]).

▶ **Theorem 18** (Bang Jensen et al. [4], Gabow [15], Post and Swamy [22])**.** *Let $D = (\{r\} \cup V, A)$ be a directed graph and $x \in \mathbb{Q}^A_{\geq 0}$ be a preflow. Let $\lambda_v := \min_{\{v\} \subseteq S \subseteq V} x(\delta^{\text{in}}(S))$ be the $r - v$ connectivity in D under capacities $\{x_a\}_{a \in A}$. Let $K > 0$ be rational. We can obtain out-branchings $B_1, \ldots, B_q$ rooted at r, and rational weights $\gamma_1, \ldots, \gamma_q \geq 0$ such that $\sum_{i=1}^q \gamma_i = K, \sum_{i: q \in B_i} \gamma_i \leq x_a$ for all $a \in A$, and $\sum_{i: v \in B_i} \geq \min\{K, \lambda_v\}$ for all $v \in V$. Moreover, such a decomposition can be computed in time that is polynomial in $|V|$ and the bit complexity of K and x.*

We require a definition and results from [13], some of which are adaptations of concepts in [6].

▶ **Definition 19.** *Let P be a path starting at s. For each $uv \in P$, say uv is **red** on P if there are nodes x, y on the $s - u$ portion of P_i and $v - t$ portion of i, respectively, such that $c_{r,x} \geq c_{r,y}$. For each $v \in P$, let red(v, P) be the maximal subset of red edges of the subpath of P containing v. Note, red(v, P) could be empty if v is not incident to a red edge. The **red intervals** of P are the maximal subpaths of its red edges.*

Intuitively, the red edges are part of intervals of P that do not make progress toward reaching t. Their total c^{reg}-costs can be shown to be comparable to their total c-costs, which is formalized as follows.

▶ **Lemma 20** (Blum et al [6])**.** *For any $s - t$ path P, $\sum_{uv \text{ red on } P} c_{u,v} \leq \frac{3}{2} c^{reg}(P)$.*

Further, if we were to keep at most one node from each maximal red interval of edges and shortcut past the other nodes, the resulting path $s = v_0, v_1, \ldots, v_k = t$ has $c_{r,v_i} < c_{r,v_{i+1}}$. So the union of any collection of paths that are shortcut in such a way forms an acyclic graph.

Now, a solution to (LP-ATSPP$_\rho$) can be viewed as a preflow of value 1 rooted at s with $\lambda_v \geq \rho$ for each $v \in V - t$ and $\lambda_t = 1$. From this observation, we round a solution using techniques from [13]. The full description is in Algorithm 2. Here, $1/2 < \delta < \rho$ is some parameter we set later to optimize the performance of the algorithm.

▶ **Lemma 21.** *The paths P_i from Step 2 satisfy $\sum_i \gamma_i \cdot c^{\text{reg}}(P_i) \leq 2 \cdot OPT_{LP}$.*

Proof. In [13], it is observed for any $s - t$ path P that $c^{\text{reg}}(P) = c(P) - c_{s,t}$ and that $c(C) = c^{\text{reg}}(C)$ for any cycle C. Thus, as x is an $s - t$ flow with value 1 we have $OPT_{LP} = \sum_{uv} c^{\text{reg}}_{u,v} x_{u,v} = (\sum_{uv} c_{u,v} x_{u,v}) - c_{s,t}$. This can be seen by, say, comparing the c^{reg}-cost with the c-cost of paths and cycles in a path/cycle decomposition of x.

Algorithm 2 Rounding (LP-ATSPP$_\rho$) in regret metrics.

Input: asymmetric metric $(V \cup \{r\}, c^{\text{reg}})$ obtained from symmetric distances c.
Output: an Hamiltonian $s-t$-rooted path P.

R1. Solve (LP-ATSPP$_\rho$) to get an optimal extreme point solution x with value OPT_{LP}.

R2. Use Theorem 18 to find a convex combination of out-branchings $B_1, \ldots, B_q$ rooted at s and weights $\gamma_1, \ldots, \gamma_q \geq 0$ summing to 1 such that t lies on each B_i and each $v \in V - \{s,t\}$ lies on at least a ρ-fraction of these branchings. Turn each B_i into a $s-t$ path P_i by adding the reverse (v,u) of each arc $(u,v) \in B_i$ that does not appear on the unique $s-t$ path in B_i and shortcutting the resulting Eulerian $s-t$ walk past repeated nodes.

R3. Define a cut requirement function $f : 2^V \to \{0,1\}$ where $f(S) = 1$ if $\sum_{i:\text{red}(v,P_i) \subseteq S} \gamma_i < \delta$ for all $v \in S$. Observe f is downward-monotone: $f(S) \geq f(T)$ for sets $\emptyset \subsetneq S \subseteq T$. Use the LP-based 2-approximation in [16] to find a forest of undirected edges F such that $|\delta(S) \cap F| \geq f(S)$. Let $\mathcal{C}$ be the components of F and let $C_1, \ldots, C_{|C|}$ be cycles on each component of F obtained by doubling and shortcutting each tree in F. For each cycle C_j of $\mathcal{C}$, let $w \in C_i$ be some *witness node* such that $\sum_{i:\text{red}(w,P_i) \subseteq V} \gamma_i \geq \delta$. Let W be the set of all witness over all C_j (note, it could be $W \cap \{s,t\} \neq \emptyset$). View each C_j as being traversed in some arbitrary direction.

R4. For each P_i, let P_i^W be the set of all nodes in $W \cap P_i$ such that all nodes of $\text{red}(w, P_i)$ are contained in the nodes of a single cycle C_j. Shortcut P_i past nodes not in $P_i^W \cup \{s,t\}$ and call this path P_i'. Note the nodes of P_i' lie in $W \cup \{s,t\}$.

R5. View P_i' with associated weights γ_i/δ as the path decomposition of an acyclic $s-t$ flow z with value $1/\delta$ with $z(\delta(w)) \geq 1$ for each $w \in W$. Further, $z(\delta^{\text{out}}(s)) = 1/\delta < 2$. By integrality of flows with upper- and lower-bounds on each node, we may decompose z as a convex combination of integral flows satisfying these bounds such that each flow supported consists of either 1 or 2 paths. Let P be the cheapest path among the flows with only one path in this decomposition. Note that P is an $s-t$ path spanning all of W.

R6. Complete P into a Hamiltonian $s-t$ path by adding all edges of the cycles C_i and shortcutting the resulting Eulerian walk.

Each P_i is obtained by adding the reverse of each edge uv of B_i not on the $s-t$ path in B_i (and then shortcutting the resulting Eulerian walk). Thus, $c(P_i) \leq 2 \cdot c(B_i) - c_{s,t}$ so $c^{\text{reg}}(P_i) \leq 2 \cdot (c(B_i) - c_{s,t})$. Thus, $\sum_i \gamma_i \cdot c^{\text{reg}}(P_i) \leq 2 \cdot \sum_i \gamma_i \cdot (c(B_i) - c_{s,t}) = (2 \cdot \sum_i \gamma_i \cdot c(B_i)) - 2 \cdot c_{s,t}$. Now, the convex combination of the B_i is dominated by x, so $\sum_i \gamma_i \cdot c(B_i) \leq \sum_e x_e \cdot c_e$. Finally, as x constitutes one unit of $s-t$ flow, the c-cost of x differs from the c^{reg}-cost of x exactly by $c_{s,t}$, so we finally see $\sum_i \gamma_i \cdot c^{\text{reg}}(P_i) \leq 2 \cdot OPT_{LP}$. ◀

The proofs of the following two lemmas proceed in a way that is very similar to related results [13] (though, their end goal was quite different). We defer their proofs to the end of this section.

▶ **Lemma 22.** *In Step 2, the function f is downward-monotone and $\sum_j c^{reg}(C_j) \leq \frac{6}{\rho - \delta} OPT_{LP}$.*

▶ **Lemma 23.** *The graph over V with edges $\cup_{i=1}^q P_i'$ is an acyclic graph. Further, for each $w \in W$ we have $\sum_{i:w \text{ lies on } P_i'} \gamma_i \geq \delta$. Finally, $\sum_{i=1}^q c^{reg}(P_i') \leq 2 \cdot OPT_{LP}$.*

We now describe how to complete the analysis.

▶ **Lemma 24.** *In Step 5, the flow z has acyclic support, sends $1/\delta$ units of flow from s to t, and has $z(\delta^{\text{in}}(w)) \geq 1$ for each $w \in W$. The resulting path P has cost $\frac{2}{2\delta - 1} \cdot OPT_{LP}$.*

Proof. We have $\sum_i \gamma_i/\delta = 1/\delta$. As each P_i' is an $s-t$ flow, we have z given by $z_{uv} = \sum_{i:uv \in P_i} \gamma_i/\delta$ is an $s-t$ flow of value $1/\delta$. Then by Lemma 23, the support of z is acyclic, $z(\delta^{\text{in}}(w)) \geq 1$ for each $w \in W$, and $\sum_{uv} c^{\text{reg}}_{u,v} z_{uv} \leq \frac{2}{\delta} \cdot OPT_{LP}$.

By integrality of flows with integral lower- and upper-bounds on the flow through each vertex, z may be decomposed into a convex-combination of integral flows f satisfying the lower-bound $f(\delta^{\text{in}}(w)) \geq 1$ for each $w \in W$ and $1 \leq f(\delta^{\text{out}}(s)) \leq 2$. Furthermore, the fraction of these flows f with $f(\delta^{\text{out}}(s)) = 1$ is exactly $2 - 1/\delta$, so the c^{reg}-cost of one such flow is at most $\frac{1}{2-1/\delta}\frac{2}{\delta} \cdot OPT_{LP} = \frac{2}{2\delta-1} \cdot OPT_{LP}$. Such a flow f has no cycles because the support of z is acyclic, so the edges supported by f form an $s-t$ path spanning all $w \in W$. ◀

The final path is formed from grafting the cycles $C_1, \ldots, C_{|\mathcal{C}|}$ into P, so the above results yield the following.

▶ **Theorem 25.** *The final path computed in Step 6 is a Hamiltonian $s-t$ path with c^{reg}-cost at most $\left(\frac{6}{\rho-\delta} + \frac{2}{2\delta-1}\right) \cdot OPT_{LP}$.*

Proof. By Lemma 24, the path P is an $s-t$ path spanning W with c^{reg}-cost at most $\frac{2}{2\delta-1} \cdot OPT_{LP}$. Each cycle C_j over a component in $\mathcal{C}$ contains precisely one node in W, so the graph $P \cup_{j=1}^{|\mathcal{C}|} C_j$ has an Eulerian $s-t$ walk that visits all nodes. By Lemma 22, the total c^{reg}-cost of all cycles is at most $\frac{6}{\rho-\delta} \cdot OPT_{LP}$. The result follows because shortcutting this Eulerian walk to get a Hamiltonian path does not increase the cost of the walk, by the triangle inequality. ◀

By setting $\delta = \frac{(2\sqrt{6}-1)\cdot\rho+6-\sqrt{6}}{10}$ (which optimizes the parameter), we get our main result showing the integrality gap is at most $\frac{300}{42-12\sqrt{6}} \cdot \frac{1}{2\rho-1} \approx \frac{23.8}{2\rho-1}$.

Proof of Lemma 22. That f is downward monotone is direct from the definition. We construct a vector x' over edges the undirected complete graph with nodes V with edge costs c. That is, for each undirected edge uv let $x'_{uv} = \frac{1}{\rho-\delta} \sum_{\substack{i: uv \text{ or } vu \\ \text{is red on } P_i}} \gamma_i$. We first claim $x'(\delta(S)) \geq f(S)$ for each $\emptyset \subsetneq S \subseteq V$. That is, suppose S is such that $f(S) = 1$ and let v satisfy $\sum_{i:\text{red}(v,P_i)\subseteq V} \gamma_i < \delta$. Since v lies on a ρ-fraction of paths in total, this means a $(\rho-\delta)$-fraction of paths P_i have some edge of $\text{red}(v, P_i)$ crossing S, as required.

From Lemma 20, the total c-cost of all red edges on P_i is at most $\frac{3}{2}c^{\text{reg}}(P_i)$. Thus, $\sum_{uv} c_{u,v}x'_{uv} \leq \frac{3}{2}\frac{1}{\rho-\delta}OPT_{LP}$. From using the LP-based 2-approximation in [16], the c-cost of the result forest is then at most $\frac{3}{\rho-\delta}OPT_{LP}$. By doubling the edges to get the cycles C_j, $\sum_j c(C_j) \leq \frac{6}{\rho-\delta}OPT_{LP}$. Finally, we chose an arbitrary direction for traversing each C_j but the c^{reg}-cost of a directed cycle is the same as its c-cost, so the result follows. ◀

Proof of Lemma 23. We claim that we do not keep two nodes from any red interval for each P_i when we form P'_i. But this is immediate from the fact that no cycle C_j contains two nodes of W.

By the definition of red intervals, any path P' obtained from a path P by shortcutting past all but one node in each red interval yields has its nodes appearing in strictly distance-increasing order. So, the P'_i paths all start at the same location, all end at the same location, and their internal nodes strictly increase in distance from s. So the union of all P'_i is an acyclic graph.

Now, consider some $w \in W$ and say it lies on cycle C_j. At least a δ-fraction of paths P_i spanning w satisfy $\text{red}(w, P_i) \subseteq C_j$ because $f(V(C_j)) = 0$, so each $w \in W$ lies on at least a δ-fraction of paths P'_i.

Since P'_i are obtained by shortcutting nodes from P_i, $\sum_{i=1}^{q} c^{\text{reg}}(P'_i) \leq \sum_{i=1}^{q} c^{\text{reg}}(P_i) \leq 2 \cdot OPT_{LP}$ by Lemma 21. ◀

A Reduction to Instances with Polynomially-Bounded Integer Distances

▶ **Theorem 26.** *For any constant $\epsilon > 0$, if there is an $\alpha(n)$-approximation for instances of* DirLat *where each $c_{u,v}$ is a positive integer bounded by a polynomial in n and $1/\epsilon$ and where $c_{u,v} \geq 1$ for nodes $u \neq v$, then there is an $(\alpha(n) + \epsilon)$-approximation for general instances of* DirLat.

Proof. Compute a value ν such that $OPT \leq \nu \leq n^2 \cdot OPT$ where OPT is the optimum solution to the given DirLat instance. For example, ν could be the smallest value such that all nodes can be covered by a single walk in the graph $G_\nu = (V + r, E_\nu)$ consisting of directed edges $E_\nu = \{uv : c_{u,v} \leq \nu\}$. This can be checked, for example, by contracting the strongly-connected components of G_ν and checking if topologically sorting the resulting directed acyclic graph results in a single chain of components with the root in the first component.

Now, the case $OPT = 0$ can detected in polynomial time as this is equivalent to checking if the strongly-connected components of the graph using only distance-0 edges forms a chain. So we assume $OPT > 0$, thus $\nu > 0$. We then assume $c_{u,v} \geq \epsilon \cdot \nu/n^3$ by increasing any distance that is smaller to this amount: the distances remain metric and the latency of any node on the optimum solution increases by at most $n \cdot \nu \leq \epsilon \cdot OPT/n$, so the total latency increases by at most $\epsilon \cdot OPT$.

Next, we may assume all distances satisfy $c_{u,v} \leq (\alpha(n) + 2\epsilon) \cdot \nu$ for the following reason. Suppose we update each distance $c_{u,v} > (\alpha(n) + 2\epsilon) \cdot \nu$ with $c_{u,v} = (\alpha(n) + 2\epsilon) \cdot \nu$. It is easy to check these updated distances also form a metric. The optimum solution cost is still OPT because no edge used by the optimum solution has its length shortened (as $\nu \geq OPT$). Also, note a solution P with $c(P) \leq (\alpha(n) + \epsilon) \cdot OPT$ will only use edges uv where $c_{u,v} < (\alpha(n) + 2\epsilon) \cdot \nu$. So an $(\alpha + \epsilon)$-approximation in the metric with these truncated distances yields an $(\alpha + \epsilon)$-approximation for the original distances.

Next, for all $u, v \in V + r$ let $d''(u, v) = \left\lfloor c_{u,v} \cdot \frac{n^4}{\nu \cdot \epsilon} \right\rfloor$. Let d' be the shortest path metric using edge distances given by d''. Let OPT' denote the optimum solution to DirLat instance with distances d'. Observe

$$d'(u, v) \leq d''(u, v) \leq \frac{n^4}{\nu \cdot \epsilon} c_{u,v}.$$

Furthermore, $c_{u,v} \leq (\alpha(n) + 2\epsilon) \cdot \nu$ for each edge uv means $d'(u, v) \leq \frac{n^4}{\epsilon} \cdot (\alpha(n) + \epsilon)$. So all distances under d' are polynomially-bounded integers. We also see $OPT' \leq \frac{n^4}{\nu \cdot \epsilon} \cdot OPT$ by consider an optimum solution to the original instance, but under the new distances d'.

Now consider a solution P with $d'(P) \leq \alpha(n) \cdot OPT'$. As d' is a metric, we may assume P is a Hamiltonian path so P traverses n edges. By replacing each edge in P with its shortest path using distances d'', we obtain a walk W with $d''(W) = d'(P) \leq \alpha(n) \cdot OPT'$. For each edge uv, we have $d''(u,v) + 1 \geq c_{u,v} \cdot \frac{n^4}{\nu \cdot \epsilon}$. So the cost of W under d can be bounded as follows where sums over edges in W include as many terms of uv as its multiplicity in W.

$$\begin{aligned} c(W) &\leq \frac{\epsilon \cdot \nu}{n^4} \cdot \sum_{uv \in W} (d''(u,v) + 1) \\ &= \frac{\epsilon \cdot \nu}{n^4} \cdot (d''(W) + |W|) \\ &\leq \frac{\epsilon \cdot \nu}{n^4} \cdot (\alpha(n) \cdot OPT' + |W|) \\ &\leq \alpha(n) \cdot OPT + \frac{\epsilon \cdot \nu}{n^2} \\ &\leq (\alpha(n) + \epsilon) \cdot OPT. \end{aligned}$$

The last two bounds use $|W| \leq n \cdot |P| \leq n^2$ and $\nu \leq n^2 \cdot OPT$. ◀

On Compact RAC Drawings

Abstract

We present new bounds for the required area of Right Angle Crossing (RAC) drawings for complete graphs, i.e. drawings where any two crossing edges are perpendicular to each other. First, we improve upon results by Didimo et al. [15] and Di Giacomo et al. [12] by showing how to compute a RAC drawing with three bends per edge in cubic area. We also show that quadratic area can be achieved when allowing eight bends per edge in general or with three bends per edge for p-partite graphs. As a counterpart, we prove that in general quadratic area is not sufficient for RAC drawings with three bends per edge.

1 Introduction

Graphs that appear in real-world applications are in fact mostly nonplanar. Experiments on the human perception of graph drawings indicate that two important parameters affecting readability are angles formed by two edges at their crossing points (the larger the better) [20, 21] as well as the number of bends along an edge (the fewer the better) [24, 25]. The first theoretical drawing model that has taken these experimental results into account is the so-called *RAC* (or *right-angle-crossing*) drawing introduced in [15]. In some sense, the RAC model generalizes the popular orthogonal graph drawing model [17]. Formally, a RAC drawing is a node-link drawing of a graph, in which edges are drawn as polylines so that the angles formed at the crossing points of two edges are always equal to $\pi/2$. Since a RAC drawing is a geometric embedding, in most studies on RAC drawings the number of bends per edge has also been taken into account. In the following, we denote a RAC drawing with at most k bends per edge as a *RAC_k drawing*.

Many main research questions of graph drawing have been studied for RAC drawings. Regarding their density, already Didimo et al. [15] showed that graphs admitting straight-line RAC drawings have at most $4n-10$ edges, which is a tight bound. They also showed that the density for graphs admitting RAC_1 or RAC_2 drawings is subquadratic, whereas all graphs admit a RAC_3 drawing. Subsequently, Arikushi et al. [6] showed that graphs admitting a RAC_1 drawing can only have $6.5n-13$ edges, while graphs admitting RAC_2 drawings can have at most $74.2n$ edges; the former bound for RAC_1 drawings was recently improved by Angelini et al. [2] to $5.5n-11$. The recognition problem for graphs admitting straight-line RAC drawings is known to be NP-hard [5], even in the case where the resulting drawing must

Table 1 Overview of area bounds on RAC drawings of general graphs.

Known Results			**Our New Results**	
RAC_3:	$\mathcal{O}(n^4)$	[15]	RAC_3:	$\mathcal{O}(n^3)$
RAC_4:	$\mathcal{O}(n^3)$	[12]	RAC_3 (p-partite):	$\mathcal{O}(p^4n^2)$
$RAC_{\geq 3}$:	$\Omega(n^2)$	[15]	RAC_3:	$\omega(n^2)$
RAC_6:	$\mathcal{O}(n^{2.75})$	[26]	RAC_8:	$\mathcal{O}(n^2)$

be upward [3] or 1-planar [8]. Note that a k-planar graph is a graph which admits a drawing where every edge is crossed at most k times. While the recognition of graphs admitting RAC_3 drawings is trivial, the corresponding problem for graphs admitting RAC_1 or RAC_2 drawings is yet unsettled. Curiously, the maximally dense graphs admitting straight-line RAC drawings have been shown to be 1-planar [18]. In addition, subclasses of 1-planar graphs have been investigated: Brandenburg et al. [9] proved that all IC-planar graphs admit a straight-line RAC drawing, which has been shown to be not true for NIC-planar graphs [7]. IC-planar and NIC-planar graphs are graphs with a 1-planar drawing where the set of vertices involved in a crossing shares at most zero and one vertices with the set of vertices involved in a different crossing, respectively. Di Giacomo et al. [11] and Hong and Nagamochi [19] studied variants of RAC drawings with restricted vertex positioning in the straight-line setting. Angelini et al. [3] showed that all graphs of maximum degree three admit a RAC_1 drawing, whereas graphs of maximum degree six admit a RAC_2 drawing.

To evaluate the area of RAC drawings, vertices and bends are assumed to be located on an integer grid. The area of a drawing then is the product of the number of horizontal and vertical grid lines appearing in a bounding axis-aligned rectangle. It is known that even planar graphs may still require quadratic area in any straight-line RAC drawing [3]. Recently, Chaplick et al. [10] showed that NIC planar graphs admit RAC_1 drawings in polynomial area, whereas 1-planar graphs admit RAC_2 drawings in polynomial area. The drawing algorithm by Didimo et al. [15] achieves RAC_3 drawings in $\mathcal{O}(n^4)$ area. Subsequently, Di Giacomo et al. [12] improved the area to $\mathcal{O}(n^3)$ for RAC_4 drawings and Rahmati and Emami [26] recently achieved $\mathcal{O}(n^{2.75})$ area for RAC_6 drawings. For the closely related family of *LAC graphs* (short for *large-angle-crossing*), in which edges may cross at angles at least $\pi/2 - \varepsilon$ for some small $\varepsilon > 0$, Di Giacomo et al. [12] also showed that the complete graph on n vertices admits a drawing with one bend per edge in $\mathcal{O}(n^2(\cot \varepsilon/2)^2)$ area, which can be assumed to be $\mathcal{O}(n^2)$ area for fixed values of ε. Note however that for very small values of ε such as $\pi/180$, the multiplicative constant is very large and may therefore be infeasible in practise. For further results on LAC drawings see also [4, 16].

It is noteworthy that these drawing algorithms only place vertices and bends on an integer grid while crossings may occur on non-grid points. The positions of crossings are implicitly defined by the positions of endpoints of the intersecting segments. Since by the crossing lemma [1, 22] there are $\Omega(n^4)$ crossings in the complete graph K_n, it is impossible to achieve an area bound of $o(n^4)$ if also the crossings are required to be on the grid. In the variant where crossings are located on the grid, the algorithm by Didimo et al. [15] for RAC_3 drawings in $\mathcal{O}(n^4)$ area yields optimal solutions. We emphasize that it is not trivial to compute RAC drawings with $\mathcal{O}(n^2)$ area with additional bends as only $\mathcal{O}(1)$ bends per edge can fit in $\mathcal{O}(n^2)$ area. Finally, tradeoffs between area and planar thickness [14] as well as number of crossings per edge [13] also have been investigated.

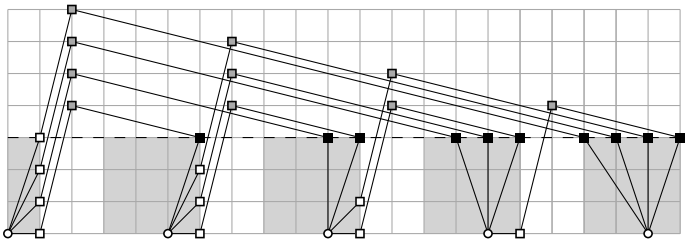

Figure 1 RAC_3 drawing of K_5 in 21×7 area.

We emphasize that we study *simple* graphs on n vertices, i.e., graphs without self-loops and parallel edges. The restriction to simple graphs is common in this line of research as each edge connecting the same vertices must be assigned distinct positions for its bends. In Section 2, we give new area upper bounds. We prove that every graph admits a RAC_3 drawing in $\mathcal{O}(n^3)$ area improving the known bound by a factor of n. Also, we show that even $\mathcal{O}(n^2)$ area can be achieved when eight bends per edge are allowed or when the input graph is p-partite. Then, in Section 3, we prove that quadratic area cannot be achieved in general for RAC_3 drawings. See also Table 1 for an overview of our new results compared to results from the literature. We conclude the paper with some open problems.

2 New Area Upper Bounds for RAC Drawings

▶ **Theorem 1.**

1. *Every n-vertex graph $G = (V, E)$ admits a RAC_3 drawing in $\mathcal{O}(n^3)$ area.*
2. *Every n-vertex graph $G = (V, E)$ admits a RAC_8 drawing in $\mathcal{O}(n^2)$ area.*
3. *Every p-partite n-vertex graph $G = (V, E)$ admits a RAC_3 drawing in $\mathcal{O}(p^4 n^2)$ area.*

Proof (of Result 1). Our algorithm is a refinement of the algorithm by Didimo et al. [15]. Note that it is easy to see that the drawings produced by the algorithm in [15] require $\Theta(n^4)$ area as two bends for each edge are located on a horizontal line.

For an example of a drawing of K_5 refer to Fig. 1. The vertices and the segments incident to vertices are drawn planar in a disjoint region of quadratic area for each vertex; see the gray regions in Fig. 1. In contrast to [15], each vertex (except for the outermost two) is incident to two types of bends (white and black squares in Fig. 1) which lead to vertices with larger and smaller indices, resp. The remaining two segments of edges use nearly horizontal or nearly vertical slopes.

We number the vertices arbitrarily from 0 to $n-1$. We place vertex v_i at position $(i \cdot n, 0)$; see white disks in Fig. 1. The three bends of edge (v_i, v_j) with $i < j$ are placed as follows: Bend $a_{i,j}$ connected to v_i is placed at $(i \cdot n + 1, j - i - 1)$; see white squares in Fig. 1. The middle bend $b_{i,j}$ is placed at $(i \cdot n + 2, n + j - i - 2)$; see gray squares in Fig. 1. Bend $c_{i,j}$ connected to v_j is placed at $(j \cdot n - j + i + 2, n - 2)$; see black squares in Fig. 1.

It remains to show that the resulting drawing is indeed RAC. Consider the start segments incident to vertex v_i, i.e., segments of types $(v_i, a_{i,j})$ for $(v_i, v_j) \in E$ and $(v_i, c_{j,i})$ for $(v_j, v_i) \in E$. Together with v_i they form a *fan* and do not intersect each other as the bend points of types $a_{i,j}$ and $c_{j,i}$ are distinct. Note that while $a_{0,n-1}$ is located at $(1, n-2)$, for other vertices v_i the bend $c_{i-1,i}$ is located at $(i \cdot n + 1, n - 2)$. These fans are drawn in disjoint *start regions* (gray shaded areas in Fig. 1); more precisely, the fan of v_i is located within a rectangle ranging from 0 to $n-2$ in y-direction and from $(i-1) \cdot n + 3$ to $i \cdot n + 1$ in x-direction. Since all segments $(b_{i,j}, c_{i,j})$ are located above the start regions and because

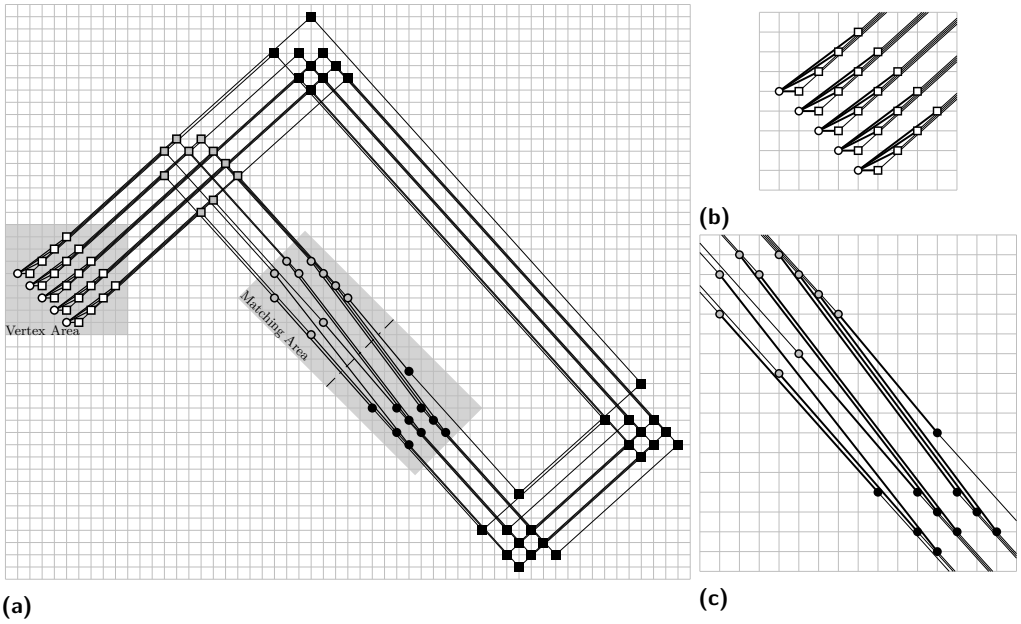

Figure 2 (a) RAC_8 drawing of K_5 in 55×47 area, (b)–(c) zoom into vertex and matching area.

segments $(a_{i,j}, b_{i,j})$ are located between x-coordinates $i \cdot n + 1$ and $i \cdot n + 2$ (i.e., they are located between two start regions), there are no crossings within start regions. As all crossings occur between segments of type $(a_{i,j}, b_{i,j})$ (which have slope $n - 1$) and $(b_{i,j}, c_{i,j})$ (which have slope $-1/(n-1)$), all proper crossings are at right angles.

It remains to prove that there are no overlaps. Recall that bend points in each start region are distinct, hence, we consider only the remaining segments. Segments of edges with a common endpoint cannot overlap. As the regions containing edges $(a_{i,j}, b_{i,j})$ and $(a_{k,l}, b_{k,l})$ for $i \neq k$ are disjoint, overlaps may only occur at segments $(b_{i,j}, c_{i,j})$ and $(b_{k,l}, c_{k,l})$ for some $i \neq k$. Since both segments have the same slope and their crossings with the horizontal at $y = n - 2$ (dashed in Fig. 1) are distinct (i.e., $c_{i,j}$ and $c_{k,l}$), they also do not overlap.

As the lowest x- and y-coordinates are both 0 whereas the largest x- and y-coordinates are $(n-1)n + 1$ and $2n - 3$, resp., the area bound follows.

Proof (of Result 2). We describe how to draw K_n for odd n in quadratic area. For even n, refer to the construction of K_{n+1}. For an example of a drawing of K_5 refer to Fig. 2. We number the vertices arbitrarily from 0 to $n - 1$. The general idea is as follows: vertices and start segments are located in the *vertex area* such that each start segment bend is connected to a segment whose slope is slightly less than 1; see Fig. 2b. Edges are treated as two half edges that are routed to the *matching area* independently with segments of slopes s and $-1/s$. One half edge is routed to the top left half of the matching area (gray bends in Fig. 2a) and the other half edge is routed to the bottom right half (black bends in Fig. 2a). In the matching area half edges are matched crossing-free realizing an edge for each pair of vertices; see Fig. 2c. We point out that in principle each half edge may be routed to either half of the matching area. When we define the matching of the bends in the matching area, we will show which half edges have to be routed to which half of the matching area.

We place vertex v_i at position $(i, -i)$; see white circles in Fig. 2b. Let e_i^j be the j-th half edge incident to vertex v_i for $0 \leq j < n - 2$. We place the bend of e_i^j that is closest to v_i at $(i + j + 1, j - i)$; see white squares in Fig. 2b. Bends incident to the same vertex v_i are

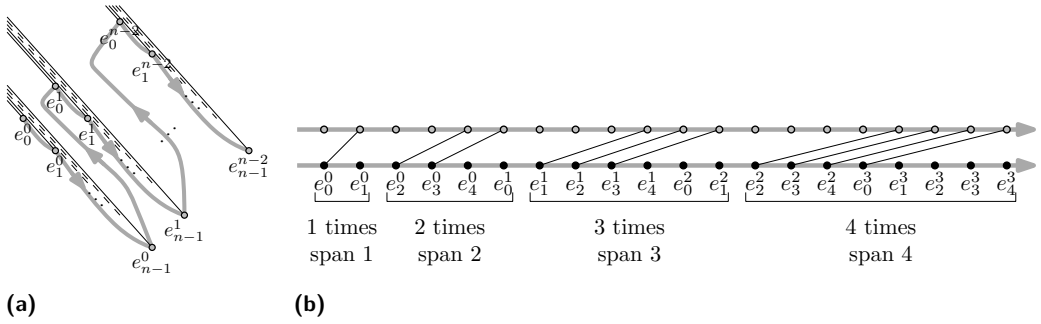

Figure 3 (a) Accessability of matching bends in the top left half of the matching area, and (b) matching assignment for $n = 5$ used for the drawing in Fig. 2.

located on a diagonal of slope 1 and all start segments of v_i are above this diagonal. Since v_i is located below the diagonal of vertex v_{i-1}, start segments do not intersect each other and all $n \cdot (n-1)$ start segment bends are within a rectangle of quadratic area tilted by $\pi/4$.

We choose $s = (2n-1)/2n$ achieving the following: If $n \cdot (n-1)$ bends are located in a rectangle R as defined by the start segment bends and a segment of slope s is added to each of these points, the next integer point used by any of those segments is located outside of R. This procedure "copies" the bends at $k \cdot 2n$ horizontal and $k \cdot (2n-1)$ vertical distance for $k \in \mathbb{Z}$. A similar property holds for segments of slope $-1/s$. Further, since s is slightly less than 1 and start segments are above the line of slope 1 through start segment bends, those additional segments of slope s do not intersect any start segment; see Fig. 2b. In the matching area all bends in the top left (bottom right, resp.) half are accessible from the bottom right (top left, resp.) without intersections; see Fig. 2c.

Next, we define the bend points of half edge e_i^j leading from vertex to matching area. Recall that the bend in the vertex area (white squares in Fig. 2a) is at $(i+j+1, j-i)$. If e_i^j is routed to the top left half of the matching area, we place one bend at $(2n+i+j+1, 2n+j-i-1)$ (gray squares in Fig. 2a) and enter the matching area with a bend at $(4n+i+j, j-i-1)$ (see gray circles in Fig. 2a). If e_i^j is routed to the bottom right half of the matching area, we instead create a sequence of three bends at $(4n+i+j+1, 4n+j-i-2)$, $(10n+i+j-2, -2n+j-i-2)$ and $(8n+i+j-2, -4n+j-i-1)$ (see black squares in Fig. 2a) and enter the matching area with a bend at $(6n+i+j-1, -2n+j-i-1)$ (see black circles in Fig. 2a). The leftmost x-coordinate is 0 (for vertex v_0), while the rightmost one is $12n-5$ (for a bend of e_{n-1}^{n-2}). Conversely, the topmost y-coordinate is $5n-4$ (for a bend of e_0^{n-2}) while the bottommost one is $-5n$ (for a bend of e_{n-1}^0). Hence, the drawing requires $(12n-5) \times (10n-3)$ area.

It remains to show that *matching segments* between matching bends are crossing-free. Consider the accessibility of matching bends from the other half of the matching area: Each matching bend in the top left half of the matching area is accessible from below the diagonal of slope -1 passing through it, since from above its incident segment of slope $-1/s$ is forming an obstacle. A similar statement is true for matching bends in the bottom right half of the matching area. We can use this observation to define an ordering of the matching bends based on their accessability. The first accessible matching bend is of half edge e_0^0; i.e., incident to v_0, the second is of e_1^0; i.e., incident to v_1. This pattern continues increasing in i until all e_i^0 are encountered; see Fig. 3a. Afterwards, all e_i^1 are encountered, in increasing order of i. This pattern repeats increasing in j, until all half edges e_i^j are encountered, in increasing order of i; see Fig. 3a.

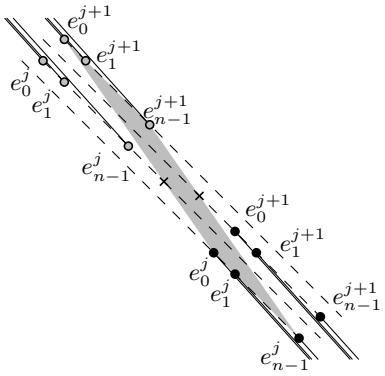

Figure 4 Area for drawing matching segments of half edges e_i^j and e_k^{j+1}.

We use the two linear orders of matching bends to define a planar matching between both halves of the matching area. Note that both linear orders are identical; see Fig. 3b. The matching that we define has two properties: First, the distance between matched bends in the linear order is bounded by $n-1$. Second, the matching ensures that every pair of vertices is connected exactly once. We now describe the specific matching: First, we connect the first matching bend of the bottom right half of the matching area with the second matching bend of the top left half of the matching area. Then, we connect the next two matching bends of the bottom right half of the matching area with the following two matching bends of the top left half of the matching area. We continue this pattern while always increasing the size of the groups of matched pairs by one which also increases the *span* of the matching segments, i.e., the distance between the connected matching bends in the linear order; see Fig. 3b. Then, there are exactly k matching segments of span k for all values $1 \leq k \leq n-1$. A matching segment of span k connects a vertex v_i whose bend is in the bottom right half of the matching area with vertex $v_{(i+k) \bmod n}$, i.e. with the neighbor whose index is k larger in the cyclic order of vertices. We prove that every pair of vertices is matched exactly once using that n is odd and that therefore the distance of vertices in the cyclic order is at most $(n-1)/2$. Due to cyclicity, segments with span $n-k > (n-1)/2$ correspond to a connection from vertex v_i in the top left half of the matching area to vertex $v_{(i-(n-k)) \bmod n} = v_{(i+k) \bmod n}$, i.e. again to the neighbor whose index is k larger in the cyclic order of vertices. Hence, for $k \leq (n-1)/2$, there are k segments of span k and $n-k$ segments of span $n-k$, which means that in total n vertices are matched to their neighbors whose indices are k larger. In order to see that all of them are distinct, we apply a recursive argument: Clearly, this is true for $k=1$. Assume that all matching segments of spans k and $n-k$ had different neighbors, then remove the matched bends that were matched with span k ($n-k$, resp.) from the left (right, resp.) end of the linear order. In total, we remove $2n$ vertices each from the ends of both linear orders, i.e., $2k$ from the left and $2(n-k)$ from the right, before finding the segments of spans $k+1$ and $n-(k+1)$. Thus, their endpoints differ.

Finally, we show that the matching segments are planar straight-line segments. First observe that since the span of segments is at most $n-1$, half edge e_i^j is matched with a half edge e_k^ℓ for $\ell \in \{j, j+1\}$. Further, notice that the diagonal on which the matching bends of the j-th half edges in the top left half of the matching area are located is halfway in between the corresponding diagonals for the matching bends of the j-th and $j+1$-th half edges in the bottom right half; see Fig. 4. We show that the intersection of the line through the bend of e_0^{j+1} in the top left half and the bend of e_0^j in the bottom right half of the matching area crosses the diagonal through the bends of e_0^j and e_{n-1}^j in the top left half of the matching

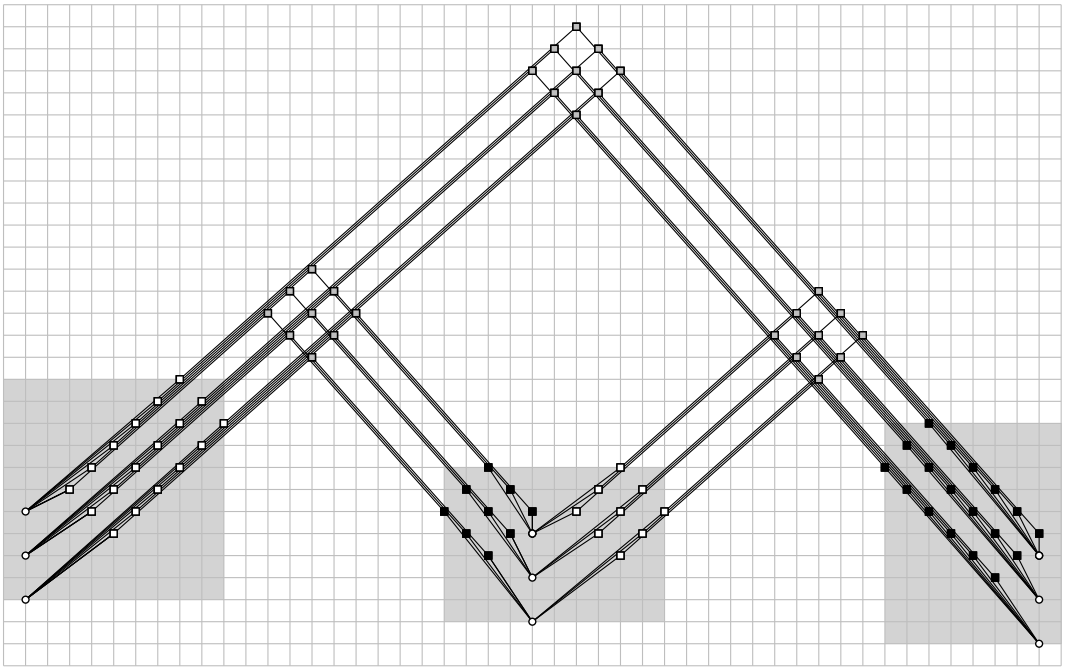

Figure 5 RAC_3 drawing of $K_{3,3,3}$ in 46×28 area.

area to the right of the bend of e^j_{n-1}; see crosses in Fig. 4. A symmetric property follows for bottom right half and consequently, segments between the j-th and $j+1$-th half edge are crossing-free. The first line goes through points $(4n+j+1, j)$ (bend of e^{j+1}_0 in the top left half of the matching area) and $(6n+j-1, -2n+j-1)$ (bend of e^j_0 in the bottom right half of the matching area) and hence has slope $-(2n+1)/(2n-2)$. The second line goes through point $(5n+j-1, -n+j)$ (bend of e^j_{n-1} in the top left half of the matching area) and has slope -1. We compute the two line equations based on the fact that we know a point on each line and the corresponding slopes:

$$y = -\frac{2n+1}{2n-2}x + \frac{8n^2+4nj+6n-j+1}{2n-2} \qquad \text{and} \qquad y = -x+4n+j+1$$

and the x-coordinate of the intersection point $x = 16/3n + j - 1/3$ that is to the right of the bend of e^j_{n-1} in the top left half of the matching area as claimed.

Proof (of Result 3). We describe how to draw $K_{(n_p)_p}$, the complete p-partite graph with n_p vertices per partition. Refer to Fig. 5 for an example drawing of $K_{3,3,3}$. If the partitions have different sizes, we augment the graph to $K_{(n_p)_p}$ where n_p is the number of vertices in the largest partition. Note that $n_p < n$ and $pn_p \geq n$. We number the partitions arbitrarily from 0 to $p-1$ and the vertices in each partition from 0 to $n_p - 1$. Let v^j_i denote the i-th vertex of the j-th partition.

We position vertex v^j_i at $(2pn_pj + 2n_pj - j, 2i - j)$; see white circles in Fig. 5. Edge (v^j_i, v^ℓ_k) with $j < \ell$ is drawn with the following three bends:

- The bend incident to vertex v^j_i is located at $(2pn_pj + n_p\ell + n_pj + k - i - j + 1, n_p\ell - n_pj + i + k - j)$; see white squares in Fig. 5.
- The middle bend is located at $(pn_p\ell + pn_pj + n_p\ell + n_pj + k - i - j + 1, pn_p\ell - pn_pj + n_p\ell - n_pj + i + k - \ell)$; see gray squares in Fig. 5.
- The bend incident to vertex v^ℓ_k is located at $(2pn_p\ell + n_p\ell + n_pj + k - i - \ell + 1, n_p\ell - n_pj + i + k - \ell)$; see black squares in Fig. 5.

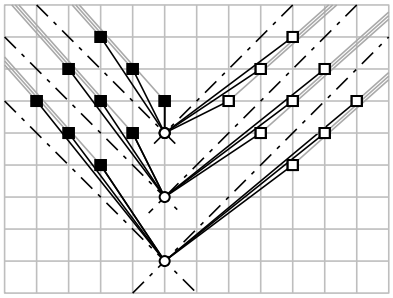

Figure 6 Detail of the vertex stars of the middle partition in Fig. 5.

The lowest x-coordinate assigned is 0 (for vertices in partition 0), while the highest x-coordinate assigned is $2p^2n_p - 2n_p - p + 1$ (for vertices in partition $p-1$). Conversely, the lowest y-coordinate is $-p+1$ (for vertex v_0^{p-1}) whereas the largest y-coordinate is $p^2n_p + n_p - p - 1$ (for the middle bend of edge $(v^0_{n_p-1}, v^{p-1}_{n_p-1})$). Since $pn_p \leq pn$, it follows, that the total area is $\mathcal{O}(p^4n^2)$.

It remains to discuss that the resulting drawing is RAC. First we have a look at the segments incident to the middle bend (i.e., the segments which are not start segments). All of these segments have slopes $(n-1)/n$ (between white and gray squares in Fig. 5) or $-n/(n-1)$ (between black and gray squares in Fig. 5). Hence, each pair of these segments is either parallel or perpendicular.

Next, we show that start segments of different partitions do not intersect; see gray shaded areas in Fig. 5. To see this, we consider the rightmost bend incident to a vertex of partition j and the leftmost incident to a vertex of partition ℓ such that $j < \ell$. The rightmost bend of partition j belongs to edge $(v_0^j, v^{p-1}_{n_p-1})$ and has x-coordinate $2pn_pj + pn_p + n_pj - j$ whereas the leftmost bend of partition ℓ belongs to edge $(v^0_{n_p-1}, v_0^\ell)$ and has x-coordinate $2pn_p\ell + n_p\ell - n_p - \ell + 2$, i.e., at least $2pn_pj + 2pn_p + n_pj - j + 1$ since $\ell \geq j+1$. Hence, the leftmost bend of partition ℓ is at least $pn_p + 1 \geq n+1$ units right of the rightmost bend of partition j. Hence, start segments from different partitions cannot intersect.

In addition, we establish that middle bends are located outside of vertex fans. To see this, consider the topmost bend of a vertex fan of partition j. This is either $y_r = pn_p + n_p - n_pj - j - 2$ (bend of edge $(v^j_{n_p-1}, v^{p-1}_{n_p-1})$) or $y_\ell = n_pj + 2n_p - j - 2$ (bend of edge $(v^0_{n_p-1}, v^j_{n_p-1})$). Since middle bends appear in groups of n_p^2 bends, we only consider the lowest of these bends which is always incident to two vertices v_0^a and v_0^b for some partitions a and b such that $b > a$. The y-coordinate of this bend is equal to $y_m = pn_p(b-a) + n_p(b-a) - b$. Clearly, $y_m \leq y_r$ is only possible if $(b-a) = 1$ and $b \geq j+2$ in which case the middle bends are between two partitions whose start segments are to the right of the start segments of partition j (and hence the middle bends are to the right as well). Also since $(b-a) \geq 1$, it holds that $y_m \geq pn_p + n_p - b$ and, since $b \leq p-1$, also $y_m \geq pn_p + n_p - p + 1$. However, even for $j = p-1$ it holds that $y_\ell = pn_p + n_p - p - 1$ and hence $y_\ell < y_m$.

Next, we show planarity for the start segments. We first observe that each vertex v_i^j is incident to two sets of bends, namely,

- those that belong to an edge (v_k^ℓ, v_i^j) for some $\ell < j$. These are located on a diagonal with slope -1 left of the vertex; see black squares in Fig. 5. We will refer to these as the *left bends* of the vertex fan.
- those that belong to an edge (v_i^j, v_k^ℓ) for some $\ell > j$. These are located on a diagonal with slope 1 right of the vertex; see white squares in Fig. 5. We will refer to these as the *right bends* of the vertex fan.

We will show that v_i^j is located on the intersection of the diagonal with slope -1 located one unit below the diagonal through its left bends and the diagonal with slope 1 located one unit above the diagonal through its right bends; see dashed diagonals in Fig. 6. Hence, the start segments do not intersect segments between its start segment bends and the corresponding middle bends. Also, since the latter "middle" segments have slope $(n-1)/n$ or $-n/(n-1)$ the start segments of vertex v_i^j do not intersect middle segments of vertices v_{i-1}^j and v_{i+1}^j (as their middle segments only intersect the diagonal defining the position of v_i^j after moving n or $n-1$ units to the left/right).

The diagonal located one unit below the left vertex fan bends passes through the point $p_\ell = (2pn_pj + n_pj + i - j + 1, n_pj + i - j - 1)$ (one unit below the bend of edge (v_0^0, v_i^j). It is easy to verify that $(2pn_pj + 2n_pj - j, 2i - j) = (1, -1) \cdot (n_pj - i - 1) + p_\ell$. Similarly, the diagonal located one unit above the right vertex fan bends passes through the point $p_r = (2pn_pj + 2n_pj + n_p - i - j + 1, n_p + i - j + 1)$ (one unit above the bend of edge (v_i^j, v_0^{j+1}). It holds that $(2pn_pj + 2n_pj - j, 2i - j) = (-1, -1) \cdot (n_p - i + 1) + p_r$ as required.

Next, we show that the start segments of partition j do not intersect the middle segments incident to a start segment bend of partition $\ell \neq j$. To do so, we show that the middle segments of partition ℓ are located above all start segments. Recall that the topmost y-coordinate of a right bend in j occurs on edge $(v_{n_p-1}^j, v_{n_p-1}^p)$ and is equal to $pn_p - n_pj + 2n_p - j - 2$, and that the topmost y-coordinate of a left bend in j occurs on edge $(v_{n_p-1}^0, v_{n_p-1}^j)$ and is equal to $n_pj + 2n_p - j - 2$. Thus, the topmost y-coordinate of any start segment bend is at most $pn_p + 2n_p - j - 2$. We consider two cases.

First, consider the case $\ell > j$. Further assume that $\ell = j + 1$ since the middle segments of partition $\ell' > \ell$ are located above those of partition ℓ. As established earlier, the horizontal distance between the start regions of partitions j and ℓ is at least $pn_p + 1$. Observe that at the leftmost x-coordinate of the start region of partition ℓ, we encounter the left bend of $(v_{n_p-1}^0), v_0^\ell)$ with y-coordinate $n_p\ell + n_p - \ell - 1 = n_pj + 2n_p - j - 2$. On the other hand, if we continue k units in x-direction, we have distance $pn_p + 1$ towards partition j and encounter a left bend with y-coordinate $n_pj + 2n_p - j - 2 - k$. Because the slope of middle segments incident to left bends is $-pn_p/(pn_p - 1)$, any such middle segment has y-coordinate at least $(pn_p+1+k)\cdot\frac{pn_p}{pn_p-1} + n_pj + 2n_p - j - 2 - k > pn_p + k + n_pj + 2n_p - j - 2 - k = pn_p + n_pj + 2n_p - j - 2$ which is larger than $pn_p + 2n_p - j - 2$. Hence, such a middle segment is above each start segment of region j.

Second, assume that $\ell < j$. Here, we can assume that $\ell = j - 1$ by a similar argument as before. Again, the horizontal distance between the start segment bends of partitions j and ℓ is at least $pn_p + 1$. At the rightmost x-coordinate that belongs to the start region of partition ℓ is the right bend of edge $(v_0^\ell, v_{n_p-1}^{p-1})$ with y-coordinate $pn_p - n_p\ell + n_p - \ell - 2 = pn_p - n_pj + 2n_p - j - 1$. If we continue k units in negative x-direction, we have a minimum distance of $pn_p + 1 + k$ towards partition j and encounter a left bend with y-coordinate $pn_p - n_pj + 2n_p - j - 1 - k$. Recall that the slope of middle segments incident to such bends is $(pn_p - 1)/pn_p$. Note that such middle segment has y-coordinate at least $(pn_p+1+k)\cdot\frac{pn_p-1}{pn_p} + pn_p - n_pj + 2n_p - j - 1 - k = 2pn_p - n_pj + 2n_p - j - 2 + -k/pn_p$ when above a start segment of region j. Since $k < jn_p$, we have that $2pn_p - n_pj + 2n_p - j - 2 + -k/pn_p > 2pn_p - n_pj + 2n_p - j - 2 + -j/p$. In addition, $j \leq (p-1)$ and we conclude that $2pn_p - n_pj + 2n_p - j - 2 + -j/p > pn_p + 3n_p - j - 2 - (p-1)(p)$ which is larger than $pn_p + 2n_p - j - 2$.

We conclude that middle segments of other partitions do not enter the start regions of other partitions. Finally, we only have to show that no two bends overlap and that no bend is located on an independent segment. First consider the start segment bends. Since middle bends are not inside vertex start regions, the only segments to consider here are the

middle segments incident to the same partition. These clearly do not overlap any of the start segment bends since the next grid points are located at least $n - 1 = pn_p - 1$ to the left/right while there are only at most $(p-1)n_p = pn_p - n_p$ bends each using consecutive x-coordinates.

Since the middle segments only shift the gridlike structure of start segment bends of the same partition, it follows, that no two bends of the same partition can overlap and that no bend is located on an independent segment from the same partition. Middle segments of two different partitions cannot overlap as well, as that would imply that one of the middle edges would pass through a start segment bend of the other partition. This is not possible since start segments of different partitions are at least $n + 1$ units horizontally apart from each other while their (consecutively pairwise) vertical distance is one. ◀

Since k-planar graphs are $\Theta(\sqrt{k})$-vertex colorable [23], we also obtain:

▶ **Corollary 2.** *Every n-vertex k-planar graph admits a (not necessarily k-planar) RAC$_3$ drawing in $\mathcal{O}(k^2n^2)$ area.*

3 An Area Lower Bound for RAC$_3$ Drawings

We show that $\mathcal{O}(n^2)$ area cannot be achieved for RAC$_3$ drawings in general. We give an outline of our proof by contradiction: First, we show there are $\Omega(n^2)$ edges that have $\Omega(n^4)$ crossings on two sets S_i and T_i of parallel segments of maximum cardinality, where segments in S_i are perpendicular to segments in T_i and may intersect. Moreover, there must exist $\Omega(n^2)$ edges with both a segment in S_i and in T_i. Then, we derive properties on the length of the segments in S_i and T_i depending on their slope. This allows us to subdivide the drawing area into a constant number of disjoint regions $\mathcal{R}$, which can contain only one endpoint of a segment from S_i or from T_i of the same edge. We then restrict the possible positions of vertices incident to such endpoints located in a region $R \in \mathcal{R}$. As a result, in Lemma 13, we obtain that the edges with both a segment from S_i and a segment from T_i induce a subgraph which is p-partite for some $p > 1$ except for a linear number of so-called complete edges. Based on this observation, in the proof of Theorem 14, we identify a complete subgraph which has too few edges with both a segment from S_i and from T_i leading to a contradiction.

▶ **Lemma 3.** *Let Γ be a RAC drawing of K_n with $\mathcal{O}(1)$ bends per edge. Then there exist two sets of parallel edge segments S_i and T_i with cardinalities $|S_i| = \Omega(n^2)$ and $|T_i| = \Omega(n^2)$ in Γ such that the segments of S_i are perpendicular to the segments of T_i.*

Proof. We use the following two properties: First, by the crossing lemma, there are $\Omega(n^4)$ crossings in any drawing of K_n. Second, all crossings appear between perpendicular edge segments. We partition the set of segments of the drawing based on their slopes. More precisely, for some $k \in \mathbb{N}$, there are $2(k+1)$ sets of edge segments $S_0, \ldots, S_k$ and $T_0, \ldots, T_k$ such that S_i and T_i are perpendicular to each other. W.l.o.g. also assume that $|S_i| \geq |T_i|$ and that $|T_i| \geq |T_{i+1}|$. Since each edge has $\mathcal{O}(1)$ bends, there are at most cn^2 segments assigned to either set S_i for a constant c. Then, $|S_0| + \sum_{i=1}^{k} |S_i| = cn^2$ or in other words $|S_0| = cn^2 - \sum_{i=1}^{k} |S_i|$. Hence, we obtain the following relation for the number of crossings:

$$\Omega(n^4) \leq cr(\Gamma) \leq |S_0||T_0| + \sum_{i=1}^{k} |S_i||T_i| = \left(cn^2 - \sum_{i=1}^{k} |S_i|\right)|T_0| + \sum_{i=1}^{k} |S_i||T_i|$$

$$= cn^2|T_0| - \sum_{i=1}^{k} (|T_0| - |T_i|)|S_i| \leq cn^2|T_0|$$

which implies that $|S_0| = \Omega(n^2)$ and $|T_0| = \Omega(n^2)$. ◀

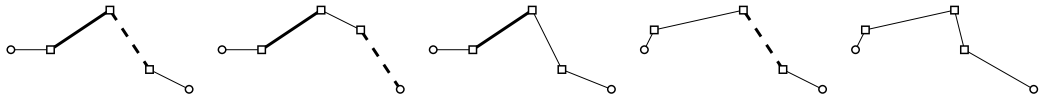

Figure 7 (a)–(b) Two edges belonging to E_i^{ST}, (c) an edge belonging to E_i^S, (d) an edge belonging to E_i^T, and, (e) an edge belonging to none of E_i^S, E_i^T and E_i^{ST}. Segments belonging to S_i are drawn bold and solid, segments belonging to T_i bold and dashed.

We show another property of edge sets contributing $\Omega(n^4)$ crossings. To this end, we consider all maximal sets of parallel edge segments that are involved in $\Omega(n^4)$ crossings and we partition these sets into two families $\mathcal{S} = \{S_1, \ldots, S_k\}$ and $\mathcal{T} = \{T_1, \ldots, T_k\}$ such that the segments in S_i and T_i are perpendicular while the segments in S_i and $S_j \cup T_j$ for $j \neq i$ are not. Observe that in contrast to the proof of Lemma 3, we now only consider segment sets S_i and T_i involved in $\Omega(n^4)$ crossings. Note that in a drawing with $\mathcal{O}(1)$ bends per edge, k is constant. In the following, we will discuss properties of pairs of sets $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$. Let E_i^S (E_i^T, resp.) denote the set of edges with segments from S_i (T_i, resp.) but not from T_i (S_i, resp.), and E_i^{ST} the set of edges with segments from both S_i and T_i; see Fig. 7 for an illustration. In addition, let $E_{i,j}^{SX}$ denote the set of edges with segments from both S_i and from X_j where $X \in S, T$ and let $E_{i,j}^{TX}$ from both T_i and from X_j where $X \in S, T$. Note that $E_{i,i}^{ST} = E_i^{ST}$. The next lemmas show that there are S_i and T_i with $|E_i^{ST}| = \Omega(n^2)$.

▶ **Lemma 4.** *Let Γ be a RAC drawing of K_n with $\mathcal{O}(1)$ bends per edge. Then, there exists either sets $S_i \in \mathcal{S}$, $X_j \in \mathcal{S} \cup \mathcal{T}$ such that $|E_{i,j}^{SX}| = \Omega(n^2)$, or sets $T_i \in \mathcal{T}$, $X_j \in \mathcal{S} \cup \mathcal{T}$ such that $|E_{i,j}^{TX}| = \Omega(n^2)$.*

Proof. First, if $|E_{i,j}^{SX}| = \Omega(n^2)$ for some $S_i \in \mathcal{S}$ and $X_j \in \mathcal{S} \cup \mathcal{T}$ or if $|E_{i,j}^{TX}| = \Omega(n^2)$ for some $T_i \in \mathcal{T}$ and $X_j \in \mathcal{S} \cup \mathcal{T}$ with $i \neq j$; the lemma holds. Otherwise $|E_{i,j}^{SX}| = o(n^2)$ for all $S_i \in \mathcal{S}$ and $X_j \in \mathcal{S} \cup \mathcal{T}$ and $|E_{i,j}^{TX}| = o(n^2)$ for all $T_i \in \mathcal{T}$ and $X_j \in \mathcal{S} \cup \mathcal{T}$ with $i \neq j$. For a contradiction, also assume that $|E_i^{ST}| = o(n^2)$ for all $1 \leq i \leq k$. Hence, E_i^{ST} participates in $o(n^4)$ crossings. Also, assume w.l.o.g. that $|\bigcup_{i=1}^k E_i^S| \geq |\bigcup_{i=1}^k E_i^T|$. Consider the graph $G' = K_n \setminus \bigcup_{i=1}^k E_i^T$. Since G' contains $\bigcup_{i=1}^k E_i^S$, G' still has $\Omega(n^2)$ edges by Lemma 3. In Γ, there exists a valid subdrawing Γ' of G'. In Γ', by the crossing lemma, there still must be $\Omega(n^4)$ crossings between E_i^S and E_i^{ST} over all i. However, there are $o(n^4)$ crossings in Γ' from E_i^{ST} for $1 \leq i \leq k$; a contradiction for constant k. ◀

▶ **Lemma 5.** *Let Γ be a RAC$_3$ drawing of K_n. Then, $|E_{i,j}^{SX}| = o(n^2)$ for each pair of sets $S_i \in \mathcal{S}$, $X_j \in \mathcal{S} \cup \mathcal{T}$ with $i \neq j$ and $|E_{i,j}^{TX}| = o(n^2)$ for each pair of sets $T_i \in \mathcal{T}$, $X_j \in \mathcal{S} \cup \mathcal{T}$ with $i \neq j$.*

Proof. Assume w.l.o.g. that $|E_{i,j}^{ST}| = \Omega(n^2)$. Since only two start segments per vertex can belong to S_i and T_j, respectively, there are $\Omega(n^2)$ edges in $E_{i,j}^{ST}$, where the segments from S_i and T_j are not start segments. Let $\tilde{E}_{i,j}^{ST}$ denote this set of edges. Consider the start segments of $\tilde{E}_{i,j}^{ST}$ and let $\mathcal{P}_{start} = \{P_1, \ldots, P_r\}$ be a partitioning of the start segments into maximal sets of parallel segments. Since each vertex can be incident to only two start segments of the same slope, it follows that $|P_\ell| = \mathcal{O}(n)$ for all $1 \leq \ell \leq r$. Hence, there are only $\mathcal{O}(n^2)$ intersections between a perpendicular pair of start segments in $\tilde{E}_{i,j}^{ST}$. Similarly, if P_ℓ is perpendicular to S_i or T_j, it takes part in only $\mathcal{O}(n^3)$ intersections.

Consider the subgraph G' induced by $\tilde{E}_{i,j}^{ST}$. Note that G' has $\Omega(n^2)$ edges and hence by the crossing lemma it must have $\Omega(n^4)$ crossings. However, as established earlier, the subdrawing in Γ of G' only has $\mathcal{O}(n^3)$ intersections; a contradiction. ◀

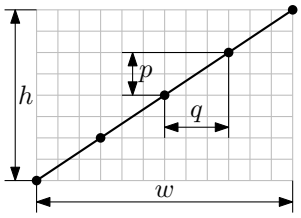

Figure 8 A fine-horizontal grid line (bold) with slope p/q, and its shared points with the coarse grid (gray lines).

The following lemma summarizes Lemmas 4 and 5.

▶ **Lemma 6.** *Let Γ be a RAC$_3$ drawing of K_n. Then, there exists a pair of sets $S_i \in \mathcal{S}$, $T_i \in \mathcal{T}$ such that $|E_i^{ST}| = \Omega(n^2)$, for some $1 \leq i \leq k$; i.e., $|E_i^{ST}| \geq c_{ST} n^2$ for an appropriate constant c_{ST} and sufficiently large n.*

Next, we investigate one pair of perpendicular segment sets $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$. In the following analysis and all illustrations, we assume w.l.o.g. that the slope of segments in S_i is positive. First, we show that segments in S_i and T_i follow the grid lines of a finer grid that is tilted w.r.t. the coarse integer grid containing vertices and bends; see Fig. 8. We use this to show that segments in S_i and T_i are long w.r.t. the smaller side of the bounding rectangle.

▶ **Lemma 7.** *Let Γ be a RAC drawing of K_n with height h and width w and with $\mathcal{O}(1)$ bends per edge. Also, let $s = p/q$ be the slope of segments in $S_i \in \mathcal{S}$ for coprime integers p and q. Then,*

1. $\max\{p, q\} \in \Omega\left(\sqrt{n^4/(w \cdot h)}\right)$ *or* $pq \in \Omega\left(n^4/\max\{w^2, h^2\}\right)$*; and*
2. $p, q \in \mathcal{O}(\min\{w, h\})$.

Proof. Since the endpoints of each segment are grid points, the slope s_i of segments in S_i and the slope $-1/s_i$ of segments in T_i are rational numbers. Hence, the intersections between S_i and T_i are located at points with rational coordinates. By scaling the grid appropriately (i.e., by the factor of $p^2 + q^2$), we achieve integer coordinates for the intersections. In other words, all intersections are located on a *fine grid* while vertices and bends are on the integer grid which we call the *coarse grid*.

More precisely, the fine grid is defined by the *fine-horizontal* grid lines of slope s_i and by the *fine-vertical* grid lines of slope $-1/s_i$ each passing through at least two of the $h \cdot w$ vertices of the coarse grid. Note that by definition all vertices of the coarse grid are also vertices of the fine grid. Depending on the values of p and q, we observe that fine grid lines may pass through more than two points of the coarse grid; see Fig. 8. This limits how many fine grid lines exist. To see this, consider two consecutive fine-horizontal grid lines ℓ_1 and ℓ_2. Both lines ℓ_i (for $i \in \{1, 2\}$) can be expressed by a line formula of form $y = p/q \cdot x + b_i$. Since each line passes through integer points it holds that $b_i = 1/q \cdot c_i$ for some $c_i \in \mathbb{Z}$. More precisely, since ℓ_1 and ℓ_2 are consecutive, $|c_2 - c_1| = 1$ and the vertical distance between two consecutive fine-horizontal grid lines is $1/q$. In addition, we can compute the horizontal distance at the same y-coordinate by setting $p/q \cdot x_1 + b_1 = p/q \cdot x_2 + b_2$. Solving this equation yields $|x_2 - x_1| = q/p \cdot |b_2 - b_1| = 1/p \cdot |c_2 - c_1| = 1/p$ implying that the horizontal distance between two consecutive fine-horizontal grid lines is $1/p$. Analogously, the horizontal (vertical, resp.) distance between two fine-vertical grid lines is $1/q$ ($1/p$, resp.). Thus, there are at most $\Theta(\max\{wp, hq\})$ fine-horizonal and $\Theta(\max\{wq, hp\})$ fine-vertical grid lines.

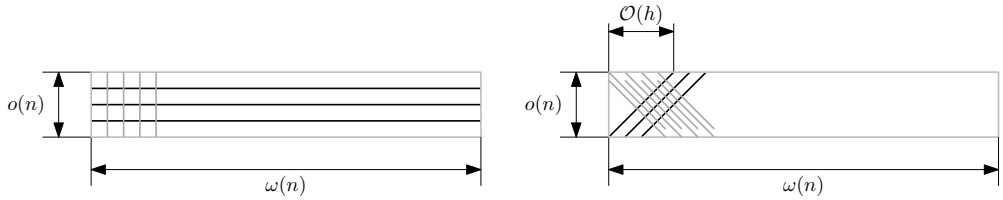

Figure 9 Proof of Lemma 8. If the area is $\omega(n) \times o(n)$, (a) there are $o(n)$ fine-horizontal grid lines (black), or, (b) fine-horizontal grid lines intersect $\mathcal{O}(h^2)$ fine-vertical grid lines (gray) each.

These two sets of grid lines intersect in $\Theta(\max\{w^2pq, whp^2, whq^2, h^2pq\})$ grid points, which must be $\Omega(n^4)$, the required number of crossings. Thus, $\max\{p,q\} \in \Omega\left(\sqrt{n^4/(w \cdot h)}\right)$ or $pq \in \Omega\left(n^4/\max\{w^2, h^2\}\right)$ which yields Property 1 of the lemma. Since the endpoints of all segments are located on the coarse grid, both $h, w \geq \max\{p,q\}$, which implies Property 2. ◀

The following lemma refines Lemma 7 for $\mathcal{O}(n^2)$ area and shows that both width and height are $\mathcal{O}(n)$ while segments in S_i and T_i have $\Omega(n)$ length.

▶ **Lemma 8.** *Let Γ be a RAC drawing of K_n with height h and width w and with $\mathcal{O}(1)$ bends per edge in $\mathcal{O}(n^2)$ area. Also, let p/q be the slope of segments in S_i such that p and q are coprime. Then,*

1. $h, w \in \Theta(n)$, *and,*
2. $\max\{p,q\} \in \Theta(n)$.

Proof. Assume for a contradiction that $h = o(n)$, i.e., $w = \omega(n)$. By Lemma 7,

1. $\max\{p,q\} \in \Omega\left(\sqrt{n^4/(w \cdot h)}\right) = \Omega(n)$ or $pq \in \Omega(n^4/\max\{w^2, h^2\}) = \Omega(h^2)$; and
2. $p, q \in \mathcal{O}(\min\{w, h\}) = \mathcal{O}(h)$

hold. By Property 2, it can only be $pq \in \Omega(h^2)$ but not $\max\{p,q\} \in \Omega(n)$. Consider the fine grid as defined in the proof of Lemma 7. First, if the fine-horizontal grid lines are in fact horizontal (i.e., $p = 0$), there can only be $\mathcal{O}(h)$ fine-horizontal grid lines since the height of the drawing is $\mathcal{O}(h)$; see Fig. 9a. Otherwise, the slope of the fine-horizontal grid lines is not horizontal. Recall that $p, q \in \mathcal{O}(h)$ since the height of the drawing is $\mathcal{O}(h)$. Since $pq = \Omega(h^2)$, $p, q \in \Theta(h)$. Hence, fine-horizontal grid lines have only length $\mathcal{O}(h)$ inside the bounding box and can only be crossed by $\mathcal{O}(h^2)$ fine-vertical grid-lines each; see Fig. 9b. Since $h = o(n)$, it is impossible to achieve $\Omega(n^4)$ crossings as in total there are only $\Theta(n^2)$ fine-horizontal grid lines. Thus, the assumption $h = o(n)$ leads to a contradiction. It follows that $h = \Theta(w)$, and hence, $w \in \Theta(n)$ and $\max\{p,q\} \in \Theta(n)$. ◀

So far, we considered properties of RAC drawings with $\mathcal{O}(1)$ bends per edge. The remaining results in this section hold specifically for RAC_3 drawings. Next, we explore connections realizable with edges in E_i^{ST} for a pair of perpendicular sets of segments $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$. Based on slope p_i/q_i of segments in S_i for coprime integers p_i and q_i, consider a checkerboard partitioning of the drawing area into a set of square-shaped disjoint regions $\mathcal{R}_i$ of side length $\max\{p_i, q_i\}/2$ each. By Lemma 8, $\max\{p_i, q_i\} \in \Theta(n)$ and $h, w \in \Theta(n)$; and hence $|\mathcal{R}_i| = \mathcal{O}(1)$. By the choice of the slope, the length of segments in S_i have to be multiples of $\sqrt{p_i^2 + q_i^2}$. In particular, each segment in S_i has length larger than $\max\{p_i, q_i\}$. Due to the length of segments in S_i and the size of regions, we observe the following:

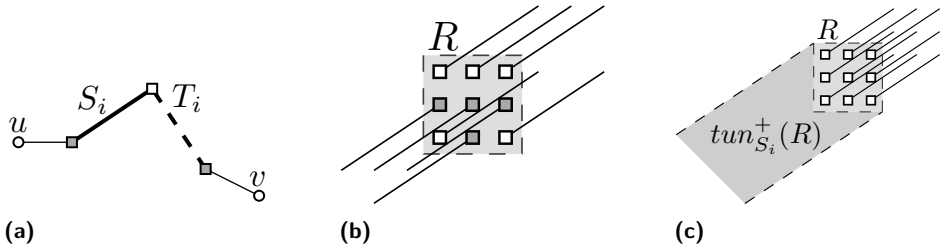

Figure 10 (a) An edge (u, v) whose middle segments (bold) belong to perpendicular set of segments $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$. The gray bend incident to u (v, resp.) is an $S_i(T_i$, resp.)-endpoint. (b) A region R with set of bends $ep^+_{S_i}(R)$ (white squares) and set of bends $ep^-_{S_i}(R)$ (gray squares). (c) A region R with set of bends $ep^+_{S_i}(R)$ (white squares), their corresponding S_i-segments, and $tun^+_{S_i}(R)$.

▶ **Observation 9.** *At most one endpoint of a segment in S_i or T_i is in region $R \in \mathcal{R}_i$. All segments of S_i or T_i with an endpoint in R cross the boundary of R.*

As each vertex can only be endpoint of two segments in S_i and of two segments in T_i, there are only $\mathcal{O}(n)$ *start segments* in S_i and T_i , i.e., segments directly incident to a vertex. Hence, we only consider the bends of edges with both a middle segment in S_i and a middle segment in T_i where *middle segments* are segments which are not start segments. Refer to Fig. 10a for an illustration of such an edge. We refer to bends that are endpoints of a middle segment in S_i and of a start segment as *S_i-endpoints*. Analogously, we define *T_i-endpoints*.

▶ **Observation 10.** *Let $e \in E$ be an edge with two middle segments from S_i and T_i. The corresponding S_i- and T_i-endpoints are located in two disjoint regions of $\mathcal{R}_i$.*

Based on Observation 10, consider S_i- and T_i-endpoints in a region $R \in \mathcal{R}_i$ independently. Let $ep_{S_i}(R)$ ($ep_{T_i}(R)$) denote the set of S_i-endpoints (T_i-endpoints, resp.) in R. Further, $ep_{S_i}(R)$ can be subdivided into $ep^+_{S_i}(R)$, i.e. the set of S_i-endpoints that are the bottom endpoints of their corresponding S_i-segment, and $ep^-_{S_i}(R)$, i.e. the set of S_i-endpoints that are the corresponding top endpoints; see Fig. 10b. In other words, the S_i-segment incident to an endpoint in $ep^+_{S_i}(R)$ leaves R in positive y direction. Similarly, we subdivide $ep_{T_i}(R)$ into $ep^+_{T_i}(R)$ and $ep^-_{T_i}(R)$.

The segments in S_i and T_i form obstacles for possible connections of S_i- and T_i-endpoints to vertices. As a result, we will identify regions which have a visibility to many of the vertices connected to one of the sets of endpoints of region R, say $ep^+_{S_i}(R)$, to which we refer as *tunnels*. The *S_i-tunnel* $tun_{S_i}(R)$ of R is the region bounded by two lines parallel to the segments in S_i enclosing R. Further, $tun_{S_i}(R)$ is split by R into *S_i^+-tunnel* $tun^+_{S_i}(R)$ below R (see Fig. 10c) and the *S_i^--tunnel* $tun^-_{S_i}(R)$ above R. Similarly, we define T_i-tunnels for R.

Next, we define so-called *plausible* positions for all but $o(n)$ vertices connected to bends in $ep^+_{S_i}(R)$; the following analysis can be analogously adapted for bends in $ep^-_{S_i}(R)$. To realize those connections, bends have to be connected to some vertices by a start segment. Consider the set of slopes $A = \{0, 1/4, 1/2, 3/4, 1, 4/3, 2, 4, \infty\}$ and the two slopes $s_\ell \in A$ and $s_r \in A$ closest to the slope p/q of segments in S_i; see Figure 11a. Further, let α_ℓ denote the angle between slopes s_ℓ and p/q and α_r the angle between slopes s_r and p/q. Observe that $0 < \alpha_\ell, \alpha_r < \pi/4$. The choice of slopes in A is arbitrary and is simply used to discretize the slope p/q with a new slope whose nominator and denominator can be both expressed as a constant. For a bend b in $ep^+_{S_i}(R)$, we define a region of *S_i^+-plausible positions* by a wedge opposite to the attached S_i-segment delimited by two rays of slopes s_ℓ and s_r, resp.; see

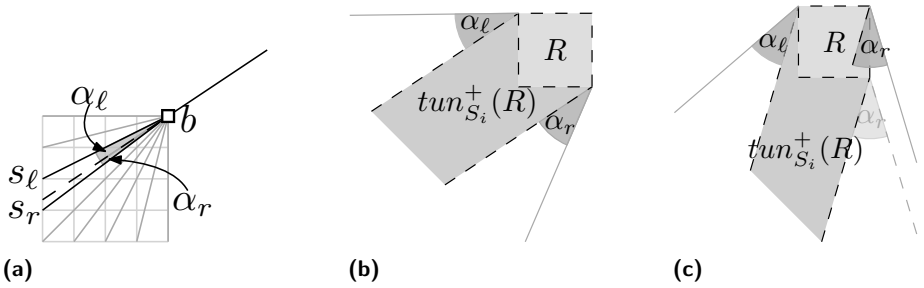

Figure 11 (a) Wedge of angle $\alpha_\ell + \alpha_r$ at bend $b \in ep^+_{S_i}(R)$ yielding S_i^+-plausible positions for b. (b)–(c) S_i^+-plausible region $plaus^+_{S_i}(R)$ of R, for different slopes of segments in S_i.

Fig. 11a. The union of the plausible positions of all bends in $ep^+_{S_i}(R)$ defines the *S_i^+-plausible region* $plaus^+_{S_i}(R)$ of R and consists of the union of R, $tun^+_{S_i}(R)$ and two attached wedges of angles α_ℓ and α_r, resp., on both sides of $tun^+_{S_i}(R)$. Observe these two wedges may be attached to two adjacent or two opposite corners of R depending on the slope of segments in S_i; see Figs. 11b and 11c. S_i^--, T_i^+- and T_i^--plausible regions are defined analogously.

▶ **Lemma 11.** *Let Γ be a RAC$_3$ drawing of K_n in $\mathcal{O}(n^2)$ area and let R be a region such that w.l.o.g. $|ep^+_{S_i}(R)| = \Omega(n^2)$. Vertices outside of $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$ are directly connected to only $\mathcal{O}(n)$ bends in $ep^+_{S_i}(R)$ in total.*

Proof. The segments in S_i can only be crossed by segments of T_i. There are at most two start segments for each vertex that belong to T_i, hence, only two start segments of each vertex can cross segments of S_i. Those can be neglected as they are only $\mathcal{O}(n)$ segments and, in the following, we only consider start segments with different slopes. Consider an S_i-endpoint b and assume that b is connected to vertex v outside of $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$. Assume w.l.o.g. that v is to the left of $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$. The segment connecting b and v has a slope diverging by more than α_ℓ from slope p/q. Hence, b may be attached to a vertex v to the left of $plaus^+_{S_i}(R)$ only if a ray of slope s_ℓ with right endpoint b does not cross any segment in S_i with endpoint in $ep^+_{S_i}(R)$. This is true because the segment between b and v will intersect at least the segments that are also intersected by the ray of slope s_ℓ.

Consider the set of S_i-endpoints B for which such a crossing-free ray of slope s_ℓ exists; see Fig. 12a. Note that all rays are parallel and do not overlap. Since all possible slopes $s_\ell \in A$ can be expressed as a quotient p_ℓ/q_ℓ for $p_\ell, q_\ell \in \mathcal{O}(1)$ and since all rays hit one integer point, the minimum distance between two such parallel rays is $\Omega(1)$. Since R has size $\mathcal{O}(n) \times \mathcal{O}(n)$, it follows that there are only $\mathcal{O}(n)$ parallel rays of slope s_ℓ and hence $|B| = \mathcal{O}(n)$. ◀

In the following, we consider a region R and its set of *neighbored regions* $\mathcal{N}(R)$. A neighbored region $R' \in \mathcal{N}(R)$ is a region obtained by shifting R $c_1 q + c_2 p$ units along the x-axis and $c_1 p - c_2 q$ units along the y-axis for integers c_1, c_2; see Fig. 12b. Note that $\mathcal{N}(R)$ contains projections of $R \in \mathcal{R}_i$ that are not necessarily part of $\mathcal{R}_i$. Region R' contains all T_i-endpoints that are reached from S_i-endpoints in R by a segment in S_i with length $|c_1| \cdot \sqrt{p^2+q^2}$ followed by a segment in T_i of length $|c_2| \cdot \sqrt{p^2+q^2}$. Assume w.l.o.g. that $c_1, c_2 > 0$. Then, the edges with S- and T-endpoints in R and R', resp., will have a bend in $ep^+_{S_i}(R)$ and $ep^+_{T_i}(R')$. The symmetric cases where $c_1 < 0$ or $c_2 < 0$ are analogous. We say that a vertex v is an *R-vertex* if it is directly connected to $\Omega(n)$ bends in $ep^+_{S_i}(R)$ but to only $o(n)$ bends in $ep^+_{T_i}(R')$. Conversely, we say that v is an *R'-vertex* if it is directly connected to $\Omega(n)$ bends in $ep^+_{T_i}(R')$ but to only $o(n)$ bends in $ep^+_{S_i}(R)$. In the following, we show that except for $\mathcal{O}(n)$ edges, the edges with S- and T-endpoints in neighbored regions

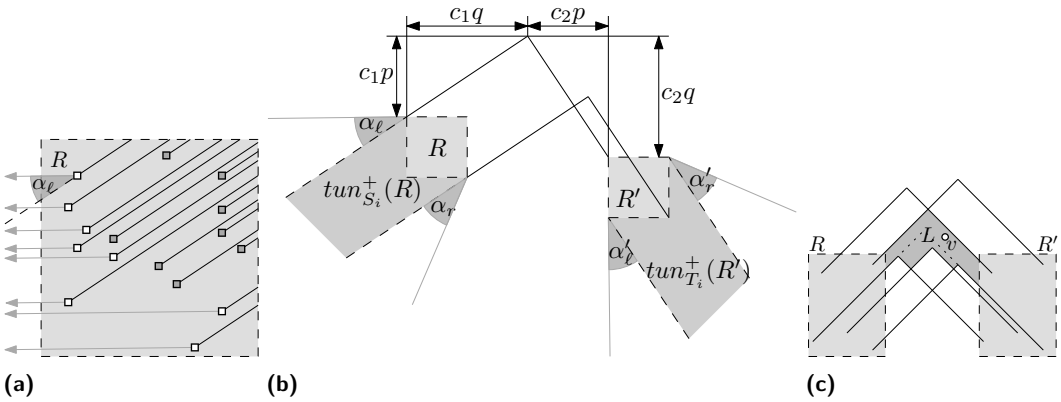

Figure 12 (a) Rays of slopes s_ℓ (arrows) attached to bends visible from outside $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$. (b) Illustration of a region R and one of its neighbored regions R'. (c) Illustration of an L-tunnel L between region R and $R' \in \mathcal{N}(R)$ with a vertex v.

induce a bipartite subgraph between R- and R'-vertices. We refer to those exceptional edges which are either connecting two R- or R'-vertices or have an endpoint which is neither R- nor R'-vertex as *complete edges*. Intuitively speaking, a complete edge connects the set of R- and R'-vertices which are otherwise behaving like the partitions of a bipartite graph. In particular, every complete edge

(i) is either incident to a vertex which is neither R- nor R'-vertex, or
(ii) has a start segment that connects an R-vertex with a bend in $ep^+_{T_i}(R')$, or,
(iii) has a start segment that connects an R'-vertex with a bend in $ep^+_{S_i}(R)$.

We refer to the special endpoint as a *complete* endpoint. We first show that vertices in the intersection of $tun^-_{S_i}(R)$ and $tun^-_{T_i}(R')$ can be complete endpoint for only $\mathcal{O}(n)$ edges. Later, we will consider the case where vertices are not located in the intersection of $tun^-_{S_i}(R)$ and $tun^-_{T_i}(R')$. Consider a vertex v located in the intersection $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$ in a so-called *L-tunnel* between R and R'. An L-tunnel is a region bounded by edges with S- and T-endpoints in R and R', resp., that is open to both R and R' such that v can see into regions R and R'; see Fig. 12c. More precisely, an L-tunnel L is an open subregion of $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$ bounded from below by an alternating sequence of S_i and T_i segments between R and R' and from above by two segments, one from S_i and one from T_i, while it is bounded to the left by the boundary of R and to the right by the boundary of R'.

▶ **Lemma 12.** *Let Γ be a RAC$_3$ drawing of K_n in $\mathcal{O}(n^2)$ area, let R be a region such that w.l.o.g. $|ep^+_{S_i}(R)| = \Omega(n^2)$ and let $R' \in \mathcal{N}(R)$. There are $\mathcal{O}(n)$ complete edges with both a bend in $ep^+_{S_i}(R)$ and in $ep^+_{T_i}(R')$ whose complete endpoints are an in L-tunnels in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$.*

Proof. Let v be a complete endpoint in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$, hence, it is connected to bends in $ep^+_{S_i}(R)$ and to bends in $ep^+_{T_i}(R')$. Further, assume that v is complete endpoint for at least two edges; the complete endpoints that we disregard only contribute $\mathcal{O}(n)$ edges. Assume w.l.o.g. that the slope of segments in S_i is less than 1. Then, the slope of segments in T_i is less than -1 and v is located above R'. Let $B(v)$ denote the set of bends that v is connected to in $ep^+_{T_i}(R')$. We further divide $B(v)$ into $B^-(v)$ and $B^+(v)$, i.e., the set of bends b such that v is located in the halfplane above and below b's segment in T_i, resp. We first show, that each $b \in B^\pm(v)$ shares its y-coordinate with no other bend $b' \in B^\pm(v)$. Then, we show that for two vertices v and v' in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$, the y-coordinates of bends in $B^\pm(v)$ and $B^\pm(v')$ differ. As a result, there are only $\mathcal{O}(n)$ bends in R', which implies that there are only $\mathcal{O}(n)$ complete edges.

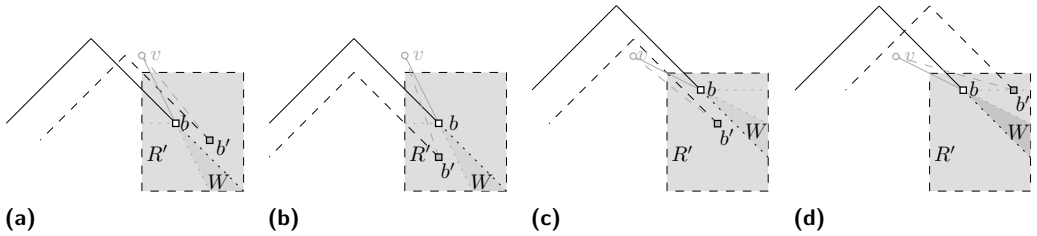

Figure 13 A bend b incident to a vertex v restricts the position of other bends b' to a wedge W.

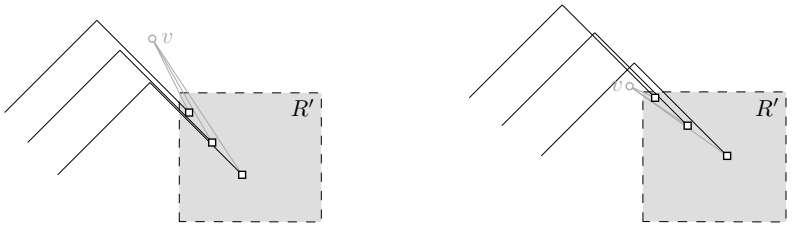

Figure 14 (a) Edges below a vertex v incident to v do not intersect while (b) edges above a vertex v incident to v pairwise intersect.

Consider a vertex v and a bend $b \in B(v)$. First, assume that $b \in B^-(v)$. Note that since v is located above R' in the intersection $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$, the segment between b and v has slope less than -1. Then v can only be incident to another bend $b' \in B^-(v)$ whose T_i-segment is below v only if b' is located in the wedge W obtained by the elongation of the T_i-segment of b and the segment between b and v. Otherwise the T_i-segment incident to b' would intersect the segment between b and v (see Fig. 13a) or the segment between b' and v would intersect the T_i-segment incident to b (see Fig. 13b). Since the angle between the two segments spanning the wedge W from above is less than π, W contains no other bend with the same y-coordinate as b. Moreover, we observe that the T_i-segments incident to such bends and consecutive S_i-segments do not cross each other (see Fig. 14a) since all S_i-(T_i-, resp.)segments between R and R' have the same length. Second, consider the case where $b \in B^+(v)$. Here, the argumentation is analogous to the previous case (see Figs. 13c and 13d). Note that in this case, the edges using bends in $B^+(v)$ pairwise intersect (see Fig. 14b). Still segments incident to v have negative slopes.

It remains to consider the dependencies of the neighborhoods of two vertices v and v' located in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$. First, consider the positions of bends in $B^-(v)$ and of bends in $B^-(v')$. There are three possibilities for the relative positioning of v and v':

1. v and v' appear in different L-tunnels such that w.l.o.g. the L-tunnel of v' appears below the bottommost bend $b_{bot}(v) \in B^-(v)$. Then v' appears in the halfplane below the segment in T_i attached to $b_{bot}(v)$. Even more, the topmost bend $b_{top}(v') \in B^-(v')$ must be located below v'; see Fig 15a. Hence, the y-coordinates of $B^-(v)$ and $B^-(v')$ are different.
2. v and v' appear in the same L-tunnel. W.l.o.g. the topmost bend $b_{top}(v') \in B^-(v')$ will be located in a wedge W below $b_{bot}(v) \in B^-(v)$ delimited by the elongation of the T_i-segment through $b_{bot}(v)$ and a horizontal through $b_{bot}(v)$; see Fig. 15b. The horizontal segment delimits W as by the choice of the size of regions, v' will be located above R', hence it also does not belong to W. Therefore, y-coordinates of $B^-(v)$ and $B^-(v')$ differ.

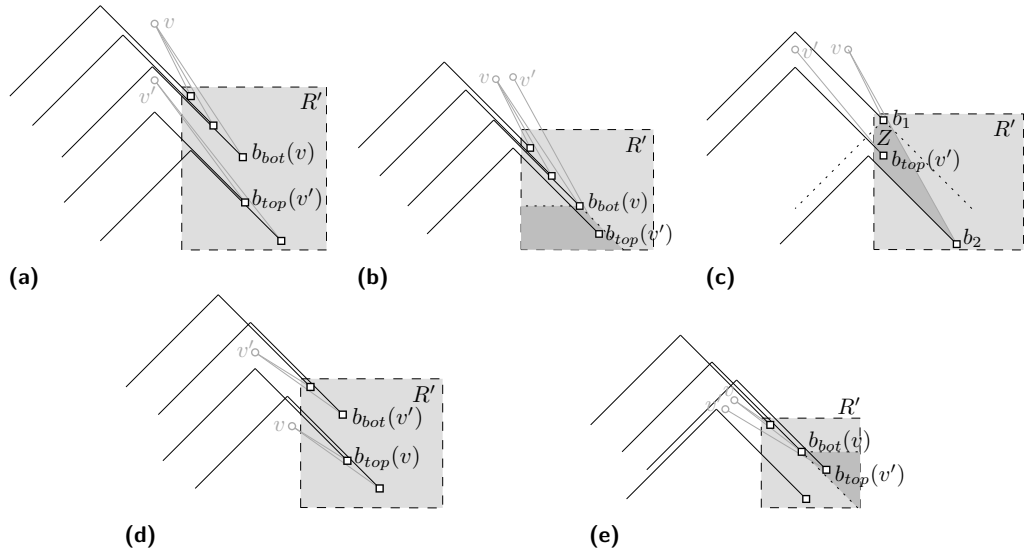

Figure 15 (a)–(c) Bends in $B^-(v)$ and bends in $B^-(v')$ have different y-coordinates. (d)–(e) Bends in $B^+(v)$ and bends in $B^+(v')$ have different y-coordinates.

3. v' is located in between the T_i-segments incident to $b_1, b_2 \in B^-(v)$. The bends in $B^-(v')$ can only be located in a region Z bounded by two lines of the slopes of S_i and T_i passing through b_1, the T_i-segment incident to b_2, the segment between v and b_2 and the boundary of region R'. All points in this region have smaller y-coordinates than b_1 and larger y-coordinates than b_2; see Fig. 15c. Note that the line parallel to segments of S_i passing through b_1 is part of the boundary as otherwise the segments incident to b_1 and a bend in $B^-(v')$, resp., would intersect preventing v' from having segments to bends in R.

Second, consider how the positions of bends in $B^+(v)$ and bends in $B^+(v')$ depend on each other. Here, there are only two possibilities for the relative positioning of v and v' which are analogous to the Cases 1 and 2 above, see Figs. 15d and 15e.

Note that a bend in $\bigcup_v B^-(v)$ and in $\bigcup_v B^+(v)$ may share a common y-coordinate. By the previous analysis, this is the only possibility for two bends in $\bigcup_v B(v)$ to share a y-coordinate. It follows that $|\bigcup_v B^-(v)| = \mathcal{O}(n)$ and $|\bigcup_v B^+(v)| = \mathcal{O}(n)$ and hence only a linear number of complete edges can be realized as claimed. ◀

Now, we summarize the partial results from Lemmas 11 and 12 to conclude that most vertices are R- or R'-vertices with only $\mathcal{O}(n)$ incident complete edges.

▶ **Lemma 13.** *Let Γ be a RAC$_3$ drawing of K_n in $\mathcal{O}(n^2)$ area. Further let R be a region such that w.l.o.g. $|ep^+_{S_i}(R)| = \Omega(n^2)$ and let $R' \in \mathcal{N}(R)$. Then there exist only $\mathcal{O}(n)$ complete edges that have a bend in $ep^+_{S_i}(R)$ and in $ep^+_{T_i}(R')$.*

Proof. Assume $tun^-_{S_i}(R)$ is delimited by the extension of two segments of S_i between R and R'. Otherwise, R can be restricted to a smaller region that only includes S_i-endpoints that are connected to T_i-endpoints located in R'. Assume that there are $\omega(n)$ complete edges with S- and T-endpoints in R and R', resp. By Lemma 12, there exist only $\mathcal{O}(n)$ complete edges with S- and T-endpoints in R and R', resp., whose complete endpoints are located in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$. Since $tun^-_{S_i}(R)$ is bounded by two segments of S_i between R and R', this covers all complete endpoints in $tun^-_{S_i}(R) \cap tun^-_{T_i}(R')$ and other complete endpoints located in

$tun^-_{S_i}(R) \cup tun^-_{T_i}(R')$ lie outside of $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$ or outside of $plaus^+_{T_i}(R') \cup tun^-_{T_i}(R')$. By Lemma 11, only $\mathcal{O}(1)$ vertices outside of $plaus^+_{S_i}(R) \cup tun^-_{S_i}(R)$ can each be connected to $\Omega(n)$ bends of $ep^+_{S_i}(R)$, also only $\mathcal{O}(1)$ vertices outside of $plaus^+_{T_i}(R') \cup tun^-_{T_i}(R')$ can each be connected to $\Omega(n)$ bends of $ep^+_{T_i}(R')$. Thus, there must be complete endpoints in $plaus^+_{S_i}(R) \cap plaus^+_{T_i}(R')$ contradicting $plaus^+_{S_i}(R) \cap plaus^+_{T_i}(R') = \emptyset$. ◀

Lemma 13 shows, that most edges with S- and T-endpoints in R and R', resp., define a bipartite subgraph. As a result, edges between R and $\mathcal{N}(R)$ define a p-partite subgraph for some constant $p > 1$. However, since the drawn graph is complete, all R-vertices have to define a clique. This will lead to a contradiction in the proof of the main theorem of this section.

▶ **Theorem 14.** *There is no RAC_3 drawing of K_n in $\mathcal{O}(n^2)$ area for sufficiently large n.*

Proof. Assume there is a RAC_3 drawing Γ of K_n in $\mathcal{O}(n^2)$ area. We show that there is a complete subgraph G' with $\Omega(n)$ vertices drawn in Γ with only $o(n^2)$ edges from E^{ST}_i for all pairs of perpendicular edge segments $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$. This contradicts the property from Lemma 6 for the subdrawing of G'. Let c_{ST} denote the multiplicative constant from Lemma 6, i.e. $|E^{ST}_i| \geq c_{ST} n^2$.

We compute $G' = (V', E')$ iteratively. We initialize G' by G. We consider all pairs of sets of segments $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$ with perpendicular slopes such that $|E^{ST}_i| \geq c_{ST} n^2$. There can be only a constant number of pairs of segment sets in $\mathcal{S}$ and $\mathcal{T}$ of size $\Omega(n^2)$. For each such pair, let $\mathcal{R}_i$ be a checkerboard partitioning of the drawing area into square-shaped disjoint regions of side length $\max\{p_i, q_i\}/2$ defined by slope p_i/q_i of S_i for coprime integers p_i and q_i. We consider all regions $R \in \mathcal{R}_i$. Due to the size of regions, there is only a constant number of regions in $\mathcal{R}_i$. Moreover, the number of neighbored regions $R' \in \mathcal{N}(R)$ is constant. Hence, there is a constant number n_{comb} of combinations of index i, region R and neighbored region R'.

We iteratively perform the following procedure while there are at least $c_{ST}|V'|^2$ edges with a bend in $ep^+_{S_i}(R)$ and a bend in $ep^{\pm}_{T_i}(R')$ for one of n_{comb} of combinations of index i, region R and neighbored region R' where $ep^{\pm}_{T_i}(R')$ is either $ep^+_{T_i}(R')$ or $ep^-_{T_i}(R')$ depending on the choice of R'. Let V_R denote the set of R- and $V_{R'}$ denote the set of R'-vertices. Assume w.l.o.g. that $|V_R| \geq |V_{R'}|$. By Lemma 13, the vertices that are neither R- nor R'-vertices are connected to $\mathcal{O}(n)$ bends in $ep^+_{S_i}(R)$, $ep^+_{T_i}(R')$ or $ep^-_{T_i}(R')$ in total. More precisely, there are $c_{comp}|V'|$ such bends for an appropriately chosen constant c_{comp}. Recall that vertices that are not incident to $\Omega(n)$ bends, say at least $c_R|V^*|$ for an appropriately chosen constant c_R, in $ep^+_{S_i}(R)$ and $ep^+_{T_i}(R')$ are either R- or R'-vertex for the resulting graph $G^* = (V^*, V^* \times V^*)$. By the prior observation, $|V_R| = \Omega(n)$, more precisely, $|V_R| \geq (|V'| - c_{comp}|V'|/c_R|V^*|)/2$. We then continue to consider the complete subgraph induced by V_R. Note that since n_{comb} is constant, by Lemma 13, this subgraph and the subgraphs in the future iterations contain only $\mathcal{O}(n)$ edges with both a segment in S_i and a segment in T_i and bends in $ep^+_{S_i}(R)$ and $ep^+_{T_i}(R')$ or $ep^-_{T_i}(R')$ for all $R' \in \mathcal{N}(R)$ for sufficiently large n. Thus, we set $G' \leftarrow (V_R, V_R \times V_R)$ and continue with the next iteration.

After performing all at most n_{comb} iterations, there are less than $c_{ST}|V'|^2$ edges with both a bend in $ep^+_{S_i}(R)$ and a bend in $ep^+_{T_i}(R')$ and $ep^-_{T_i}(R')$ for all combinations of index i, region $R \in \mathcal{R}_i$ and neighbored region $R' \in \mathcal{N}(R)$. Hence, the resulting subgraph G' is drawn with $|E^{ST}_i| < c_{ST}|V'|^2$ for each pair of sets of segments $S_i \in \mathcal{S}$ and $T_i \in \mathcal{T}$ with perpendicular slopes which contradicts Lemma 6. ◀

Our proofs explicitly use the assumption of quadratic area (Lemmas 8 to 12) and three bends per edge (Lemmas 11 to 13). Even for $\omega(n^2)$ area, our proof does not apply.

4 Open Questions

We raise the following open questions:

(i) How many bends are needed for achieving quadratic area RAC drawings? We showed that three are insufficient and that eight are enough.

(ii) Is cubic area optimal for RAC_3 drawings? Our lower bound proof might be extendable.

(iii) Is quadratic area achievable in simple RAC drawings? In *simple drawings*, every pair of edges shares at most one point (crossing or endpoint); a property our algorithms do not guarantee.

Abstract

Under the word RAM model, we design three data structures that can be constructed in $O(n\sqrt{\lg n})$ time over n points in an $n \times n$ grid. The first data structure is an $O(n \lg^{\epsilon} n)$-word structure supporting orthogonal range reporting in $O(\lg \lg n + k)$ time, where k denotes output size and ϵ is an arbitrarily small constant. The second is an $O(n \lg \lg n)$-word structure supporting orthogonal range successor in $O(\lg \lg n)$ time, while the third is an $O(n \lg^{\epsilon} n)$-word structure supporting sorted range reporting in $O(\lg \lg n + k)$ time. The query times of these data structures are optimal when the space costs must be within $O(n \operatorname{polylog} n)$ words. Their exact space bounds match those of the best known results achieving the same query times, and the $O(n\sqrt{\lg n})$ construction time beats the previous bounds on preprocessing. Previously, among 2d range search structures, only the orthogonal range counting structure of Chan and Pătraşcu (SODA 2010) and the linear space, $O(\lg^{\epsilon} n)$ query time structure for orthogonal range successor by Belazzougui and Puglisi (SODA 2016) can be built in the same $O(n\sqrt{\lg n})$ time. Hence our work is the first that achieve the same preprocessing time for optimal orthogonal range reporting and range successor. We also apply our results to improve the construction time of text indexes.

1 Introduction

Two dimensional orthogonal range search problems have been studied intensively in the communities of computational geometry, data structures and databases. The goal of these problems is to maintain a set, N, of points on the plane in a data structure such that one can efficiently compute aggregate information about the points contained in an axis-aligned query rectangle Q. Among these problems, *orthogonal range counting* and *orthogonal range reporting* are perhaps the most fundamental; the former counts the number of points contained in $N \cap Q$ while the latter reports them. Another well-known problem is *orthogonal range successor*, which asks for the point in $N \cap Q$ with the smallest x- or y-coordinate. Range

counting, reporting and successor have many applications including text indexing [23, 8, 6, 25], Lempel-Ziv factorization [4] and consensus trees in phylogenetics [18], to name a few. See [22] for a survey on the connection between text indexing and various range searching techniques.

Most work on orthogonal range searching [13, 17, 11, 28, 32] focuses on achieving the best tradeoffs between query time and space, and preprocessing time is often neglected. However, the preprocessing time of a data structure matters when it is used as a building block of an algorithm processing plain data, as the total running time includes that needed to build the structure. Furthermore, an orthogonal range search structures with fast construction time are preferred when preprocessing huge amounts of data, e.g., when used as components of text indexes built upon large data sets from search engines and bioinformatics applications. The work of Chan and Pătraşcu [12] is the first that breaks the $O(n \lg n)$ bound on the construction time of 2d orthogonal range counting structures; they designed an $O(n)$-word structure with $O(\lg n / \lg \lg n)$ query time that can be built in $O(n\sqrt{\lg n})$ time. Their ideas were further extended to design an $O(n \lg \sigma / \sqrt{\lg n})$-time algorithm to build a binary wavelet trees over a string of length n drawn from $[\sigma]$ [26, 2][1], which is a key data structure used in succinct text indexes. More recently, Belazzougui and Puglisi [4] showed how to construct, in $O(n\sqrt{\lg n})$ time, an $O(n)$-word data structure supporting range successor in $O(\lg^{\epsilon} n)$ time, and applied this algorithm to achieve new results on Lempel-Ziv parsing.

The previous work on constructing orthogonal range search structures in $O(n\sqrt{\lg n})$ time focuses on linear space data structures. To achieve optimal query time for 2d orthogonal range reporting and range successor using near-linear space, however, the best tradeoffs under the word RAM model requires superlinear space [11, 32]. The increased space costs are needed to encode more information, posing new challenges to fast construction. We thus investigate the problem of designing data structures with optimal query times for range reporting and range successor that can be built in $O(n\sqrt{\lg n})$ time, while matching the space costs of the best known solutions. We also consider a closely related problem called *sorted range reporting* [28] to achieve similar goals. In this problem, we report all points in $N \cap Q$ in a sorted order along either x- or y-axis. The query time should depend on the number of points actually reported even if the procedure is ended early by user.

Previous Work. The research on 2d orthogonal range reporting has a long history [30, 13, 1, 17, 27, 19, 9, 11]. Researchers have achieved three best tradeoffs between query time and space costs under the word RAM model; we follow the state of the art and assume that the input points are in rank space. The solution with optimal query time of $O(\lg \lg n + k)$ and space cost of $O(n \lg^{\epsilon} n)$ words is due to Alstrup et al. [1], while the best linear-space solution is designed by Chan et al [11] which answers a query in $O((1+k) \lg^{\epsilon} n)$ time, where k is the output size and ϵ is an arbitrarily small constant. Chan et al. also proposed an $O(\lg \lg n)$-word structure with $O((1+k) \lg \lg n)$ query time and another tradeoff matching that of Alstrup et al. [1].

The 2d orthogonal range successor problem was also studied extensively. After a series of work [21, 20, 15, 14, 31], Nekrich and Navarro [28] gave two solutions to this problem; the first uses $O(n)$ words and answers a query in $O(\lg^{\epsilon} n)$ time, while the second uses $O(n \lg \lg n)$ words to answer a query in $O((\lg \lg n)^2)$ time. Zhou [32] decreased the query time of the latter to $O(\lg \lg n)$ without increasing space costs. By definition, a solution to orthogonal range successor can be used to answer sorted range reporting queries. Furthermore, Nekrich and Navarro [28] also designed a data structure using $O(n \lg^{\epsilon} n)$ words to support sorted range

[1] In this paper, $[\sigma]$ denotes $\{0, 1, \ldots, \sigma - 1\}$.

reporting in $O(\lg\lg n + k)$ time. Hence, the best three time-space tradeoffs for the original 2d orthogonal range reporting problem has also been achieved for the sorted version. The optimality of the $O(\lg\lg n + k)$ query time for orthogonal range reporting and the $O(\lg\lg n)$ query time for orthogonal range successor when no more than $O(n \operatorname{polylog} n)$ space can be used is established by a lower bound on range emptiness [29].

Alstrup et al. [1] claimed that their structure for optimal orthogonal range reporting can be constructed in $O(n \lg n)$ expected time. Even though preprocessing times are not given in [11, 28, 32], straightforward analyses reveal that the other data structures we surveyed here can be built in $O(n \lg n)$ worst-case time (Bille and Gørtz [6] also claimed that the preprocessing time of the $O(n \lg\lg n)$-word structure of Chan et al. [11] is $O(n \lg n)$). Hence, when faster preprocessing time is needed in their solution to Lempel-Ziv decomposition, Belazzougui and Puglisi [4] had to design a new linear-space data structure for orthogonal range successor with $O(n\sqrt{\lg n})$ preprocessing time and $O(\lg^{\epsilon} n)$ query time. No attempts have been published to achieve similar preprocessing times for other tradeoffs.

Our Results. Under the word RAM model, we design the following three data structures that can be constructed in $O(n\sqrt{\lg n})$ time over n points in an $n \times n$ grid:

- An $O(n \lg^{\epsilon} n)$-word structure supporting orthogonal range reporting in $O(\lg\lg n + k)$ time, where k denotes the output size and ϵ is an arbitrarily small constant;
- An $O(n \lg\lg n)$-word structure supporting orthogonal range successor in $O(\lg\lg n)$ time;
- An $O(n \lg^{\epsilon} n)$-word structure supporting sorted range reporting in $O(\lg\lg n + k)$ time.

The query times of these structures are optimal when space costs must be within $O(n \operatorname{polylog} n)$ words. Their exact space bounds match those of the best known results achieving the same query times, and the $O(n\sqrt{\lg n})$ construction time beats the previous bounds on preprocessing. Note that even though our third result implies the first one, our data structure for the first is much simpler. In addition, our results can be used to improve the construction time of text indexes. For a text string T of length n over alphabet $[\sigma]$, we design

- A text index of $O(n \lg\sigma \lg^{\epsilon} n)$ bits that can be constructed in $O(n \lg\sigma/\sqrt{\lg n})$ time and can report the $\mathtt{occ}$ occurrences of a pattern of length p in time $O(p/\log_{\sigma} n + \log_{\sigma} n \lg\lg n + \mathtt{occ})$, where ϵ is any small positive constant. This improves one result of Munro et al. [25] who designed the first text indexes with both sublinear construction time and query time for small σ; for the same time-space tradeoff, their preprocessing time is $O(n \lg\sigma \lg^{\epsilon} n)$.
- A text index of $O(n \lg^{1+\epsilon} n)$ bits for any constant $\epsilon > 0$ built in $O(n\sqrt{\lg n})$ time that supports position-restricted substring search [23] in $O(p/\log_{\sigma} n + \lg p + \lg\lg\sigma + \mathtt{occ})$ time. Previous indexes with similar query performance require $O(n \lg n)$ construction time.

Overview of Our Approach. We first discuss why some obvious approaches will not work. The modern approach of Chan et al [11] for orthogonal range reporting is based on a problem called ball inheritance which they defined over range trees. This solution is well-known for its simplicity, and by choosing different parameters in their approach to ball inheritance, they obtain all three best known tradeoffs. One natural idea is to redesign the structures stored at range tree nodes to use bit packing to speed up construction. However, even though we have achieved construction time matching the state of the art for these structures, it is still not enough to construct the data structures for the tradeoffs of ball inheritance that we need quickly enough. Another idea is to tune the parameters in the approach of Belazzougui and Puglisi [4], hoping to obtain the tradeoffs that we aim for, as they already showed how to construct in $O(n\sqrt{\lg n})$ time a linear space, $O((k+1) \lg^{\epsilon} n)$ query

time structure for orthogonal range reporting. Their solution uses many trees grouped into $O(\lg^\epsilon n)$ levels of granularity. If we borrow ideas from [11] and set parameters to achieve different tradeoffs, we would use $O(1/\epsilon)$ or $O(\lg\lg n)$ levels of granularity. However, to return a point in the answer, their query algorithm would perform operations requiring $O(\lg\lg n)$ time at each level of granularity. Thus, at best, the former would give an $O(n\lg^\epsilon n)$-word structure with $O((k+1)\lg\lg n)$ query time and the latter an $O(n\lg\lg n)$-word structure with $O((k+1)(\lg\lg n)^2)$ query time. Either solution is inferior to best known tradeoffs. This however is fine in the original solution, as the total cost of spending $O(\lg\lg n)$ time at each of the $O(\lg^\epsilon n)$ levels is bounded by $O(\lg^{\epsilon'} n)$ for any $\epsilon' > \epsilon$.

We thus design new approaches. For optimal orthogonal range reporting, our overall strategy is to perform two levels of reductions, making it sufficient to solve ball inheritance in special cases with fast preprocessing time. More specifically, we first use a generalized wavelet tree and range minimum/maximum structures to reduce the problem in the general case to the special case in which the points are from a $2^{\sqrt{\lg n}} \times n'$ (narrow) grid, where $n' \leq n$. In this reduction, we need only support ball inheritance over a wavelet tree with high fanout. We further reduce the problem over points in a narrow grid to that over a (small) grid of size at most $2^{\sqrt{\lg n}} \times 2^{2\sqrt{\lg n}}$. This is done by grouping points and selecting representatives from each group, so that previous results with slower preprocessing time can be used over a smaller set of representatives. Finally, over the small grid, we solve ball inheritance when the coordinates of each point can be encoded in $O(\sqrt{\lg n})$ bits. The ball inheritance structures in both special cases can be built quickly by redesigning components with fast preprocessing, though the second case requires a twist to the approach of Chan et al [11]. Our solutions to optimal range successor and sorted range reporting are based on similar strategies, though we preform more levels of reductions.

In the main body of this paper, we describe our data structures for optimal range reporting and successor, while those for optimal sorted range reporting are deferred to the full version of this paper.

2 Preliminaries

In this section, we describe and sometimes extend the previous results used in this paper. The proofs omitted from this section can be found in the full version of this paper.

Notation. We adopt the word RAM model with word size $w = \Theta(\lg n)$ bits, where n denotes the size of the given data. Our complete solutions use several sets of homogeneous components. We present a lemma to bound the costs of each different type of components, which is then applied over the entire set of these components to calculate the total cost. The size, n', of the data that each component represents may be less than n which is the input size of the entire problem, so when the cost of constructing the component is bounded by a function of the form $f(n')/\operatorname{polylog}(n)$ to take advantage of the word size, we keep both n' and n in the lemma statement, as commonly done in previous work on similar topics. In this case, the construction algorithm usually uses a universal table of $o(n)$ bits, whose content solely depends on the value of n, and hence can be constructed once in $o(n)$ time and used for all data structure components of the same type. Thus unless otherwise stated, these lemmas assume the existence of such a table without stating so explicitly in the lemma statements, and we define and analyze the table in the proof. This also applies to algorithms that manipulate sequences of size n'. Occasionally the query algorithms of a data structure may need a universal table as well, and we explicitly state it if this is the case.

We say a sequence $A \in [\sigma]^n$ is in *packed* form if the bits of its elements are concatenated and stored in as few words as possible. Thus, when packed, A occupies $\lceil n\lceil \lg \sigma \rceil / w \rceil$ words.

Generalized Wavelet Trees. Given a sequence $A[0..n-1]$ drawn from alphabet $[\sigma]$, a d-ary generalized wavelet tree [24] T_d over A is a balanced tree in which each internal node has d children, where $2 \leq d \leq \sigma$. For simplicity, assume that σ is a power of d. Each node of T_d then represents a range of alphabet symbols defined as follows: At the leaf level, the i-th leaf from the left represents the integer range $[i, i]$ for each $i \in [0..\sigma - 1]$. The range represented by an internal node is the union of the ranges represented by its children. Hence the root represents $[0, \sigma - 1]$, and T_d is a complete tree having $\log_d \sigma + 1$ levels. Each node u is further associated with a subsequence, $A(u)$, of A, in which $A(u)[i]$ stores the i-th entry in A that is in the range represented by u. Thus the root is associated with the entire sequence A. To save storage, $A[u]$ is not stored explicitly in [24]. Instead, each internal node u stores a sequence $S(u)$ of integers in $[d]$, where $S(u)[i] = j$ if $A(u)[i]$ is within the range represented by the jth child of u. All the $S(u)$'s built for internal nodes occupy $O(n \lg \sigma)$ bits in total.

Generalized wavelet trees share fundamental ideas with range trees but are more suitable for compact data structures over sequences which may contain duplicate values. When we use them in this paper, we sometimes explicitly store $A(u)$ for each node u, and may even associate with u an additional array $I(u)$ in which $I(u)[i]$ stores the index of $A(u)[i]$ in the original sequence A. We call $A(u)$ the *value array* of u, and $I(u)$ the *index array*. In this paper, if we construct value and/or index arrays for each node, we explicitly state so. If not, it implies that we build a wavelet tree in which each node u is associated with $S(u)$ only. Furthermore, unless otherwise specified, we apply the standard pointer-based implementation to represent the tree structure of a wavelet tree, which is preprocessed in time linear to the number of tree nodes such that the lowest common ancestor of any two nodes can be located in $O(1)$ time [5]. We also number the levels of the tree incrementally starting from the root level, which is level 0. We have the following two lemmas on constructing wavelet trees:

▶ **Lemma 1.** *Let $A[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$ and $I[0..n'-1]$ be a packed sequence in which $I[i] = i$ for each $i \in [0..n'-1]$, where $n' \leq n$ and $\sigma \leq 2^{O(\sqrt{\lg n})}$. Given A and I as input, a d-ary wavelet tree over A with value and index arrays in packed form can be constructed in $O(n' \lg \sigma(\lg n' + \lg \sigma)/\lg n + \sigma)$ time, where d is an arbitrary power of 2 with $2 \leq d \leq \sigma$. If index arrays are not constructed, the construction time can be lowered to $O(n' \lg^2 \sigma / \lg n + \sigma)$; this bound still applies when neither value nor index arrays are built.*

▶ **Lemma 2.** *Let $A[0..n-1]$ be a sequence drawn from alphabet $[\sigma]$. A d-ary wavelet tree over A with value and index arrays can be built in $O(n \lg \sigma / \lg d)$ time where $2 \leq d \leq \sigma$.*

A sequence $A[0..n-1]$ drawn from $[\sigma]$ can be viewed as a point set $N = \{(A[i], i) | 0 \leq i \leq n-1\}$. Let T be a d-ary wavelet tree constructed over A. Then *ball inheritance* [11] can be defined over T which asks for the support of these operations: i) `point`(v, i), which returns the point $(A(v)[i], I(v)[i])$ in N for an arbitrary node v in T and an integer i; and ii) `noderange`(c, d, v), which, given a range $[c, d]$ and a node v of T, finds the range $[c_v, d_v]$ such that $I(v)[i] \in [c, d]$ iff $i \in [c_v, d_v]$. If we store the value and index arrays explicitly, it is trivial to support these operations, but the space cost is high. To save space, we only store $S(v)$ for each node v and design auxiliary structures. The following lemma presents previous results:

▶ **Lemma 3** ([11, Theorem 2.1], [10, Lemma 2.3])**.** *A generalized wavelet tree over a sequence $A[0..n-1]$ drawn from $[\sigma]$ can be augmented with ball inheritance data structure in $O(n \lg n f(\sigma))$ bits to support* `point` *in $O(g(\sigma))$ time and* `noderange` *in $O(g(\sigma) + \lg \lg n)$ time, where (a) $f(\sigma) = O(1)$ and $g(\sigma) = O(\lg^\epsilon \sigma)$; (b) $f(\sigma) = O(\lg \lg \sigma)$ and $g(\sigma) = O(\lg \lg \sigma)$; or (c) $f(\sigma) = O(\lg^\epsilon \sigma)$ and $g(\sigma) = O(1)$.*

Data Structures for `rank` and `select`. Given a sequence A drawn from alphabet $[\sigma]$, a $\texttt{rank}_c(A, i)$ operation computes the number of elements equal to c in $A[0..i]$, where $c \in [\sigma]$, while a $\texttt{select}_c(A, i)$ returns the index of the entry of A containing the i-th occurrence of c. We have the following two lemmas on building `rank`/`select` structures.

▶ **Lemma 4.** *Let $A[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$, where $n' \leq n$ and $\sigma = O(\text{polylog}\, n)$. A data structure of $n'\lceil \lg \sigma \rceil + o(n' \lg \sigma)$ bits supporting* `rank` *in $O(1)$ time can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma)$ time.*

▶ **Lemma 5** ([2, Lemma 2.1])**.** *Given a packed bit sequence $B[0..n-1]$, a systematic data structure occupying $o(n)$ extra bits can be constructed in $O(n/\lg n)$ time, which supports* `rank` *and* `select` *in constant time.*

In the above lemma, a data structure is *systematic* if it requires the input data to be stored verbatim along with the additional information for answering queries. A restricted version of `rank` is called *partial rank*; a partial rank operation, $\texttt{rank}'(A, i)$, computes the number of elements equal to $A[j]$ in $A[0..j]$. The following lemma presents a solution to supporting $\texttt{rank}'$, which is an easy extension of [3, Lemma 3.5].

▶ **Lemma 6.** *Given a sequence $A[0..n-1]$ drawn from alphabet $[\sigma]$, a data structure of $O(n \lg \sigma)$ bits can be constructed in $O(n + \sigma)$ time, which supports* $\texttt{rank}'$ *in constant time.*

Range Minimum/Maximum. Given a sequence A of n integers, a range minimum/maximum query $\texttt{rmq}(i, j)$/$\texttt{rMq}(i, j)$ with $i \leq j$ returns the position of a minimum/maximum element in the subsequence $A[i..j]$. Fischer and Heun [16] considered this problem:

▶ **Lemma 7** ([16])**.** *Given an array A of n integers, a data structure of $O(n)$ bits can be constructed in $O(n)$ time, which answers* `rmq`/`rMq` *in $O(1)$ time without accessing A.*

We further build an auxiliary structure upon a packed sequence A under the *indexing model*: after the the data structure is built, A itself need not be stored verbatim; to answer a query, it suffices to provide an operator that can retrieve any element in A.

▶ **Lemma 8.** *Let $A[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$, where $\sigma \leq 2^{\sqrt{\lg n}}$ and $n' \leq n$. There is a data structure using $O(n' \lg \lg n)$ extra bits constructed in $O(n' \lg \sigma / \lg n)$ time, which answers* `rmq`/`rMq` *in $O(1)$ time and $O(1)$ accesses to the elements of A. The query procedure uses a universal table of $o(n)$ bits.*

3 Fast Construction of $\texttt{rank}'$ Query Structures

In this section we focus on how to efficiently construct data structures for $\texttt{rank}'$ queries over a sequence $A[0..n'-1]$ drawn from alphabet $[\sigma]$, where $n' \leq n$ and $\sigma \leq 2^{\sqrt{\lg n}}$. This is needed to solve ball inheritance in a special case. Lemma 4 already solves this problem when $\sigma \leq \lg n$, so we assume $\lg n < \sigma \leq 2^{\sqrt{\lg n}}$ in the rest of this section.

In our solution, we conceptually divide sequence A into chunks of length σ. For simplicity, assume that n' is a multiple of σ. Let A_k denote the kth chunk, where $0 \leq k \leq n'/\sigma - 1$. For each $c \in [0, \sigma - 1]$, we define the following data structures:

- A bitvector $B_c = 1^{\texttt{rank}_c(A_0,\sigma)}01^{\texttt{rank}_c(A_1,\sigma)}0 \ldots 1^{\texttt{rank}_c(A_{n'/\sigma-1},\sigma)}0$, which encodes the number of occurrences of symbol c in each chunk in unary. B_c is represented using Lemma 5 to support `rank` and `select` in constant time.
- A sequence $P_c[0..n'/\sigma - 1]$, in which $P_c[i] = \texttt{rank}'(A_i, c)$ for each $i \in [0, n'/\sigma - 1]$, i.e., $P_c[i]$ stores the answer to a partial rank query performed locally within A_i at position c.

Note that we have one B_c for each alphabet symbol c, while we have one P_c for each relative position c in the chunks of A. We have the following lemma on supporting queries using these data structures, with a space analysis.

▶ **Lemma 9.** *The data structures in this section occupy $n' \lg \sigma + o(n' \lg \sigma)$ extra bits and support* `rank'` *in $O(1)$ time and $O(1)$ accesses to elements of A.*

Proof. In B_c, each 1 bit corresponds to an occurrence of symbol c in A, while each 0 corresponds to a chunk. Thus, these bit vectors have n' 1s and $n'/\sigma \times \sigma = n'$ 0s in total. Therefore, the lengths of all these bit vectors sum up to $2n'$. By Lemma 5, $o(n')$ bits are needed to augment them to support `rank` and `select`. As each chunk has σ elements, encoding an entry of each P_c requires $\lceil \lg \sigma \rceil$ bits. Thus $P_0, \ldots, P_{\sigma-1}$ occupy $n' \lceil \lg \sigma \rceil$ bits in total. The total space usage of all the data structures in this section is therefore $2n' + o(n') + n' \lceil \lg \sigma \rceil$ bits, which is $n' \lg \sigma + o(n' \lg \sigma)$ when $\sigma > \lg n$.

A query $\texttt{rank}'(A, j)$ can be answered as follows:

$$\texttt{rank}'(A, j) = select_0(B_c, t) - (t-1) + P_\tau[t], where\ \tau = j \bmod \sigma, t = \lfloor \frac{j}{\sigma} \rfloor, and\ c = A[j]$$

As the `select` query over B_c takes constant time, answering $\texttt{rank}'(A, j)$ requires $O(1)$ time and a single access to A. ◀

Next, we consider how to construct the sequences B_c's efficiently.

▶ **Lemma 10.** *Bitvectors $B_0, B_1, \ldots, B_{\sigma-1}$ can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma)$ time.*

Proof. We first construct a sequence $M[0..n' + n'/\sigma - 1]$ in which each element is encoded in $\lceil \lg \sigma \rceil + 1$ bits. In M, n' elements are *regular elements*, and the rest are *boundary elements* each of which is an integer whose binary expression simply consists of $\lceil \lg \sigma \rceil + 1$ 0-bits. M is divided into n'/σ chunks, and each chunks contains σ regular elements followed by a boundary element. The subsequence of the σ regular elements in the i-th chunk can be obtained by appending a 1-bit to the end of the binary expression of each element in A_k.

Next we show how to create M efficiently with the help of a universal table U. This table has an entry for each possible pair (D, t), where D is a sequence of length $b = \lfloor \frac{\lg n}{2\lceil \lg \sigma \rceil} \rfloor$ drawn from $[\sigma]$ and t is an integer in $[0, b]$. If $t = 0$, this entry stores a sequence of length b which is obtained by appending a 1-bit to the end of the binary expression of each element in D. Otherwise, this entry stores a sequence of length $b+1$ consisting of three sections: the first section is obtained by appending a 1-bit to the end of the binary expression of each of the first t elements in D, the second section is a boundary element, and the third section is obtained by appending a 1-bit to the end of the binary expression of each of the last $b - t$ elements in D. As there are at most $n^{1/2}$ possible sequences of length b drawn from σ and t has $b+1$ possible values, U has at most $n^{1/2}(b+1)$ entries. Since each entry is encoded in at most $(b+1)(\lceil \lg \sigma \rceil + 1) = O(\text{polylog}(n))$ bits, U uses $o(n)$ bits. With U, we can scan A and process b of its elements in constant time; whether or where a boundary element should be created when processing these b elements can be inferred by keeping track of the number of elements that we have scanned so far. Note that at most one boundary element will be created when reading b elements from A, as $b < \lg n < \sigma$. The time needed to create M is hence $O(n'/b) = O(n' \lg \sigma / \lg n)$.

From M we determine the content of $B_0, B_1, \ldots, B_{\sigma-1}$ by constructing a tree T over M similar to large extent to a binary wavelet tree and associating each node u of T with a sequence $M(u)$. At the root node r of T, we set $M(r) = M$, and we perform the following recursive procedure at any node u at level l of T where $l \in [0, \lceil \lg \sigma \rceil - 1]$: We create the left

child, u_0, and the right child, u_1, of u, and perform a linear scan of $M(u)$. During the scan, for each $i \in [0, |M(u) - 1|]$, if $M(u)[i]$ is a boundary element, it is appended to both $M(u_0)$ and $M(u_1)$. If $M(u)[i]$ is not a boundary element and its lth most significant bit is 0, $M(u)[i]$ is appended to $M(u_0)$. If its lth significant bit is 1, it is appended to $M(u_1)$. After generating the sequences $M(u_0)$ and $M(u_1)$, we discard the sequence $M(u)$. We finish recursion after we create $\lceil \lg \sigma \rceil$ levels, i.e., we only examine the first $\lceil \lg \sigma \rceil$ bits of each element of M to determine the tree structure. Thus, this tree has σ leaves, and the sequences associated with the leaves from left to right are named M_0, M_1, ..., $M_{\sigma-1}$. They form a partition of M.

To speed up this process, we use a universal table U'. Recall that $b = \lfloor \frac{\lg n}{2\lceil \lg \sigma \rceil} \rfloor$. U' has an entry for each possible pair (E, c), where E is a sequence of length b drawn from universe $[2\sigma]$ and c is an integer in $[0, \lceil \lg \sigma \rceil - 1]$. This entry stores a pair of packed sequences E_0 and E_1 defined as follows: E_0 or E_1 stores the boundary elements in E and the regular elements in E whose c-th most significant bit is 0 or 1, respectively. The elements in E_0 retain their relative order in E, and the same is true with E_1. As U' has $2^{b \times (\lceil \lg \sigma \rceil + 1)} \times \lceil \lg \sigma \rceil$ entries and each entry stores a pair of packed sequences occupying $O(b\lceil \lg \sigma \rceil)$ bits in total, U' uses $o(n)$ bits. By performing table lookups in U', we can process $M(u)$ in $O(|M(u)| \lg \sigma / \lg n + 1)$ time. Note that we assign n' regular and $2^l \times \frac{n'}{\sigma}$ boundary elements to the nodes at tree level l. Summing over all $O(\sigma)$ nodes of the tree, the total time required to construct this tree is $O(\sum_{l=0}^{\lceil \lg \sigma \rceil - 1}((n' + 2^l \times \frac{n'}{\sigma}) \lg \sigma / \lg n) + \sigma) = O(n' \lg^2 \sigma / \lg n + \sigma)$.

To construct bitvectors B_c for any $0 \le c \le \sigma - 1$, a crucial observation is that the i-th bit in B_c is the same as the least significant bits of the i-th elements of M_c. Thus it takes $O(|B_c|(\lg \sigma + 1)/ \lg n + 1)$ time to compute the content of B_c using bit packing. B_c can then be represented in $O(|B_c|/ \lg n + 1)$ time to support `rank` and `select` by Lemma 5. Summing over all σ bitvectors, the time required to construct B_0, B_1, ..., $B_{\sigma-1}$ from $M_0, M_1, \ldots, M_{\sigma-1}$ is $O(n' \lg \sigma / \lg n + \sigma)$.

Overall, given A, the construction time of these bit vectors is

$$O(n' \lg \sigma / \lg n + (n' \lg^2 \sigma / \lg n + \sigma) + (n' \lg \sigma / \lg n + \sigma)) = O(n' \lg^2 \sigma / \lg n + \sigma). \quad \blacktriangleleft$$

It remains to show how to build all sequences $P_0, P_1, \ldots, P_{\sigma-1}$ efficiently.

▶ **Lemma 11.** *Sequences $P_0, P_1, \ldots, P_{\sigma-1}$ can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma)$ time.*

Proof. The construction consists of two phases. In the first phase, we compute the set of pairs $R_k = \{(i, \texttt{rank}'(A_k, i)) | 0 \le i \le \sigma - 1\}$ for each chunk A_k. Even though $P_i[k] = \texttt{rank}'(A_k, i)$ and thus the entries of all the P_i's have been computed in this phase, the pairs themselves generated for A_k are not in any order that allows us to directly assign values from these pairs to entries of P_i's quickly enough. Thus, in the second phase, we reorganize all n' pairs computed from all the chunks, to construct $P_0, P_1, \ldots, P_{\sigma-1}$ efficiently.

We first show how to compute the pair set R_k for each A_k efficiently. Let $I[0, \sigma - 1]$ denote a packed sequence such that $I[i] = i$ for each $i \in [0, \sigma - 1]$. Note that I can be constructed once in $O(\sigma)$ time and shared with all chunks. By Lemma 1, a binary wavelet tree, in which node u is associated with $A(u)$ and $I(u)$ as defined before, over A_k could be constructed in $O(\sigma \lg^2 \sigma / \lg n + \sigma)$ time. However, the second term $O(\sigma)$, when summed over all n'/σ chunks, is too expensive to afford. Thus, we modify the structure of a wavelet tree to decrease this term. In the modified tree, when a node v satisfies $|A(v)| \le b = \lfloor \frac{\lg n}{2\lceil \lg \sigma \rceil} \rfloor$, we make v a leaf node without any descendants. With this modification, we observe the following two properties. First, if a leaf node l satisfies $|A(l)| > b$, then the tree level of l must be $\lg \sigma$ and all entries of $A(l)$ store the same symbol. Second, as there are at most $\lceil \sigma / b \rceil$ nodes at each level, the modified tree has $O(\sigma / b \times \lg \sigma) = O(\sigma \lg^2 \sigma / \lg n)$ nodes. The

$O(\sigma)$ term in construction time in Lemma 1 follows from the fact that a wavelet tree has $O(\sigma)$ leaves. With fewer leaves, the modified tree can be constructed in $O(\sigma \lg^2 \sigma / \lg n)$ time. After this tree is constructed, we only keep the sequences $A(l)$ and $I(l)$ for each leaf node l and call them *leaf sequences*. We discard the rest of the tree.

To further compute R_k using these leaf sequences, observe that, for any symbol α, there exists one leaf l such that $A(l)$ contains all the occurrences of α in A. Thus $(I(l)[i], \texttt{rank}'(A_k, I(l)[i])) = (I(l)[i], \texttt{rank}'(A(l), i))$ holds, which we can use to reduce the problem of computing the pairs in R_k to the problem of computing the answer to a partial rank query at each position of $A(l)$ for each leaf l. Hence for each leaf l, we define a packed sequence $Q(l)[0..|A(l)|-1]$ in which $Q(l)[i] = \texttt{rank}'(A(l), i)$ to store these answers. To construct $Q(l)$ efficiently, we consider two cases. When $|A(l)| \leq b$, we apply a universal table U'' to generate $Q(l)$ in constant time. U'' has an entry for each possible pair (F, x), where F is a sequence of length b drawn from universe $[\sigma]$, and x is an integer in $[0, b]$. This entry stores a packed sequence $G[0..x]$ in which $G[i] = \texttt{rank}'(F, i)$. Similar to U in the proof of Lemma 10, U'' uses $o(n)$ bits. When $|A(l)| > b$, all entries of $A(l)$ store the same symbol. Thus, we have $Q(l)[i] = i$ for each $i \in [0, |A(l)|-1]$, and hence we can create $Q(l)$ by copying the first $|A(l)|$ elements from the sequence I which we created before. In either case, $Q(l)$ can be constructed in $O(|A(l)| \lg \sigma / \lg n + 1)$ time. Let l_i denote the $(i+1)$-st leaf visited in a preorder traversal of the tree, and f the number of leaves. Since $\sum_{i=0}^{f} |Q(l_i)| = \sigma$ and $f = O(\sigma \lg^2 \sigma / \lg n)$, the total time required to build $Q(l_0), Q(l_1), \ldots, Q(l_{f-1})$ is $O(\sigma \lg^2 \sigma / \lg n)$. Then we construct the concatenated packed sequence $I_k = I(l_0)I(l_1)\ldots I(l_{f-1})$ and $Q_k = Q(l_0)Q(l_1)\ldots Q(l_{f-1})$. It requires $O(\sigma \lg^2 \sigma / \lg n)$ time to concatenate these sequences if we process $\Theta(\lg n)$ bits, i.e., $O(1)$ words, in constant time by performing bit operations. Since for any $i \in [0, \sigma-1]$, $(I_k[i], Q_k[i])$ is a distinct pair in R_k, I_k and Q_k store all the pairs in R_k. We perform the steps in this and the previous paragraphs for all the chunks in A, and the total time spent in this phase is $O(n' \lg^2 \sigma / \lg n + \sigma)$.

Next we construct $P_0, P_1, \ldots, P_{\sigma-1}$ efficiently using the pairs computed in the previous phase. We first build in $O(n' \lg^2 \sigma / \lg n)$ time two concatenated packed sequences each of length n': $I' = I_0 I_1 \ldots I_{n'/\sigma-1}$ and $Q = Q_0 Q_1 \ldots Q_{n'/\sigma-1}$. Then we construct a binary wavelet tree over I'. Each node, u, of the wavelet tree is associated with two sequences, $I'(v)$ which contains all the elements of I' whose values are within the range represented by v, retaining their relative order in I', and $Q(v)$ in which $Q(v)[i]$ is the element in Q corresponding to $I'(v)[i]$. The wavelet tree construction algorithm of Lemma 1 can be modified easily to construct this wavelet tree in $O(n' \lg^2 \sigma / \lg n + \sigma)$ time. Let l'_i denote the $(i+1)$st leaf of this wavelet tree in preorder. Observe that all the entries in $I'(l'_i)$ store i, and $I'(l'_i)[j]$ initially came from A_j, i.e., $I'(l'_i)[j]$ corresponds to the ith position in chunk A_j. Therefore, $Q(l'_i)[j] = P_i[j]$, and we have $P_i = Q(l'_i)$. The processing time required for this phase is also $O(n' \lg^2 \sigma / \lg n + \sigma)$, which is the same as the bound for the first phase. Therefore, the total time required to construct all sequences $P_0, P_1, \ldots, P_{\sigma-1}$ is $O(n' \lg^2 \sigma / \lg n + \sigma)$. ◀

Combining Lemmas 4, 9, 10 and 11, we have the following result:

▶ **Lemma 12.** *Let $A[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$, where $n' \leq n$ and $\sigma = O(2^{O(\sqrt{\lg n})})$. With the help of a universal table of $o(n)$ bits, a data structure using $n' \lceil \lg \sigma \rceil + o(n' \lg \sigma)$ extra bits can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma)$ time to support* $\texttt{rank}'$ *queries in $O(1)$ time and $O(1)$ accesses to elements of A.*

4 Fast Construction of Data Structures for Ball Inheritance

We now solve, with fast preprocessing, ball inheritance for the special cases needed later to match the time and space bounds in parts (b) and (c) of Lemma 3. The omitted proofs are deferred to the full version of this paper. One strategy is to construct the solution of Chan et al. [11] by replacing some of their components with those we designed with faster preprocessing. This yields:

▶ **Lemma 13.** *Let $X[0, n-1]$ be a sequence drawn from alphabet $[\sigma]$ denoting the point set $N = \{(X[i], i) | 0 \le i \le n-1\}$, where $2^{\sqrt{\lg n}} \le \sigma \le n$. A $2^{\sqrt{\lg n}}$-ary wavelet tree over X occupying $O(n \lg \sigma \cdot f(\sigma) + n \lg n)$ bits can be constructed in $O(n \lg \sigma / \sqrt{\lg n})$ time to support* `point` *in $O(g(\sigma))$ time and* `noderange` *in $O(\lg \lg n + g(\sigma))$ time, where (a) $f(\sigma) = O(\lg(\lg \sigma / \sqrt{\lg n}))$ and $g(\sigma) = O(\lg(\lg \sigma / \sqrt{\lg n}))$; or (b) $f(\sigma) = O(\lg^{\epsilon} \sigma)$ and $g(\sigma) = O(1)$ for any constant $\epsilon > 0$. The* `noderange` *query requires a universal table of $o(n)$ bits.*

▶ **Lemma 14.** *Let $X[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$ and $Y[0..n'-1]$ be a packed sequence in which $Y[i] = i$ for each $i \in [0..n'-1]$, where $\sigma = O(2^{O(\sqrt{\lg n})})$ and $n' = O(\sigma^{O(1)})$. Given X and Y as input, a d-ary wavelet tree over X using $O(n' \lg \sigma \lg(\lg \sigma / \lg d) + \sigma w)$ bits of space can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma \log_d \sigma)$ time to support* `point` *in $O(\lg(\lg \sigma / \lg d))$ time and* `noderange` *in $O(\lg \lg \sigma)$ time, where d is a power of 2 upper bounded by $min(\sigma, 2^{\sqrt{\lg n}})$.*

This strategy however cannot achieve, with the preprocessing time as in Lemma 14, part (c) of Lemma 3 when the coordinates of points can be encoded in $O(\sqrt{\lg n})$ bits. For this special case, we twist the approach of Chan et al.: they only store point coordinates explicitly at the leaf level of the wavelet tree, while we take advantage of the smaller grid size to store coordinates at more levels. This allows us to build `rank'` structures at fewer levels of the tree, decreasing the preprocessing time. The details are as follows.

Recall that, when used to represent the given point set N, each node u of the d-ary wavelet tree T is conceptually associated with an ordered list, $N(u)$, of points whose x-coordinates are within the range represented by u, and these points are ordered by y-coordinate. Assume for simplicity that σ is a power of d, and that both $1/\epsilon$ and $\tau = \log_d^{\epsilon} \sigma$ are integers. We assign a color to each level of T: Level 0 is assigned color 0, while any other Level l is assigned color $\max\{c \mid \tau^c \text{ divides } l \text{ and } 0 \le c \le 1/\epsilon - 1\}$. For each node u of T at a level assigned with color $1/\epsilon - 1$, we store the coordinates of the points in $N(u)$ explicitly. For any other node v (let l be the level l of v and c the color assigned to level l), we do not store $N(v)$. Instead, for each $i \in [0, |N(v)|]$, we store a *skipping pointer* $Sp(v)[i]$, which stores, at the closest level l' satisfying $l' > l$ and l' is a multiple of τ^{c+1}, the descendant of v at level l' containing point $N(v)[i]$ in its ordered list of points. This descendant is encoded by its rank among all the descendants of v at level l' in left-to-right order. We use Lemma 12 to support $O(1)$-time `rank'` over $Sp(v)$. Then, since both $N(u)$ and $N(Sp(u)[i])$ order points by y-coordinate, a `rank'`$(Sp(u), i)$ query gives the position of the point $N(u)[i]$ in $N(Sp(u)[i])$. Thus, to compute `point`(v, i), we follow skip pointers starting from v by performing `rank'`, until we reach a level with color $1/\epsilon - 1$, where we retrieve coordinates. With this we have:

▶ **Lemma 15.** *Let $X[0..n'-1]$ be a packed sequence drawn from alphabet $[\sigma]$ and $Y[0..n'-1]$ be a packed sequence in which $Y[i] = i$ for each $i \in [0..n'-1]$, where $\sigma = O(2^{O(\sqrt{\lg n})})$ and $n' = O(\sigma^{O(1)})$. Given X and Y as input, a d-ary wavelet tree over X using $O(n' \lg \sigma \log_d^{\epsilon} \sigma + \sigma w)$ bits for any positive constant ϵ can be constructed in $O(n' \lg^2 \sigma / \lg n + \sigma \log_d \sigma)$ time to support* `point` *in $O(1)$ time and* `noderange` *in $O(\lg \lg \sigma)$ time, where d is a power of 2 upper bounded by $min(\sigma, 2^{\sqrt{\lg n}})$. The* `noderange` *query requires a universal table of $o(n)$ bits.*

5 Optimal Orthogonal Range Reporting with Fast Preprocessing

We now design data structures that support orthogonal range reporting in optimal time and can be constructed fast. Previously, with a solution to ball inheritance, Chan et al. [11] was able to design a relatively simple approach achieving three current best tradeoffs for orthogonal range reporting. However, we have only designed alternative solutions to ball inheritance with fast construction time in special cases. Therefore, we design a different data structure with optimal query time for orthogonal range reporting. The strategy is to use a generalized wavelet tree and our solution to range minimum/maximum (Lemma 8) to reduce the orthogonal range reporting problem in the general case to the special case in which the points are from a $2^{\sqrt{\lg n}} \times n'$ (narrow) grid. In this reduction, we need only support ball-inheritance over a wavelet tree with high fanout which is solved by part (b) of Lemma 13. We further reduce the range reporting problem over points in a narrow grid to this problem over a (small) grid of size at most $2^{\sqrt{\lg n}} \times 2^{2\sqrt{\lg n}}$, to which we can apply Lemma 15 for ball inheritance. Hence we describe our solutions over a small, narrow and general grid in this order, as the solution to the next case uses that to the previous.

5.1 Orthogonal Range Reporting in a Small Grid

▶ **Lemma 16.** *Let N be a set of δ points with distinct y-coordinates in a $2^{\sqrt{\lg n}} \times \delta$ grid where $\delta \leq 2^{2\sqrt{\lg n}}$. Given packed sequences X and Y respectively encoding the x- and y-coordinates of these points where $Y[i] = i$ for any $i \in [0, \delta - 1]$, a data structure occupying $O(\delta \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}})$ bits can be constructed in $O(\delta + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ time to support orthogonal range reporting over N in $O(\lg \lg n + \mathtt{occ})$ time, where ϵ is an arbitrary positive constant and $\mathtt{occ}$ is the number of reported points.*

Proof. We build a binary wavelet tree T over X augmented with support for ball inheritance. By Lemma 15, T occupies $O(\delta \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}})$ bits and can be built in $O(\delta + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ time. It also supports `point` in $O(1)$ time and `noderange` in $O(\lg \lg n)$ time. For any internal node v of T, its value array $A(v)$ is built at some point when augmenting T to solve ball inheritance, though $A(v)$ may be discarded eventually. When $A(v)$ was available, we build a data structure $M(v)$ to support range minimum and maximum queries over $A(v)$ using Lemma 8. As T has $\lceil \sqrt{\lg n} \rceil$ non-leaf levels and the total length of the value arrays of the nodes at each tree level is δ, over all internal nodes, these structures use $O(\delta \sqrt{\lg n} \lg \lg n)$ bits in total and the overall construction time is $\sum_v O(|A(v)|/\sqrt{\lg n} + 1) = O(\delta + 2^{\sqrt{\lg n}})$. These costs are subsumed in the storage and construction costs of T. Recall that $A(v)$ stores the x-coordinates of the set, $N(v)$, of points from N whose x-coordinates are within the range represented by v, and the entries of $A(v)$ are ordered by the corresponding y-coordinates of these points. Thus any entry of $A(v)$ can be retrieved by `point` in constant time. Therefore, even after $A(v)$ is discarded, $M(v)$ can still support `rmq`/`rMq` over $A(v)$ in $O(1)$ time.

Given a query range $Q = [a, b] \times [c, d]$, we first locate the lowest common ancestor u of l_a and l_b in constant time, where l_a and l_b denote the a-th and b-th leftmost leaves of T, respectively. Let u_l and u_r denote the left and right children of u, respectively, $[c_l, d_l] = \mathtt{noderange}(c, d, u_l)$ and $[c_r, d_r] = \mathtt{noderange}(c, d, u_r)$. Then $Q \cap N = (([a, +\infty) \times [c_l, d_l]) \cap N(u_l)) \cup (([0, b] \times [c_r, d_r]) \cap N(u_r))$. In this way, we reduce a 2-d 4-sided range reporting in N to 2-d 3-sided range reporting in $N(u_l)$ and $N(u_r)$. To report points in $([a, +\infty) \times [c_l, d_l]) \cap N(u_l)$, we need only report the points in $N(u_l)[c_l, d_l]$ whose x-coordinates are at least a. This can be done by performing range maximum queries over $A(u_l)$ recursively

as follows. We perform $\texttt{rMq}(c_l, d_l)$ to get the index m of the point p that has the maximum x-coordinate in $N(u_l)[c_l, d_l]$, and retrieve its coordinates $(p.x, p.y)$ by $\texttt{point}(u_l, m)$. If $p.x \geq a$, we report p and perform the same process recursively in $N(u_l)[c_l, m-1]$ and $N(u_l)[m+1, d_l]$. Otherwise we stop. The points in $([0, b] \times [c_r, d_r]) \cap N(u_r)]$ can be reported in a similar way. To analyze the query time, observe that we perform `noderange` twice in $O(\lg \lg n)$ time. The recursive procedure is called $O(\texttt{occ})$ times, and each time it is performed, it uses $O(1)$ time. All other steps require $O(1)$ time. Therefore, the overall query time is $O(\lg \lg n + \texttt{occ})$. ◀

5.2 Orthogonal Range Reporting in a Narrow Grid

Our solution for points in a $2^{\sqrt{\lg n}} \times n'$ grid for any $n' \leq n$ uses the following previous result:

▶ **Lemma 17** ([11, Section 2], [6, Lemma 5]). *Given a set, N, of n points in $[u] \times [u]$, a data structure of $O(n \lg^{1+\epsilon} n)$ bits can be constructed in $O(n \lg n)$ time, which supports orthogonal range reporting over N in $O(\lg \lg u + \texttt{occ})$ time, where $\texttt{occ}$ is the number of reported points.*

The following lemma presents our solution for a narrow grid:

▶ **Lemma 18.** *Let N be a set of n' points with distinct y-coordinates in a $2^{\sqrt{\lg n}} \times n'$ grid where $n' \leq n$. Given packed sequences X and Y respectively encoding the x- and y-coordinates of these points where $Y[i] = i$ for any $i \in [0, n'-1]$, a data structure occupying $O(n' \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}} + n'w/2^{\sqrt{\lg n}})$ bits can be constructed in $O(n' + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ time to support orthogonal range reporting over N in $O(\lg \lg n + \texttt{occ})$ time, where ϵ is an arbitrary positive constant and $\texttt{occ}$ is the number of reported points.*

Proof. Let $b = 2^{2\sqrt{\lg n}}$. We need only consider the case in which $n' > b$ as Lemma 16 applies otherwise. Assume for simplicity that n' is divisible by b. We divide N into n'/b subsets, and for each $i \in [0, n'/b - 1]$, the ith subset, N_i, contains points in N whose y-coordinates are in $[ib, (i+1)b - 1]$. Let p be a point in N_i. We call its coordinates $(p.x, p.y)$ *global coordinates*, while $(p.x', p.y') = (p.x, p.y \bmod b)$ its *local coordinates* in N_i; the conversion between global and local coordinates can be done in constant time. Hence the points in N_i with their local coordinates can be viewed as a point set in a $2^{\sqrt{\lg n}} \times 2^{2\sqrt{\lg n}}$ grid, and we apply Lemma 16 to construct an orthogonal range search structure over N_i.

We also define a point set $\hat{N}$ in a $2^{\sqrt{\lg n}} \times n'/b$ grid. For each set N_i where $i \in [0, n'/b - 1]$ and each $j \in [0, 2^{\sqrt{\lg n}} - 1]$, we store a point (j, i) in $\hat{N}$ iff there exists at least one point in N_i whose x-coordinate is j. Thus the number of points in $\hat{N}$ is at most $n'/b \times 2^{\sqrt{\lg n}} = n'/2^{\sqrt{\lg n}}$. We apply Lemma 17 to construct an orthogonal range search structure over $\hat{N}$. In addition, for each $i \in [0, n'/b - 1]$ and $j \in [0, 2^{\sqrt{\lg n}} - 1]$, we store a list $P_{i,j}$ storing the local y-coordinates of the points in N_i whose x-coordinates are equal to j.

Given a query range $Q = [x_1, x_2] \times [y_1, y_2]$, we first check if $\lfloor y_1/b \rfloor$ is equal to $\lfloor y_2/b \rfloor$. If it is, then the points in the answer to the query reside in the same subset $N_{\lfloor y_1/b \rfloor}$, and we can retrieve these points by performing an orthogonal range query in $N_{\lfloor y_1/b \rfloor}$, which requires $O(\lg \lg n + \texttt{occ})$ time by Lemma 16. Otherwise, we decompose Q into three subranges $Q_1 = [x_1, x_2] \times [y_1, b(\lfloor y_1/b \rfloor + 1) - 1]$, $Q_2 = [x_1, x_2] \times [b(\lfloor y_1/b \rfloor + 1), b\lfloor y_2/b \rfloor - 1]$ and $Q_3 = [x_1, x_2] \times [b\lfloor y_2/b \rfloor, y_2]$. The points in $N \cap Q_1$ and $N \cap Q_3$ are in $N_{\lfloor y_1/b \rfloor}$ and $N_{\lfloor y_2/b \rfloor}$, respectively, and by Lemma 16, they can be reported in $O(\lg \lg n + \texttt{occ}_1)$ and $O(\lg \lg n + \texttt{occ}_3)$ time, respectively, where $\texttt{occ}_1 = |N \cap Q_1|$ and $\texttt{occ}_3 = |N \cap Q_3|$. The points in $N \cap Q_2$ are in $N_{\lfloor y_1/b \rfloor + 1}, N_{\lfloor y_1/b \rfloor + 2}, \ldots, N_{\lfloor y_2/b \rfloor - 1}$. To retrieve them, we first perform an orthogonal range query in $\hat{N}$ with query range $\hat{Q} = [x_1, x_2] \times [\lfloor y_1/b \rfloor + 1, \lfloor y_2/b \rfloor - 1]$. Let (x, y) be a point

in $\hat{N} \cap \hat{Q}$. The existence of this point means that is at least one point in $N_y \cap Q_2$ whose x-coordinates are equal to x; the local y-coordinates of these points are stored in $P_{y,x}$ which we retrieve and convert to global coordinates. After examining all the points in $\hat{N} \cap \hat{Q}$ and retrieving their corresponding points in $N \cap Q_2$ in this way, we have computed all the points in $N \cap Q_2$ in $O(\lg\lg n + \mathtt{occ}_2)$ time where $\mathtt{occ}_2 = |N \cap Q_2|$. The overall query processing time is thus $O(\lg\lg n + \mathtt{occ})$.

To bound the storage costs, by Lemma 16, the orthogonal range reporting structure over each N_i uses $O(2^{2\sqrt{\lg n}} \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}})$ bits. Thus, the range reporting structures over $N_0, N_1, \ldots, N_{n/b-1}$ occupy $O((n'/b) \times (2^{2\sqrt{\lg n}} \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}})) = O(n' \lg^{1/2+\epsilon} n + n'w/2^{\sqrt{\lg n}})$. As there are at most $n'/2^{\sqrt{\lg n}}$ points in $\hat{N}$, by Lemma 17, the range reporting structure for $\hat{N}$ occupies $O(n' \lg^{1+\epsilon} n/2^{\sqrt{\lg n}}) = o(n')$ bits. There are n' points in all $P_{i,j}$'s and each of their local y-coordinates can be encoded in $\lg b = 2\sqrt{\lg n}$ bits. In addition, each $P_{i,j}$ requires a pointer to encode its memory location, so $n'/b \times 2^{\sqrt{\lg n}} = n'/2^{\sqrt{\lg n}}$ pointers are needed. Therefore, the total storage cost of all $P_{i,j}$'s is $O(n'w/2^{\sqrt{\lg n}} + n'\sqrt{\lg n})$. Thus the space costs of all structures add up to $O(n' \lg^{1/2+\epsilon} n + n'w/2^{\sqrt{\lg n}})$ bits. Note that the above analysis assumes $n' > b$. Otherwise, $O(n' \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}})$ bits are needed, so we use $O(n' \lg^{1/2+\epsilon} n + w \cdot 2^{\sqrt{\lg n}} + n'w/2^{\sqrt{\lg n}})$ as the space bound on both cases.

Regarding construction time, when $n' > b$, observe that the point sets $N_0, N_1, \ldots, N_{n'/b-1}$ and $\hat{N}$, as well as the sequences $P[i,j]$ for $i = 0, 1, \ldots, n'/b-1$ and $j = 0, 1, \ldots, 2^{\sqrt{\lg n}} - 1$, can be computed in $O(n')$ time. By Lemma 17, The range reporting structure for $\hat{N}$ can be built in $O(n'/b \times \lg n) = o(n')$ time. Finally, the total construction time of the range reporting structures for $N_0, N_1, \ldots, N_{n/b-1}$ is $O(n'/2^{2\sqrt{\lg n}} \times (2^{2\sqrt{\lg n}} + \sqrt{\lg n} \times 2^{\sqrt{\lg n}})) = O(n')$, which dominates the total preprocessing time of all our data structures. When $n' \leq b$, the construction time is $O(n' + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ by Lemma 16, so we use $O(n' + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ as the upper bound on construction time in both cases. ◀

5.3 Orthogonal Range Reporting in an $n \times n$ Grid

We first describe a solution that is slight more general, which requires the grid to be of size $\sigma \times n$ with $2^{\sqrt{\lg n}} \leq \sigma \leq n$, as it will be needed for some applications to be described later.

▶ **Lemma 19.** *Given a sequence $X[0, n-1]$ drawn from alphabet $[\sigma]$ denoting the point set $N = \{(X[i], i) | 0 \leq i \leq n-1\}$, a data structure of $O(n \lg^{1+\epsilon} \sigma + n \lg n)$ bits for any constant $\epsilon > 0$ can be constructed in $O(n \lg \sigma / \sqrt{\lg n})$ time to support orthogonal range reporting over N in $O(\lg\lg n + \mathtt{occ})$ time, where $2^{\sqrt{\lg n}} \leq \sigma \leq n$ and $\mathtt{occ}$ is the number of reported points.*

Proof. We build a $2^{\sqrt{\lg n}}$-ary wavelet tree T upon $X[0, n-1]$ with support for ball inheritance using part (b) of Lemma 13. As in the proof of Lemma 16, for each internal node $v \in T$, we build a data structure $M(v)$ to support range minimum and maximum queries over its value array $A(v)$ in constant time using Lemma 8, even $A(v)$ is not be explicitly stored. Recall that $A(v)$ stores the x-coordinates of the ordered list, $N(v)$, of points from N whose x-coordinates are within the range represented by v, and these points are ordered by y-coordinate. Furthermore, v is associated with another sequence $S(v)$ drawn from alphabet $[2^{\sqrt{\lg n}}]$, in which $S(v)[i]$ encodes the rank of the child of v that contains $N(v)[i]$ in its ordered list. Let $\hat{S}(v)$ denote the point set $\{(S(v)[i], i) | 0 \leq i \leq |S(v)| - 1\}$, and we use Lemma 18 to build a structure supporting orthogonal range reporting over $\hat{S}(v)$.

Given a query range $Q = [a, b] \times [c, d]$, we first locate the lowest common ancestor u of l_a and l_b in constant time, where l_a and l_b denote the a-th and b-th leftmost leaves of T, respectively. Let u_i denote the ith child of u, for any $i \in [0, 2^{\sqrt{\lg n}} - 1]$. We first locate two children, $u_{a'}$ and $u_{b'}$, of u that are ancestors of l_a and l_b, respectively. They can be found in constant time by simple arithmetic as each child of u represents a range of equal size. Then the answer, $Q \cap N$, to the query can be partitioned into three point sets $A_1 = Q \cap N(v_{a'})$, $A_2 = Q \cap (N(v_{a'+1}) \cup N(v_{a'+2}) \cup \ldots N(v_{b'-1}))$ and $A_3 = Q \cap N(v_{b'})$. With $O(\lg \lg n)$-time support for `noderange` and constant-time support for `point` and `rmq`/`rMq`, we can use the algorithm in the proof of Lemma 16 to perform 3-sided range queries over $N(v'_a)$ and $N(v'_b)$ to compute $A_1 \cup A_3$ in $O(\lg \lg n + |A_1| + |A_3|)$ time. To compute A_2, observe that any entry, $\hat{S}(v)[i]$, can be obtained by replacing the x-coordinate of point $N(v)[i]$ with the rank of the child whose ordered list contains $N(v)[i]$. Hence, by performing range reporting over $\hat{S}$ to compute $S \cap ([a' + 1, b' - 1] \times [c_v, d_v])$, where $[c_v, d_v] =$ `noderange`(c, d, v), we can find the set of points in $\hat{S}(v)$ corresponding to the points in A_2. For each point returned, we use `point` to find its original coordinates in N and return it as part of A_2. This process uses $O(\lg \lg n + |A_2|)$ time. Hence we can compute $Q \cap N$ as $A_1 \cup A_2 \cup A_3$ in $O(\lg \lg n +$ `occ`$)$ time.

Now we analyze the space costs. T with support for ball inheritance uses $O(n \lg^{1+\epsilon} \sigma + n \lg n)$ bits for any positive ϵ. For each internal node v, since $w = \Theta(\lg n)$, the data structure for range reporting over $\hat{S}$ uses $O(|S(u)| \lg^{1/2+\epsilon'} n + 2^{\sqrt{\lg n}} \lg n + |S(u)| \lg n / 2^{\sqrt{\lg n}})$ bits for any positive ϵ'. This subsumes the cost of storing $M(u)$ which is $O(|S(u)| \lg \lg n)$ bits. As T has $O(\sigma / 2^{\sqrt{\lg n}})$ internal nodes, the total cost of storing these structures at all internal nodes is $\sum_u O(|S(u)| \lg^{1/2+\epsilon'} n + 2^{\sqrt{\lg n}} \lg n + |S(u)| \lg n / 2^{\sqrt{\lg n}}) = O(n \lg \sigma / \sqrt{\lg n} \times \lg^{1/2+\epsilon'} n + \sigma \lg n) = O(n \lg \sigma \lg^{\epsilon'} n + \sigma \lg n)$. As $\lg n \leq \lg^2 \sigma$ and $\sigma \leq n$, this is bounded by $O(n \lg^{1+2\epsilon'} \sigma)$. Setting $\epsilon' = \epsilon/2$, the space bound turns to be $O(n \lg^{1+\epsilon} \sigma)$ bits. Overall, the data structures occupy $O(n \lg^{1+\epsilon} \sigma + n \lg n)$ bits.

Finally, we analyze the construction time. As shown in Lemma 13, T with support for ball inheritance can be constructed in $O(n \lg \sigma / \sqrt{\lg n})$ time. For each internal node u of T, constructing $M(u)$ and the range reporting structure over $\hat{S}(v)$ requires $O(|S(u)| + \sqrt{\lg n} \cdot 2^{\sqrt{\lg n}})$ time. As T has $O(\sigma / 2^{\sqrt{\lg n}})$ internal nodes, these structures over all internal nodes can be built in $\sum_u O(|S(u)| + \sqrt{\lg n} \times 2^{\sqrt{\lg n}}) = O(n \lg \sigma / \sqrt{\lg n} + \sigma \sqrt{\lg n}) = O(n \lg \sigma / \sqrt{\lg n})$ as $\sigma \leq n$. The preprocessing time of all data structures is hence $O(n \lg \sigma / \sqrt{\lg n})$. ◀

Our result on points over an $n \times n$ gird immediately follows.

▶ **Theorem 20.** *Given a set, N, of n points in rank space, a data structure of $O(n \lg^{1+\epsilon} n)$ bits for any constant $\epsilon > 0$ can be constructed in $O(n\sqrt{\lg n})$ time to support orthogonal range reporting in $O(\lg \lg n +$* `occ`$)$ *time, where* `occ` *is the number of reported points.*

6 Optimal Orthogonal Range Successor with Fast Preprocessing

In this section, we assume that a range successor query asks for the lowest point in the query rectangle. The following theorem presents our result on fast construction of structures for optimal range successor; we provide a proof sketch, while leaving the full proof to the full version of this paper:

▶ **Theorem 21.** *Given n points in rank space, a data structure of $O(n \lg \lg n)$ words can be constructed in $O(n\sqrt{\lg n})$ time to support orthogonal range successor in $O(\lg \lg n)$ time.*

Proof (sketch). Our approach is similar to that in Section 5, but more levels of reductions are required. Let the sequence $X[0, n-1]$ denote the point set $N = \{(X[i], i) | 0 \leq i \leq n-1\}$. We build a $2^{\sqrt{\lg n}}$-ary wavelet tree T upon $X[0, n-1]$ with support for ball inheritance using part (a) of Lemma 13. As shown in the proof of Lemma 19, a query can be answered by locating the lowest common ancestor, u, of the two leaves corresponding to the end points of the query x-range, and then performing two 3-sided queries over the point sets represented by two children of u and one 4-sided query over $S(u)$. For the 3-sided queries, Zhou [32] already designed an indexing structure, which, with our $O(\lg\lg n)$-time support for `point` and `noderange`, can answer a 3-sided query in $O(\lg\lg n)$ time. The construction time is linear, but it is fine since T has only $O(\sqrt{\lg n})$ levels. The 4-side query over $S(u)$ is a range successor query over n' points in a $2^{\sqrt{\lg n}} \times n'$ (medium narrow) grid for any $n' \leq n$.

For such a medium narrow grid, we use the sampling strategy in Lemma 18 to reduce the problem to range successor over a set of n' points in a $2^{\sqrt{\lg n}} \times n'$ grid where $n' \leq 2 \times 2^{2\sqrt{\lg n}} - 1$. The sampling is adjusted, as we need select at most $2^{\sqrt{\lg n}}$ sampled points from each subset. The grid size of $2^{\sqrt{\lg n}} \times n'$ with $n' \leq 2 \times 2^{2\sqrt{\lg n}} - 1$ is the same as that in Lemma 16, so one may be tempted to apply the same strategy of building a binary wavelet tree to reduce it to the problem of building index structures for 3-sided queries. However, we found that, to construct the structure of Zhou [32] over n' points whose coordinates are encoded in $O(\sqrt{\lg n})$ bits, $O(n' \lg\lg n/\sqrt{\lg n})$ time is required, which is a factor of $\lg\lg n$ more than the preprocessing time of the `rmq` structure needed in the proof of Lemma 16. This factor comes from rank reduction in [32], which requires us to sort packed sequences. To overcome this additional cost, we build a $\lg^{1/4} n$-ary wavelet tree over the x-coordinates, whose number of levels is a factor of $O(\lg\lg n)$ less than that of a binary wavelet tree. As discussed for the general case, this strategy reduces the current problem to orthogonal range successor over n' points in an $\lg^{1/4} n \times n'$ (small narrow) grid with $n' \leq n$.

For a small narrow grid, there are two cases. If $n' > \lg n$, we build a binary wavelet tree of height $O(\lg\lg n)$. In the query algorithm, after finding the lowest common ancestor of the two leaves corresponding to the end points of the query x-range, we do not perform 3-sided queries. Instead, we traverse the two paths leading to these two leaves. This requires us to traverse down $O(\lg\lg n)$ levels, and at each level, we perform certain `rank`/`select` operations in constant time, with the right auxiliary structures at each node. No extra support for ball inheritance is needed as we can simply go down the tree level by level to map information. Finally, if $n' < \lg n$, we use sampling to reduce it to even smaller grids of size at most $\lg^{1/4} n \times \lg^{3/4} n$, over which a query can be answered using a table lookup. ◀

7 Applications

We now apply our range search structures to the text indexing problem, in which we preprocess a text string $T \in [\sigma]^n$, where $\sigma \leq n$. Given a pattern string $P[0..p-1]$, a *counting query* computes the number of occurrences of P in T and a *listing query* reports these occurrences.

Text indexing and searching in sublinear time. When both T and P are given in packed form, a text index of Munro et al. [25] occupies $O(n \lg \sigma)$ bits, can be built in $O(n \lg \sigma/\sqrt{\lg n})$ time and supports counting queries in $O(p/\log_\sigma n + \lg n \log_\sigma n)$ time (there are other tradeoffs, but this is their main result). Thus for small alphabet size which is common in practice, they achieve both $o(n)$ construction time and $o(p)$ query time, while previous results achieve at most one of these bounds. To support listing queries, however, they need to increase space cost to $O(n \lg \sigma \lg^\epsilon n)$ bits and construction time to $O(n \lg \sigma \lg^\epsilon n)$, and then a listing query

can be answered in $O(p/\log_\sigma n + \log_\sigma n \lg\lg n + \texttt{occ})$. The increase in storage and construction costs stems from one component they used which is an orthogonal range reporting structure over $t = O(n/r)$ points in a $\sigma^{O(r)} \times t$ grid, for $r = c\log_\sigma n$ for any constant $c < 1/4$. We can apply Lemma 19 over this point set to decrease the construction time of their index for listing queries to match that for counting queries:

▶ **Theorem 22.** *Given a packed text string T of length n over an alphabet of size σ, an index of $O(n \lg\sigma \lg^\epsilon n)$ bits can be built in $O(n \lg\sigma/\sqrt{\lg n})$ time for any positive constant ϵ. Given a packed pattern string P of length p, this index supports listing queries in $O(p/\log_\sigma n + \log_\sigma n \lg\lg n + \texttt{occ})$ time where* occ *is the number of occurrences of P in T.*

Position-restricted substring search. In a position-restricted substring search [23], we are given both a pattern P and two indices $0 \le l \le r \le n-1$, and we report all occurrences of P in $T[l..r]$. Makinen and Navarro [23] solves this problem using an index for the original text indexing problem and a two-dimensional orthogonal range reporting structure. Different text indexes and range reporting structures yield different tradeoffs. The tradeoff with the fastest query time supports position-restricted substring search in $O(p + \lg\lg n + \texttt{occ})$ time, where occ is the output size, and it uses $O(n \lg^{1+\epsilon} n)$ bits and can be constructed in $O(n \lg n)$ time. Again, the construction time of the range reporting structure is the bottleneck, which can be improved by Theorem 20. We can also use a new text index by Bille et al. [7] to achieve speedup when P is given as a packed sequence. We have:

▶ **Theorem 23.** *Given a text T of length n over an alphabet of size σ, an index of $O(n \lg^{1+\epsilon} n)$ bits can be built in $O(n\sqrt{\lg n})$ time for any constant $0 < \epsilon < 1/2$. Given a packed pattern string P of length p, this index supports position-restricted substring search in $O(p/\log_\sigma n + \lg p + \lg\lg\sigma + \texttt{occ})$ time, where* occ *in the size of the output.*

Abstract

Given an edge weighted graph and a forest F, the *2-edge connectivity augmentation problem* is to pick a minimum weighted set of edges, E', such that every connected component of $E' \cup F$ is 2-edge connected. Williamson et al. gave a 2-approximation algorithm (WGMV) for this problem using the primal-dual schema. We show that when edge weights are integral, the WGMV procedure can be modified to obtain a half-integral dual. The 2-edge connectivity augmentation problem has an interesting connection to routing flow in graphs where the union of supply and demand is planar. The half-integrality of the dual leads to a tight 2-approximate max-half-integral-flow min-multicut theorem.

1 Introduction

Let $G = (V, E)$ be an undirected graph with integer edge costs $c : E \to \mathbb{Z}^+$ and let $f : 2^V \to \mathbb{Z}^+$ be a requirement function on sets of vertices. We wish to find a set of edges, E' of minimum total cost such that for every set S the number of edges in E' across S is at least the requirement of S, ie. $f(S)$. This problem captures many scenarios in network design and has been the subject of much investigation. The Steiner forest problem, minimum weight maximum matching and other problems can be modeled by requirement functions which are *proper* and 0-1 (see Definition 3) and for such functions Agrawal, Klein, Ravi [1] and Goemans, Williamson [5] gave a primal-dual algorithm that is a 2-approximation. The key idea of primal-dual algorithms is to use complementary slackness to guide the construction of the dual and primal solutions which are within a factor 2 of each other.

To use this approach for the Steiner network design problem where the requirements of sets are not just 0-1, Williamson et al. [8] extend the primal dual algorithm of GW to the setting of 0-1 *uncrossable* requirement functions (see Definition 5); we call this the WGMV algorithm. The idea was to augment the connectivity of the solution in rounds with each round augmenting the requirements of unsatisfied sets by 1. The WGMV algorithm for uncrossable functions also builds a dual solution and while the primal solution constructed is integral, nothing is known of the integrality of the dual solution. In particular while for proper functions it is possible to argue that the dual solution constructed by the GW procedure is half-integral the same is not true for the WGMV procedure for uncrossable functions as is illustrated by the example in Section 4.1.

For weakly supermodular requirement functions (see Definition 4) Jain [6] gave a 2-approximation algorithm based on iterative rounding. Although this algorithm does not build a dual solution, the iterative rounding technique saw a lot of interesting applications and quickly became an integral part of tool-kit of approximation algorithms. This together with the fact that the dual solution constructed by the WGMV procedure seems useful only for certifying the approximation guarantee of the procedure, implied that there were no further results on the nature and properties of the dual solution.

In [2] the authors show that the problem of finding maximum multiflow when the union of the supply and demand edges forms a planar graph can be reduced to the problem of finding a large dual solution for a suitable cut-covering problem with uncrossable requirement function. In addition, a primal solution would correspond to a multicut and a half-integral dual solution would correspond to a half-integral multiflow. Therefore, a primal solution which is within twice a half-integral dual solution would imply a 2-approximate max-half-integral-multiflow min-multicut theorem for such graph classes. In [2] the authors also show instances where max-half-integral-multiflow min-multicut gap can be arbitrarily close to 2, implying that our result is best possible.

In this paper we show that a suitable modification to the WGMV procedure does indeed lead to a half-integral dual solution of value at least half the primal solution.

▶ **Theorem 1.** *Let $G = (V, E)$ be an undirected graph with edge costs $c : E \to \mathbb{Z}^+$ and a uncrossable requirement function $f : 2^V \to \{0, 1\}$. One can find a subset of edges F and an assignment, y, of non-negative half-integral dual variables to sets such that for all edges $e \in E$, $\sum_{S:e\in\delta(S)} y_S \leq c_e$ and $\sum_{e\in F} c_e \leq 2\sum_S f(s)y_S$.*

To achieve this we need to build an alternate stronger analysis of the 2-approximation of the WGMV algorithm and these are the main results of this paper. In Section 3 we argue that the Goemans-Williamson algorithm for proper functions leads to half-integral duals. To prove the above, we come up with a notion of parity of a node with respect to the current dual solution. The crux of our argument is to show that all nodes in an active set have the same parity. We then employ the idea of ensuring that all nodes in an active set have the same parity to modify the WGMV procedure in Section 6. However our procedure for ensuring uniform parity entails reducing some edge costs by 1/2. Since this decrease in edge costs also needs to be bounded by the dual solution we need a stronger guarantee on the total degree of the active sets in each iteration of the WGMV procedure. We develop this alternate analysis in Section 5. Finally, Section 7 shows how maximum flow in Seymour graphs corresponds to building the dual solution for a suitable uncrossable cut cover problem and lets us claim the following result which is also best possible.

▶ **Theorem 2.** *Let $G + H$ be planar. There exists a feasible half-integral flow of value F and a multicut of value C such that $C \leq 2F$. Further, such a flow and cut can be computed in polynomial time.*

2 Preliminaries

Given a graph $G = (V, E)$ with edge costs $c : E \to \mathbb{R}^+$ and a 0-1 requirement function $f : 2^V \to \{0, 1\}$ we are interested in picking a subset of edges E' of minimum total cost such that every set with requirement 1 has at least one edge of E' across it. In other words, for all $S \subseteq V$, $|\delta_{E'}(S)| \geq f(S)$, where $|\delta_{E'}(S)|$ is the number of edges in E' which have exactly one endpoint in S.

▶ **Definition 3.** *A function $f : 2^V \to \{0,1\}$ is called **proper** if $f(V) = 0, f(S) = f(V - S)$ for all $S \subseteq V$ and for any disjoint $A, B \subseteq V$, $f(A \cup B) \leq \max\{f(A), f(B)\}$.*

▶ **Definition 4.** *A function $f : 2^V \to \{0,1\}$ is called **weakly supermodular** if $f(V) = f(\phi) = 0$ and for any $A, B \subseteq V$, $f(A)+f(B) \leq \max\{f(A\cap B)+f(A\cup B), f(A\setminus B)+f(B\setminus A)\}$.*

▶ **Definition 5.** *A function $f : 2^V \to \{0,1\}$ is called **uncrossable** if $f(V) = f(\phi) = 0$ and for any $A, B \subseteq V$, if $f(A) = f(B) = 1$, then either $f(A \cap B) = f(A \cup B) = 1$ or $f(A \setminus B) = f(B \setminus A) = 1$.*

It is easy to argue that every proper function is also weakly supermodular and every weakly supermodular function is also uncrossable. In this paper we will only be interested in uncrossable requirement functions and shall refer to the problem in this setting as the *uncrossable cut cover problem* (UCC). The following integer program for UCC is well known.

$$\begin{array}{rcll} \text{minimize} & & \sum_{e\in E} c_e x_e & \\ \text{subject to} & & & \\ \sum_{e\in\delta(S)} x_e & \geq & f(S) & S \subseteq V \\ x_e & \in & \{0,1\} & e \in E \end{array}$$

We can relax the integrality constraint on x_e to $0 \leq x_e \leq 1$ to get a linear programming relaxation of the above. The dual program of the relaxation can be given as:

$$\begin{array}{rcll} \text{maximize} & & \sum_{S\subseteq V} f(S)y(S) & \\ \text{subject to} & & & \\ \sum_{S:e\in\delta(S)} y_S & \leq & c_e & e \in E \\ y_S & \geq & 0 & S \subseteq V \end{array}$$

Williamson et al. [8] gave a primal-dual 2-approximation algorithm for the above integer program for uncrossable f.

3 Half-integrality of the GW-dual for proper functions

We first argue that the Goemans-Williamson (GW) algorithm - for the case when requirement functions are proper and edge costs are integral - constructs a half-integral dual whose value is at least half the primal integral solution.

The GW algorithm proceeds by raising dual variables corresponding to sets of vertices and picking edges which are tight into the current solution. An edge e is tight when the sum of dual variables of sets containing exactly one end-point of e equals $c(e)$. The algorithm raises dual of all minimal sets S such that $f(S) = 1$ but no edge going across S has been picked in the current solution. We imagine growing the duals in a continuous manner and define a notion of time: $t = 0$ at start of the algorithm and y_S increases by δ during $[t, t + \delta]$ if S is a minimally unsatisfied set at every point of time in $[t, t + \delta]$. If f is proper, these minimal sets correspond exactly to the connected components formed by the set of tight edges. Let C be a connected component at time t. If $f(C) = 1$ then C is active while C is inactive if $f(C) = 0$. In each iteration, the GW procedure raises dual variables of all active sets simultaneously till an edge goes tight. At this point the connected components are recomputed and the algorithm continues with the next iteration unless all sets are inactive. Let F be the set of tight edges picked after the first phase. In a second phase, called the *reverse delete*, the GW algorithm considers the edges of F in the reverse order in which they were added to F. If the removal of an edge from F does not violate the requirement function of any set then the edge is removed.

We shall only be concerned with the first phase of the GW algorithm since it is in this phase that the dual variables, $y : 2^V \to \mathbb{R}_{\geq 0}$ are set. Let $\mathcal{S} = \{S : y_S > 0\}$ and note that this family of sets is laminar. For $v \in S, S \in \mathcal{S}$, we define the parity of v with respect to S as $\pi_v(S) = \left\{\sum_{T:v\in T\subseteq S} y_T\right\}$, where $\{x\}$ denotes the fractional part of x. If S is active at time t then there exists a vertex $v \in S$ which for all times in $[0, t]$ was in an active component; we call such a vertex an *active vertex* of set S.

We now argue that the GW procedure ensures that for all $S \in \mathcal{S}$, for all $u, v \in S$, $\pi_u(S) = \pi_v(S)$. We call this quantity the parity of set S, $\pi(S)$, and show that $\pi(S) \in \{0, 1/2\}$. Let S be formed by the merging of sets S_1, S_2 at time t. We induct on the iterations of the GW procedure and assume that all vertices in S_1 (respectively S_2) have the same parity with respect to S_1 (respectively S_2). If S_1 is active at time t then $\pi(S_1) = \pi_v(S_1) = \{t\}$ where v is an active vertex of set S_1. Similarly if S_2 is active at time t then $\pi(S_2) = \{t\}$. Thus if both S_1, S_2 are active at time t then $\pi(S_1) = \pi(S_2)$ and hence all vertices of S have the same parity with respect to S. Let $e = (u, v), u \in S_1, v \in S_2$ be the edge which gets tight when S_1, S_2 merge at time t. Since $l(e)$ is integral and $\sum_{T:u\in T\subseteq S_1} y_T + \sum_{T:v\in T\subseteq S_2} y_T = l(e)$, we have that $\pi(S_1) = \pi(S_2) \in \{0, 1/2\}$.

Suppose only S_1 is active at time t. By our induction hypothesis $\pi(S_2) \in \{0, 1/2\}$. Once again, since $l(e)$ is integral and $\sum_{T:u\in T\subseteq S_1} y_T + \sum_{T:v\in T\subseteq S_2} y_T = l(e)$, we have that $\pi(S_1) = \pi(S_2)$ which implies that all vertices of S have the same parity with respect to S.

Since $\pi(S), \pi(S_1) \in \{0, 1/2\}$, it must be the case that $\{y_S\} \in \{0, 1/2\}$. Since this is true for all sets $S \in \mathcal{S}$ this implies that the duals constructed by the GW procedure are half-integral.

4 The WGMV algorithm

We now give a brief description of the algorithm in [8]. Given an undirected graph $G = (V, E)$ with edge costs $c_e \geq 0$ and a uncrossable function f we wish to find a set of edges $F' \subseteq E$ such that for any $S \subseteq V, |F' \cap \delta(S)| \geq f(S)$. A set S is said to be unsatisfied if $f(S) = 1$ but no edge crosses S in the current solution.

The algorithm works in iterations. At the beginning of every iteration the algorithm computes a collection of minimally unsatisfied sets. Williamson et al.[8] show that minimally unsatisfied sets are disjoint and can be found in polynomial time (follows easily from uncrossability). Raise the dual variables corresponding to all minimally unsatisfied sets simultaneously until some edge is tight (the total dual across it equals its cost). All edges that go tight are added to a set T. The edges of T are considered in an arbitrary order and $e \in T$ is added to F if it crosses a minimally unsatisfied set. Note that whenever an edge is added to F the collection of minimally unsatisfied sets is recomputed. The *growth phase* of the WGMV procedure stops when all sets are satisfied; let F be the set of edges picked in this phase.

The edges of F are considered in the reverse order in which they were picked. An edge $e \in F$ is dropped from the solution if its removal keeps the current solution feasible.

At the end of the procedure, we have a set of edges F and a feasible dual solution y_S such that $\sum_{e\in F} c_e x_e \leq 2\sum_S f(S)y_S$. By weak duality, $\sum_{e\in F} c_e x_e \geq \sum_S f(S)y_S$ and this shows that the cost of solution picked by the algorithm is at most twice the optimal.

4.1 Duals constructed by WGMV are not half-integral

In the example in Figure 1, the red edges are not edges of the graph G. For a set $S \subseteq V$,$f(S) = 1$ iff there is exactly one red edge with exactly one end point in S. Thus this problem corresponds to picking edges so as to augment the red tree into a 2-edge connected

Algorithm 1 Primal-Dual Algorithm for uncrossable functions.

```
1: procedure WGMV( G = (V, E) with cost c_e, uncrossable function f)
2:     y ← 0, F ← φ
3:     while ∃S ⊆ V such that S is not satisfied do
4:         Compute C, the collection of minimally unsatisfied sets with respect to F.
5:         Increase y_C for all C ∈ C simultaneously until some edge e ∈ δ(C), C ∈ C is tight
   (c_e = Σ_{S:e∈δ(S)} y_S)
6:         Add all tight edges to T
7:         for all e ∈ T do
8:             if ∃C ∈ C, e ∈ δ(C) then
9:                 F ← F ∪ {e}; Recompute C
10:    for all e ∈ F do
11:        // Edges of F are considered in the reverse order in which they were added to F
12:        if F \ {e} is feasible then
13:            F ← F \ {e}
14:    return F
```

graph. It is known that f is uncrossable. In each iteration the WGMV procedure raises dual variables corresponding to all minimally unsatisfied sets. The edge (c, d) gets tight in the first iteration. At the end of the first iteration $y_{\{e\}} = 1/2$ and so in the second iteration $y_{\{e\}}$ increases to 3/4 and $y_{\{b,c,d\}}$ to 1/4 before edge (b, e) goes tight.

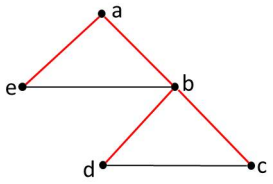

Figure 1 Example showing that the duals constructed by the WGMV procedure are not half-integral.

5 A stronger analysis of the WGMV algorithm

To analyse the algorithm, Willimason et al.[8] argue that in each iteration the total contribution of the dual variables to the primal solution is at most twice the increase in the value of the dual solution. This then, added over all iterations, implies that $\sum_{e\in F} c_e x_e \leq 2\sum_S f(S)y_S$. If in an iteration the dual values of all active sets increases by δ then the contribution of the dual variables to the primal solution equals δ times the total degree of the active sets in F. On the other hand the increase in the value of the dual solution is δ times the number of active sets and hence Williamson et al. argue that in each iteration the average degree of the active sets in F is at most 2.

Let $\mathcal{S}$ be the collection of minimally unsatisfied sets identified during a run of the algorithm. Note thst we do not claim that $y_S > 0$ for $S \in \mathcal{S}$. The uncrossability of f implies that $\mathcal{S}$ is a laminar family. Add V, the set of all vertices, to $\mathcal{S}$ and construct a tree, $\mathcal{T} = (X, Y)$, which has vertex set $X = \{v_S | S \in \mathcal{S}\}$. v_A is the parent of v_B iff A is the minimal set in $\mathcal{S}$ containing B.

Each set $S \in \mathcal{S}$ is labelled with the number of the iteration in which S became satisfied; let $l : \mathcal{S} \to [T]$ be this function. Let $\mathcal{S}^i$ be the sets with label at least i; these are the minimally unsatisfied sets encountered in iterations i or later. Similarly, each edge $e \in F$ is labeled with the number of the iteration in which it became tight. We overload notation and let $l : F \to [T]$ also denote this function. Let $F^i \subseteq F$ be edges with label at least i. We note a few properties of these labels.

1. if $B \subset A$ then $l(B) \leq l(A)$.
2. if $e \in \delta_F(S)$ then $l(e) \geq l(S)$

Let $v_{B_1}, v_{B_2}, \ldots v_{B_p}$ be the children of node v_A in $\mathcal{T}$ (see Figure 2). We number sets so that $l(B_1) \geq l(B_2) \geq \cdots \geq l(B_p)$. Let $p_i \in [p]$ be the largest index such that $l(B_{p_i}) \geq i$. Hence all sets $B_j, j \in [p_i]$ are in $\mathcal{S}^i$. Let $X^i_A = A \setminus \cup_{j \in [p_i]} B_j$ and H^i_A be a graph whose nodes correspond to sets $X^i_A, B_1, \ldots, B_{p_i}$ and edges correspond to the edges between these sets in F. Since sets $B_j, j \in [p_i]$ have label at least i, edges in H^i_A have label at least i and hence they are in F^i.

▷ Claim 6. H^i_A is a forest.

Proof. For contradiction assume H^i_A has a cycle and consider the edge of the cycle, say $e = (u, v)$, which was added last to F. We consider two cases.

$u \in B_r$ and $v \in B_s$, $r, s \in [p_i]$. When e was picked, both B_r, B_s had another edge in F across them and were therefore satisfied. Recall that $\mathcal{S}$ is the collection of all the minimally unsatisfied sets encountered during the growth phase of the algorithm. Picking e did not lead to any unsatisfied set in $\mathcal{S}$ getting satisfied and this is a contradiction.

$u \in B_r$ and $v \in X^i_A$, $r \in [p_i]$. No subset of vertices in X^i_A is unsatisfied in the i^{th} (or any subsequent) iteration. When e was picked, B_r had another edge in F across it and was therefore satisfied. Once again picking e did not lead to any unsatisfied set in $\mathcal{S}$ getting satisfied and this is a contradiction. ◁

Since H^i_A is a forest on $p_i + 1$ vertices it contains at most p_i edges.

▶ **Definition 7.** *A set $A \in \mathcal{S}$ is* critical *in iteration i if H^i_A is a tree of which the node corresponding to X^i_A, is a leaf.*

For a set $A \in \mathcal{S}^i$, let $\alpha^i(A) = \delta_F(A) \setminus \cup_{S \subset A, S \in \mathcal{S}^i} \delta_F(S)$. Thus $\alpha^i(A)$ is the set of edges of F which have one endpoint in the set $A \setminus \cup_{S \subset A, S \in \mathcal{S}^i} S$ and the other endpoint in $V \setminus A$. Equivalently $\alpha^i(A)$ is the subset of edges in $\delta_F(A)$ which are incident on vertices in X^i_A. We note the following important property of $\alpha^i(A)$.

▷ Claim 8. Let $A \in \mathcal{S}^i$. The collection of sets $\left\{\alpha^i(S) | S \in \mathcal{S}^i, S \subseteq A\right\}$ forms a partition of the set $\delta_F(A)$.

Let $\mathcal{A}^i$ be the collection of minimally unsatisfied sets whose dual is raised in iteration i of the WGMV algorithm. These are the *active sets* in iteration i. Note that

1. $\mathcal{A}^i \subseteq \mathcal{S}^i$.
2. A set $S \in \mathcal{S}$ is contained in $\mathcal{S}^i$ if and only if there exits an $A \in \mathcal{A}^i$ such that $A \subseteq S$.
3. If $A \in \mathcal{A}^i$ then no subset of A is in $\mathcal{S}^i$ which implies $\alpha^i(A) = \delta_F(A)$.

▶ **Lemma 9.** $\sum_{S \in \mathcal{S}^i} \left|\alpha^i(S)\right| \leq 2\left|\mathcal{A}^i\right| - 2 + \left|\mathcal{R}^i\right|$ *where $\mathcal{R}^i$ is the collection of critical sets in iteration i.*

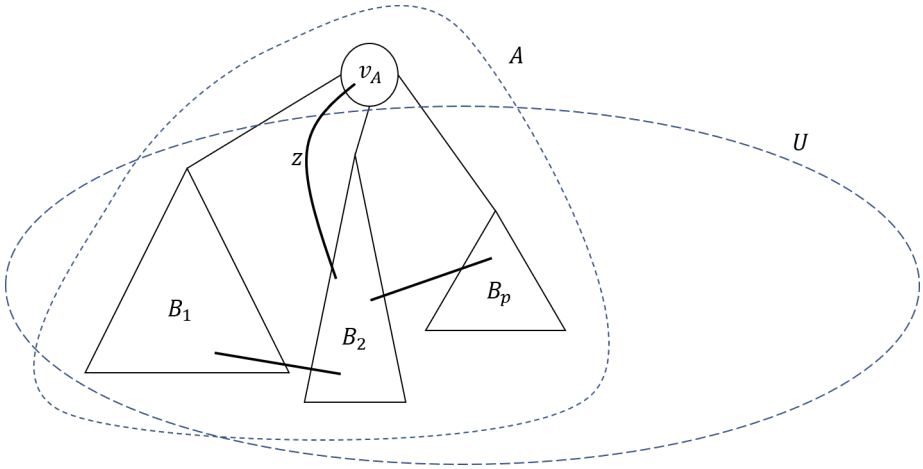

Figure 2 Illustrating the notation used. A is a critical set. The thick edges are the edges in H^i_A.

Proof. We show an argument built on redistributing tokens which help us prove the above lemma. We begin by assigning every node of tree $\mathcal{T}$ a number of tokens equal to two less than twice the number of its children in $\mathcal{S}^i$. Thus a node with 1 child in $\mathcal{S}^i$ gets no tokens. We also give every node that corresponds to a critical set in iteration i an additional token. It is easy to see that the total number of tokens distributed initially is $2\left|\mathcal{A}^i\right| - 2 + \left|\mathcal{R}^i\right|$.

v_A transfers one token to each edge in H^i_A incident on X^i_A and 2 tokens each to remaining edges in H^i_A. If v_A has p_i children in $\mathcal{S}^i$ and is critical in iteration i, it was assigned $2p_i - 1$ tokens and these are sufficient to undertake the above assignment. If v_A is not critical then it was assigned $2p_i - 2$ tokens and again this is sufficient to complete the transfer of tokens to edges in H^i_A.

For every edge in $e \in F^i$ there is a unique $A \in \mathcal{S}^i$ such that e is in H^i_A. If e has an endpoint in X^i_A it is assigned 1 token by v_A. Note that this edge contributes 1 to the sum on the left. The remaining edges of F^i are assigned 2 tokens each and this is also their contribution to the sum on the left. This establishes that the sum on the left equals the number of tokens assigned to edges which is at most the number of tokens assigned to nodes which in turn equals the quantity in the right. ◀

▶ **Lemma 10.** *If A is critical in iteration i then $\alpha^i(A) \neq \phi$.*

Proof. Since A is critical, H^i_A is a tree and X^i_A is a leaf node. Let e be the unique edge in H^i_A incident to X^i_A. Consider the step in the reverse delete phase when edge e was considered and was retained in F only because its deletion would have caused some set to become unsatisfied. Let $U \subseteq V$ be the minimal such set and note that e is the only edge in F' across U at this step.

▷ Claim 11. $\forall j \in [p_i]$, $U \cap B_j = \phi$ or $U \cap B_j = B_j$.

Proof. For a contradiction assume that for some $j \in [p_i]$, $\phi \neq U \cap B_j \subset B_j$. Since $f(B_j) = f(U) = 1$ by uncrossability either $f(B_j \cap U) = 1$ or $f(B_j \setminus U) = 1$. In either case, during the growth phase we must have added an edge, say g, to F between $B_j \setminus U$ and $B_j \cap U$ in an iteration before B_j became a minimally unsatisfied set. Thus, in the reverse delete phase when we considered e, edge g was in F and hence e was not the only edge across U. ◁

If $U \cap A$ includes some sets $B_j, j \in [p_i]$ and not the others then the number of edges across the set U will be more than 1. Thus either $\cup_{j \in p_i} B_j \subseteq A \cap U$ or $\cup_{j \in [p_i]} B_j \subseteq A \setminus U$. Since $f(A) = f(U) = 1$ by uncrossability we have either $f(A \cap U) = 1$ or $f(A \setminus U) = 1$. If $\cup_{j \in [p_i]} B_i \subseteq A \cap U$ then $f(A \setminus U) \neq 1$ as that would imply a minimal unsatisfied set in X^i_A which would be a contradiction. Similarly if $\cup_{j \in [p_i]} B_j \subseteq A \setminus U$ then $f(A \cap U) \neq 1$. Hence we need to consider only two cases

1. $\cup_{j \in [p_i]} B_j \subseteq A \cap U$ and $f(A \cap U) = f(A \cup U) = 1$: F should have an edge across the set $A \cup U$. Since the only edge across U goes to $A \setminus U$, there should be an edge across A that is incident to X^i_A.
2. $\cup_{j \in [p_i]} B_j \subseteq A \setminus U$ and $f(A \setminus U) = f(U \setminus A) = 1$: F should have an edge across the set $U \setminus A$. Since the only edge across U goes from $A \cap U$ to $A \setminus U$, there should be an edge across A that is incident to $A \cap U \subseteq X^i_A$.

Hence in both cases we conclude that there is an edge across A incident to X^i_A which implies $\alpha^i(A) \neq \phi$. ◀

▶ **Lemma 12.** *The total degree (in F) of sets in $\mathcal{A}^i$ is at most twice $\left|\mathcal{A}^i\right|$.*

Proof. A set in $\mathcal{A}^i$ cannot be critical in iteration i. Further for $S \in \mathcal{A}^i$, $\left|\alpha^i(S)\right|$ equals the degree of S in F. By Lemma 10 if A is critical in iteration i then $\alpha^i(A) \neq \phi$. Hence $\sum_{S \in \mathcal{S}^i} \left|\alpha^i(S)\right| \geq \sum_{S \in \mathcal{A}^i} |\delta_F(A)| + \left|\mathcal{R}^i\right|$ where $\mathcal{R}^i$ is the collection of critical sets. Applying Lemma 9, we obtain $\sum_{S \in \mathcal{A}^i} |\delta_F(A)| \leq 2\left|\mathcal{A}^i\right| - 2$ which proves the lemma. ◀

6 Modifying WGMV

We now modify the WGMV algorithm so that the duals obtained are half-integral while ensuring that the primal solution has cost at most twice the dual solution. In doing so we are guided by the fact that the GW algorithm constructed half-integral duals since the parity of all vertices in a set was identical. This property does not hold true for the WGMV algorithm as seen in the example in Figure 1.

As before, let $\mathcal{S}$ be the set of minimally unsatisfied sets during a run of the algorithm. Our modification to the WGMV algorithm involves reducing costs of some edges in $\delta(S), S \in \mathcal{S}$ by $1/2$. Let $\delta'(S) \subseteq \delta(S)$ denote the subset of edges whose cost was reduced by $1/2$ when considering S. We now define the *parity* of an edge e with respect to a set $S \in \mathcal{S}, e \in \delta(S)$ as

$$\pi_e(S) = \left\{ \sum_{e \in \delta(T), T \subseteq S} y_T + \tfrac{1}{2} |\{T \subseteq S | e \in \delta'(T)\}| \right\}$$

where as before $\{x\}$ denotes the fractional part of x. Our modification to the WGMV procedure is:

> Let S be a set which becomes minimally unsatisfied at time t and let $x \in S$ be an active vertex of set S. Then $\pi_x(S) = \{t\}$. For edge $e \in \delta(S)$, if $\pi_e(S) \neq \{t\}$ then decrease c_e by $1/2$ (note e gets included in $\delta'(S)$).

We decrease the costs of edges in $\delta(S)$ in the above manner only when S becomes minimally unsatisfied and need to argue that the total cost of edges in F can still be bounded by twice the sum of the dual variables. Our modification allows us the following claim.

▷ Claim 13. $\forall S \in \mathcal{S}, \forall e, f \in \delta(S), \pi_e(S) = \pi_f(S)$

When we increase dual variables of sets in $\mathcal{A}^i$ in iteration i, one or more edges go tight and these are added to a set T. Let t^i be the time at which we stop growing dual variables of sets in $\mathcal{A}^i$. The edges of T are considered in an arbitrary order and $e \in T$ is added to F if it

crosses a minimally unsatisfied set. Note that whenever an edge is added to F the collection of minimally unsatisfied sets is recomputed. Let $\mathcal{C}$ be the collection of minimally unsatisfied sets after all edges in T have been considered. For every $S \in \mathcal{C}$ and every edge $e \in \delta(S)$, if $\pi_e(S) \neq \{t\}$ then we reduce the cost of edge e by $1/2$. All edges that go tight after this step are included in T and the process repeated until no edge gets added to T. The minimally unsatisfied sets at this stage are the active sets, $\mathcal{A}^{i+1}$ for iteration $i+1$.

Algorithm 2 Modification to an iteration of the WGMV algorithm.

$\mathcal{C}$ is the collection of minimally unsatisfied sets with respect to F.
T is the set of tight edges which have not yet been included in F.
repeat
  for all $e \in T$ **do**
    if $\exists C \in \mathcal{C}, e \in \delta(C)$ **then**
      $F \leftarrow F \cup \{e\}$; compute $\mathcal{C}$
  $T \leftarrow \phi$
  for all $C \in \mathcal{C}$ **do**
    for all $e \in \delta(C)$ **do**
      if $\pi_e(C) \neq \{t\}$ **then**
        $c_e \leftarrow c_e - 1/2$
        if e is tight **then**
          $T \leftarrow T \cup \{e\}$
until $T = \phi$

Let $\mathcal{C}^i$ be the collection of sets in $\mathcal{S}$ which properly contain a set in $\mathcal{A}^i$ and are subsets of some set in $\mathcal{A}^{i+1}$. Formally, $\mathcal{C}^i = \left\{S \in \mathcal{S} | \exists A \in \mathcal{A}^i, \exists B \in \mathcal{A}^{i+1}, A \subset S \subseteq B\right\}$. Note that

1. $\mathcal{A}^{i+1} \setminus \mathcal{A}^i \subseteq \mathcal{C}^i$,
2. $\mathcal{A}^i \cap \mathcal{C}^i = \phi$,
3. any edge whose cost is reduced by $1/2$ in iteration i goes across a set in $\mathcal{C}^i$,
4. $\mathcal{C}^i \cap \mathcal{C}^{i+1} = \phi$ for $i \in [T-1]$

Before $A \in \mathcal{C}^i$ was considered in iteration i we would have considered the sets in $\mathcal{S}^i$ corresponding to children of node v_A in tree $\mathcal{T}$. Let $B_j, j \in [p_i]$ be these sets and note that they belong to $\mathcal{C}^i \cup \mathcal{A}^i$. For each $B_j, j \in [p_i]$ we would already have reduced the cost of edges $e \in \delta(B_j)$ if $\pi_e(B_j) \neq \left\{t^i\right\}$. Hence when considering A we would only be reducing the cost of edges in $\delta(A)$ which are incident to $A \setminus \cup_{j \in [p_i]} B_j = X^i_A$. Thus the edges of F whose cost is reduced when considering $A \in \mathcal{C}^i$ are subsets of $\alpha^i(A)$, let this subset be $\beta^i(A)$.

After iteration i, (reduced) cost of an edge e is $c_e - \sum_{S: e \in \delta(S)} y_S$, where y is the dual value after iteration i. Note that as the algorithm proceeds, (reduced) cost of edges decrease. To prove that the modified WGMV procedure gives a 2-approximate solution, we bound the total reduction in costs of edges in F by twice the total increase in the value of dual variables. In iteration i, the total reduction in edge costs of F due to increase of dual variables of sets A^i equals $\gamma^i \sum_{S \in \mathcal{A}^i} |\delta_F(S)| = \gamma^i \sum_{S \in \mathcal{A}^i} \left|\alpha^i(S)\right|$, where $\gamma^i = t^i - t^{i-1}$ is the increase in the dual variable of a set in $\mathcal{A}^i$. The other reduction occurs when we reduce by $1/2$ the costs of edges due to parity considerations. The total reduction in the cost of edges of F due to this reason is at most $1/2 \sum_{S \in \mathcal{C}^i} \left|\beta^i(S)\right|$.

To prove the approximation guarantee of WGMV, authors in [8] show that in every iteration the total reduction in cost of edges in F is at most twice the total increase in dual values in that iteration. To prove the approximation guarantee of modified WGMV, we need

to charge the reduction in edge costs across iterations. To do this, we introduce a procedure for marking and unmarking sets. All sets are unmarked before the first iteration of the algorithm. In the first iteration a set $A \in \mathcal{S}$ is not marked

1. if A is critical or,
2. if node v_A exhausts all its tokens and $\alpha^1(A) = \phi$

All other sets in $\mathcal{S}$ are marked in iteration 1. Let M be the number of sets which are marked.

In iteration i we unmark a set $S \in \mathcal{C}^i$ if it is critical and $\beta^i(S) \neq \phi$. Let M_i be the number of sets unmarked in iteration i. In Lemma 16 we argue that we unmark a set only if it has a mark on it.

▶ **Lemma 14.** *In any iteration $i > 1$,*

$$\gamma^i \sum_{S \in \mathcal{A}^i} \left|\alpha^i(S)\right| + (1/2) \sum_{s \in \mathcal{C}^i} \left|\beta^i(S)\right| - M_i/2 \leq 2\gamma^i(|A_i| - 1)$$

Proof. Recall $\mathcal{R}^i$ is the collection of critical sets in iteration i.

$$\gamma^i \sum_{S \in \mathcal{S}^i} \left|\alpha^i(S)\right| \geq \gamma^i \sum_{S \in \mathcal{A}^i} \left|\alpha^i(S)\right| + \gamma^i \sum_{S \in \mathcal{C}^i} \left|\alpha^i(S)\right| + \gamma^i \sum_{S \in \mathcal{S}^i \setminus \mathcal{A}^i \cup \mathcal{C}^i} \left|\alpha^i(S)\right| \tag{1}$$

By Lemma 10 we obtain

$$\gamma^i \sum_{S \in \mathcal{S}^i \setminus \mathcal{A}^i \cup \mathcal{C}^i} \left|\alpha^i(S)\right| \geq \gamma^i \left|\mathcal{R}^i \setminus \mathcal{C}^i\right| \tag{2}$$

and the unmarking procedure gives

$$\gamma^i \sum_{S \in \mathcal{C}^i} \left|\alpha^i(S)\right| + M_i/2 \geq (1/2) \sum_{S \in \mathcal{C}^i} \left|\beta^i(S)\right| + \gamma^i \left|\mathcal{R}^i \cap \mathcal{C}^i\right| \tag{3}$$

Inequality 3 holds since

1. if S is not critical it contributes $\gamma^i\left|\alpha^i(S)\right|$ to the left and $\left|\beta^i(S)\right|$ to the right and $\beta^i(S) \subseteq \alpha^i(S)$.
2. if S is critical but $\beta^i(S) = \phi$ then S contributes $\gamma^i\left|\alpha^i(S)\right|$ to the left and γ^i to the right and $\alpha^i(S) \neq \phi$.
3. if S is critical and $\beta^i(S) \neq \phi$ then S contributes $\gamma^i\left|\alpha^i(S)\right| + 1/2$ to the left and $(1/2)\left|\beta^i(S)\right| + \gamma^i$ to the right. Since $\phi \neq \beta^i(S) \subseteq \alpha^i(S)$ and $\gamma^i \geq 1/2$, the contribution to the left is more than the contribution of S to the right.

Adding inequalities 1, 2 and 3 we get

$$\gamma^i \sum_{S \in \mathcal{S}^i} \left|\alpha^i(S)\right| \geq \gamma^i \sum_{S \in \mathcal{A}^i} \left|\alpha^i(S)\right| + \gamma^i \sum_{S \in \mathcal{C}^i} \left|\beta^i(S)\right| + \gamma^i \left|\mathcal{R}^i\right| - M_i/2 \tag{4}$$

Inequality 4 when combined with the inequality in Lemma 9 and together with the fact that $\gamma^i \geq 1/2$ proves the lemma. ◀

Iteration 1 differs from other other iterations since we mark sets in this iteration. For iteration 1 we make the following claim.

▶ **Lemma 15.**

$$\gamma^1 \sum_{S \in \mathcal{A}^1} \left|\alpha^1(S)\right| + (1/2) \sum_{s \in \mathcal{C}^1} \left|\alpha^1(S)\right| + (1/2)(M - M_1) \leq 2\gamma^1(|A_1| - 1)$$

Proof. Inequalities 1 and 3 remain unchanged for iteration 1 (with 1 replacing i) while inequality 2 is modified due to the marks placed on sets. A is marked if it is not critical and $\alpha^1(A) \neq \phi$; let m be the number of such sets. This together with Lemma 10 gives

$$\gamma^1 \sum_{S \in \mathcal{S}^1 \setminus \mathcal{A}^1 \cup \mathcal{C}^1} \left|\alpha^1(S)\right| \geq \gamma^1 \left|\mathcal{R}^1 \setminus \mathcal{C}^1\right| + m/2 \tag{5}$$

Adding inequalities 1, 3 (with $i = 1$) and inequality 5 we get

$$\gamma^1 \sum_{S \in \mathcal{S}^1} \left|\alpha^1(S)\right| \geq \gamma^1 \sum_{S \in \mathcal{A}^1} \left|\alpha^1(S)\right| + \gamma^1 \sum_{S \in \mathcal{C}^1} \left|\beta^1(S)\right| + \gamma^1 \left|\mathcal{R}^1\right| + (1/2)(m - M_1) \tag{6}$$

Recall that we also mark a set A when node v_A does not exhaust all its tokens. Note that the number of such sets is $M - m$ and hence the inequality on Lemma 9 becomes

$$\sum_{S \in \mathcal{S}^1} \left|\alpha^1(S)\right| + M - m \leq 2(\left|\mathcal{A}^1\right| - 1) + \left|\mathcal{R}^1\right| \tag{7}$$

Combining inequality 6 and inequality 7 and using the fact that $\gamma^i \geq 1/2$ proves the lemma. ◀

Summing the inequality in Lemma 15 and Lemma 14 over all iterations gives us

$$\sum_{i \in [T]} \left(\gamma^i \sum_{S \in \mathcal{A}^i} \alpha^i(S) + (1/2) \sum_{s \in \mathcal{C}^i} \beta^i(S) - M_i/2 \right) + M/2 \leq \sum_{i \in [T]} 2\gamma^i(|A_i| - 1)$$

Since we unmark a set only if it has been marked in iteration 1 (Lemma 16), $M \geq \sum_{i \in [t]} M_i$. Therefore, the total reduction in the cost of the edges of F over all iterations (which is the total cost of edges in F) is at most the quantity on the left of the above inequality. Hence the cost of the solution F is at most twice the total dual raised over all iterations and this completes the proof of Theorem 1.

It remains to show that a set is unmarked only if it has been marked in iteration 1.

▶ **Lemma 16.** *If $A \in \mathcal{C}^i$ is critical in iteration i but not marked in iteration 1 then $\beta^i(A) = \phi$.*

Proof. Let $\{B_j | j \in [p]\}$ be the sets corresponding to children of v_A and $X^1_A = A \setminus \cup_{j \in [p]} B_j$. If H^1_A has a tree spanning nodes corresponding to sets X^1_A, $B_j, j \in [p]$, then edges of $\delta(A)$ would have equal parity. If A becomes a minimal unsatisfied set at time t then B_1 was active till time t. Therefore the parity of edges in $\delta(B_1)$ and hence those of all edges in $\delta(A)$ would equal $\{t\}$ which would imply $\beta^i(A) = \phi$.

Since A is unmarked either it is critical in iteration 1 or v_A exhausts all its tokens and $\alpha^1(A) = \phi$. In the former case we have a tree spanning nodes corresponding to sets X^1_A, $B_j, j \in [p]$. In the latter case if there is no such tree there would be a tree spanning nodes corresponding to sets $B_j, j \in [p]$ and no edge in $\delta_F(A)$ incident to X^1_A. Again, this implies that all edges in $\delta_F(A)$ have equal parity. ◀

7 Computing half-integral flow in Seymour graphs

In this section, we describe the connection between multicommodity flows/multicuts and connectivity augmentation problems from [2]. In particular, we will be interested in `2ECAP`, a special case of the `UCC` problem defined in [2].

▶ **Definition 17** (2-edge connectivity Augmentation Problem (2ECAP)). *Given an undirected graph (without loops but possible parallel edges) $G = (V, E \cup Y)$ and edge weights $w : E \to \mathbb{Z}_{\geq 0}$ find a minimum weight set of edges $E' \subseteq E$ such that each connected component of $(V, E' \cup Y)$ is 2-edge connected.*

For every $S \subseteq V$, let $f : S \to \{0, 1\}$ be defined as follows: $f(S) = 1$ iff exactly one edge of Y crosses the cut $(S, V \setminus S)$, otherwise it is zero. 2ECAP can be formulated equivalently as: find a minimum weight subset of edges $E' \subseteq E$ such that at least $f(S)$ edges of E' cross the cut $(S, V \setminus S)$. It is well known that f as defined above is uncrossable and hence the WGMV algorithm can be used to compute a 2-approximate solution.

Now, we define the multicommodity flow problem. Let $G = (V, E)$ be a simple undirected graph with edge capacities $c : E \to \mathbb{Z}_{\geq 0}$ (called the supply graph) and $H = (V, F)$ be a simple graph each edge of which corresponds to a commodity and the endpoints of that edge are the source/sink of that commodity (called the demand graph). Given any G and H, an instance of sum multicommodity flow asks for a feasible flow of maximum total value between the end points of demand edges. A minimum multicut is a set of edges of G of minimum total weight whose removal disconnects endpoints of all the demand edges in G. It is easy to see that the value of minimum multicut (C) is always greater than the value of the maximum flow (F). Given a class of instances, the maximum value of the ratio between C and F is known as the `flow-multicut gap` for the class. This gap is $\theta(\log k)$ for general G, H while it is $O(1)$ for planar G and arbitrary H. There is rich literature on proving `flow-multicut gaps` [3, 4, 7].

If we restrict the flow to be integral (resp. half integral), we call the flow-multicut gap as the integral (resp. half integral) `flow-multicut gap`. An instance of the multicommodity flow/multicut problem is called a Seymour instance if the union of the supply and demand graphs is planar. In [2], the authors establish a `flow-multicut gap` of at most 2 for Seymour instances by showing that the problem of computing a multicut in a Seymour instance is equivalent to solving an appropriate instance of 2ECAP in the planar dual of the supply and demand graph. Given a planar graph G, let G^* denotes its planar dual. Formally,

▶ **Lemma 18** ([2]). *C is a multicut for the instance (G, H) if and only if C^* is a feasible solution to 2ECAP for the instance $(V^*, E^* \cup F^*)$.*

The WGMV algorithm immediately gives a 2-approximation algorithm for multicuts in Seymour instances. In order to prove the `flow-multicut gap`, [2] shows that the duals constructed by the WGMV algorithm correspond to flow paths in G and that this correspondence is value preserving, ie. total flow is equal to the total value of the dual and if the duals constructed are integral (resp. half integral), then the corresponding flows are integral (resp. half integral). Formally,

▶ **Lemma 19** ([2]). *There exists a flow of value $\sum_{S \subseteq V^*} y_S$ in G.*

[2] show how to extract a half-integral flow of value at least half of any given fractional flow and an integral flow of value at least half any given half integral flow. This shows a half integral (resp. integral) flow-multicut gap of 4 (resp. 8). Using our modified WGMV algorithm, we obtain a half integral dual (and hence half integral flow) of value at least half the cost of the 2ECAP solution and hence the multicut. This gives us a 2 (resp. 4) approximate half-integral (resp. integral) `flow-multicut` theorem for Seymour instances.

▶ **Theorem 20.** *Let $G + H$ be planar. There exists a feasible integral flow of value F and a multicut of value C such that $C \leq 4F$. Further, such a flow and cut can be computed in polynomial time.*

[2] shows a class of Seymour instances such that the half-integral flow-multicut gap approaches 2 from below. This, along with our upper bound of 2 proves that Theorem 2 is tight. The best known lower bound for the integral `flow-multicut gap` is also 2 and it remains an interesting open question to determine the exact gap.

Abstract

We present a simple wavefront-like approach for computing multiplicatively weighted Voronoi diagrams of points and straight-line segments in the Euclidean plane. If the input sites may be assumed to be randomly weighted points then the use of a so-called overlay arrangement [Har-Peled&Raichel, Discrete Comput. Geom. 53:547–568, 2015] allows to achieve an expected runtime complexity of $\mathcal{O}(n \log^4 n)$, while still maintaining the simplicity of our approach. We implemented the full algorithm for weighted points as input sites, based on CGAL. The results of an experimental evaluation of our implementation suggest $\mathcal{O}(n \log^2 n)$ as a practical bound on the runtime. Our algorithm can be extended to handle also additive weights in addition to multiplicative weights, and it yields a truly simple $\mathcal{O}(n \log n)$ solution for solving the one-dimensional version of this problem.

1 Introduction

The multiplicatively weighted Voronoi diagram (MWVD) was introduced by Boots [4]. Aurenhammer and Edelsbrunner [2] present a worst-case optimal incremental algorithm for constructing the MWVD of a set of n points in $\mathcal{O}(n^2)$ time and space. They define spheres on the bisector circles (that are assumed to be situated in the xy-plane) and convert them into half-planes in $\mathbb{R}^3$ using a spherical inversion. Afterwards, these half-planes are intersected. Thus, every Voronoi region is associated with a polyhedron. Finally, the intersection of every such polyhedron with a sphere that corresponds to the xy-plane is inverted back to $\mathbb{R}^2$. We are not aware of an implementation of their algorithm, though. (And it seems difficult to implement.) In any case, the linear-time repeated searches for weighted nearest points indicate that its complexity is $\Theta(n^2)$ even if the combinatorial complexity of the resulting Voronoi diagram is $o(n^2)$. Later Aurenhammer uses divide&conquer to obtain an $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space algorithm for the one-dimensional weighted Voronoi diagram [1].

Har-Peled and Raichel [8] show that a bound of $\mathcal{O}(n \log^2 n)$ holds on the expected combinatorial complexity of a MWVD if all weights are chosen randomly. They sketch how to compute MWVDs in expected time $\mathcal{O}(n \log^3 n)$. Their approach is also difficult to implement because it uses the algorithm by Aurenhammer and Edelsbrunner [2] as a subroutine.

Vyatkina and Barequet [13] present a wavefront-based strategy to compute the MWVD of a set of n lines in the plane in $\mathcal{O}(n^2 \log n)$ time. The Voronoi nodes are computed based on edge and break-through events. An edge event takes place when an wavefront edge disappears. A break-through event happens whenever a new wavefront edge appears.

Since the pioneering work of Hoff et al. [10] it has been well known that discretized versions of Voronoi diagrams can be computed using the GPU framebuffer. More recently, Bonfiglioli et al. [3] presented a refinement of this rendering-based approach. It is obvious that their approach could also be extended to computing approximate MWVDs. However, the output of such an algorithm is just a set of discrete pixels instead of a continuous skeletal structure. Its precision is limited by the resolution of the framebuffer and by the numerical precision of the depth buffer.

2 Our Contribution

Our basic algorithm allows us to compute MWVDs in worst-case $\mathcal{O}(n^2 \log n)$ time and $\mathcal{O}(n^2)$ space. A refined version makes use of the result by Har-Peled and Raichel [8]: We use their overlay arrangement to keep the expected runtime complexity bounded by $\mathcal{O}(n \log^4 n)$ if the point sites are weighted randomly. Hence, for the price of a multiplicative factor of $\log n$ we get an algorithm that is easier to implement. Our experiments suggest that this bound is too pessimistic in practice and that one can expect the actual runtime to be bounded by $\mathcal{O}(n \log^2 n)$. However, our experiments also show that one may get a quadratic runtime if the weights are not chosen randomly. Our algorithm does not require the input sites to have different multiplicative weights, and it can be extended to additive weights and to (disjoint) straight-line segments as input sites. Furthermore, it yields a truly simple $\mathcal{O}(n \log n)$ solution for computing MWVDs in one dimension, where all input points lie on a line.

Our implementation is based on exact arithmetic and the Computational Geometry Algorithms Library (CGAL) [12]. It is publicly available on GitHub under `https://github.com/cgalab/wevo`. To the best of our knowledge, this is the first full implementation of an algorithm for computing MWVDs that achieves a decent expected runtime complexity.

3 Preliminaries

Let $S := \{s_1, s_2, \ldots, s_n\}$ denote a set of n distinct weighted points in $\mathbb{R}^2$ that are indexed such that $w(s_i) \leq w(s_j)$ for $1 \leq i < j \leq n$, where $w(s_i) \in \mathbb{R}^+$ is the weight associated with s_i. It is common to regard the weighted distance $d_w(p, s_i)$ from an arbitrary point p in $\mathbb{R}^2$ to s_i as the standard Euclidean distance $d(p, s_i)$ from p to s_i divided by the weight of s_i, i.e., $d_w(p, s_i) := \frac{d(p,s_i)}{w(s_i)}$. The *(weighted) Voronoi region* $\mathcal{VR}_w(s_i, S)$ of s_i relative to S is the set of all points of the plane such that no site s_j in $S \setminus \{s_i\}$ is closer to p than s_i, that is, $\mathcal{VR}_w(s_i, S) := \{p \in \mathbb{R}^2 : d_w(p, s_i) \leq d_w(p, s_j) \text{ for all } j \in \{1, 2, \ldots, n\}\}$. Then the multiplicatively weighted Voronoi diagram (MWVD), $\mathcal{VD}_w(S)$, of S is defined as $\mathcal{VD}_w(S) := \bigcup_{s_i \in S} \partial\, \mathcal{VR}_w(s_i, S)$.

A connected component of a Voronoi region is called a *face*. For two distinct sites s_i and s_j of S, the *bisector* $b_{i,j}$ of s_i and s_j models the set of points of the plane that are at the same weighted distance from s_i and s_j. Hence, a non-empty intersection of two Voronoi

regions is a subset of the bisector of the two defining sites. Following common terminology, a connected component of such a set is called a *(Voronoi) edge* of $\mathcal{VD}_w(S)$. An end-point of an edge is called a *(Voronoi) node*. It is known that the bisector between two unequally weighted sites forms a circle[1]. An example of a MWVD is shown in Figure 1.

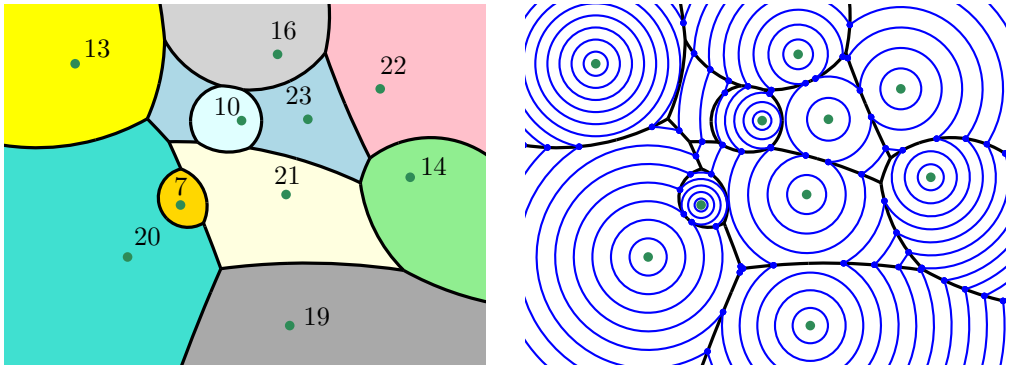

Figure 1 Left: The numbers next to the points indicate their weights and the corresponding MWVD is shown. Right: Wavefronts (in blue) for equally-spaced points in time.

The wavefront $\mathcal{WF}(S,t)$ emanated by S at time $t \geq 0$ is the set of all points p of the plane whose minimal weighted distance from S equals t. More formally,

$$\mathcal{WF}(S,t) := \left\{ p \in \mathbb{R}^2 : \min_{s_i \in S} d_w(p, s_i) = t \right\}.$$

The wavefront consists of circular arcs which we call *wavefront arcs*. A common end-point of two consecutive wavefront arcs is called *wavefront vertex*; see the blue dots in Figure 1.

4 Offset Circles

For the sake of descriptional simplicity, we start with assuming that no point in the plane has the same weighted distance to more than three sites of S. For $t \geq 0$, the *offset circle* $c_i(t)$ of the i-th site s_i is given by a circle centered at s_i with radius $t \cdot w(s_i)$. We find it convenient to regard $c_i(t)$ as a function of either time or distance since at time t every point on $c_i(t)$ is at Euclidean distance $t \cdot w(s_i)$ from s_i, i.e., at weighted distance t. We specify a point of $c_i(t)$ relative to s_i by its polar angle α and its (weighted) polar radius t and denote it by $p_i(\alpha, t)$.

For $1 \leq i < j \leq n$, consider two sites $s_i, s_j \in S$ and assume that $w(s_i) \neq w(s_j)$. Then there exists a unique closed time interval $[t_{ij}^{min}, t_{ij}^{max}]$ during which the respective offset circles of s_i, s_j intersect. We say that the two offset circles *collide* at their mutual *collision time* t_{ij}^{min}, and s_j starts to *dominate* s_i at the domination time t_{ij}^{max}. For all other times t within this interval the two offset circles $c_i(t)$ and $c_j(t)$ intersect in two disjoint points $v_{i,j}^l(t)$ and $v_{i,j}^r(t)$. These *(moving) vertices* trace out the bisector between s_i and s_j; see Figure 2. Since $v_{i,j}^l(t)$ and $v_{i,j}^r(t)$ are defined by the same pair of offset circles we refer to $v_{i,j}^l(t)$ as the *vertex married to* $v_{i,j}^r(t)$, and vice versa. Every other pair of moving vertices defined by two different pairs of intersecting offset circles is called *unmarried*. To simplify the notation, we will drop the parameter t if we do not need to refer to a specific time. Similarly, we drop the superscripts l and r if no distinction between married and unmarried vertices is necessary.

[1] Apollonius of Perga defined a circle as a set of points that have a specific distance ratio to two foci.

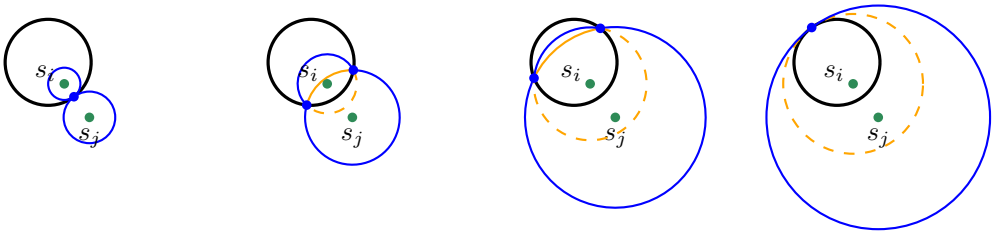

Figure 2 Two married vertices (highlighted by the blue dots) trace out the bisector b_{ij} (in black).

5 A Simple Event-Based Construction Scheme

In this section we describe a simulation of a propagation of the wavefront $\mathcal{WF}(S,t)$ to compute $\mathcal{VD}_w(S)$. Since the wavefront is given by a subset of the arcs of the arrangement of all offset circles, one could attempt to study the evolution of all arcs of that arrangement over time. However, it is sufficient to restrict our attention to a subset of arcs of that arrangement. We note that our wavefront can be seen as a kinetic data structure [7].

Clearly, the arc along $c_i(t)$ which is inside $c_j(t)$ will not belong to $\mathcal{WF}(\{s_i,s_j\},t^*)$ for any $t^* > t$. We will make use of this observation to define *inactive* and *active arcs* that are situated along the offset circles.

▶ **Definition 1** (Active point). *A point p on the offset circle $c_i(t)$ is called* inactive *at time t (relative to S) if there exists $j > i$, with $1 \le i < j \le n$, such that p lies strictly inside of $c_j(t)$. Otherwise, p is* active *(relative to S) at time t. A vertex $v_{i,j}(t)$ is an* active vertex *if it is an active point on both $c_i(t)$ and $c_j(t)$ at time t; otherwise, it is an* inactive vertex.

▶ **Lemma 2.** *If $p_i(\alpha,t)$ is inactive at time t then $p_i(\alpha,t')$ will be inactive for all times $t' \ge t$.*

An inactive point $p_i(\alpha,t)$ cannot be part of the wavefront $\mathcal{WF}(S,t)$. Lemma 2 ensures that none of its future incarnations $p_i(\alpha,t')$ can become part of the wavefront $\mathcal{WF}(S,t')$.

▶ **Definition 3** (Active arc). *For $1 \le i \le n$ and $t \ge 0$, an* active arc *of the offset circle $c_i(t)$ at time t is a maximal connected set of points on $c_i(t)$ that are active at time t. The closure of a maximal connected set of inactive points of $c_i(t)$ forms an* inactive arc *of $c_i(t)$ at time t.*

Every end-point of an active arc of $c_i(t)$ is given by the intersection of $c_i(t)$ with some other offset circle $c_j(t)$, i.e., by a moving vertex $v_{i,j}(t)$. This vertex is active, too.

▶ **Definition 4** (Arc arrangement). *The* arc arrangement (AA) *of S at time t, $\mathcal{A}(S,t)$, is the arrangement induced by all active arcs of all offset circles of S at time t.*

As time t increases, the offset circles expand. This causes the vertices of $\mathcal{A}(S,t)$ to move, but it will also result in topological changes of the arc arrangement.

▶ **Definition 5** (Collision event). *Let $p_i(\alpha,t_{ij}^{min}) = p_j(\alpha+\pi,t_{ij}^{min})$ be the point of intersection of the offset circles of s_i and s_j at the collision time t_{ij}^{min}, for some fixed angle α. A* collision event *occurs between these two offset circles at time t_{ij}^{min} if the points $p_i(\alpha,t)$ and $p_j(\alpha+\pi,t)$ have been active for all times $0 \le t \le t_{ij}^{min}$.*

At the time of a collision a new pair of married vertices $v_{i,j}^l(t)$ and $v_{i,j}^r(t)$ is created. Of course, we have $v_{i,j}^l(t_{ij}^{min}) = v_{i,j}^r(t_{ij}^{min}) = p_i(\alpha,t_{ij}^{min})$.

▶ **Definition 6** (Domination event). *Let $p_i(\alpha, t_{ij}^{max}) = p_j(\alpha, t_{ij}^{max})$ be the point of intersection of the offset circles of s_i and s_j at the domination time t_{ij}^{max}, for some fixed angle α. A* domination event *occurs between these two offset circles at time t_{ij}^{max} if the points $p_i(\alpha, t)$ and $p_j(\alpha, t)$ have been active for all times $0 \leq t \leq t_{ij}^{max}$.*

At the time of a domination event the married vertices $v_{i,j}^l(t_{ij}^{max})$ and $v_{i,j}^r(t_{ij}^{max})$ coincide and are removed.

▶ **Definition 7** (Arc event). *An* arc event *e occurs at time t_e when an active arc a_i shrinks to zero length because two unmarried vertices $v_{i,j}(t_e)$ and $v_{i,k}(t_e)$ meet in a point p_e on $c_i(t_e)$.*

Lemma 2 implies that $p_i(\alpha, t)$ has been active for all times $t \leq t_e$ if $p_i(\alpha, t_e) = p_e$. At the time of an arc event two unmarried vertices trade their places along an offset circle. Now suppose that the two unmarried vertices $v_{i,j}(t_e)$ and $v_{i,k}(t_e)$ meet in a point p_e along $c_i(t_e)$ at the time t_e of an arc event, thereby causing an active arc of $c_i(t_e)$ to shrink to zero length. Hence, the offset circles of s_i, s_j and s_k intersect at the point p_e at time t_e. If $c_j(t)$ and $c_k(t)$ did not intersect for $t < t_e$ then we also get a collision event between $c_j(t)$ and $c_k(t)$ at time t_e, see Figure 3a. (This configuration can occur for any relative order of the weights $w(s_i), w(s_j), w(s_k)$.) Otherwise, one or both of the married vertices $v_{j,k}^l(t_e)$ and $v_{j,k}^r(t_e)$ must also coincide with p_e. If both coincide with p_e then we also get a domination event between $c_j(t)$ and $c_k(t)$ at time t_e and we have $w(s_j) < w(s_k)$, see Figure 3b. The scenarios remaining for the case that only one of $v_{j,k}^l(t_e)$ and $v_{j,k}^r(t_e)$ coincides with p_e are detailed in the following lemma.

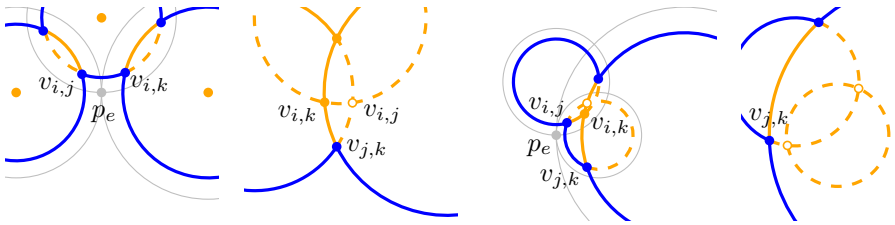

Figure 3 (a) The configuration shortly before (left) and after (right) a collision event as well as an arc event occur simultaneously at the same point p_e. In the left figure the offset arcs at the time of the event are shown in gray. Arcs and vertices that are on $\mathcal{WF}(\{s_i, s_j, s_k\}, t)$ are highlighted in blue. Other active arcs and vertices are depicted by solid orange lines and filled disks, while inactive arcs and vertices are depicted by dashed orange lines and circles. (b) The configuration shortly before and after a domination event and an arc event occur simultaneously at the same point p_e.

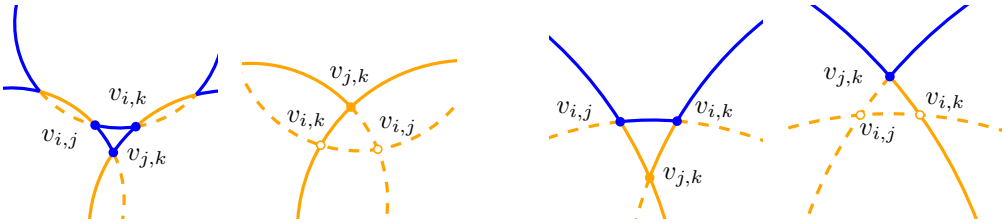
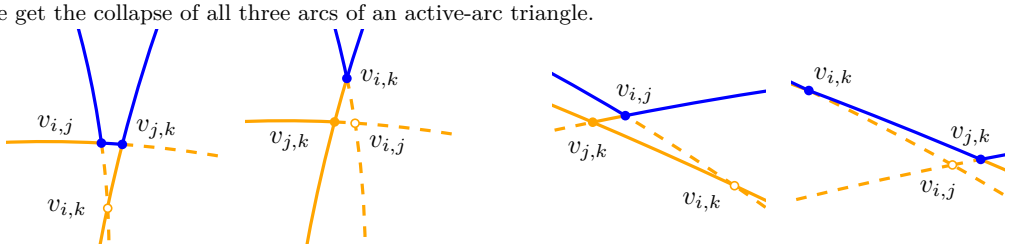
▶ **Lemma 8.** *Let $i < j < k$ and consider an arc event such that exactly the three vertices $v_{i,j}(t_e)$, $v_{i,k}(t_e)$, and $v_{j,k}(t_e)$ coincide at time t_e. Then either*

- *all three vertices were active before the event, see Figure 4a, or*
- *$v_{i,j}$ and $v_{j,k}$ were active and $v_{i,k}$ was inactive before the event, see Figure 4b, or*
- *$v_{i,k}$ and $v_{j,k}$ were active and $v_{i,j}$ was inactive before the event, see Figure 4c.*

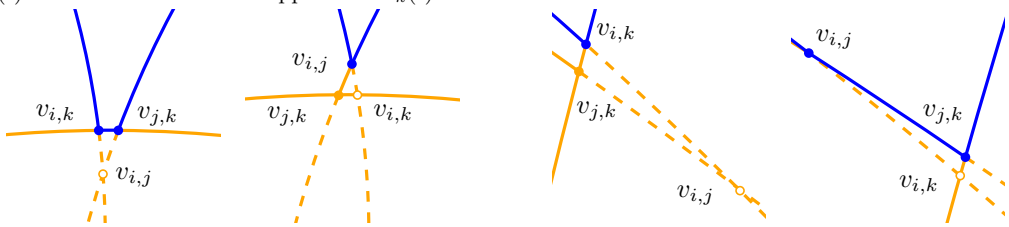
We now describe an event-handling scheme that allows us to trace out $\mathcal{VD}_w(S)$ by simulating the expansion of the arcs of $\mathcal{A}(S, t)$ as t increases, see Figure 5. We refer to this process as *arc expansion*.



(a) The two possible configurations shortly before (shown in the left figures) and after (shown in the right figures) one active arc disappears on $c_i(t)$ if no collision or domination event occurs at the same point. We get the collapse of all three arcs of an active-arc triangle.



(b) The two possible configurations shortly before (left) and after (right) one active arc disappears on $c_j(t)$ and another active arc appears on $c_k(t)$.



(c) The two possible configurations shortly before (left) and after (right) one active arc disappears on $c_k(t)$ and another active arc appears on $c_j(t)$.

Figure 4 The six different configurations that can occur for arc events for $1 \leq i < j < k \leq n$.

For each site we maintain a search data structure to keep track of all active arcs during the arc expansion. This *active offset* o_i of s_i holds the set of all arcs of $c_i(t)$ which are active at time t sorted in counter-clockwise angular order around s_i, and supports the following basic operations in time logarithmic in the number of arcs stored:

- It supports the insertion and deletion of active arcs as well as the lookup of their corresponding vertices.
- It supports point-location queries, allowing us to identify that active arc within o_i which contains a query point p on $c_i(t)$.

Every active offset contains at most $2(n-1)$ vertices and, thus, $O(n)$ active arcs. Hence, each such operation on an active offset takes $\mathcal{O}(\log n)$ time in the worst case.

Checking and handling the configurations shown in Figures 3a to 4 can be done by using only basic operations within the respective active offsets. The events themselves are stored in a priority queue $\mathcal{Q}$ ordered by the time of their occurrence. If two events take place simultaneously at the same point then collision events are prioritized higher than arc events, and arc events have to be handled before domination events. Four auxiliary operations are utilized that allow a more compact description of this process. Each one takes $\mathcal{O}(\log n)$ time.

- The *collapse-operation* takes place from $v_{i,x}$ to $v_{j,k}$ within an active offset o_x, with $x \in \{j,k\}$, in which $v_{i,x}$ and $v_{j,k}$ bound an active arc a_x that is already part of o_x; see Figure 6a. It determines the neighboring active arc a'_x of a_x that is bounded (on one side) by $v_{i,x}$, deletes a_x from o_x, and replaces $v_{i,x}$ by $v_{j,k}$ in a'_x.

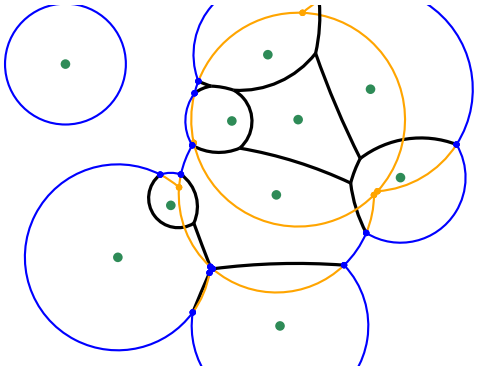


Figure 5 A snapshot of the arc expansion for the input shown in Figure 1. Active arcs that are currently not part of the wavefront are drawn in orange.

- The counterpart of the collapse-operation is the *expand-operation*; see Figure 6b. It happens from $v_{j,k}$ to $v_{i,x}$ in which $v_{j,k}$ bounds an active arc a'_x within o_x. The expansion will either move along a currently inactive or an already active portion of the offset circle of s_x. In the latter case, $v_{j,k}$ is replaced by $v_{i,x}$ in a'_x. In any case, we insert the respective active arc that is bounded by $v_{i,x}$ and $v_{j,k}$ into o_x.
- A *split-operation* involves two active offsets o_i and o_j as well as a point p_e which is situated within the active arcs $a_i := (v_{i,s}, v_{i,e})$ and $a_j := (v_{j,s'}, v_{j,e'})$ within o_i and o_j, respectively; see Figure 7a. Two married vertices $v^l_{i,j}$ and $v^r_{i,j}$ are created. Afterwards a_i and a_j are removed from o_i and o_j, respectively. Two new active arcs $(v_{i,s}, v^l_{i,j})$ and $(v^r_{i,j}, v_{i,e})$ are created and inserted into o_i. Furthermore, the three active arcs $(v_{j,e}, v^r_{i,j})$, $(v^r_{i,j}, v^l_{i,j})$, and $(v^l_{i,j}, v_{j,e})$ are inserted into o_j. If a_i and a_j were wavefront arcs then the newly created married vertices coincide with wavefront vertices and the newly inserted active arcs except $(v^r_{i,j}, v^l_{i,j})$ are marked as wavefront arcs.
- During a *merge-operation*, exactly two offset circles interact; see Figure 7b. The active arcs a_i and a_j bounded by the two corresponding married vertices $v^r_{i,j}$ and $v^l_{i,j}$ are removed from o_i and o_j, respectively. Additionally, the active arcs $(v_{j,s}, v^r_{i,j})$ and $(v^l_{i,j}, v_{j,e})$ that were adjacent to a_j within o_j are removed. Finally, a new active arc $a'_j := (v_{j,s}, v_{j,e})$ is inserted into o_j. If a_j was a wavefront arc then a'_j is also marked as a wavefront arc.

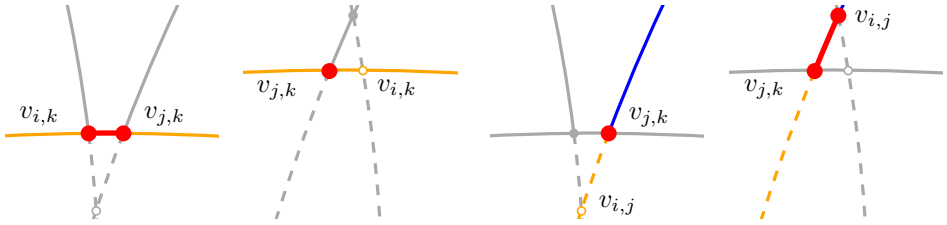

Figure 6 (a) A collapse-operation from $v_{i,k}$ to $v_{j,k}$ takes place within o_k. (b) An expand-operation happens within o_j from $v_{j,k}$ to $v_{i,j}$.

Domination events and arc events are easy to detect. The point and time of a collision is trivial to compute for any pair of offset circles, too. Unfortunately there is no obvious way to identify those pairs of circles for which this intersection will happen within portions of these offset circles which will still be active at the time of the collision. Hence, for the rest of

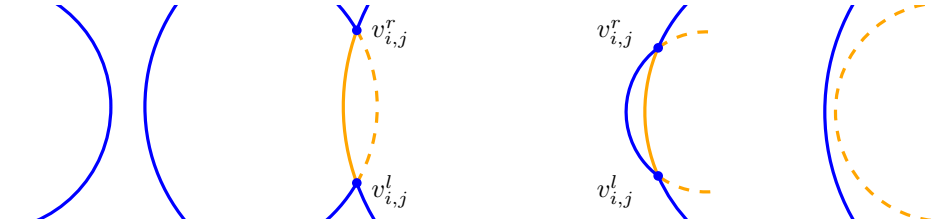

Figure 7 (a) A split-operation happens when at the time of a collision event. (b) A merge-operation happens at the time of a domination event.

this section we assume that all collisions among all pairs of offset circles are computed prior to the actual arc expansion. Lemma 9 verifies that our algorithm correctly simulates the arc expansion.

▶ **Lemma 9.** *For time $t > 0$, the arc arrangement $\mathcal{A}(S,t)$ can be obtained from $\mathcal{A}(S,0)$ by modifying it according to all collision events, domination events and arc events that occur till time t, in the order in which they appear.*

If the maximum weight of all sites is associated with only one site then there will be a time t when the offset circle of this site dominates all other offset circles, i.e., when $\mathcal{WF}(S,t)$ contains only this offset circle as one active arc. Obviously, at this time no further event can occur and the arc expansion stops. If multiple sites have the same maximum weight then $\mathcal{Q}$ can only be empty once $\mathcal{WF}(S,t)$ contains only one loop of active arcs which all lie on offset circles of these sites and if all wavefront vertices move along rays to infinity.

▶ **Lemma 10.** *An active arc or active vertex within an active offset is identified and marked as a wavefront arc (wavefront vertex, resp.) at time $t \geq 0$ if and only if it lies on $\mathcal{WF}(S,t)$.*

If we allow points in $\mathbb{R}^2$ to have the same weighted distance to more than three sites then we need to modify our strategy. In particular, we need to take care of constellations in which more than three arc events happen simultaneously at the same point. In such a case it is necessary to carefully choose the sequence in which the corresponding arc events are handled. More precisely, an arc event may only be handled (without corrupting the state of the active offsets) whenever the respective active vertices are considered neighboring within the active offsets. If the active vertices that participate in an arc event are not currently neighboring then we can always find an arc event whose active vertices are neighboring that happens simultaneously at the same location by walking along the corresponding active offsets. By dealing with the arc events in this specific order, we generate multiple coinciding Voronoi nodes of degree three. Domination events that occur simultaneously at the same point p_e are processed in increasing order of the weights. Note that this order can already be established at the time when an event is inserted into $\mathcal{Q}$, at no additional computational cost. Simultaneous multiple collision events at the same point p_e either involve arcs that are not active or coincide with arc events. These arc events automatically establish a sorted order of the active arcs around p_e, thus allowing us to avoid an explicit (and time-consuming) sorting.

▶ **Lemma 11.** *During the arc expansion $\mathcal{O}(n^2)$ collision and domination events are computed.*

We know that collision events create and domination events remove active vertices (and make them inactive for good). A collapse of an entire active-arc triangle causes two vertices to become inactive. During every other arc event at least one active vertex becomes inactive,

but at the same time one inactive vertex may become active again. In order to bound the number of arc events it is essential to determine how many vertices can be active and how often a vertex can undergo a *reactivation*, i.e., change its status from inactive to active. (Note that Lemma 2 is not applicable to a moving vertex since its polar angle does not stay constant.) We now argue that the total number of reactivations of inactive vertices is bounded by the number of different vertices that ever were active during the arc expansion.

▶ **Lemma 12.** *Every reactivation of a moving vertex during an arc event forces another moving vertex to become inactive and remain inactive for the rest of the arc expansion.*

▶ **Lemma 13.** *Let h be the number of different vertices that ever were active during the arc expansion. Then $\mathcal{O}(h)$ arc events can take place during the arc expansion.*

▶ **Theorem 14.** *The multiplicatively weighted Voronoi diagram $\mathcal{VD}_w(S)$ of a set S of n weighted point sites can be computed in $\mathcal{O}(n^2 \log n)$ time and $\mathcal{O}(n^2)$ space.*

Additionally, in the full version [9] we argue that the one-dimensional MWVD can be computed efficiently using a wavefront-based strategy.

▶ **Theorem 15.** *The multiplicatively weighted Voronoi diagram $\mathcal{VD}_w(S)$ of a set S of n weighted point sites in one dimension can be computed in $\mathcal{O}(n \log n)$ time and $\mathcal{O}(n)$ space.*

6 Reducing the Number of Collisions Computed

Experiments quickly indicate that the vast majority of pairwise collisions computed a priori never ends up on pairs of active arcs. Furthermore, the resulting Voronoi diagrams show a quadratic combinatorial complexity only for contrived input data. We make use of the following results to determine all collision events in near-linear expected time. Throughout this section, we assume that for each site $s_i \in S$ the corresponding weight $w(s_i)$ is independently sampled from some probability distribution.

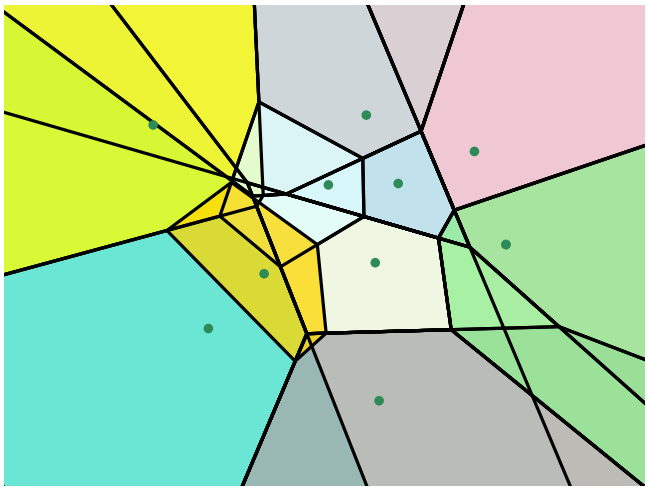

Figure 8 The overlay arrangement is generated by inserting the sites ordered by decreasing weights.

▶ **Definition 16** (Candidate Set). *Consider an arbitrary (but fixed) point $q \in \mathbb{R}^2$, and let s be its nearest neighbor in S under the weighted distance. Let $s' \in S \setminus \{s\}$ be another site. Since s is the nearest neighbor of q we know that either s has a higher weight than s' or a*

smaller Euclidean distance to q than s'. Thus, one can define a candidate set *for a weighted nearest neighbor of q which consists of all sites $s \in S$ such that all other sites in S either have a smaller weight or a larger Euclidean distance to q.*

▶ **Lemma 17** (Har-Peled and Raichel [8]). *For all points $q \in \mathbb{R}^2$, the candidate set for q among S is of size $\mathcal{O}(\log n)$ with high probability.*

▶ **Lemma 18** (Har-Peled and Raichel [8]). *Let K_i denote the Voronoi cell of s_i in the unweighted Voronoi diagram of the i-th suffix $S_i := \{s_i, \ldots, s_n\}$. Let $\mathcal{OA}$ denote the arrangement formed by the overlay of the regions $K_1, \ldots, K_n$. Then, for every face f of $\mathcal{OA}$, the candidate set is the same for all points in f.*

Figure 8 shows a sample overlay arrangement. Kaplan et al. [11] prove that this overlay arrangement has an expected complexity of $\mathcal{O}(n \log n)$. Note that their result is applicable since inserting the points in sorted order of their randomly chosen weights corresponds to a randomized insertion. These results allow us to derive better complexity bounds.

▶ **Theorem 19** (Kaplan et al. [11]). *The expected combinatorial complexity of the overlay of the minimization diagrams that arises during a randomized incremental construction of the lower envelope of n hyperplanes in $\mathbb{R}^d$, for $d \geq 2$, is $\mathcal{O}(n^{\lfloor d/2 \rfloor})$, for d even, and $O(n^{\lfloor d/2 \rfloor} \log n)$, for d odd. The bounds for d even and for $d = 3$ are tight in the worst case.*

▶ **Lemma 20.** *If a collision event occurs between the offset circles of two sites $s_i, s_j \in S$ then there exists at least one candidate set which includes both s_i and s_j.*

▶ **Theorem 21.** *All collision events can be determined in $\mathcal{O}(n \log^3 n)$ expected time by computing the overlay arrangement $\mathcal{OA}$ of a set S of n input sites.*

Thus, the number h of vertices created during the arc expansion can be expected to be bounded by $\mathcal{O}(n \log^3 n)$. Lemma 13 tells us that the number of arc events is in $\mathcal{O}(h)$. Therefore, $\mathcal{O}(n \log^3 n)$ events happen in total.

▶ **Theorem 22.** *A wavefront-based approach allows to compute the multiplicatively weighted Voronoi diagram $\mathcal{VD}_w(S)$ of a set S of n (randomly) weighted point sites in expected $\mathcal{O}(n \log^4 n)$ time and expected $\mathcal{O}(n \log^3 n)$ space.*

7 Extensions

Consider a set S' of n disjoint weighted straight-line segments in $\mathbb{R}^2$. A wavefront propagation among weighted line segments requires us to refine our notion of "collision". We call an intersection of two offset circles a *non-piercing collision event* if it marks the initial contact of the two offset circles. That is, it occurs when the first pair of moving vertices appear. We call an intersection of two offset circles a *piercing collision event* if it takes place when two already intersecting offset circles intersect in a third point for the first time; see Figure 9. In this case, a second pair of moving vertices appear.

Hence, a minor modification of our event-based construction scheme is sufficient to extend it to weighted straight-line segments; see Figure 10. We only need to check whether a piercing collision event that happens at a point p_e at time t_e currently is part of $\mathcal{WF}(S', t_e)$. In such a case the two new vertices as well as the corresponding active arc between them need to be flagged as part of $\mathcal{WF}(S', t_e)$.

An extension to additive weights can be integrated easily into our scheme by simply giving every offset circle a head-start of $w_a(s_i)$ at time $t = 0$, where $w_a(s_i) \geq 0$ denotes the real-valued additive weight that is associated with s_i.

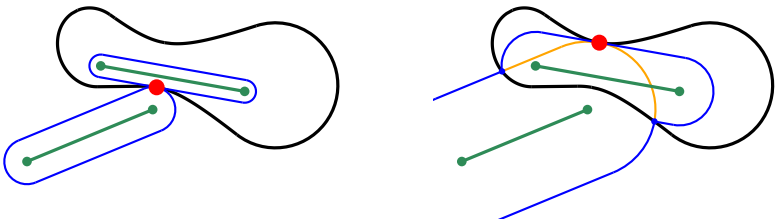

Figure 9 An example of a non-piercing (left) as well as a piercing collision event (right).

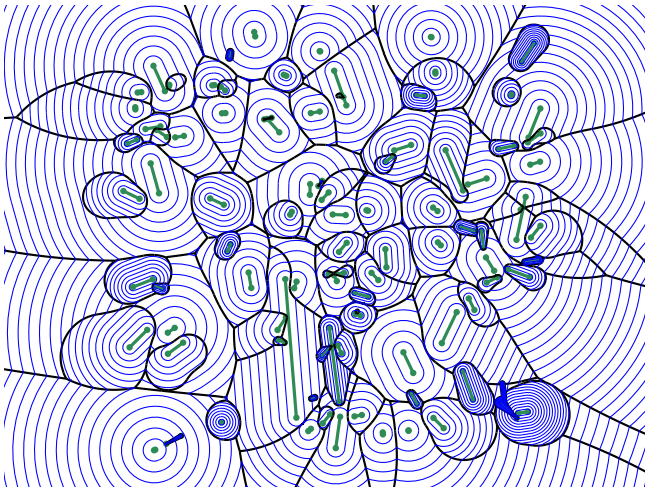

Figure 10 The MWVD of a set of weighted points and weighted straight-line segments together with a family of wavefronts for equally-spaced points in time.

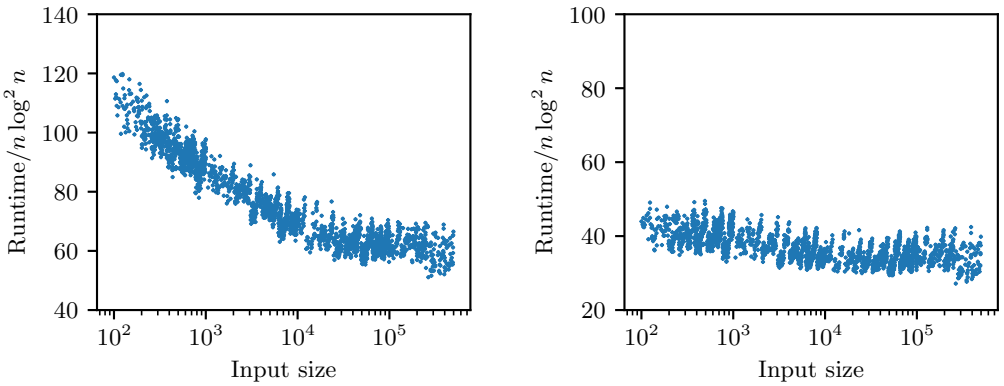
8 Experimental Evaluation

We implemented our full algorithm for multiplicatively weighted points as input sites[2], based on CGAL and exact arithmetic[3]. In particular, we use CGAL's `Arrangement_2` package for computing the overlay arrangement and its `Voronoi_diagram_2` package for computing unweighted Voronoi diagrams. The computation of the MWVD itself utilizes CGAL's `Exact_circular_kernel_2` package which is based on the `Gmpq` number type. The obvious advantage of using exact number types is that events are guaranteed to be processed in the right order even if they occur nearly simultaneously at nearly the same place. One of the main drawbacks of exact number types is their memory consumption which is significantly (and sometimes unpredictably) higher than when standard floating-point numbers are used.

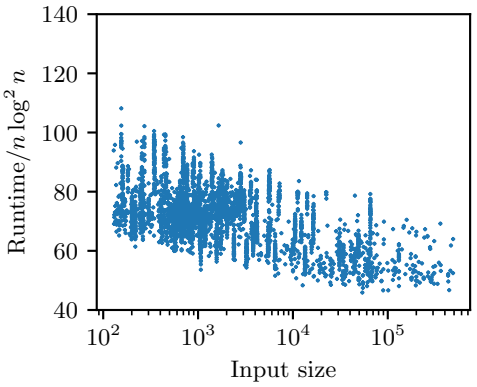
We used our implementation for an experimental evaluation and ran our code on over 8000 inputs ranging from 256 vertices to 500 000 vertices. For all inputs all weights were chosen uniformly at random from the interval $[0, 1]$. All tests were carried out with CGAL 5.0 on an Intel Core i9-7900X processor clocked at 3.3 GHz.

[2] We do also have a prototype implementation that handles both weighted points and weighted straight-line segments. It was used to generate Figure 10.

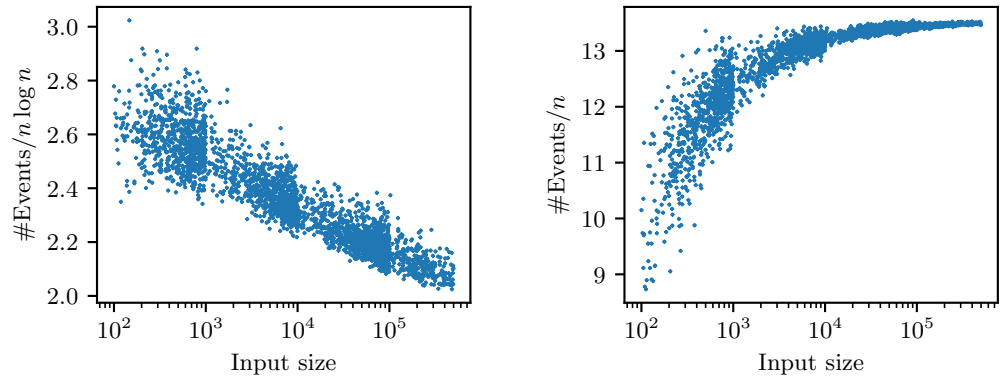
[3] We have not spent enough time on fine-tuning an implementation based on conventional floating-point arithmetic. The obvious crux is that inaccurately determined event times (and locations) may corrupt the state of the arc arrangement and, thus, cause a variety of errors during the subsequent arc expansion.



(a) Left: The overall runtime results for inputs with randomly generated weights and point coordinates. Right: The runtime consumed by the computation of the corresponding overlay arrangements. All runtimes were divided by $n \log^2 n$.



(b) The overall runtime results for inputs with randomly generated weights and vertices of real-world polygons and polygons of the Salzburg database of polygonal data [5, 6] taken as input points. The runtimes were divided by $n \log^2 n$.



(c) The left plot shows the total number of (valid and invalid) collision events (divided by $n \log n$); the right plot shows the number of arc events (divided by n) processed during the arc expansion. All point coordinates and weights were generated randomly.

Figure 11 Experimental evaluation.

In any case, the number of events is smaller than predicted by the theoretical analysis. This is also reflected by our runtime statistics: In Figures 11a and 11b the runtime that was consumed by the computation of a MWVD is plotted. We ran our tests on two different input classes: The point locations were either generated randomly, i.e., they were chosen according to either a uniform or a normal distribution, or obtained by taking the vertices of real-world polygons or polygons of the brand-new Salzburg database of polygonal data [5, 6]. Summarizing, our tests suggest an overall runtime of $\mathcal{O}(n \log^2 n)$ for both input classes. In particular, the actual geometric distribution of the sites does not have a significant impact on the runtime if the weights are chosen randomly: For real-world, irregularly distributed sites the runtimes are scattered more wildly than in the case of uniformly distributed sites, but they do not increase. The numbers of collision events and arc events that occurred during the arc expansion are plotted in Figure 11c. Our tests suggest that we can expect to see at most $3n \log n$ collision events and at most most $14n$ arc events to occur. Note that the number of arc events forms an upper bound on the number of Voronoi nodes of the final MWVD. That is, random weights seem to result in a linear combinatorial complexity of the MWVD.

It is natural to ask how much these results depend on the randomness of the weights. To probe this question we set up a second series of experiments: We sampled points uniformly within a square with side-length $\sqrt{2}$ and then tested different weights. Let $d(s)$ be the distance of the site $s \in S$ from the center of the square, and let $r(s)$ be a number uniformly distributed within the interval $[0, 1]$. Of course, $0 \leq d(s) \leq 1$. Then we assign $\alpha \cdot d(s) + \beta \cdot r(s) / (\alpha + \beta)$ as weight to s, with α and β being the same arbitrary but fixed non-negative numbers for all sites of S. Figure 12 shows the results obtained for the same sets of points and the (α, β)-pairs $(1, 0)$, $(9, 1)$, $(7, 3)$, $(1, 1)$ and $(0, 1)$. This test makes it evident that the bounds on the complexities need not hold if the weights are not chosen randomly, even for a uniform distribution of the sites. Rather, this may lead to a linear number of candidates per candidate set and a quadratic runtime complexity, as shown in Figure 12.

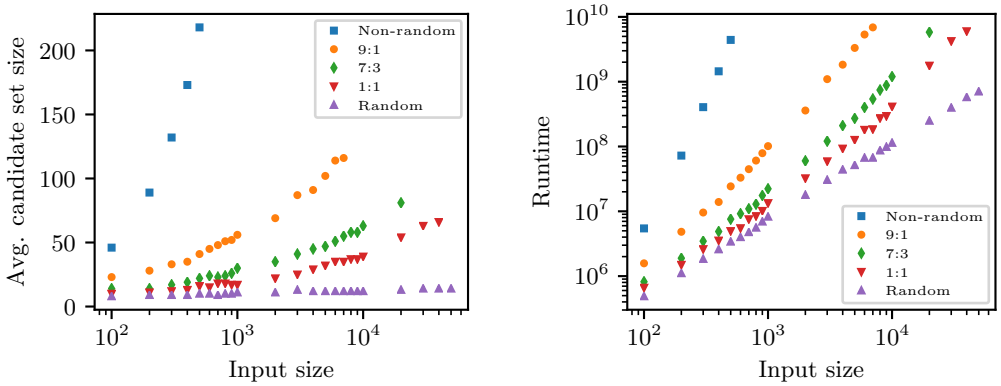


Figure 12 The plots show how the average number of candidates (left) and the total runtime (right) depend on the weights assigned to the sites. Each marker on the x-axes indicates the number n of input sites uniformly distributed within a square.

9 Conclusion

We present a wavefront-like approach for computing the MWVD of points and straight-line segments. Results by Kaplan et al. [11] and Har-Peled and Raichel [8] allow to predict an $\mathcal{O}(n \log^4 n)$ expected time complexity for point sites with random weights. We also discuss a robust, practical implementation which is based on CGAL and exact arithmetic. Extensive tests of our code indicate an average runtime of $\mathcal{O}(n \log^2 n)$ if the sites are weighted randomly. To the best of our knowledge, there does not exist any other code for computing MWVDs that is comparatively fast. A simple modification of our arc expansion scheme makes it possible to handle both additive and multiplicative weights simultaneously. Our code is publicly available on GitHub under `https://github.com/cgalab/wevo`. Figure 13 shows several examples of MWVDs computed by our implementation.

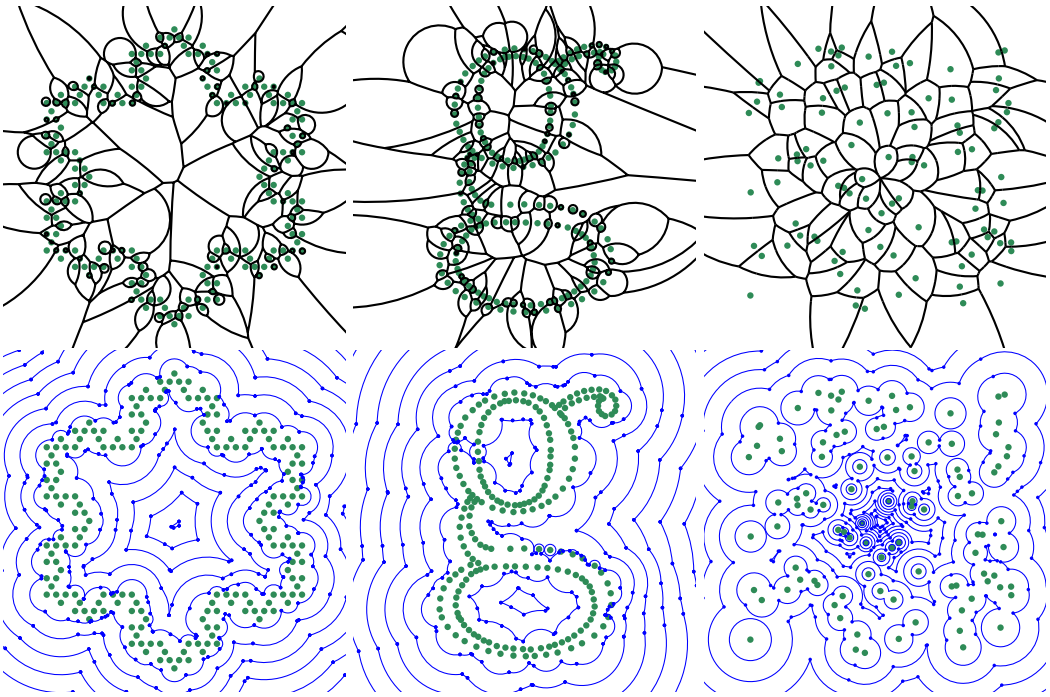

Figure 13 Several examples of MWVDs are shown in the top figures. The bottom figures illustrate a series of uniformly distributed wavefronts that have been derived from the corresponding MWVDs.

Abstract

With input sizes becoming massive, coresets – small yet representative summary of the input – are relevant more than ever. A weighted set C_w that is a subset of the input is an ε-coreset if the cost of any feasible solution S with respect to C_w is within $[1\pm\varepsilon]$ of the cost of S with respect to the original input. We give a very general technique to compute coresets in the fully-dynamic setting where input points can be added or deleted. Given a static (i.e., not dynamic) ε-coreset-construction algorithm that runs in time $t(n,\varepsilon,\lambda)$ and computes a coreset of size $s(n,\varepsilon,\lambda)$, where n is the number of input points and $1-\lambda$ is the success probability, we give a fully-dynamic algorithm that computes an ε-coreset with worst-case update time $O((\log n)\cdot t(s(n,\varepsilon/\log n,\lambda/n),\varepsilon/\log n,\lambda/n))$ (this bound is stated informally), where the success probability is $1-\lambda$. Our technique is a fully-dynamic analog of the merge-and-reduce technique, which is due to Har-Peled and Mazumdar [17] and is based on a technique of Bentley and Saxe [3], that applies to the insertion-only setting where points can only be added. Although, our space usage is $O(n)$, our technique works in the presence of an adaptive adversary, and we show that $\Omega(n)$ space is required when adversary is adaptive.

As a concrete implication of our technique, using the result of Braverman et al. [4], we get fully-dynamic ε-coreset-construction algorithms for k-median and k-means with worst-case update time $O(\varepsilon^{-2}k^2\log^5 n\log^3 k)$ and coreset size $O(\varepsilon^{-2}k\log n\log^2 k)$ ignoring $\log\log n$ and $\log(1/\varepsilon)$ factors and assuming that $\varepsilon=\Omega(1/\operatorname{poly}(n))$ and $\lambda=\Omega(1/\operatorname{poly}(n))$ (which are very weak assumptions made only to make these bounds easy to parse). This results in the first fully-dynamic constant-approximation algorithms for k-median and k-means with update times $O(\operatorname{poly}(k,\log n,\varepsilon^{-1}))$. Specifically, the dependence on k is only quadratic, and the bounds are worst-case. The best previous bound for both problems was *amortized* $O(n\log n)$ by Cohen-Addad et al. [10] via randomized $O(1)$-coresets in $O(n)$ space.

We also show that under the OMv conjecture [18], a fully-dynamic $(4-\delta)$-approximation algorithm for k-means must either have an amortized update time of $\Omega(k^{1-\gamma})$ or amortized query time of $\Omega(k^{2-\gamma})$, where $\gamma>0$ is a constant.

1 Introduction

Clustering is an ubiquitous notion that one encounters in computer-science areas such as data mining, machine learning, image analysis, bioinformatics, data compression, and computer graphics, and also in the fields of medicine, social science, marketing, etc. Today, when the input data has become massive, one would rather run an algorithm on a small but representative summary of the input, and for clustering problems, a *coreset* serves that function perfectly. The concept of a coreset was defined first in computational geometry as a small subset of a point set that approximates the shape of the point set. The word coreset has now evolved to mean an appropriately weighted subset of the input that approximates the original input with respect to solving a computational problem.

Let P be a problem for which the input is a weighted subset[1] $X_w \subseteq U$; think of U as in a metric space (U, d), so U is unweighted and d is the distance function. Let $n := |X_w|$ and $W := \sum_{x \in X_w} w(x)$. We also refer to elements of U as points. The goal in the problem P then is to output S^* that belongs to the feasible-solution space (or *query* space) Q such that the cost $c(S^*, X_w)$ is minimized. For example, in the *k-median* (respectively, *k-means*) problem, Q is the set of all (unweighted) subsets of X_w of cardinality at most k and $c(S, X_w) := \sum_{x \in X_w} w(x) \min_{s \in S} d(x, s)$ (respectively, $\sum_{x \in X_w} w(x) \min_{s \in S}(d(x, s))^2$). Then, for the problem P, a weighted set C_w such that $C_w \subseteq X_w$ is an *ε-coreset* if, for any feasible solution $S \in Q$, we have that $c(S, X_w) \in [1 \pm \varepsilon] c(S, C_w)$; we sometimes say that the *quality* of coreset C_w is ε. For many problems, fast coreset-construction algorithms exist; e.g., for k-median and k-means, $\tilde{O}(nk)$-time[2] algorithms for computing ε-coresets of size $O(\varepsilon^{-2} k \operatorname{polylog}(n))$ exist.

Throughout the paper, we assume that the cost function c for the problem P is *linear*: for any weighted subsets $Y_w^1, Y_w^2 \subseteq U$ with disjoint supports and any $S \in Q$, we have that $c(S, Y_w^1 \cup Y_w^2) = c(S, Y_w^1) + c(S, Y_w^2)$, where the union $Y_w^1 \cup Y_w^2$ is the weighted union. It is easy to see that k-median and k-means cost functions are linear.

Our goal in this paper is to give *dynamic algorithms* for computing a coreset. In the dynamic setting, the input changes over time. A dynamic algorithm is a data structure that supports three types of operations: *Insert*(p, w), which inserts a point p with weight w into X_w; *Delete*(p), which removes point p from X_w; and *Query*$()$, which outputs a coreset of X_w. Weight updates can be simulated by deleting and re-inserting a given point, or the data structure may support a separate weight-changing operation. This is known as the *fully* dynamic model as opposed to the *insertion-only* setting where a point can only be inserted. At any time instant, a coreset is maintained by the algorithm, and the complexity measure of interest is the *update* time, i.e., how fast the solution can be updated after receiving a point update, and also the *size* of the coreset, which determines the *query* time. Suppose there is a dynamic coreset-construction algorithm, say ALG_D, for a problem P. Then a solution for the problem P can be maintained dynamically by running ALG_D, and on query, a solution is computed by querying ALG_D and running a static (i.e., not dynamic) algorithm for P on the returned coreset. In this paper, we give a very general technique on how to maintain a coreset in the fully-dynamic setting: given a *static* coreset-construction algorithm for any problem P, we show how to turn it into a dynamic coreset-construction algorithm for P.

[1] When using a set operation such as union or notation such as $\subseteq$ with one or more weighted sets, we mean it for the underlying unweighted sets. Also, all weights are nonnegative.

[2] Logarithmic factors are hidden in the $\tilde{O}$ notation.

Intuitively, our technique is to the fully-dynamic setting as the merge-and-reduce technique is to the insertion-only setting. The *merge-and-reduce* technique, which is based on a technique of Bentley and Saxe [3], is due to Har-Peled and Mazumdar [17] and is a fundamental technique to obtain an insertion-only coreset-construction algorithm using a static coreset-construction algorithm, say ALG_S, as a black box. Loosely speaking, it is as follows. At any time instant, the algorithm maintains up to $\lceil \log n \rceil$ buckets. For $i \in \{1, 2, \ldots, \lceil \log n \rceil\}$, the bucket B_i has capacity 2^{i-1}, each bucket can be either *full*, (i.e. at capacity 2^{i-1}) or *empty*, and each point goes in exactly one bucket. Then at any time-instant, the current number of points uniquely determines the states of the buckets. Whenever a point is inserted, the states of the buckets change like a binary counter. That is, the new point goes into B_i, where B_i is the smallest-index empty bucket, and all the points in $\cup_{j=1}^{i-1} B_j$ are moved to B_i (*merge*). Note that this creates a full bucket B_i. Then a coreset is computed on B_i by running ALG_S on it (*reduce)*. The overall coreset is then just union of all non-empty buckets.

We show that a similar result can be achieved in the fully-dynamic setting. Our main result is the following theorem (stated slightly informally).

▶ **Theorem 1.** *Assume that there is a static coreset construction algorithm for a problem P with linear cost function that* ***a)*** *runs in time $t_P(n_s, \varepsilon_s, \lambda_s, W_s)$,* ***b)*** *always outputs a set of cardinality at most $s_P(\varepsilon_s, \lambda_s, W_s)$ and total weight at most $(1+\delta)W_s$, and* ***c)*** *has the guarantee that the output is an ε_s-coreset with probability at least $1-\lambda_s$, where n_s is the number of* integer*-weighted input points and W_s is the total weight of points.*

Then there is a fully-dynamic coreset-construction algorithm for P that, with rational*-weighted input points,* ***a)*** *always maintains an output set of cardinality at most $s_P(\varepsilon, \lambda, W)$,* ***b)*** *has the guarantee that the output is an ε-coreset with probability at least $1-\lambda$, and* ***c)*** *has worst-case update time*

$$O\left((\log n) \cdot t_P\left(s_P^*, \frac{\varepsilon}{\log n}, \frac{\lambda}{n}, W\right)\right),$$

where $W = O((1+\delta)^{\lceil \log n \rceil} \operatorname{poly}(n))$, $s_P^* = s_P\left(\frac{\varepsilon}{\log n}, \frac{\lambda}{n}, W\right)$, and n is the current number of points.

We mention below a concrete implication of the above theorem for k-median and k-means using the result of Braverman et al. [4].

▶ **Theorem 2.** *For the k-median and k-means problems, there is a fully-dynamic algorithm that maintains a set of cardinality $O(\varepsilon^{-2}k(\log n \log k \log(k\varepsilon^{-1} \log n) + \log(1/\lambda)))$, that is an ε-coreset with probability at least $1-\lambda$, and has worst-case update time*

$$O\left(\varepsilon^{-2}k^2 \log^5 n \log^3 k \log^2(\varepsilon^{-1})(\log\log n)^3\right),$$

assuming that $\varepsilon = \Omega(1/\operatorname{poly}(n))$ and $\lambda = \Omega(1/\operatorname{poly}(n))$. [3]

Ignoring $\log\log n$ and $\log(1/\varepsilon)$ above, the coreset cardinality is $O(\varepsilon^{-2}k \log n \log^2 k)$ and worst-case update time is $O(\varepsilon^{-2}k^2 \log^5 n \log^3 k)$. It can be easily proved that running an α-approximation algorithm for k-median on an ε-coreset gives a $2\alpha(1+\varepsilon)$-approximation whereas that for k-means gives a $4\alpha(1+\varepsilon)$-approximation. Any such polynomial-time static algorithm – say, e.g., $(5+\varepsilon')$-approximation algorithm for k-median by Arya et al. [2] and

[3] We make these very weak assumptions to simplify some extremely unhandy factors involving ε and λ in the expression for the update time.

16-approximation algorithm for k-means by Gupta and Tangwongsan [15] – can be run on our output coreset in $O(\text{poly}(k, \log n, \varepsilon^{-1}))$ time to obtain a constant approximation. This is the first fully-dynamic constant-approximation algorithm for k-median and k-means whose *worst-case* time per operation is polynomial in k, $\log n$, and ε^{-1}. The best previous result was a randomized algorithm with *amortized* $O(n \log n)$ update time and $O(n)$ space by Cohen-Addad et al. [10].

With a simple reduction, we also show a conditional lower bound on the time per operation for k-means. The following theorem is proved as Theorem 20 in Section 4.

▶ **Theorem 3.** *Let $\gamma > 0$ be a constant. Under the OMv conjecture [18], for any $\delta > 0$, there does not exist a fully-dynamic algorithm that maintains a $(4 - \delta)$-approximation for k-means with amortized update time $O(k^{1-\gamma})$ and query time $O(k^{2-\gamma})$ such that over a polynomial number of updates, the error probability is at most $1/3$.*

Our technique

At the core, our technique is simple. We always maintain a balanced binary tree of depth $\lceil \log n \rceil$ containing exactly n leaf nodes (recall that n is the current number of points). Each node corresponds to a subset of X_w, the current input: each leaf node corresponds to a singleton (hence n leaf nodes), and an internal node corresponds to the weighted union of the sets represented by its children. If the cardinality of the union exceeds a certain threshold, then we use the static coreset-construction algorithm to compute its coreset. The root gives a coreset of the whole input.

We next explain how we handle updates in this data structure. Point insertions are straightforward: create a new leaf node and run all the static-algorithm instances at the nodes on the leaf-to-root path. The way we handle point deletions is similar in spirit to the way delete-min works in a min-heap data structure: whenever a point at leaf-node ℓ_d is deleted, we swap contents of ℓ_d with those of the rightmost leaf-node, say ℓ_r, and delete ℓ_r, thus maintaining the balance of the tree. Then we run all the static-algorithm instances at the nodes on the two affected leaf-to-root paths.

However, there are some complications that require new techniques to make it work in *worst-case* time. To maintain guarantees for the output coreset quality and overall success probability, we need to adapt the parameters ε_s and λ_s used for the static algorithm at the internal nodes. The problem is that both depend on n, which changes over time and thus might become outdated. To show an *amortized* update-time bound, we can simply rerun the static algorithms at all internal nodes whenever n has changed by a constant factor. To achieve our worst-case bound, we use two *refresh pointers* that point at leaf nodes, and after each update operation, we rerun using the new values of ε_s and λ_s all the static-algorithm instances at the nodes on the leaf-to-root path from the leaf nodes pointed to by the refresh pointers. This keeps the outputs of the static-algorithm instances at the internal nodes always fresh. After every update, we move these pointers to the right so that they point to the next leaf nodes.

Further complications are caused by fractional weights at the leaf nodes and fractional intermediate-output weights. A problem arises when the weights in X_w are fractional, and the static algorithm expects integer-weighted input [9]. Even if the static algorithm can handle fractional weights [12, 4], there can be a problem. The output of the static algorithm at an internal node is the input for the static algorithm at its parent. Naïvely feeding these output fractional weights directly to the static algorithm at the parent may result in numbers exponential in n near the root, thus prohibitively increasing the update time. To deal with

these problems, rounding is needed for the input, i.e., at the leaf nodes, as well as for each intermediate-output at an internal node. Thus, we propose a more sophisticated rounding scheme and show that the rounding errors accumulated by our rounding are not too high.

We note that our balanced binary-tree data structure may be used to get dynamic algorithms in the following situations. Let $f : \mathbb{R}^{\dim} \to \mathbb{R}^{\dim}$ be a *multi-valued* function. Suppose for any u and v with disjoint supports and for any $f_u \in f(u)$ and $f_v \in f(v)$, we have $f_u + f_v \in f(u + v)$. Also suppose that $f(f(v)) \subseteq f(v)$ for any v. Now, given input v, we want to compute some vector in $f(v)$. If there is a static algorithm for this, then using our technique, we can maintain some vector in $f(v)$ for a dynamically changing vector v. The allowed dynamic operation on v is "add a to the ith coordinate of v," where $a \in \mathbb{R}$. The resulting dynamic algorithm is fast if the static algorithm always outputs a "small" vector; this is true for coresets because coresets are small by nature. Thinking about coresets in the above language, each point is an identity vector in $\mathbb{R}_+^{|U|}$, and then each weighted set of points naturally identifies with a vector. An ε-coreset reduces the number of points drastically. Union of coresets of two disjoint sets is a coreset of the union of those two sets (see Lemma 5). Although an ε-coreset of an ε-coreset is not an ε-coreset, it is a $(2\varepsilon + \varepsilon^2)$-coreset (see Lemma 6).

Space

In the merge-and-reduce technique, a bucket B_i will not actually contain 2^{i-1} points but just a coreset of 2^{i-1} points that would have been there otherwise at any time instant. Thus, using space just $\lceil \log n \rceil$ times the coreset size for a bucket, one can get a coreset of the whole input [17]. This makes it also applicable in the more restricted streaming model, where the input points arrive in a sequence and the goal is to compute a coreset using sublinear space. In the fully-dynamic setting, deletions also need to be handled, and hence no deterministic or randomized algorithm against an adaptive adversary that stores only a coreset is possible: the adversary generating the input could simply ask a query and then delete all points in the returned coreset. Hence, an algorithm that does not store any information about the non-coreset points would not be able to maintain a valid coreset. Even though we store all the points in our fully-dynamic technique, i.e., its space usage is $O(n)$, it works against an adaptive adversary because we never make any assumption about the next update and perform each update independently of all previous updates. By a straightforward reduction from the communication problem of INDEX, we show that $\Omega(n)$ space is required in the presence of an adaptive adversary. The proof of the following theorem appears in Section 4.

▶ **Theorem 4.** *A fully-dynamic algorithm that obtains any bounded approximation for* 1*-median or* 1*-means that works in the presence of an adaptive adversary and has success probability* $1 - 1/(8n^2)$ *must use* $\Omega(n)$ *space, where* n *is the current number of points.*

Comparison with the sparsification technique

Our technique is close to the sparsification technique of Eppstein et al. [11] that is used to speed up dynamic graph algorithms. There, one has to assume that the number of vertices in the input graph, say n_v, does not change, but the edge set changes dynamically, and the bounds are obtained in terms of n_v and m, the current number of edges. Their dynamic edge-tree structure is based on a fixed vertex-partition tree. In the vertex-partition tree, a node at level i corresponds to a vertex-set of cardinality $n_v/2^i$, and a vertex-set at a node is a union of its children's vertex sets (cf. our technique). To start using the edge tree, the vertex-partition tree has to be built first and hence the knowledge of n_v is necessary. Neither

do we need such a fixed structure nor any information about the number of points. Also, in the sparsification technique, there is no analog of weight handling/rounding. Another crucial difference is that they do not use a routine analogous to our refresh-pointers routine because their internal-node guarantees are always fresh. As we discussed before, these refresh pointers are critical for us also in making sure that the error introduced by the unavoidable rounding of output weights of the static-algorithm instances is kept in check.

1.1 Related Work

The most related work is by Cohen-Addad et al. [10] who give an $O(1)$-coreset for k-median and k-means in *amortized* update time of $O(n \log n)$.

For k-median and k-means, the first coreset-construction algorithms were by Har-Peled and Mazumdar [17] for Euclidean metrics and by Chen [9] for general metrics. Improved algorithms computing smaller coresets were later obtained by Har-Peled and Kushal [16] and by Feldman and Langberg [12]. The current known best is by Braverman et al. [4]: $O(\varepsilon^{-2}k \log k \log n)$-size coresets in $\tilde{O}(nk)$ time, who also give an excellent summary of the literature on coresets that we highly recommend. Note that by merge-and-reduce technique, each improvement also gave rise to better (insertion-only) streaming coreset constructions. For k-median and k-means, Frahling and Sohler [14] gave the first coreset-construction algorithm in the dynamic-streaming setting where points can be added or removed. It uses space and update time of $O(\text{poly}(\varepsilon^{-1}, \log m, \log \Delta))$ for constant k and dim when the points lie in the discrete Euclidean metric space $\{1, \ldots, \Delta\}^{\dim}$; for k-median, this was recently improved to $O(\varepsilon^{-2}k \,\text{poly}(\dim, \log \Delta))$ space and update time of $O(\text{poly}(\varepsilon^{-1}, k, \dim, \log \Delta))$ by Braverman et al. [5]. Coreset constructions with improvements in certain parameters in the Euclidean settings have been obtained [13, 24].

The k-median and k-means problems have received significant attention in the algorithms community [8, 20, 19, 7, 2, 23, 21, 15, 22, 1, 6]. The best approximation ratio for k-median is 2.675 by Byrka et al. [6] and that for k-means is $9 + \varepsilon$ by Ahmadian et al. [1].

2 Preliminaries

Let us fix a problem P with the input X_w, the set of feasible solutions Q, and the linear cost function $c : Q \times \mathcal{W} \to \mathbb{R}_+$, where $\mathcal{W}$ is the set of all weighted subsets[4] of X_w. All the numbers encountered are nonnegative.

The computational model

The input set X_w is a weighted set of n points having rational weights whose numerators and denominators are bounded by $O(\text{poly}(n))$. The algorithm works in the random access machine model with word size $O(\log n)$. Each memory word can be accessed in constant time. With each update, a new point is inserted, an existing point is deleted, or the weight of an existing point is modified by adding or subtracting a nonnegative number. The net weight of each point always stays nonnegative with its numerator and denominator always bounded by $O(\text{poly}(n))$.

We will prove some basic lemmas about coresets. Using these, we can take weighted union of two coresets without any loss (Lemma 5) and take a coreset of a coreset without much loss (Lemma 6).

[4] To be precise: denote unweighted version of X_w by X', then $\mathcal{W}$ is essentially $\mathbb{R}_+^{X'}$.

▶ **Lemma 5.** *If C_w^1 and C_w^2 are ε-coresets of X_w^1 and X_w^2, respectively, with respect to a linear cost function c such that $X_w^1 \cap X_w^2 = \emptyset$, then $C_w^1 \cup C_w^2$ is an ε-coreset of $X_w^1 \cup X_w^2$.*

Proof. By linearity of c: for any $S \in Q$,

$$c(S, X_w^1 \cup X_w^2) = c(S, X_w^1) + c(S, X_w^2) \in [1\pm\varepsilon]\left(c(S, C_w^1) + c(S, C_w^2)\right) = [1\pm\varepsilon]c(S, C_w^1 \cup C_w^2)\,,$$

where, recall that, $C_w^1 \cup C_w^2$ is a weighted union. ◀

▶ **Lemma 6.** *If C'_w is an ε-coreset of C_w, and C''_w is a δ-coreset of C'_w, both with respect to c, then C''_w is an $(\varepsilon + \delta + \varepsilon\delta)$-coreset of C_w with respect to c.*

Proof. For any $S \in Q$, we have $c(S, C_w) \in [1\pm\varepsilon]c(S, C'_w)$ and $c(S, C'_w) \in [1\pm\delta]c(S, C''_w)$. So,

$$c(S, C_w) \geqslant (1-\varepsilon)c(S, C'_w) \geqslant (1-\varepsilon)(1-\delta)c(S, C''_w) \geqslant (1 - \varepsilon - \delta - \varepsilon\delta)c(S, C''_w)\,,$$

and $c(S, C_w) \leqslant (1+\varepsilon)c(S, C'_w) \leqslant (1+\varepsilon)(1+\delta)c(S, C''_w) = (1 + \varepsilon + \delta + \varepsilon\delta)c(S, C''_w)$. ◀

Let C_w^1 be an ε-coreset of C_w and C_w^2 be an ε-coreset of C_w^1. Then we say that C_w^1 and C_w^2 are, respectively, 1-level and 2-level ε-coresets of C_w. Extending this notion, we define an i-level ε-coreset to be an ε-coreset of an $(i-1)$-level ε-coreset.

▶ **Lemma 7.** *If C_w^ℓ is an ℓ-level ε-coreset of C_w, then C_w^ℓ is a $\left(\sum_{i=1}^{\ell} \binom{\ell}{i}\varepsilon^i\right)$-coreset of C_w.*

Proof. The proof is by induction on ℓ. Base case is when $\ell = 1$, and by definition, a 1-level coreset is an ε-coreset. By induction hypothesis, we have that $C_w^{\ell-1}$ is a $\left(\sum_{i=1}^{\ell-1} \binom{\ell-1}{i}\varepsilon^i\right)$-coreset of C_w. Now, C_w^ℓ is an ε-coreset of $C_w^{\ell-1}$, hence C_w^ℓ is an $\left(\varepsilon + (1+\varepsilon)\sum_{i=1}^{\ell-1} \binom{\ell-1}{i}\varepsilon^i\right)$-coreset of C_w by Lemma 6. Now, use Lemma 8, which appears below, with $\alpha = \varepsilon$ to finish the proof. ◀

We prove two basic lemmas.

▶ **Lemma 8.** *For any positive integer ℓ and $\alpha \in \mathbb{R}_+$, we have $\alpha + (1+\alpha)\sum_{i=1}^{\ell-1} \binom{\ell-1}{i}\alpha^i = \sum_{i=1}^{\ell} \binom{\ell}{i}\alpha^i$.*

Proof idea. The proof is provided in Appendix A and uses elementary identities involving binomial coefficients and algebraic manipulations. ◀

▶ **Lemma 9.** *For any positive integer ℓ and $\alpha \in [0, 1]$, we have $\sum_{i=1}^{\ell} \binom{\ell}{i} \left(\frac{\alpha}{2\ell}\right)^i \leqslant \alpha$.*

Proof. $\sum_{i=1}^{\ell} \binom{\ell}{i} \left(\frac{\alpha}{2\ell}\right)^i \leqslant \sum_{i=1}^{\ell} \ell^i \frac{\alpha^i}{2^i \ell^i} = \sum_{i=1}^{\ell} \frac{\alpha^i}{2^i} \leqslant \sum_{i=1}^{\ell} \frac{\alpha}{2^i} \leqslant \alpha$. ◀

Now, as a corollary to Lemma 7, we get the following using Lemma 9.

▶ **Corollary 10.** *If C_w^ℓ is an ℓ-level $(\varepsilon/(2\ell))$-coreset of C_w, then C_w^ℓ is an ε-coreset of C_w.*

As we discussed earlier, rounding of the weights at internal nodes is needed in our dynamic algorithm to achieve the desired worst-case update time. Towards that, we need two lemmas.

In the next lemma, think of a/b as the original weight of the point, c/d as the weight that we want to approximate a/b with, and D as the cost of this point with respect to a feasible solution in Q. So the lemma says that by rounding, the cost of the point stays within $1 \pm b/d$ of the original cost.

▶ **Lemma 11.** *For positive integers a, b, and d, let $c = \lfloor ad/b \rfloor$. Then $cD/d \in [1 \pm b/d]aD/b$ for any nonnegative real D.*

Proof. By the definition of c, we have that $c/d \leqslant a/b \leqslant c/d + 1/d$, and $1/d \leqslant a/d$ because $a \geqslant 1$; hence $a/b \geqslant c/d \geqslant a/b - a/d$, which implies that $aD/b \geqslant cD/d \geqslant aD/b - aD/d = (1 - b/d)aD/b$. ◀

The proof of the following lemma is very similar. Here, think that we approximate the weight r of a point by $\lfloor r \rfloor + c/d$ and the cost of the point stays within $1 \pm 1/d$ of the original cost.

▶ **Lemma 12.** *Let $r \geqslant 1$ be a rational number, a and b be positive integers such that $a/b = r - \lfloor r \rfloor$, d be any positive integer, and $c = \lfloor ad/b \rfloor$. Then $(\lfloor r \rfloor + c/d)D \in (1 \pm 1/d)rD$ for any nonnegative real D.*

Proof. By the definition of c and using $r \geqslant 1$, we get that $a/b \geqslant c/d \geqslant a/b - r/d$; adding $\lfloor r \rfloor$ and multiplying by D finishes the proof. ◀

3 A Dynamic Coreset

We describe our dynamic algorithm for maintaining an ε-coreset for a problem P with query space Q that uses a static coreset algorithm, say, ALG_S.

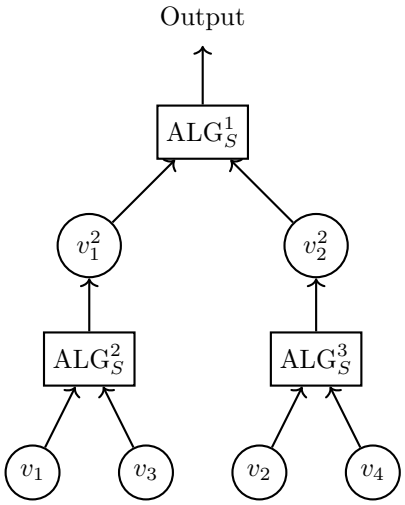

Figure 1 An ALG_S node takes input from two point-nodes. If the union of the sets has cardinality greater than s', then the ALG_S node computes a coreset of cardinality at most s' and passes it on to the point-node above it (its parent). The number of leaf nodes is always n, and the number of levels is always $O(\log n)$, where n is the current number of points.

The main idea is described in Figure 1 using a tree with a special structure. Each node is of one of the two types: a point-node representing a weighted set of points or an alg-node representing an instance of ALG_S. We sometimes use a point-node to denote the point set it represents and an alg-node to denote the ALG_S instance it represents. Each level contains either only point-nodes or only alg-nodes. All leaf nodes are point-nodes and represent a weighted singleton with an input point. Each alg-node gets as input the weighted union of its children, and its output is represented by its parent node (which is a point-node). When running ALG_S at an alg-node A, if the union of its children has cardinality larger than s', then A would compute a coreset of cardinality at most s' otherwise it would just output the weighted union. We will later fix this threshold s' for computing a coreset. An example of

how insertions and deletions are handled is shown in Figure 2 (where all weights are assumed to be one). For the ease of description, from now onwards, we will think of this tree with alg-nodes being collapsed into their parent nodes. Then each leaf node would contain a weighted singleton and each internal node would contain the output of the ALG_S instance run on the weighted union of its children's sets.

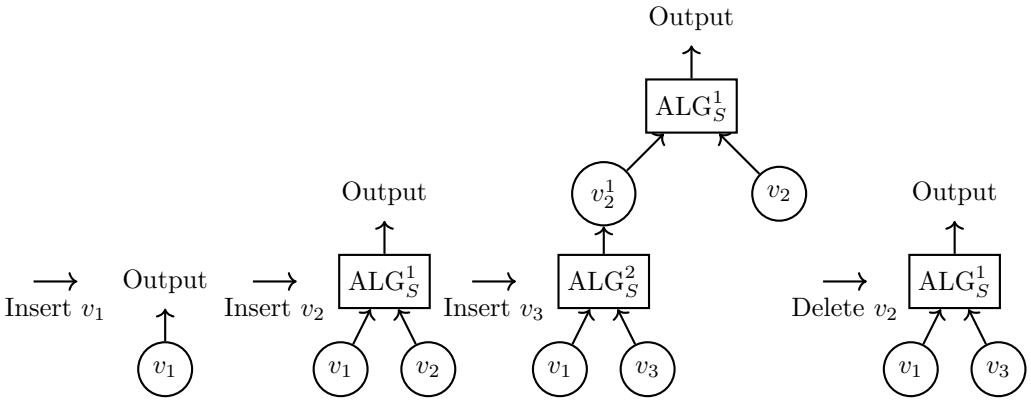

Figure 2 An example of how insertions and deletions are handled. We start with an empty tree. The first point that is inserted is represented by v_1. We use a point and the node that represents it interchangeably. Then v_2 is inserted followed by v_3. Next, if v_4 is inserted, we get exactly the tree shown in Figure 1, and if v_2 is deleted, then we get the last tree.

We guarantee that the resulting tree then will always be a *complete* binary tree, i.e., every level except possibly the lowest is completely filled, and the nodes at the lowest level are packed to the left. To describe the updates briefly, let ℓ_r denote the rightmost leaf node at the lowest level; for simplicity, assume that the lowest level is not full. Insertion is straightforward: the new point goes in a new leaf node to the right of ℓ_r. For deletion of a point at leaf node ℓ_d, if $\ell_d \neq \ell_r$, then we replace contents of ℓ_d with those of ℓ_r and delete ℓ_r. See Section 3.1 for details of these operations. For weight update, the tree does not change.

▶ Remark 13. Since a coreset will not be computed until a node has more than s' points, the tree can be modified so that each leaf node corresponds to a set of $\Theta(s')$ points. Then the number of nodes in the tree is $\Theta(n/s')$. This reduces the additional space used for maintaining this tree. This is important when the number of points is very large. See Section 3.2 for further details. This is essentially the same idea as used for asymmetric sparsification in Section 3.4 in Eppstein et al. [11].

We call the leaf nodes at the same level as that of the leftmost leaf node to be at level 0. We increment these level numbers naturally as we move upwards in the tree. Since we maintain a complete binary tree, the root, which is at the highest level, is on level $\lceil \log n \rceil$. After a point insertion, deletion, or weight update, we recompute all the nodes that are affected by running ALG_S from scratch. Once we update a leaf node, all the nodes on its leaf-to-root path are affected. Since at most two leaf nodes are updated after every point update, we run at most $2\lceil \log n \rceil$ instances of ALG_S. Finally, to reduce the cardinality of our output coreset, we run another *outer* instance of ALG_S with $\varepsilon_s = \varepsilon/3$ and $\lambda_s = \lambda/2$ with input as the output of the root. Here, ε_s and λ_s are parameters for ALG_S as described below, and our goal is to compute an ε-coreset with probability at least $1-\lambda$. The outer instance is run after every update.

The static coreset algorithm ALG_S takes as input an integer weighted set of n_s points with total weight W_s and always returns a weighted set of cardinality at most $s(\varepsilon_s, \lambda_s, W_s)$; this set is an ε_s-coreset with probability at least $1-\lambda_s$. Let the running time of ALG_S be $t(n_s, \varepsilon_s, \lambda_s, W_s)$. We assume that the functions t and s are nondecreasing in W_s and nonincreasing in ε_s and λ_s, and also that t is nondecreasing in n_s. We call such functions t and s *well-behaved.*

We note that t and s implicitly depend on the query space Q as well. In particular, for k-median and k-means, they depend on k and the dimension or the cardinality of the universe from which a solution is allowed to be picked. Also, assume that the total weight of ALG_S's output is at most $1+\delta$ times the total input weight and it outputs a coreset of points with integer weights. For the dynamic algorithm, n denotes the current number of points, and we assume that any input weight is a rational number with numerator and denominator bounded by n^c, for a fixed constant c.

▶ **Theorem 14.** *Assume that there is a static algorithm* ALG_S *that takes as input an integer-weighted set of* n_s *points with total weight* W_s *and always returns an integer-weighted set of cardinality at most* $s(\varepsilon_s, \lambda_s, W_s)$ *with total weight at most* $(1+\delta)W_s$*, and this set is an* ε_s*-coreset with probability at least* $1-\lambda_s$*. Let the running time of* ALG_S *be* $t(n_s, \varepsilon_s, \lambda_s, W_s)$*, and assume that both* s *and* t *are well-behaved. Then there is a fully-dynamic algorithm that, on* rational*-weighted input points, always maintains an* $s\left(\frac{\varepsilon}{3}, \frac{\lambda}{2}, W_p\right)$*-cardinality weighted set. This set is an* ε*-coreset with probability at least* $1-\lambda$*. Its worst-case update time is*

$$O\left(t\left(2s^*, \frac{\varepsilon}{6\lceil \log n_p\rceil}, \frac{\lambda}{2n_p}, W_p\right)\cdot\left(1+\log(1+\delta)+\frac{\log \varepsilon^{-1}}{\log n}\right)\cdot \log n\right),$$

where $W_p = (1+\delta)^{\lceil \log n_p\rceil} n_p^{c''}\lceil 1/\varepsilon\rceil$*,* c'' *is a constant,* $s^* = s\left(\frac{\varepsilon}{6\lceil \log 2n_p\rceil}, \frac{\lambda}{4n_p}, W_p\right)$*, and* $8n/3 \leqslant n_p \leqslant 8n$*.*

Proof. We first prove that the output of the algorithm is an ε-coreset if every non-outer ALG_S instance outputs an ε_s-coreset of its input for some $\varepsilon_s \leqslant \varepsilon/(6\lceil \log n\rceil)$ and the outer ALG_S instance outputs an $(\varepsilon/3)$-coreset of its input. We prove the following by induction on level number: every node at level ℓ contains a $(\sum_{i=1}^{\ell}\binom{\ell}{i}\varepsilon_s^i)$-coreset of the leaf nodes in its subtree. In the base case, a node at level 1 contains an ε_s-coreset of its input trivially. An ALG_S instance A at level i gets as input two sets, say C'_w and C''_w, each of which is a $(\sum_{i=1}^{\ell-1}\binom{\ell-1}{i}\varepsilon_s^i)$-coreset for the leaf nodes in their respective nodes' subtrees. Hence, $C'_w \cup C''_w$ is a $(\sum_{i=1}^{\ell-1}\binom{\ell-1}{i}\varepsilon_s^i)$-coreset for leaf nodes in the subtree rooted at A by Lemma 5. Now, A outputs an ε_s-coreset of $C'_w \cup C''_w$, hence by Lemma 6, its output is an $(\varepsilon_s + (1+\varepsilon_s)\sum_{i=1}^{\ell-1}\binom{\ell-1}{i}\varepsilon_s^i)$-coreset of the leaf nodes in its subtree, which, by Lemma 8, means a $(\sum_{i=1}^{\ell}\binom{\ell}{i}\varepsilon_s^i)$-coreset. This completes the induction step. Hence, the root node, which is at level $\lceil \log n\rceil$, contains $(\sum_{i=1}^{\lceil \log n\rceil}\binom{\lceil \log n\rceil}{i}\varepsilon_s^i)$-coreset. Now, since $\varepsilon_s \leqslant \varepsilon/(6\lceil \log n\rceil)$, by Lemma 9, the output at the root is an $(\varepsilon/3)$-coreset. The outer ALG_S instance outputs an $(\varepsilon/3)$-coreset of this, hence, by Lemma 6, the final output is an $(2\varepsilon/3 + \varepsilon^2/9)$-coreset, which is an ε-coreset of all points.

Recall that the running time of ALG_S is $t(n_s, \varepsilon_s, \lambda_s, W_s)$ to compute an ε_s-coreset with probability at least $1-\lambda_s$, where n_s is the number of points in the input. Our output success probability will depend on λ_s, and ε depends on ε_s as proved in the previous paragraph. We will need $\varepsilon_s \leqslant \varepsilon/(6\lceil \log n\rceil)$ and $\lambda_s \leqslant \lambda/(2n)$, so these depend on n, which can change a lot over time. We now show how to maintain these guarantees for ε_s and λ_s after each update.

Towards this, we need a little tweak to our algorithm and an additional maintenance routine that we call the *refresher*. The algorithm works in phases. The refresher routine maintains two *refresh* pointers that always point to consecutive leaf nodes, say r_1 and r_2.

The refresh pointers are reset after the end of a phase as follows. If the number of leaf nodes is a power of 2, then r_1 and r_2 point to the two leftmost leaf nodes, otherwise they point to the two leftmost leaf nodes at the level above the lowest level. Assume, for completeness, that the very first phase ends after receiving two points, so the tree is just two leaf nodes and their parent as the root.

For each subsequent phase, let n_0 be the value of n at the beginning of the phase. Each phase ends after $n_0/2$ updates, and we set $n_p = 4n_0$. This guarantees that n_p is greater than n throughout the whole phase and even the next phase (details appear below). After receiving an update, we rerun all the ALG_S instances on the leaf-to-root path starting at r_1 and r_2 (at most $2\lceil \log n \rceil$ such instances). This is the refresher routine. Then we move the refresh pointers to the next two leaf nodes on the right. If we reach the right end, then we go to the next level if it exists, otherwise we stop. If we stop, then we achieved the goal of (re-)running all the ALG_S instances that are present at the end of the phase at least once in this phase (this will become clearer below). After the refresher routine, we execute the update which affects at most two leaf nodes. We rerun all the ALG_S instances that are affected by this update, again, at most $2\lceil \log n \rceil$ such instances. So in total, at most $4\lceil \log n \rceil$ of non-outer ALG_S instances are run after an update and one outer instance, which explains the $\log n$ factor in the update time. We now explain the parameters used in the ALG_S instances. For all the non-outer ALG_S instances, we use $\varepsilon_s = \varepsilon/(6\lceil \log n_p \rceil)$ and $\lambda_s = \lambda/(2n_p)$. (This explains the ε_s and λ_s parameters of the functions t and s in the theorem statement.) Note here that the running time of the outer instance is going to be less than any non-outer instance because t is non-increasing in ε_s and λ_s.

As we use $n_p = 4n_0$ and there could be at most $n_0/2$ insertions in a phase, the final value of n is at most $3n_0/2$, and, thus, n_p is always greater than n. In fact, crucially, n_p is an upper bound on n for even the next phase; in the next phase, $n \leqslant n_0 + n_0/2 + (n_0 + n_0/2)/2 = 9n_0/4 \leqslant n_p$. Also, in the current phase, $n_0/2 \leqslant n \leqslant 3n_0/2$, hence $8n/3 \leqslant n_p \leqslant 8n$, as required (cf. the theorem statement).

We now prove that any non-outer ALG_S instance uses $\varepsilon_s \leqslant \varepsilon/(6\lceil \log n \rceil)$ and $\lambda_s \leqslant \lambda/(2n)$ at any time instant. Let L be the set of leaf nodes at the beginning of the phase; therefore, $|L| = n_0$. An ALG_S instance that exists at the end of the phase is either on the leaf-to-root path for some leaf in L or it was created/updated in this phase. At the end of the phase, the refresh pointers will hit all surviving leaf nodes in L; the argument is as follows. Each phase lasts for $n_0/2$ updates, $|L| = n_0$, and we move the two refresh pointers to the right on next two leaf nodes after each update. Importantly, new leaf nodes are added only to the right of the rightmost leaf node at the lowest level, and hence, the refresher routine will have hit all surviving leaf nodes in L before hitting a newly created leaf node.

This shows that, in any case (being either hit by a point update or by the refresher routine), each ALG_S instance is run with $n_p = 4n_0$, setting up these instances for the next phase. This means that at any time instant, each ALG_S instance was created/updated in the current phase or created/updated in the previous phase, thus showing that $\varepsilon_s \leqslant \varepsilon/(6\lceil \log n \rceil)$ and $\lambda_s \leqslant \lambda/(2n)$ for all ALG_S instances at all times.

At any time instant, there are at most n non-outer instances of ALG_S, each with success probability at least $1 - \lambda/(2n)$, and the outer ALG_S instance has success probability at least $1 - \lambda/2$. Hence, the final success probability is at least $1-\lambda$ by the union bound over these $n + 1$ instances.

How to handle weights

We will need one further tweak to argue that each weight ever encountered by the algorithm can be stored using $O(1+\log(1+\delta)+\log(1/\varepsilon)/\log n)$ words, which also explains that factor in the update time. By assumption, an insertion or weight update comes with a weight that is a fraction with the numerator and the denominator bounded by n^c for some fixed constant c. After receiving such an update, we approximate the weight by a fraction that has numerator bounded by $n_p^{c'}\lceil 1/\varepsilon\rceil$, where $c'=2c+1$ is also a fixed constant, and the denominator is equal to $n_p^{c+1}\lceil 1/\varepsilon\rceil$[5]. The change in the cost due to this approximation is at most ε/n_p times the original cost; hence, by the linearity of the cost function, the output coreset quality is affected by at most an additive factor of $O(\varepsilon/n)$. More formally, the following claim holds by Lemma 11 and using $b/d\leqslant\varepsilon/n_p$ below (think of D below as cost).

▷ Claim 15. Let $d=n_p^{c+1}\lceil 1/\varepsilon\rceil$. Given a rational number a/b, where a and b are integers, $a\leqslant n_p^c$ and $b\leqslant n_p^c$, let $f=\lceil ad/b\rceil$. Then $f\leqslant n_p^{2c+1}\lceil 1/\varepsilon\rceil$ and $(f/d)D\in[1\pm\varepsilon/n_p](a/b)D$ for any nonnegative real D.

Recall that due to the refresher routine, at any time instant, the denominator of the weight at any leaf node can be one of the two: $n_p^{c+1}\lceil 1/\varepsilon\rceil$ or $n_{pp}^{c+1}\lceil 1/\varepsilon\rceil$, where n_{pp} is the value of n_p for the previous phase. When the two children of an internal node use different denominators, this complicates our rounding scheme. Thus, when taking a union of the children's sets at an internal node, for each weight, we make its numerator an integer and the denominator equal to $(n_pn_{pp})^{c+1}\lceil 1/\varepsilon\rceil$, which is a common multiple of $n_p^{c+1}\lceil 1/\varepsilon\rceil$ and $n_{pp}^{c+1}\lceil 1/\varepsilon\rceil$ – the only possible denominators of an input weight after rounding. Next, we run the ALG_S instance with integer weights as given by the numerator, then (implicitly) dividing the output weights by the denominator $(n_pn_{pp})^{c+1}\lceil 1/\varepsilon\rceil$ afterwards. Since each ALG_S instance can increase the total weight by at most a factor of $1+\delta$, the sum of the numerators of all weights at level i is always bounded by $n(1+\delta)^i(n_pn_{pp})^{c'}\lceil 1/\varepsilon\rceil$. Since $i\leqslant\lceil\log n\rceil$ and $n_{pp}=\Theta(n_p)$, there exists a constant c'', such that the sum of the numerators of all weights at any level i and all the possible numerators and denominators are bounded by $(1+\delta)^{\lceil\log n_p\rceil}n_p^{c''}\lceil 1/\varepsilon\rceil=:W_p$, and hence, can be stored in $O(1+\log(1+\delta)+\log(1/\varepsilon)/\log n)$ words as desired (see the beginning of the paragraph before Claim 15). This also justifies the W_s parameters of the functions t and s in the theorem statement.

Now we put everything together. The outer ALG_S instance outputs a weighted set of size at most $s\left(\frac{\varepsilon}{3},\frac{\lambda}{2},W_p\right)$. This set is an ε-coreset with probability at least $1-\lambda$, which we proved by a union bound over all ALG_S instances. We set $s'=s\left(\frac{\varepsilon}{6\lceil\log n_p\rceil},\frac{\lambda}{2n_p},W_p\right)$, which is the threshold for computing a coreset at each internal node, i.e., (recall that) if the number of points at an internal node is greater than s', then we run ALG_S to compute a coreset. An upper bound on the threshold for the current phase and the previous phase is $s^*=s\left(\frac{\varepsilon}{6\lceil\log 2n_p\rceil},\frac{\lambda}{4n_p},W_p\right)$ because the n_p value for the previous phase can be at most twice that of the current phase. Then the worst-case update time is dominated by the non-outer

[5] The static algorithm ALG_S expects integer-weighted input and outputs integer-weighted points, whereas our dynamic algorithm handles fractional weights. If fractional weights are naïvely stored in our dynamic algorithm, then at internal nodes, combining two fractions may result in larger magnitude numbers. E.g., naïvely handling two points with weights a/b and c/d so as to be used in ALG_S results in weights $ad/(bd)$ and $bc/(bd)$. Thus, at level i, the numerators and denominators may be as large $(\mathrm{poly}(n))^{2^i}$. Note that some rounding would be needed even if ALG_S can handle rational weights, because its output may be points with rational weights having much larger magnitude; e.g., even if the output magnitude is about only quadratic in that of the input, the blowup near the root in our dynamic algorithm would be nth power of the input. In fact, we do this rounding in the proof of Theorem 2.

ALG_S instances, each running in time $t\left(2s^*, \frac{\varepsilon}{2\lceil\log n_p\rceil}, \frac{\lambda}{2n_p}, W_p\right)$, and we run $O(\log n)$ of these after receiving an update. An additional factor of $1+\log(1+\delta)+\log(1/\varepsilon)/\log n$ appears because each weight may need memory worth $O(1+\log(1+\delta)+\log(1/\varepsilon)/\log n)$ words, and we need constant time to access each memory word. ◀

Before proving the concrete bounds for k-median and k-means that are stated in Theorem 2, we prove a weaker theorem that is a direct consequence of Theorem 14 using the static algorithm of Chen [9].

▶ **Theorem 16.** *For the k-median and k-means problems, there is a fully-dynamic algorithm that maintains a set of cardinality $O(\varepsilon^{-2}k\log^2(n/\varepsilon)(k\log n+\log(1/\lambda)))$, that is an ε-coreset with probability at least $1-\lambda$, and has worst-case update time*

$$O\left(\varepsilon^{-2}k^2\log^3 n\log^2\frac{n}{\varepsilon}\log\frac{n}{\lambda}\left(k\log n+\log\frac{n}{\lambda}\right)\log\log\frac{n}{\varepsilon}\left(1+\frac{\log\varepsilon^{-1}}{\log n}\right)\right).$$

Ignoring the $\log\log n$ factors, for $\lambda=\Omega(1/\operatorname{poly}(n))$ and $\varepsilon=\Omega(1/\operatorname{poly}(n))$, the coreset cardinality is $O(\varepsilon^{-2}k^2\log^3 n)$, and the worst-case update time is $O(\varepsilon^{-2}k^3\log^7 n)$.

Proof. Chen's algorithm takes in an integer weighted set and outputs also an integer weighted set. Its output has the same total weight as the input, so $\delta=0$ (see Theorem 14). Also, for Chen's algorithm, $s(\varepsilon_s,\lambda_s,W_s)=O(\varepsilon_s^{-2}k(k\log n+\log(1/\lambda_s))\log^2 W_s)$ and the running time $t(n_s,\varepsilon_s,\lambda_s,W_s)=O(n_sk\log(1/\lambda_s)\log\log W_s)$ (see Theorems 3.6 and 5.5 in Chen [9]), which is dominated by the computation of a bicriteria approximation. Note that both s and t are well-behaved. Using $W_p=O(\operatorname{poly}(n)/\varepsilon)$,

$$s^*=O\left(\varepsilon^{-2}k\log^2 n\log^2\frac{n}{\varepsilon}\left(k\log n+\log\frac{n}{\lambda}\right)\right),$$

and $\delta=0$ in Theorem 14 gives the desired bounds using the functions t and s above. ◀

Now we use the result of Braverman et al. [4] to get better bounds as stated in Theorem 2 in the introduction section. Unfortunately, we cannot use Theorem 14 as a complete black box for this because in this case, on integer weighted input, ALG_S does not output an integer weighted coreset. The proof of the following theorem is thus an extension of the proof of Theorem 14.

▶ **Theorem 2.** *For the k-median and k-means problems, there is a fully-dynamic algorithm that maintains a set of cardinality $O(\varepsilon^{-2}k(\log n\log k\log(k\varepsilon^{-1}\log n)+\log(1/\lambda)))$, that is an ε-coreset with probability at least $1-\lambda$, and has worst-case update time*

$$O\left(\varepsilon^{-2}k^2\log^5 n\log^3 k\log^2(\varepsilon^{-1})(\log\log n)^3\right),$$

assuming that $\varepsilon=\Omega(1/\operatorname{poly}(n))$ and $\lambda=\Omega(1/\operatorname{poly}(n))$.

Proof. Our dynamic algorithm expects to have at its disposal a static algorithm ALG_S that takes integer-weighted input and outputs an integer-weighted coreset. Since the algorithm of Braverman et al. that we use as ALG_S outputs on *integer* weighted input a coreset with *fractional* weights, we need some modifications. Hence, before ALG_S is ready to be used in the dynamic algorithm, we round its output to turn it into integers.

Weight-Rounding Modifications for $\mathbf{ALG}_S$

- Let input to ALG_S be Y_w which is a set of n_s points with integer weights $w(1), \ldots, w(n_s)$.
- We run ALG_S on the same points with scaled weights $s'w(1), \ldots, s'w(n_s)$, where s' is the desired cardinality of the output coreset (which is the same as the threshold for computing a coreset at an internal node in this case). We set s' later in a such a way that it can be computed by our dynamic algorithm. This step of multiplying input weights by s' is done to make sure that each of the fractional weights output by ALG_S is at least 1 (see Line 6 of Algorithm 2 in Braverman et al. [4]).
- Let the output C_w of ALG_S be a weighted set of s' points with fractional weights $w_o(1), \ldots, w_o(s')$. Using the rounding strategy of Lemma 12, round these fractional weights to have an integer numerator and the denominator equal to $\lceil (\log n_p)/\varepsilon \rceil$ to get weights $\tilde{w}(1), \ldots, \tilde{w}(s')$, where n_p is as defined in the proof of Theorem 14. Formally, for $i \in \{1, \ldots, s'\}$:

$$\tilde{w}(i) = \lfloor w_o(i) \rfloor + \frac{\left\lfloor (w_o(i) - \lfloor w_o(i) \rfloor) \left\lceil \frac{\log n_p}{\varepsilon} \right\rceil \right\rfloor}{\left\lceil \frac{\log n_p}{\varepsilon} \right\rceil}.$$

  Since $w_o(i) \geqslant 1$, by Lemma 12, for any real $D \geqslant 0$, we have $\tilde{w}(i)D \in [1 \pm \varepsilon/\log n_p] w_o(i) D$.
- Hence, by the linearity of the cost function, C_w with weights $\tilde{w}(1)/s', \ldots, \tilde{w}(s')/s'$ is an $(\varepsilon_s + 2\varepsilon/\log n_p)$-coreset of Y_w with weights $w(1), \ldots, w(n_s)$ if C_w with weights $w_o(1), \ldots, w_o(s')$ is an ε_s-coreset of Y_w with weights $s'w(1), \ldots, s'w(n_s)$. Note that $\tilde{w}(i)/s'$ can be represented as a fraction with an integer numerator and denominator equal to $s'\lceil (\log n_p)/\varepsilon \rceil$.
- The additive loss of $2\varepsilon/\log n_p$ in the coreset quality due to this rounding is tolerable because every non-outer ALG_S instance will be run with $\varepsilon_s = O(\varepsilon/\log n_p)$[6]. Hence, the coreset quality at internal nodes will always be $O(\varepsilon_s + \varepsilon/\log n_p) = O(\varepsilon/\log n)$, as desired.
- This rounding ensures that on integer-weighted input with total weight W, the output weights of ALG_S are fractions with integer numerator bounded by $(1+\delta)Ws'\lceil (\log n_p)/\varepsilon \rceil$ and integer denominator equal to $s'\lceil (\log n_p)/\varepsilon \rceil$. Here, $1+\delta$ is the factor by which ALG_S can increase the total weight.

To handle rational weights in the dynamic algorithm, we first proceed as described in the paragraph on how to handle weights in the proof of Theorem 14. Recall that we assume that each insertion or weight update by the adversary comes with a weight that is a fraction with the numerator and the denominator bounded by n^c for some fixed constant c, and we set $c' = 2c+1$. Also, each leaf node was created/updated in the current phase or created/updated in the previous phase and thus uses the value either n_p or n_{pp}, where n_{pp} is the value of n_p for the previous phase. We then showed the following. At any time instant, the weight of the point at a leaf node is rounded in such a way that the numerator is bounded by $n_p^{c'}\lceil 1/\varepsilon \rceil$ and the denominator is equal to $n_p^{c+1}\lceil 1/\varepsilon \rceil$, or the numerator is bounded by $n_{pp}^{c'}\lceil 1/\varepsilon \rceil$ and the denominator is equal to $n_{pp}^{c+1}\lceil 1/\varepsilon \rceil$. Due to this rounding, the output coreset quality is affected by at most an additive factor of $\max\{2\varepsilon/n_p, 2\varepsilon/n_{pp}\} = O(\varepsilon/n)$. We now prove the following more general statement towards the current proof.

---

[6] If we go for smaller additive loss, say ε/n_p, the denominators of resulting numbers due to this rounding would become exponential in n_p. And if we go for a larger additive loss, it would worsen the coreset quality at non-outer instances to $\omega(\varepsilon/\log n_p)$ resulting in the quality of the output coreset worse than ε.

▶ **Lemma 17.** *At any time instant, every weight at a node at level i has an integer numerator and a denominator that is a factor of $(n_p n_{pp})^{c+1}\lceil 1/\varepsilon\rceil(s'_p s'_{pp}\lceil(\log n_p)/\varepsilon\rceil\lceil(\log n_{pp})/\varepsilon\rceil)^i =: D(i)$, where s'_p and s'_{pp} are values of the threshold s' in the current and the previous phase, respectively.*

Proof. We prove this statement by induction over the sequence of nodes updated by the algorithm.

In the base case, the first ever node update will be due to creation of a leaf node, and the weight will have denominator $n_p^{c+1}\lceil 1/\varepsilon\rceil$. Next we discuss the induction step. Let the update be on a node at level i, so we run the *modified* ALG_S instance with all weights having a denominator that is a factor of $D(i-1)$, which is true by induction hypothesis. Then, since the modified ALG_S adds a factor of $s'_p\lceil(\log n_p)/\varepsilon\rceil$ to the denominator, all resulting output weights have a denominator that is a factor of $D(i-1)s'_p\lceil(\log n_p)/\varepsilon\rceil$, which is a factor of $D(i)$. This finishes the induction step for the case when the node update is not the last of the phase. When the node being updated is the last of the phase, we have to be careful. In this case, we need to show that for all weights in all nodes, n_{pp} or s'_{pp} do not appear in the denominator, as this will set these denominators for the next phase. Towards this, we need the following claim.

▷ Claim 18. Let u be a node at level i. Fix a time instant. Suppose, in the current phase, all nodes in the subtree rooted at u were updated and u was updated after the update of the last-updated leaf node in the subtree. Then the denominator of the weights at u is a factor of $n_p^{c+1}\lceil 1/\varepsilon\rceil(s'_p\lceil(\log n_p)/\varepsilon\rceil)^i$ at the fixed time instant.

We omit the proof of this claim as it can be proved easily by induction on the level number at any fixed time instant.

After the last node update of the phase, every node in the tree has been updated in the current phase and the premise of Claim 18 holds due to the refresher routine. Hence, by Claim 18, after the last node update of the phase, i.e., just before the new phase begins, all denominators at level i are a factor of $n_p^{c+1}\lceil 1/\varepsilon\rceil(s'_p\lceil(\log n_p)/\varepsilon\rceil)^i$. Since n_p and s'_p of this phase will become n_{pp} and s'_{pp} in the next phase, the induction hypothesis stays true for the next phase as well. This finishes the proof of Lemma 17. ◀

Since an ALG_S instance may increase the total weight by at most a factor of $1+\delta$, the sum of the numerators of weights at any level i is at most

$$n_p(1+\delta)^i(n_p n_{pp})^{c'}\left\lceil\frac{1}{\varepsilon}\right\rceil\left(s'_p s'_{pp}\left\lceil\frac{\log n_p}{\varepsilon}\right\rceil\left\lceil\frac{\log n_{pp}}{\varepsilon}\right\rceil\right)^i;$$

this can be seen by an easy induction on the level number. Using this bound, we set the threshold s' in a way similar to that in the proof of Theorem 14: we set

$$s'_p = s\left(\frac{\varepsilon}{6\lceil\log n_p\rceil}, \frac{\lambda}{2n_p}, W_p\right),$$

where

$$W_p = (1+\delta)^{\lceil\log n_p\rceil} n_p^{c_1}\left(k\left\lceil\frac{\log n_p}{\varepsilon}\right\rceil\right)^{c_2\lceil\log n_p\rceil},$$

and c_1 and c_2 are chosen to be large enough constants so that W_p upper bounds the sum of the numerators of all weights at any level. From now onwards, we assume that $\lambda = \Omega(1/\operatorname{poly}(n))$. For ALG_S, the function s is $s(\varepsilon_s, \lambda_s, W_s) = O(\varepsilon_s^{-2}k(\log k \log W_s + \log(1/\lambda_s)))$ and $\delta = O(\varepsilon)$.

Then, using $n_{pp} = \Theta(n_p)$, we get that both s'_p and s'_{pp} are $O\left(\left(k\left\lceil\frac{\log n_p}{\varepsilon}\right\rceil\right)^{c_3}\right)$, where c_3 is a fixed constant (so, independent of c_1 and c_2). Observe that W_p and thus s'_p are determined by the phase and hence can be computed by our algorithm. More concretely, we get that both s'_p and s'_{pp} are

$$O\left(\varepsilon^{-2}k\log^3 n\log k\log\frac{k\log n}{\varepsilon}\right).$$

All possible numerators and denominators encountered by the algorithm are bounded by

$$N := O\left(\operatorname{poly}(n)\left(\frac{k\log n}{\varepsilon}\right)^{O(\log n)}\right),$$

so, can be stored in $m := (\log N)/\log n = O(\log((k\log n)/\varepsilon))$ words.

The running time of ALG_S is $t(n_s, \varepsilon_s, \lambda_s, W_s) = O(n_s k\log(1/\lambda_s)\log\log W_s)$, which, similar to Chen's algorithm, is dominated by computation of a bicriteria approximation. At a non-outer ALG_S instance, $n_s = O(s'_p)$, $\varepsilon_s = O(\varepsilon/\log n_p)$, $\lambda_s = O(\lambda/n_p)$, and $W_s \leqslant W_p$. With every update, $O(\log n)$ instances of ALG_S are run, and an additional m factor appears because a weight may need up to m words. Hence, the worst-case update time assuming $\varepsilon = \Omega(1/\operatorname{poly}(n))$ and $\lambda = \Omega(1/\operatorname{poly}(n))$ is

$$O\left(t\left(s'_p, \frac{\varepsilon}{\log n}, \frac{\lambda}{n}, W_p\right)m\log n\right) = O\left(\varepsilon^{-2}k^2\log^5 n\log k\log^2\left(\frac{k\log n}{\varepsilon}\right)\log\log\left(\frac{k\log n}{\varepsilon}\right)\right)$$

and a looser, easier to parse, bound is $O\left(\varepsilon^{-2}k^2\log^5 n\log^3 k\log^2(1/\varepsilon)(\log\log n)^3\right)$. The output coreset cardinality is

$$s\left(\frac{\varepsilon}{3}, \frac{\lambda}{2}, W_p\right) = O\left(\varepsilon^{-2}k\left(\log n\log k\log\left(\frac{k\log n}{\varepsilon}\right) + \log\frac{1}{\lambda}\right)\right).$$

This finishes the proof of Theorem 2. ◀

3.1 The Binary-Tree Structure

We describe the tree structure in more detail, especially, how insertions and deletions are handled. We always maintain a complete binary tree, in which every level except possibly the lowest is completely filled, and the nodes in the lowest level are packed to the left. We also maintain the property that each internal node has exactly two children. Our data structure behaves somewhat like a heap, though a crucial difference is that we do not have keys. This structure supports insertion and deletion of a leaf node. Insertion of a new leaf-node ℓ works as follows.

- If the current number of leaf nodes is a power of 2, then let v be the leftmost leaf node,
- Else let v be the leftmost leaf node in the level above the lowest level.
- Let p be v's parent.
- Create a new node u.
- Make p to be u's parent; u replaces v, so if v was p's right (respectively, left) child, then u is now p's right (respectively, left) child.
- Make v to be u's left child and ℓ to be u's right child. This way, ℓ the rightmost leaf node at the lowest level.

Deletion of a leaf-node ℓ works as follows. Let v be the rightmost leaf node at the lowest level, p be v's parent, and v' be v's sibling. Replace ℓ's contents by v's contents and replace p's contents by the contents of v'. Delete v and v'.

3.2 Reducing the Number of Nodes

The tree can be modified to have each leaf node correspond to a set of $\Theta(s')$ points to reduce the additional space used for maintaining this tree (pointers and such). Recall that s' is the threshold for computing a coreset. To reduce the number of nodes in the tree this way, we maintain the invariant that each leaf node, except possibly one, contains a set of size s_ℓ with $s'/2 \leqslant s_\ell \leqslant s'$. To maintain this invariant, we use a pointer p_s that points to a leaf node with less than $s'/2$ elements if such a leaf node exists.

Whenever a point is inserted, we add it to the leaf node, say ℓ_e pointed to by p_s. If ℓ_e now contains at least $s'/2$ points, then we make p_s a null pointer. If p_s was a null pointer already, then we create a new leaf node, say ℓ_n, insert the new point in ℓ_n, and make p_s point to ℓ_n. The new leaf node ℓ_n is inserted in the tree as described in Section 3.1.

Whenever a point is deleted, we check if the leaf node, say ℓ_d that contains it now contains less than $s'/2$ points. If ℓ_d contains less than $s'/2$ points, and p_s points to some leaf node, say ℓ_e, then we move points in ℓ_d into ℓ_e and delete ℓ_d. (Deletion of a leaf node is handled as described in Section 3.1.) If p_s does not point to any leaf node, then we make it point to ℓ_d.

As usual, we recompute all nodes on the affected leaf-to-root path.

4 Lower Bounds

In this section, we show lower bounds. We first see a space lower bound and then a conditional lower bound on the time per operation.

4.1 Space Lower Bound

We show a simple and very general space lower bound. Consider any problem that on input X has to output a feasible solution that is a subset of X. Moreover, if X non-empty, then all feasible solutions are also non-empty. Call such a problem *compliant*. Clearly, computing any bounded approximation for k-median and k-means and the problem of constructing any coreset with bounded quality are compliant. To get a linear space lower bound for fully-dynamic algorithms that solve a compliant problem, we use the communication problem of INDEX. In INDEX_N, Alice's input is an N-bit string and Bob's input is an index $I \in \{1, 2, \ldots, N\}$. Alice sends one message to Bob, and he needs to correctly output the bit at position I. By a well-known communication complexity lower bound, Alice must send a message of size $(1 - H_2(3/4))N \geqslant 2N/11$ bits so that Bob can correctly output with a success probability of $3/4$; here H_2 is the binary entropy function.

▶ **Theorem 19.** *A fully-dynamic algorithm for a compliant problem that works in the presence of an adaptive adversary and has success probability $1 - 1/(8n^2)$ must use space $\Omega(n)$, where n is the current input size.*

Proof. We describe the reduction for any compliant problem in a metric space, such as 1-median or 1-means, but it can be naturally generalized to any compliant problem. Alice defines

$$X = \{j : j\text{th bit in her string } = 1\},$$

and distance between any two points of X to be 1. She runs the fully-dynamic algorithm on X and sends the memory snapshot to Bob. Bob queries for a solution and if X is nonempty, a nonempty solution S_1 would be returned. He deletes the points in S_1 and queries again to get S_2, and so on until $\emptyset$ is returned. There would be at most N such queries. Note that

this works because the algorithm works under an adaptive adversary. If one of the S_ℓs in this process contains I, which is Bob's input for the index problem, then Bob outputs 1, else he outputs 0. In the worst case, Bob makes N queries, where query number i would have failure probability at most $1/(8(N-i+1)^2)$. So overall failure probability by the union bound is at most

$$\sum_{i=1}^{N} \frac{1}{8(N-i+1)^2} \leqslant \frac{1}{8}\sum_{i=1}^{\infty}\frac{1}{i^2} = \frac{1}{8}\frac{\pi^2}{6} \leqslant \frac{1}{4}\,.$$

Alice communicated as many bits as the space usage of the dynamic algorithm. Then, by the INDEX_N lower bound, the space usage of the algorithm is at least $2N/11 \geqslant 2n/11$ bits. ◀

4.2 Conditional Lower Bounds on the Time Per Operation

Now, we show conditional lower bounds on the time per update and query for fully-dynamic k-means algorithms. They are based on the *OMv-conjecture* [18]: You are given an $N \times N$ Boolean matrix M that can be preprocessed in polynomial time. Then, an online sequence of N-dimensional Boolean vectors $v^1, \ldots, v^N$ is presented and the task is to compute each Mv^i (using Boolean matrix-vector multiplication) before seeing the next vector v^{i+1}. The conjecture is that finding all the N answers takes time $\Omega(N^{3-\gamma})$ for any constant $\gamma > 0$. In [18] also the following *OuMv problem* was presented: You are given an $N \times N$ Boolean matrix M that can be preprocessed in polynomial time and an online sequence of Boolean vector pairs $(u^1, v^1), \ldots, (u^N, v^N)$ with the goal to compute each $(u^i)^T M v^i$ (using Boolean matrix-vector multiplication) before seeing the next vector pair (u^{i+1}, v^{i+1}). Under the OMv conjecture, finding N answers for the OuMv problem such that the error probability is at most $1/3$ takes time $\Omega(N^{3-\gamma})$ for any constant $\gamma > 0$. We will show a reduction from the latter problem to prove the following result.

▶ **Theorem 20.** *Let $\gamma > 0$ be a constant. Under the OMv conjecture, for any $\delta > 0$, there does not exist a fully-dynamic algorithm that maintains a $(4-\delta)$-approximation for k-means with amortized update time $O(k^{1-\gamma})$ and query time $O(k^{2-\gamma})$ such that over a polynomial number of updates the error probability is at most $1/3$.*

Proof. For the ease of presentation, we assume that k is even; if k is odd, the construction can be easily adapted. We set $N = k/2$. Given an OuMv instance with $N \times N$ matrix M, we construct the following metric space with distance function d from it:

The metric space U consists of $4N$ points numbered from 1 to $4N$. For any $1 \leqslant i < j \leqslant N$ and $N+1 \leqslant i < j \leqslant 2N$, the distance $d(i,j) = 2$. Furthermore, for $1 \leqslant i \leqslant N$ and $N+1 \leqslant j \leqslant 2N$, the distance $d(i,j) = 1$ if $M_{i,j-N} = 1$, and $d(i,j) = 2$ otherwise. Additionally, all $2N$ points $2N+1, \ldots, 4N$ are at distance 100 from each other and from all the other points.

We use a k-means data structure to solve a $u^T M v$ computation as follows: Initially the set X is empty. When given a vector pair (u, v), let p be the number of ones in v and in u. Note that $p \leqslant 2N$. We insert the points i such that $u_i = 1$ and the points j such that $v_{j-N} = 1$ into X and additionally $2N+1-p$ of the points ℓ with $\ell > 2N$. Thus $|X| = 2N+1 = k+1$. Then we ask a k-means query. Afterwards, we delete the inserted points.

If $u^T M v = 1$, then there exist indices i and j such that $u_i = 1, M_{i,j} = 1$, and $v_j = 1$. Consider the optimal solution that consists of all points in X except for point i. Note that the cost of this solution for the k-means problem is 1.

If $u^T Mv = 0$, then any optimal solution must also consist of $2N + 1 - p$ of the points ℓ with $\ell > 2N$, and all but one of the other points in X. But as none of the points in X has distance smaller than 2 to any other point in X, the cost of the solution is at least 4 for k-means. Thus, any $(4 - \delta)$-approximation for k-means can distinguish between the cases $u^T Mv = 1$ and $u^T Mv = 0$. Hence, the OMv conjecture implies that it takes at least time $\Omega(N^{2-\gamma})$ time to execute the above $2N$ update operations and 1 query operation. This implies the claimed lower bound. ◀

Abstract

In recent years, significant advances have been made in the design and analysis of fully dynamic maximal matching algorithms. However, these theoretical results have received very little attention from the practical perspective. Few of the algorithms are implemented and tested on real datasets, and their practical potential is far from understood. In this paper, we attempt to bridge the gap between theory and practice that is currently observed for the *fully dynamic maximal matching problem*. We engineer several algorithms and empirically study those algorithms on an extensive set of dynamic instances.

1 Introduction

The matching problem is one of the most prominently studied combinatorial graph problems having a variety of practical applications. A matching $\mathcal{M}$ of a graph $G = (V, E)$ is a subset of edges such that no two elements of $\mathcal{M}$ have a common end point. Many applications require matchings with certain properties, like being maximal (no edge can be added to $\mathcal{M}$ without violating the matching property) or having maximum cardinality. These problems can be solved in polynomial time. For example, Micali and Vazirani [31] compute a maximum cardinality matching in $O(m\sqrt{n})$ time. For the weighted case, the fastest algorithm is by Galil et. al [19] requiring $O(mn \log n)$ time which improves the $O(n^3)$ time algorithm [18] for sparse graphs.

However, often the underlying graphs change over time, e.g., edges are inserted or deleted in the graph as the time progresses. For example, new relations between objects of a network may be created or removed over time (for example [30]). Even though the matching problem can be solved in polynomial time, computing a new matching from scratch every time the graph changes is an expensive task on huge networks, as this ignores the previously computed

information on the given instance. Hence, in the recent years significant advances have been made in the design and analysis of fully dynamic maximal matching algorithms. These theoretical algorithmic ideas have received very little attention from the practical perspective. Only a few of the dynamic algorithms are implemented and tested on real datasets, and hence their practical potential is far from being understood.

Contribution and Outline. In this paper, we start to bridge the gap between theory and practice that is currently observed for the *fully dynamic maximal matching problem*. We engineer several dynamic maximal matching algorithms as well as an algorithm that is able to maintain the maximum matching. To this end, we look at an algorithm due to Baswana, Gupta and Sen [4], which performs edge updates in $O(\sqrt{n})$ time and maintains a 2-approximate maximum matching, the algorithm of Neiman and Solomon [33], which takes $O(\sqrt{n+m})$ time to maintain a 3/2-approximate maximum matching, as well as two *novel* dynamic algorithms: a random walk-based algorithm as well as a dynamic algorithm that searches for augmenting paths using a (depth bounded) blossom algorithm. Without depth bound, the latter algorithm is able to maintain a maximum matching. We perform extensive experiments comparing the performance of these algorithms on the real-world and artificially generated instances. Experiments indicate that maintaining optimum matchings can be done much more efficiently than the naive algorithm that recomputes maximum matchings from scratch (more than an order of magnitude faster). Second, all non-optimum dynamic algorithms that we consider in this work are able to maintain near-optimum matchings in practice while being multiple orders of magnitudes faster than the naive optimum dynamic algorithm.

2 Preliminaries

2.1 Basic Concepts

Let $G = (V = \{0, \ldots, n-1\}, E)$ be an *undirected graph* without parallel edges and self-loops. We set $n = |V|$, and $m = |E|$, $N(v) := \{u : \{v, u\} \in E\}$ denotes the *neighbors* of v. The degree of a vertex v is $d(v) := |N(v)|$. A matching $\mathcal{M} \subseteq E$ in a graph is a set of edges without common vertices. The *cardinality* or *size* of a matching is simply the cardinality of the edge subset $\mathcal{M}$. We call a matching *maximal*, if there is no edge in E that can be added to $\mathcal{M}$. A *maximum cardinality matching* $\mathcal{M}_{\text{opt}}$ is a matching that contains the largest possible number of edges of all matchings. An α-*approximate* maximum matching is a matching, that contains at least $\frac{|\mathcal{M}_{\text{opt}}|}{\alpha}$ edges. A vertex is called *free* or *unmatched* if it is not incident to an edge of the matching. Otherwise, we call it *unfree* or *matched*. For a matched vertex u with $\{u, v\} \in \mathcal{M}$, we call vertex v the *mate* of u, which we denote as $\text{mate}(u) = v$. For an unmatched vertex u, we define $\text{mate}(u) = \perp$. An *augmenting path* is defined as a cycle-free path in the graph G, that starts and ends on a *free* vertex and where edges from $\mathcal{M}$ alternate with edges from $E \setminus \mathcal{M}$. The *trivial augmenting path* is a single edge, that has both its endpoints unmatched. Throughout this paper, we call such an edge a *free* edge. If we take an augmenting path and resolve it by matching every unmatched edge and unmatching every matched edge, we increase the cardinality of the matching by one. Any matching without *augmenting paths* is a maximum matching [5] and any matching with no augmenting paths of length at most $2k-3$ is a $(k/(k-1))$-approximate maximum matching [23]. Hence, a maximal matching having no augmenting paths of length one (or free edges) is a 2-approximate maximum matching. Throughout the paper, we omit the inverse Ackermann function from complexity statements.

Our focus in this paper are *fully dynamic graphs*, where the number of vertices is fixed, but edges can be added and removed. All the algorithms evaluated can handle edge insertions as well as edge deletions. In the following, Δ denotes the maximum degree that can be found in any state of the dynamic graph.

2.2 Related Work

Computing large or maximum matchings in graphs is a well researched topic. Edmonds [17] gave an algorithm that can compute a maximum cardinality matching in a static graph in time $O(mn^2)$. This result was later improved to $O(mn^{0.5})$ by Micali and Vazirani [31]. Recently, algorithms use simple data reductions rules such as [25] to speed up computations, or shrink-trees instead of blossoms [16] to speed up computations in static graphs. In practice, these algorithms can still be time consuming for many applications involving large graphs. Hence, several near linear time approximation algorithms exist in practice such as the local max algorithm [11], the path growing algorithm [15] and the global paths algorithm [28]. As the focus of this work are dynamic graphs, we refer the reader to the quite extensive related work section of [16] for more recent static matching algorithms.

In the dynamic setting, the maximum matching problem has been prominently studied ensuring α-approximate guarantees. A major exception is the randomized algorithm by Sankowski [36] which maintains a maximum matching in $O(n^{1.495})$ update time. One can trivially maintain a maximal (2-approximate) matching in $O(n)$ update time by resolving all trivial augmenting paths of length one. Ivković and Llyod [24] designed the first fully dynamic algorithm to improve this bound to $O((n+m)^{\sqrt{2}/2})$ update time. Later, Onak and Rubinfeld [34] presented a randomized algorithm for maintaining a $O(1)$-approximate matching in a dynamic graph that takes $O(\log^2 n)$ expected amortized time for each edge update. This result led to a flurry of results in this area. Baswana, Gupta and Sen [4] improved the approximation ratio of [34] from $O(1)$ to 2 and the amortized update time to $O(\log n)$. Further, Solomon [38] improved the update time of [4] from amortized $O(\log n)$ to *constant*. However, the first deterministic data structure improving [24] was given by Bhattacharya et al. [8] maintaining $(3+\epsilon)$ approximate matching in $\tilde{O}(min(\sqrt{n}, m^{1/3}/\epsilon^2))$ amortized update time, which was further improved to $(2+\epsilon)$ requiring $O(\log n/\epsilon^2)$ update time by Bhattacharya et al. [9]. Recently, Bhattacharya et al. [7] achieved the first $O(1)$ amortized update time for a deterministic algorithm but for a weaker approximation guarantee of $O(1)$. For worst-case bounds, the best results are by Gupta and Peng [21] requiring $O(\sqrt{m}/\epsilon)$ update time for $(1+\epsilon)$ approximation, Neiman and Solomon [33] requiring $O(\sqrt{m})$ update time for 3/2 approximation, Bernstein and Stein [6] requiring $m^{1/4}/\epsilon^{2.5}$ for $(3/2+\epsilon)$ approximation. Recently, Charikar and Solomon [12], and Arar et al. [2] (using [10]), independently presented the first algorithms requiring $O(poly \log n)$ worst-case update time both maintaining $(2+\epsilon)$ approximation. Recently, Grandoni et al. [20] gave an incremental matching algorithm that achieves a $(1+\epsilon)$-approximate matching in constant deterministic amortized time. Despite this variety of different algorithms, to the best of our knowledge, there has been no effort made so far, to engineer and evaluate these algorithms on real-world instances.

3 Algorithms

We now present the fully dynamic algorithms for the maximal matching problem under consideration. We implemented and tested a variety of simple, combinatorial algorithms that seemed likely to work well in practice. We begin with random walk based dynamic algorithms, followed by dynamic algorithms based on (bounded) augmenting path search and finally

review the algorithms by Baswana, Gupta and Sen [4] and Neiman and Solomon [33]. All of the algorithms are fully dynamic. Throughout this section, we provide a brief description of these algorithms and their implementation. In each case, we explain how we handle initialization, edge insertions and edge deletions separately.

3.1 Random Walk-based Algorithms

In general finding long augmenting paths in networks is an expensive step. The main idea of the random walk based methods proposed in this section is to use random walks in order to detect augmenting paths, and hence to improve the size of the matching. We start by explaining the general idea to use random walks for finding augmenting paths and then explain how we handle edge insertions and deletions.

3.1.1 Random Walks For Augmenting Paths

The algorithm works as follows: we start at a free vertex u and randomly choose a neighbour w of u. If this neighbour is free, then we match the edge (u, w) and our random walk stops. If w is matched, we unmatch $(w, \text{mate}(w))$ and match (u, w). Note that $u \neq \text{mate}(w)$ since u is free in the beginning and therefore $\text{mate}(u) = \perp$, but $\text{mate}(\text{mate}(w)) = w$ and $w \neq \perp$. Afterwards, the previous mate of w is free. Hence, we continue our random walk at this vertex. Our random walk performs $O(\frac{1}{\epsilon})$ steps (see below). Here, ϵ basically controls the quality of the matching (see below). Since picking a random neighbor can be done in constant time, the overall time for the random walk update algorithm is $O(\frac{1}{\epsilon})$. Note that the length of the random walk is a natural parameter of the algorithm that we will investigate in the experimental evaluation.

Also note that if the algorithm does not end by matching two free vertices, the matching may not be maximal even if it was initially – this can be the case if the vertex freed last is incident to a free vertex. There are multiple possibilities to fix this. Our default is to undo all changes that have been done in this case. The overall running time of a random walk is then $O(1/\epsilon)$. Another possibility is Δ-*settling:* The algorithm tries to settle visited vertices. The algorithm scans through their neighbors to find a free vertex and stops if once it was successful or the number of steps exceeds $1/\epsilon$. If the random walk was not successful, the algorithm tries to match the last vertex touched by the random walk by scanning its neighbors instead of undoing all changes. This also ensures that the matching is maximal but requires $O(\Delta)$ additional time per visited vertex. The running time of the Δ-settling random walk is then $O(\Delta/\epsilon)$.

We now explain how we perform edge insertions and deletions.

Edge Insertion. Our algorithm handles edge insertions as follows: when inserting an edge (u, v), if both the endpoints are free, we match it. Note that the simple algorithms stops here if at least one of the endpoints is not free. The random walk based algorithms try to improve insertion by doing the following: If both endpoints are matched, thus prohibiting to match the inserted edge, we do nothing. If only one of the endpoints is matched, w.l.o.g let this be u, we unmatch u and $w := \text{mate}(u)$ and match (u, v). We then start a random walk as described above to find augmenting paths from w. If the random walk is unsuccessful to further increase the size of the matching, we undo all changes and restore the matching to the state before we unmatched u and w.

Edge Deletion. Deleting a matched edge (u, v) leaves the two endpoints u and v free. If possible, our algorithm matches them in $O(\Delta)$ time by scanning their neighbors in order to maintain a maximal matching. If u and v cannot be matched and the matching before edge deletion was maximal, then the matching remains maximal. However, a free vertex may be a starting point for an augmenting path of arbitrary length. Hence, we start a random walk as described above from u if it is free and do the same for v.

3.1.2 Analysis

The algorithm can maintain a $(1+\epsilon)$-approximation, if the random walks are of appropriate length and repeated sufficiently often. More precisely, if the algorithm uses random paths of length $2/\epsilon - 1$ and the process is repeated until successful or $\Delta^{2/\epsilon-1} \log n$ times, then with high probability the matching is a $(1+\epsilon)$ approximation of the maximum matching (at each point in time).

▶ **Lemma 1.** *The random walk based algorithm maintains a $(1+\epsilon)$-approximate maximum matching if the length of the walk is $2/\epsilon - 1$ and the walks are repeated $\Delta^{2/\epsilon-1} \log n$ times.*

Proof. If no augmenting path of length $\leq 2/\epsilon - 1$ exists, then the matching is a $(\frac{1/\epsilon+1}{1/\epsilon}) = (1+\epsilon)$-approximate maximum matching. To see this, rewrite the length of the path to $2(1/\epsilon+1)-3$ and set $k = 1/\epsilon+1$ in the approximation lemma above. If there is such a path from a free node, then the probability of finding it is $\geq (\frac{1}{\Delta})^{2/\epsilon-1}$ since one possibility is the that random walker makes the "correct" decision at every vertex of the path. The probability that λ random walks of length $2/\epsilon - 1$ do not find an augmenting path of length $2/\epsilon - 1$ is $\leq (1 - \frac{1}{\Delta^{2/\epsilon-1}})^{\lambda} \leq e^{-\frac{1}{\Delta^{2/\epsilon-1}} \cdot \lambda}$. Thus for $\lambda \geq \Delta^{2/\epsilon-1} \log n$ the probability is $\leq 1/n$. ◀

Parallelization. Note that multiple repetitions of the random walks can be easily parallelized as they are completely independent if changes are made thread-local. If one random walker finds an augmenting path, it is accepted and the other random walkers can be stopped.

3.2 Blossom-based (Optimum) Algorithms

Note that the random walk algorithm also yields a static $(1+\epsilon)$-approximate maximum matching algorithm: use a simple greedy algorithm as initialization and then run the random walks as stated above from the remaining free nodes. However, the amount of repetitions to achieve the approximation is fairly high. Simply, running a modified BFS to find augmenting paths bounded in depth by $2/\epsilon - 1$ from a free node has a theoretically faster running time $O(\Delta^{2/\epsilon-1})$ per free node. Note however that the theoretical bound for the dynamic random walk algorithm is fairly pessimistic: our algorithm stops as soon as *one* augmenting path has been found – this path can also be shorter or in practice there may be multiple possibilities for augmenting paths so that the probability of finding it increases. So the natural question arises, whether a bounded augmenting path search is superior over random walk based methods stated above. Hence, we propose the following dynamic algorithms for the dynamic matching problem.

In most implementations (such as Boost [37]) finding an augmenting path starting from a free node takes $\Omega(n+m)$ running time due to initialization of the data structures of the modified BFS. These data structures are initialized every time an augmenting path search is started. Hence, the observed performance of Edmonds blossom algorithm to find an optimum matching in libraries such as Boost is $\Theta(n(n+m))$ if no algorithm to initialize the matching is used and $O(F(n+m))$ if some greedy algorithm is used as initialization and

F is the number of remaining free nodes after greedy initialization. The later is the reason why in practice greedy initialization strategies generally help to find optimum matchings. However, finding an augmenting path can easily be implemented such that it a) stops as soon as an augmenting path is found, and b) has running time $\Theta(n' + m')$, where n' and m' refers to the number of nodes and edges touched by the augmenting path search modified BFS [39, 29]. The first augmenting path search needs time $O(n + m)$ to initialize the typical data structures. All searches then do book keeping of the changes they made in the data structures and undo them afterwards. Note that this clearly changes the behaviour of the algorithm in practice: if there are many short augmenting paths the algorithm will run much faster than $\Theta(n(n + m))$. The implementation does not change the worst-case complexity, but improves the best case to $O(m)$ [29]. In fact, in our experience the static version of our implementation scales close to linear in m in practice (as there are many short augmenting paths in real world instances). In the following, we always use this variant of augmenting path search and each of the dynamic operations does book keeping to be able to quickly search for augmenting paths.

Edge Insertion. Let (u, v) be the inserted edge. If u and v are free, then we match that edge directly. Otherwise, we start an augmenting path search from u if u is free and from v if v is free. If both u and v are not free, then we perform a breadth first search from u to find a free node reachable via an alternating path. From this node we start an augmenting path search. Note that an augmenting path must use (u, v) as both connected components did not contain an augmenting path with the component before as the algorithm maintains a maximum matching. Also note that the last case will be an expensive step in practice as the algorithm tries to maintain a maximum matching, newly inserted edges will often not result in a new augmenting path and hence the augmenting path search takes $\Theta(n + m)$ time. Without the third case of the algorithm, we call it *unsafe*. That is in case both u and v are not free, the unsafe configuration of the algorithm does nothing.

Not using the unsafe option, the algorithm maintains a maximum matching. This is due to the fact that if the graph did not contain an augmenting path before insertion, the only way we can create one is due to the insertion of the new edge. The first and second case are obvious. In the third case, after finding a single free node, the augmenting path search must use the newly inserted edge (u, v) (which is not matched, but both endpoints are non-free). Hence, it is sufficient to find a single free node. After running the augmenting path search, the matching size has either increased by one, or there was no augmenting path. Hence, the matching must be maximum. Lastly, note that the third case is only necessary if both endpoints of the inserted edge are in different connected components.

Note that when considering insertions only, the algorithm is more expensive than just running the static algorithm. This is due to the fact that the static algorithm runs an augmenting path search from each free *node* once, while our dynamic algorithm does try to find augmenting paths every time we insert an edge (since the graph may have changed at other places not close to the inserted edge). The overall worst case complexity in this case is $O(m(n + m))$ compared to $O(n(n + m))$ for the static algorithm. In our experiments, this effect is especially noticeable if we start a search from a node where a previous augmenting path search has been unsuccessful.

Hence, besides using the unsafe option which drops the property that the matching is maximum, we propose the following optimization called *lazy augmenting path search*. Here, we start an augmenting path search from u and v only if at least $m'/2$ edges have been inserted or deleted since the last augmenting path search from u or v or no augmenting path

search has been started. Note that this effectively amortizes the cost for the augmenting path search, yielding amortized constant time per edge. Our experiments indicate that this speeds up the overall time of the algorithm drastically, while being only slightly worse than the optimum algorithm. Our third optimization limits the search depth of the augmenting path search to $2/\epsilon - 1$. This ensures that there is no augmenting path of length $2/\epsilon - 1$ and hence is a deterministic $(1+\epsilon)$-approximate matching algorithm (if the deletion part algorithm ensures this as well, and the algorithm is run with the safe option). Note that the worst case complexity of the optimum version of the insertion operation is $O(n+m)$, but in practice augmenting paths (if present) are much shorter. The bounded version of our algorithm has, however, worse case complexity of $O(\Delta^{2/\epsilon-1})$.

Edge Deletion. Let (u, v) be the deleted edge. After the deletion we start an augmenting path search from any free endpoint u or v. Depending on the configuration of the algorithm this either does a full run for an augmenting path or stops when the augmenting path search reached depth $2/\epsilon - 1$. In the first case, this guarantees that the matching is maximum if it was maximum before and in the latter case, our algorithm maintains an $(1+\epsilon)$ approximate maximum matching. If case we use lazy augmenting path search, we start an (depth bounded) augmenting path search from u and v only if at least $m'/2$ edges have been inserted or deleted since the last augmenting path search from u or v. Otherwise, we limit augmenting path search from u and v to augmenting paths of length $\min(3, 2/\epsilon - 1)$.

3.3 Baswana, Gupta and Sen Algorithm

Baswana, Gupta and Sen (BGS) presented an randomized algorithm in [4], that maintains a maximal matching in a dynamic graph in *amortized* $O(\sqrt{n})$ update time with high probability. They also present a multi-level variant that runs in $O(\log n)$ amortized time. To be self contained, we briefly review the main concepts of the algorithm and follow their description closely.

Levels and Ownership of Edges. The algorithm uses the concept of *ownership* for edges. More precisely, based upon the number of edges that a vertex *owns*, the algorithm partitions the set of vertices into two levels 0 and 1. An edge is always owned by at least one of its endpoints. If both endpoints are at level 0, then both vertices own the edge. If only one endpoint is at level 1, then this endpoint owns the edge. If both endpoints are at level 1, then exactly one endpoint, namely the first mentioned vertex owns the edge. If a new edge (u, v) with $level(u) = level(v) = 1$ is inserted, it will therefore be owned by the vertex u.

Algorithm 1 RANDOM-SETTLE(u): find a random edge (u, v) from the set of owned edges of u, matches it and returns the previous mate of v.

Let (u, v) be a uniformly randomly selected edge from $\mathcal{O}_u$
forall $(v, w) \in \mathcal{O}_u$ **do**
  remove (v, w) from $\mathcal{O}_w$
if v *is matched* **then**
  $x \leftarrow \text{mate}(v)$; $M \leftarrow M \setminus \{(v, x)\}$
else
  $x \leftarrow$ NULL
$M \leftarrow M \cup \{(u, v)\}$, LEVEL$(u) \leftarrow 1$, LEVEL$(v) \leftarrow 1$
return z

The set $\mathcal{O}_u$ denotes the set of edges owned by a vertex u. The level of an edge is defined by $level(e = \{u, v\}) = \max(level(u), level(v))$. BGS maintains the following invariants: (1) Every vertex on level 1 is matched. (2) Every free vertex on level 0 has all neighbours matched. (3) Every vertex on level 0 owns less then $\sqrt{n}$ edges (at any moment of time). (4) Both endpoints of each matched edge are on same level.

Edge Insertion. Let (u, v) be the edge being inserted. If either u or v are at level 1, then there is no violation of any invariant. The algorithm adds (u, v) to $\mathcal{O}_u$ if level$(u) = 1$ and to $\mathcal{O}_v$ otherwise. If both endpoints of (u, v) are at level 0, then the algorithm proceeds as follows: If both endpoints are free, the edge is added to the matching. Adding the edge (u, v) to the sets $\mathcal{O}_u$ and $\mathcal{O}_v$ increases the number of edges owned by u and v. If at least one set $\mathcal{O}_u$ or $\mathcal{O}_v$ exceeds the threshold of $\sqrt{n}$ in size, the vertex with the higher number of owned edges will be *repaired*. Let u be that vertex. Repairing a vertex u is done by calling the procedure Random-Settle on u. As a result, u moves to level 1 and gets matched to some vertex y selected randomly uniformly from the set of owned edges $\mathcal{O}_u$. The vertex y is also moved to level 1 to satisfy invariant 4. If w and x were the earlier mates of u and y at level 0, respectively, then matching u and y has rendered w and x free. The algorithm tries to settle each of those by scanning their set of owned edges for free vertices.

Edge Deletion. Let (u, v) be an edge that is deleted. If the edge has not been matched, then after removing the edge from the graph all invariants still hold. If it has been matched, then u and v are now free. Therefore, the first invariant may be violated. If (u, v) is at level 0, then the algorithm tries to settle both endpoints by scanning their sets of owned edges. If (u, v) is at level 1, then u the algorithm does the following: First, u disowns all its edges whose other endpoint is at level 1. If $\mathcal{O}_u$ is still greater than or equal to $\sqrt{n}$, then u stays at level 1 and executes Random-Settle(u). If u owns less than $\sqrt{n}$ edges, it moves to level 0 and tries to settle it by scanning its set of owned edges. The transition of u from level 1 to 0 leads to an increase in the number of edges owned by each of its neighbors at level 0. This may violate the size constraint of owned edges for those neighbors. Hence, the algorithm calls Random-Settle for each neighbor that violates the constraint, which moves it to level 1.

3.4 Neiman and Solomon Algorithm

In contrast to the BGS algorithm [4], which is randomized, Neiman and Solomon (NS) [33] present a deterministic algorithm for maintaining a maximal matching in a dynamic graph. Their approach guarantees, that the maintained matching is a 3/2-approximate maximum matching and that update time is $O(\sqrt{m})$ in *worst case*, where m denotes the number of edges present in the graph in the moment of the update. NS maintains the following invariants: There are no augmenting paths of length ≤ 3, ensuring 3/2-approx matching. All free vertices have degree at most $\sqrt{2n + 2m}$.

▶ **Lemma 2** ([33]). *Any free vertex of degree larger than $\sqrt{m}$ can always be matched, so as to generate a free vertex with degree less than $\sqrt{m}$. This can be achieved in $O(\sqrt{m})$ time.*

Edge Insertion. Let (u, v) be the edge being inserted. If both the endpoints are free, the edge is simply added to the matching. Also, if both endpoints are matched it does not entail any further processing. However, if exactly one endpoint of the edge, say u, is matched, they try to remove a possible augmenting path of length 3 as follows. The neighbours of the mate of u say $u' = \text{mate}(u)$, are scanned for a free vertex, say x. If such a free vertex exists, an augmenting path of length 3 has been found, which is augmented increasing the matching size.

Edge Deletion. Let (u, v) be the edge being deleted. If the edge was unmatched, its deletion cannot create any new augmenting paths. However, if it was a matched edge, both the endpoints become free after the edge deletion. First, the algorithm checks for both freed vertices whether they have free neighbours and if so matches the freed vertices with those free neighbours. Now, in order to eliminate augmenting paths of length 3 starting from a free vertex, say u, all neighbours w of u are scanned checking if mate(w) has a free neighbour. By providing appropriate data structures, this can be done in $O(\sqrt{n})$ time. If an augmenting path has been found, it is augmented increasing the size of the matching by one. If no augmenting path has been found, vertex u remains free, but only if its degree is at most $\sqrt{2m}$. If the degree of u exceeds $\sqrt{2m}$, using Lemma 2 a surrogate can be found in $O(\sqrt{m})$.

The overall update time of the algorithm is bound by the bounded degree of all free vertices, making any linear search through the neighbourhood $N(u)$ of a vertex u cost at most $O(\sqrt{n+m})$. Bounding the degree can further be achieved in $O(\sqrt{m})$ time using Lemma 2.

4 Experimental Evaluation

Implementation and System

We implemented the algorithms described in the previous section. The codes are written in C++ and have been compiled using g++-7.3.0 with flags `-O3`. All codes are sequential. We plan to further improve the codes and then to release them to make it available to a larger audience. Our experiments are conducted on one core of a machine with AMD Opteron Processors 6174 with 2.2GHz and 256GB of RAM. *Dynamic Graph Data Structure:* our algorithms use the following dynamic graph data structure. For each node v, we maintain a vector L_v of adjacent nodes, and a hash table $\mathcal{H}_v$ that maps a vertex u that is incident to v to its position in L_v. This data structure allows for expected constant time insertion and deletion as well as a constant time operation to select a random neighbor of v. The deletion operation on (v, u) is implemented as follows: get the position of u in L_v via a lookup in $\mathcal{H}_v(u)$. Swap the element in L_v with the last element w in the vector and update the position of w in $\mathcal{H}_v$. Finally, pop the last element (now u) from L_v and delete its entry from $\mathcal{H}_v$.

Instances and Methodology

By default we perform ten repetitions per instance. We measure the total time taken to compute all edge insertions and deletions and generally use the *geometric mean* when averaging over different instances in order to give every instance a comparable influence on the final result. In order to compare different algorithms, we use *performance profiles* [14]. These plots relate the matching size / running time of all algorithms to the corresponding matching size / running time produced / consumed by each algorithm. More precisely, the y-axis shows $\#\{\text{objective} \geq \tau * \text{best}\}/\#\text{instances}$, where objective corresponds to the result of an algorithm on an instance and best refers to the best result of any algorithm shown within the plot. When we look at running time, the y-axis shows $\#\{\text{t} \leq \text{fastest}/\tau\}/\#\text{instances}$ (as a function of the parameter τ), where t corresponds to the time of an algorithm on an instance and fastest refers to the time of the fastest algorithm on that instance. The parameter $\tau \leq 1$ in this equation is plotted on the x-axis. For each algorithm, this yields a non-decreasing, piecewise constant function. Thus, if we are interested in the number of instances where an algorithm is the best/fastest, we only need to look at $\tau = 1$.

Instances

We evaluate our algorithms on a number of large graphs. These graphs are collected from [3, 13, 27, 26, 35]. Table 3 summarizes the main properties of the benchmark set. Our benchmark set includes a number of graphs from numeric simulations as well as complex networks. These include static graphs as well as real dynamic graphs. As our algorithms do only handle undirected graphs, we consider all input graphs to be undirected by ignoring edge directions and we remove self-loops and parallel edges. We perform *two different types* of experiments. First, we use the algorithms using insertions only, i.e. we start with an empty graph and insert all edges of the static graph in a random order. We do this with all graphs from Table 3. Second, we use real dynamic instances from Table 4. Most of these instances, however, only feature insertions (with the exception being `dewiki` and `wiki-simple-en` which have both real insert and real delete operations). Hence, we perform additional experiments with fully dynamic graphs from these inputs, by undoing x percent of the update operations performed last.

4.1 Random Walk and Blossom-based Algorithms

In this section, we use our algorithms with random insertions only. More precisely, we use the static graphs from Table 3. For each experiment, we start with an empty graph and insert edges of the static input in random order until all edges are insert all edges are inserted compare the result of our dynamic algorithms the maximum matching on the final graph Edmond [17].

Random Walk-Based Algorithms. We start with random walk-based algorithms. Preliminary experiments have shown that decreasing ϵ is more effective in getting better solutions than performing more repeated random walks at the start node. Hence, we exclude algorithms that perform multiple repetitions of random walks per insert operation here from the evaluation and focus on the different values of ϵ. We vary $\epsilon \in \{0.1, 0.25, 0.5, 1, 2\}$. Recall that the path length of a single random walk is then bounded by $2/\epsilon - 1$. If *all* paths of that length were explored, the algorithms would be guaranteed to give a $(1+\epsilon)$-approximation. Figure 1 summarizes the result. It is not surprising that the algorithm needs more running time for smaller ϵ, but also yields better results with increasing path lengths. On average, the algorithm is 2.4%, 3.2%, 4.2%, 5.5%, 11.5% percent away from the optimum for $\epsilon = 0.1, 0.25, 0.5, 1, 2$ respectively. Thus, even though the algorithms are not guaranteed to explore all paths of length $2/\epsilon - 1$, they achieve in practice an approximation that is much better than the theoretical bound for algorithms that explore all such paths. The strongest configuration ($\epsilon = 0.1$) is at most 1% away from the optimum matching size in 50% of the cases. Note that the random walk algorithm does not achieve the guarantee of 1% approximation as claimed by Lemma 1 since we did not perform the vast amount of repetitions necessary to get the result in expectation – instead we performed a single repetition of the random walker for each insertion. As excepted the running time does increase with decreasing ϵ. However, due to random walks that can finish early because they managed to match an edge, the effect is less visible than theory expects. The running time increase over the random walk using $\epsilon = 2$ (which is essentially a random walker not allowed to move, and hence boils down to the very simple greedy algorithm), is 12%, 17%, 21%, 27% for $\epsilon = 1, 0.5, 0.25, 0.1$, respectively.

Enabling Δ-settling generally improves the result. On average, the random walk with Δ-settling is now 1.1%, 1.4%, 1.8%, 2.2%, 3.7% away from the optimum matching for $\epsilon = 0.1, 0.25, 0.5, 1, 2$, respectively. On average in our experiments using Δ-settling has a negligible impact on running time. Hence, we recommend to use Δ-settling when using random walk-based algorithms and do so in the following unless otherwise mentioned.

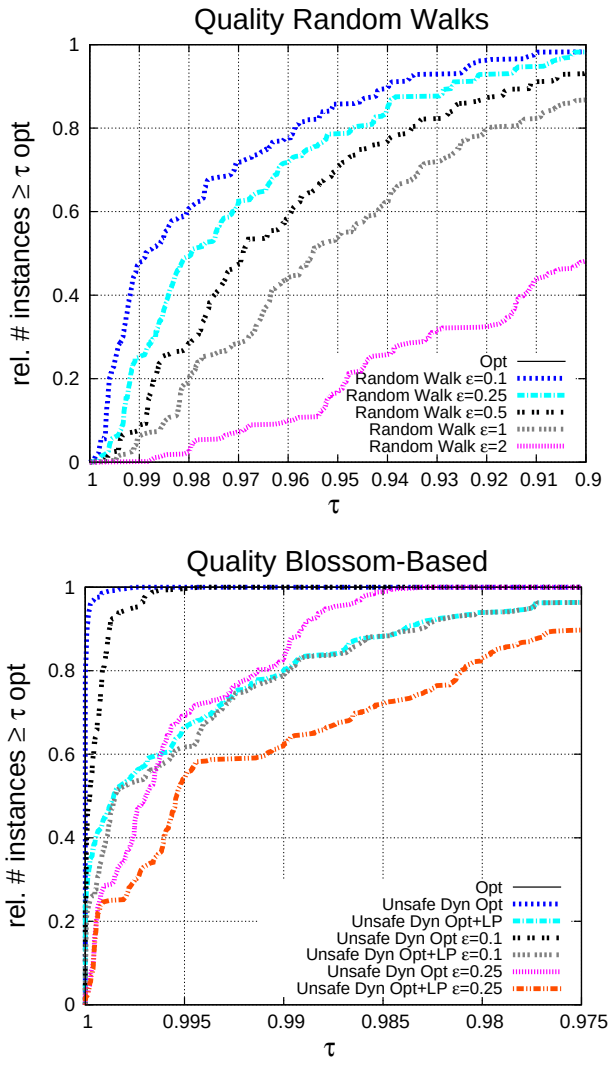

Figure 1 Performance profile for matching size $|\mathcal{M}|$ for Random Walk and for Unsafe Dyn Opt.

(Optimum) Blossom-Based Algorithms. We now consider dynamic blossom-based algorithms from Section 3.2. We start this section with the version of the algorithm that maintains the optimum matching, and compare it to the naive dynamic optimum matching algorithm that recomputes a maximum matching from scratch each time an edge is inserted. Since the running time of the naive optimum algorithm is fairly excessive, we run it only on the graphs of our benchmark set having less than 25k nodes. First of all, our dynamic algorithm that maintains the optimum matching is more than an order of magnitude faster than the naive optimum algorithm (roughly a factor 12). We expect that the difference will be even more pronounced if even larger graphs are used. Running our dynamic optimum algorithm with the unsafe option indeed significantly speeds up the algorithm – the lazy augmenting path search configuration is more than two orders of magnitude over the safe version of our algorithm (roughly a factor 115). The improvements in running time stem

from the fact that our algorithms try to maintain a very large matching. Hence, the case that is executed by the safe option often does not find an augmenting path which implies that the augmenting path search has to look at the overall network and hence reaches its worst-case complexity. Of course, the unsafe option does not have a guarantee on optimality anymore. In our experiments, the unsafe option computes matchings that are 0.02% worse than the optimum on average. We conclude that the algorithm maintains near-optimum matchings while being three orders of magnitude faster than the naive optimum dynamic algorithm. Henceforth, we only consider the unsafe version of our algorithm.

We now switch our set of graphs back to all of our benchmark graphs from Table 3. Using lazy augmenting path search in the unsafe algorithm additionally speedups up computations. Unsafe+LP is on average 20.5 faster than the unsafe algorithm without lazy augmenting path search – again at the cost of solution quality. The algorithm is already only 30% slower than running the static algorithm a *single* time on the final graph that contains all edges. On the other hand, the unsafe dynamic algorithm using lazy augmenting path search computes 0.6% worse matchings that the unsafe algorithm without lazy augmenting path search.

Lastly, we focus on the third variation of the algorithm, which is to bound the depth of the augmenting path search to that is done during update operations. The depth is bounded to $2/\epsilon - 1$ so that given ϵ and running the safe option of the algorithm would maintain a $1 + \epsilon$ approximate matching. We, however, only consider the unsafe version of the algorithm. We use same values of $\epsilon = 0.1, 0.25, 0.5, 1$ as in the random walk-based algorithms section, but do not consider $\epsilon = 2$, since this is again essentially the very simple greedy algorithm. Moreover, we run the algorithm with and without the lazy augmenting path search.

First of all, running without lazy augmenting path search, the algorithm indeed maintains the approximation guarantee. On average, the algorithm is 0.1%, 0.4%, 1.5% and 3.6% worse than the optimum algorithm for $\epsilon = 0.1, 0.25, 0.5, 1$, respectively. Using the lazy augmenting path search, speeds up to algorithm by a factor of 5.52, 2.65, 2.03, 1.76 for $\epsilon = 0.1, 0.25, 0.5, 1$, respectively. With lazy augmenting path search, the algorithm is 0.6%, 1.00%, 2.2%, 4.3% worse than the optimum for $\epsilon = 0.1, 0.25, 0.5, 1$, respectively (and hence still achieves the approximation guarantee). The algorithm using $\epsilon = 0.1$ is only 0.2% worse than the algorithm not bounding the depth. However, the algorithm is also not much faster. On average, bounding the search depth with $\epsilon = 0.1$ improves running time by 6%. Figure 1 shows a summarizing performance profile.

4.2 Comparison of Algorithms

Dynamic Sequences from Static Graphs. We now compare all of the different non-optimal algorithms against each other for the insertion-only case. For random-walks, we always enable Δ-settling, for blossom-based algorithm always use the unsafe option and with and without lazy augmenting path search. Table 1 shows average results for matching size and running time after all edges and operations have been performed. Figure 2 shows performance profiles for running time and for matching size.

First of all, both the blossom-based (with lazy augmenting path search) and random walk-based algorithms dominate the algorithms by Neiman Solomon and Baswana Gupta Sen (BGS). The algorithms find consistently larger matchings and do so in less time. However, note that the real-world instances we look at rarely have nodes with more than $\sqrt{n}$ neighbors, so that the BGS algorithm is roughly similar to the simple greedy algorithm. We also try to use $c \cdot \sqrt{n}$ as a threshold for different values of c, but this always resulted in worse matching sizes.

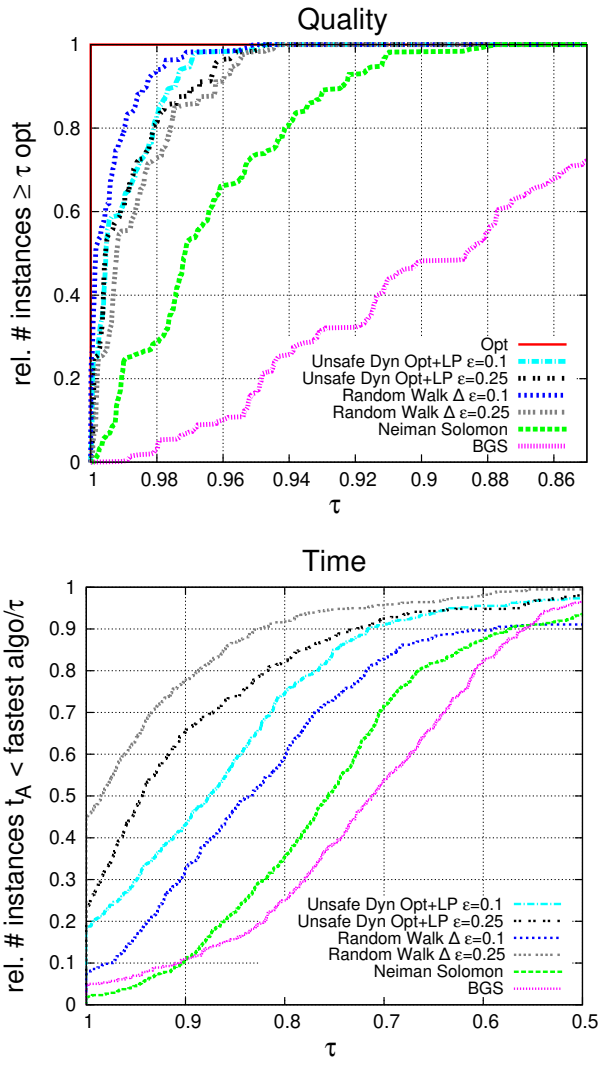

Figure 2 Performance profile for matching size $|\mathcal{M}|$ and time for all algorithms. In all cases, if an algorithm has a curve closer to the upper left corner, then the algorithm is better.

In general, performance differences in running time are not very big (except if we don't use lazy augmenting path search in the blossom-based algorithms). Secondly, for the same values of ϵ the blossom-based algorithms compute slightly better results than their random walk-based counter parts. This is not surprising as the blossom-based algorithms explore larger subgraphs for each edge that has been inserted. We conclude here that both types of algorithms are feasible in practice and have an advantage in solution quality over Neiman Solomon and Baswana Gupta Sen on graphs with random insertions. Moreover, both of these algorithm yield a clear trade-off between running time and solution quality via the ϵ parameter. On the other hand, all of the algorithms considered here are roughly five orders of magnitude faster than the naive dynamic optimum algorithm (only considering instances having less than 25k nodes) and except Baswana Gupta Sen, all of these algorithms are within a 4% range of the optimum matching size.

Real-World Dynamic Instances. We now switch to the real-world dynamic instances. As already mentioned, most of these instances are insertion-only. Hence, we perform additional experiments with fully dynamic graphs from these inputs, by undoing x percent of the update operations performed last (call them $\mathcal{O}_x$). More precisely, we perform the operations in $\mathcal{O}_x$ in reverse order. More precisely, if an edge operation was an insertion in $\mathcal{O}_x$, we perform a delete operation and if it was a delete operation we insert it. As before, we compute the update on the graph after each removal/insertion. The connection to practice in this case, is that with undoing operations, we want to restore a previous state. Table 2 summarizes the results of the experiment and Figure 3 compares the algorithms on the two real-world dynamic graphs dewiki and wiki_simple_en. Overall, the situation is similar to experiments with random insertions that we have seen before. The random walk with Δ-settling and $\epsilon = 0.5$ dominates Baswana, Gupta, Sen and Neiman Solomon in terms of running time *and* matching size for every number of undo operations. The blossom-based algorithm with lazy path search, however, yields smaller matchings if no operations are undone. We believe that this is due to the edges not being inserted randomly and hence the lazy augmenting path search heuristic is less effective, and misses augmenting paths that have been created over time. If operations are undone, the blossom-based algorithms outperform Neiman Solomon in terms of matching size, but are also considerably slower as the deletion operations search for augmenting paths of lengths three (except for $\epsilon = 1$). The blossom-based algorithm without lazy augmenting path search get very close to the optimum solutions. The best algorithm here is blossom-based algorithm without lazy augmenting path search for $\epsilon = 1/3$. On average, it computes solutions that are $< 0.6\%$ away from the optimum (for every amount of undo operations done).

In general, all algorithms improve quality relative to the optimum matching size, if we undo operations. This is due to the fact that the matching may have changed over time and hence new (short) augmenting paths may be found. In case of random-walks this is also simply due to the fact that additional work is performed and the likelihood to find an augmenting path is increased by running additional random walks. Summing up, all of the algorithms, except Baswana, Gupta, Sen, compute/maintain very large matchings. Blossom-based and random walk-based algorithm are highly flexible and are able to trade solution quality for time. Overall, random walk-based algorithms seem to be the method of choice in practice.

Table 1 Random insertions from static graphs: mean of the matching size relative to optimum after all operations have been done as well as mean increase in running time over Random Walk,Δ,$\epsilon = 0.25$.

5 Conclusion

We looked at several dynamic matching algorithms including Baswana, Gupta and Sen [4], Neiman and Solomon [33], as well as random walk-based algorithms and blossom-based algorithms. We performed extensive experiments comparing the performance of these algorithms on the real-world and artificially generated instances. In terms of results, first we have shown that maintaining optimum matchings can be done much more efficiently than the naive algorithm that recomputes maximum matchings from scratch. Second, we have seen that all non-optimum dynamic algorithms that we considered in this work are able to maintain near-optimum matchings in practice while being multiple orders of magnitudes faster than the naive optimum dynamic algorithm. In practice, random walk-based algorithms with Δ-settling will be the method of choice.

In future work, it may be interesting to transfer results to the weighted case, and to combine our algorithms with simple data reductions rules such as [25]. It could be interesting to use these dynamic matching algorithms to derive dynamic multilevel algorithms for example for graph partitioning [32, 1]. Another direction will be to explore the parallelization potential of random walk-based algorithms. Lastly, it may be interesting to incorporate dynamic transitive closure algorithms (e.g. [22]) into the delete operation of the dynamic optimum matching algorithm to further reduce the number of augmenting path searches.

Abstract

We present a practically efficient algorithm that finds all global minimum cuts in huge undirected graphs. Our algorithm uses a multitude of kernelization rules to reduce the graph to a small equivalent instance and then finds all minimum cuts using an optimized version of the algorithm of Nagamochi, Nakao and Ibaraki. In shared memory we are able to find all minimum cuts of graphs with up to billions of edges and millions of minimum cuts in a few minutes. We also give a new linear time algorithm to find the most balanced minimum cuts given as input the representation of all minimum cuts.

1 Introduction

We consider the problem of finding *all minimum cuts* of an undirected network where edges are weighted by positive integers. A *minimum cut* in a graph is a partition of the vertices into two sets so that the total weight of edges crossing the boundary between the blocks is minimized. The problem of finding all minimum cuts has applications in many fields. In particular, minimum cuts in similarity graphs can be used to find clusters [57, 25]. As the minimum cut is often highly skewed, a variety of techniques to find more balanced bipartitions with small cuts were developed [16, 24, 53]. However, these balanced variations of the problem are generally NP-complete. In contrast to that, we find all minimum cuts in practice in a similar timescale than finding an arbitrary minimum cut and can thus output the minimum cut that is least skewed. In community detection, the absence of a small cut inside a cluster can indicate a likely community in a social network [10]. Other applications for finding all minimum cuts can be found in network reliability [34, 51], where a minimum cut in a network

has the highest risk to disconnect the network; in VLSI design [40] and graph drawing [32], in which minimum cuts are used to separate the network; and finding all minimum cuts is an important subproblem for edge-connectivity augmentation algorithms [19, 47].

The problem of finding all minimum cuts is closely related to the *(global) minimum cut problem*, which aims to find *some* minimum cut in the graph. The classical algorithm of Gomory and Hu [23] solves the minimum cut problem by solving n minimum-s-t cut problems. Using the push-relabel algorithm [22] this results in a total running time of $\mathcal{O}\left(n^2 m \log \frac{n^2}{m}\right)$. Nagamochi et al. [43, 46] give an algorithm for the minimum cut problem, which is based on edge contractions instead of maximum flows. Their algorithm has a worst case running time of $\mathcal{O}\big(nm + n^2 \log n\big)$ but performs far better in practice on many graph classes [12, 31, 28]. Henzinger et al. [26] give a fast shared-memory parallel algorithm for the minimum cut problem based on their algorithm which finds a minimum cut very fast in practice.

Even though a graph can have up to $\binom{n}{2}$ minimum cuts [33], there is a compact representation of all minimum cuts of a graph called *cactus graph* with $\mathcal{O}(n)$ vertices and edges. A cactus graph is a graph in which each edge belongs to at most one simple cycle. Karzanov and Timofeev [36] give the first polynomial time algorithm to construct the cactus representation for all minimum cuts. Picard and Queyranne [50] show that all minimum cuts separating two specified vertices can be found from a maximum flow between them. Thus, similar to the classical algorithm of Gomory and Hu [23] for the minimum cut problem, we can find all minimum cuts in $n-1$ maximum flow computations. The algorithm of Karzanov and Timofeev [36] combines all those minimum cuts into a cactus graph representing all minimum cuts. Nagamochi and Kameda [44] give a representation of all minimum cuts separating two vertices s and t in a so-called (s,t)-cactus representation. Based on this (s,t)-cactus representation, Nagamochi et al. [45] give an algorithm that finds all minimum cuts and gives the minimum cut cactus in $\mathcal{O}\big(nm + n^2 \log n + n^* m \log n\big)$, where n^* is the number of vertices in the cactus.

Karger and Stein [35] give a randomized algorithm to find all minimum cuts in $\mathcal{O}\big(n^2 \log^3 n\big)$ time by contracting random edges. Based on the algorithm of Karzanov and Timofeev [36] and its parallel variant given by Naor and Vazirani [48] they show how to give the cactus representation of the graph in the same asymptotic time. Ghaffari et al. [20] recently gave an algorithm that finds all *non-trivial minimum cuts* of a simple unweighted graph in $\mathcal{O}\big(m \log^2 n\big)$ time. Using the techniques of Karger and Stein the algorithm can trivially give the cactus representation of all minimum cuts in $\mathcal{O}\big(n^2 \log n\big)$. While there are multiple implementations of the algorithm of Karger and Stein [12, 21, 28] for the minimum cut problem, to the best of our knowledge there are no published implementations of either of the algorithms to find the cactus graph representing all minimum cuts (with or without data reduction techniques).

In the last two decades significant advances in FPT algorithms have been made: an NP-hard graph problem is fixed-parameter tractable (FPT) if large inputs can be solved efficiently and provably optimally, as long as some problem parameter is small. This has resulted in an algorithmic toolbox that are by now well-established. Few of the new techniques are implemented and tested on real datasets, and their practical potential is far from understood. However, recently the engineering part in area has gained some momentum. There are several experimental studies in the area that take up ideas from FPT or kernelization theory, e.g. for independent sets (or equivalently vertex cover) [2, 11, 14, 41, 29, 30], for cut tree construction[3], for treewidth computations [7, 54, 39], for the feedback vertex set problem [37, 18], for the dominating set problem [1], for the minimum cut [26, 28], for the multiterminal cut problem [27], for the maximum cut problem [17] and for the cluster editing problem [8]. Recently, this type of data reduction techniques is also applied for problem in P such as matching [38].

Our Results

We give an algorithm that finds all minimum cuts on very large graphs. Our algorithm is based on the recursive algorithm of Nagamochi et al. [45]. We combine the algorithm with a multitude of techniques to find edges that can be contracted without affecting any minimum cut in the graph. Some of these techniques are adapted from techniques for the global minimum cut problem [49, 46]. Using these and newly developed reductions we are able to decrease the running time by up to multiple orders of magnitude compared to the algorithm of Nagamochi et al. [45] and are thus able to find all minimum cuts on graphs with up to billions of edges in a few minutes. Based on the cactus representation of all minimum cuts, we are able to find the most balanced minimum cut in time linear to the size of the cactus. As our techniques are able to find the most balanced minimum cut (and all others too) of graphs with billions of edges in mere minutes, this allows the use of minimum cuts as a subroutine in sophisticated data mining and graph analysis tools.

2 Basic Concepts

Let $G = (V, E, c)$ be a weighted undirected simple graph with vertex set V, edge set $E \subset V \times V$ and non-negative edge weights $c : E \to \mathbb{N}$. We extend c to a set of edges $E' \subseteq E$ by summing the weights of the edges; that is, let $c(E') := \sum_{e=(u,v)\in E'} c(u, v)$ and let $c(u)$ denote the sum of weights of all edges incident to vertex v. Let $n = |V|$ be the number of vertices and $m = |E|$ be the number of edges in G. The *neighborhood* $N(v)$ of a vertex v is the set of vertices adjacent to v. The *weighted degree* of a vertex is the sum of the weights of its incident edges. For brevity, we simply call this the *degree* of the vertex. For a set of vertices $A \subseteq V$, we denote by $E[A] := \{(u, v) \in E \mid u \in A, v \in V \setminus A\}$; that is, the set of edges in E that start in A and end in its complement. A cut $(A, V \setminus A)$ is a partitioning of the vertex set V into two non-empty *partitions* A and $V \setminus A$, each being called a *side* of the cut. The *capacity* or *weight* of a cut $(A, V \setminus A)$ is $c(A) = \sum_{(u,v)\in E[A]} c(u, v)$. A *minimum cut* is a cut $(A, V \setminus A)$ that has smallest capacity $c(A)$ among all cuts in G. We use $\lambda(G)$ (or simply λ, when its meaning is clear) to denote the value of the minimum cut over all $A \subset V$. For two vertices s and t, we denote $\lambda(G, s, t)$ as the capacity of the smallest cut of G, where s and t are on different sides of the cut. $\lambda(G, s, t)$ is also known as the *minimum s-t-cut* of the graph. If all edges have weight 1, $\lambda(G, s, t)$ is also called the *connectivity* of vertices s and t. The connectivity $\lambda(G, e)$ of an edge $e = (s, t)$ is defined as $\lambda(G, s, t)$, the connectivity of its incident vertices. At any point in the execution of a minimum cut algorithm, $\hat{\lambda}(G)$ (or simply $\hat{\lambda}$) denotes the smallest upper bound of the minimum cut that the algorithm discovered until that point. For a vertex $u \in V$ with minimum vertex degree, the size of the *trivial cut* $(\{u\}, V \setminus \{u\})$ is equal to the vertex degree of u. Many algorithms tackling the minimum cut problem use *graph contraction*. Given an edge $e = (u, v) \in E$, we define $G/(u, v)$ (or G/e) to be the graph after *contracting edge* (u, v). In the contracted graph, we delete vertex v and all edges incident to this vertex. For each edge $(v, w) \in E$, we add an edge (u, w) with $c(u, w) = c(v, w)$ to G or, if the edge already exists, we give it the edge weight $c(u, w) + c(v, w)$.

A graph with n vertices can have up to $\Omega(n^2)$ minimum cuts [33]. To see that this bound is tight, consider an unweighted cycle with n vertices. Each set of 2 edges in this cycle is a minimum cut of G. This yields a total of $\binom{n}{2}$ minimum cuts. However, all minimum cuts can be represented by a cactus graph C_G with up to $2n$ vertices and $\mathcal{O}(n)$ edges [45]. A cactus graph is a connected graph, in which any two simple cycles have at most one vertex in common. In a cactus graph, each edge belongs to at most one simple cycle.

To represent all minimum cuts of a graph G in an edge-weighted cactus graph $C_G = (V(C_G), E(C_G))$, each vertex of C_G represents a possibly empty set of vertices of G and each vertex in G belongs to the set of one vertex in C_G. Let Π be a function that assigns to each vertex of C_G it set of vertices of G. Then every cut $(S, V(C_G)\backslash S)$ corresponds to a minimum cut $(A, V\backslash A)$ in G where $A = \cup_{x \in S} \Pi(x)$. In C_G, all edges that do not belong to a cycle have weight λ and all cycle edges have weight $\frac{\lambda}{2}$. A minimum cut in C_G consists of either one tree edge or two edges of the same cycle. We denote by n^* the number of vertices in C_G and m^* the number of edges in C_G. The weight $c(v)$ of a vertex $v \in C_G$ is equal to the number of vertices in G that are assigned to v.

3 Algorithm Description

Our algorithm combines a variety of techniques and algorithms in order to find all minimum cuts in a graph. The algorithm is based on the contractions of edges which cannot be part of a minimum cut. Thus, we first show that an edge e that is not part of any minimum cut in graph G can be contracted and all minimum cuts of G remain in the resulting graph G/e.

▶ **Lemma 1** ([35]). *If an edge $e = (u, v)$ is not part of any minimum cut in graph G, all minimum cuts of G remain in the resulting graph G/e.*

Proof. Let (A, B) be an arbitrary minimum cut of G. For an edge $e = (u, v)$, which is not part of any minimum cut, we know that $e \notin E[A]$, so either u and v are both in vertex set A or both in vertex set B. This is still the case in G/e. Thus, the edge e can be contracted even if we aim to find every minimum cut of G. ◀

Lemma 1 is very useful to reduce the size of the graph by a multitude of techniques to identify such edges. We first give a short overview of our algorithm and then explain the techniques in more detail. First, we use the shared-memory parallel heuristic minimum cut algorithm VieCut [28] in order to find an upper bound $\hat{\lambda}$ for the minimum cut which is very likely to be the correct value. VieCut is a multilevel algorithm that uses the label propagation algorithm to contract heavily connected clusters. Having a tight bound for the minimum cut allows the contraction of many edges, as multiple reduction techniques depend on the value of the minimum cut. We adapt contraction techniques originally developed by Nagamochi et al. [43, 46] and Padberg et al. [49] to the problem of finding all minimum cuts. Section 3.1 explains these contraction routines. On the resulting graph we find all minimum cuts using an optimized variant of the algorithm of Nagamochi, Nakao and Ibaraki [45] and return the cactus graph which represents them all. A short description of the algorithm and an explanation of our engineering effort are given in Section 3.2. Afterwards, in Section 3.3 we show how we combine the parts into a fast algorithm to find all minimum cuts of large networks.

3.1 Edge Contraction

As shown in Lemma 1, edges that are not part of any minimum cut can be safely contracted. We build a set of techniques that aim to find contractible edges and run these in alternating order until neither of them finds any more contractible edges. We now give a short introduction to these.

For efficiency, we perform contractions in bulk. If our algorithm finds an edge that can be contracted, we merge the incident vertices in a thread-safe union-find data structure [5]. After each run of a contraction technique that finds contractible edges, we create the contracted

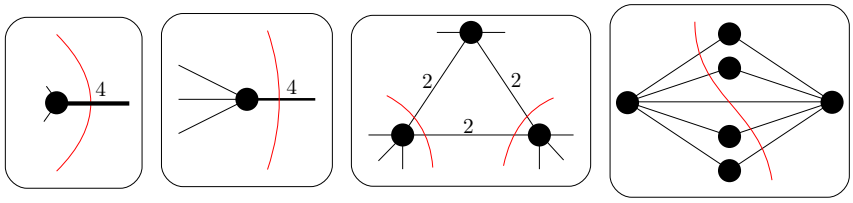

Figure 1 Contraction: (1) `HeavyEdge`, (2) `ImbalancedVertex`, (3) `ImbalancedTriangle`, (4) `HeavyNeighborhood`.

graph using a shared-memory parallel hash table [42]. In this contracted graph, each set of vertices of the original graph is merged into a single node. The contraction of this vertex set is equivalent to contracting a spanning tree of the set. After contraction we check whether a vertex in the contracted graph has degree $< \hat{\lambda}$. If it does, we found a cut of smaller value and update $\hat{\lambda}$ to this value.

3.1.1 Connectivity-based Contraction

The connectivity of an edge $e = (s, t)$ is the weight of the minimum cut that separates s and t, i.e. the *minimum s-t-cut*. For an edge that has connectivity $> \hat{\lambda}$, we thus know that there is no cut separating s and t (i.e. no cut that contains e) that has value $\leq \hat{\lambda}$. Thus, we know that there cannot be a minimum cut that contains e, as $\hat{\lambda}$ is by definition at least as large as λ. However, solving the minimum s-t-cut problem takes significant time, so computing the connectivity of each edge does not scale to large networks. Hence, as part of their algorithm for the global minimum cut problem, Nagamochi et al. [43, 46] give an algorithm that computes a lower bound $q(e)$ for the connectivity of every edge e of G in a total running time of $\mathcal{O}(m + n \log n)$. Each of the edges whose connectivity lower bound is already larger than $\hat{\lambda}$ can be contracted as it cannot be part of any minimum cut. Their algorithm builds *edge-disjoint maximum spanning forests* and contracts all edges that are not in the first $\lambda - 1$ spanning forests, as those connect vertices that have connectivity at least λ [26]. This is possible as the incident vertices of any such edge e are connected in each of the first $\lambda - 1$ spanning forests and by e and thus have a connectivity of at least λ. In other words, there can not be any cut smaller than λ which contains e.

Henzinger et al. [26] give a fast shared-memory parallel variant of their algorithm. As both of these algorithms only aim to find a single minimum cut, they also contract edges that have connectivity equal to $\hat{\lambda}$, as they only want to see whether there is a cut better than the best cut known previously. As we want to find all minimum cuts, we can only contract edges whose connectivity is strictly larger than $\hat{\lambda}$. Nagamochi et al. could prove that at least one edge has value $\hat{\lambda}$ in their routine and can thus be contracted. We do not have such a guarantee when trying to find edges that have connectivity $> \hat{\lambda}$. Consider for example an unweighted tree, whose minimum cut has a value of 1 and each edge has connectivity 1 as well.

3.1.2 Local Contraction Criteria

Padberg and Rinaldi [49] give a set of *local reduction* routines which determine whether an edge can be contracted without affecting the minimum cut. Their reductions routines were shown to be very useful in order to find a minimum cut fast in practice [12, 31, 28]. We adapt the routines originally developed for the minimum cut problem so that they hold for

the problem of for finding all minimum cuts. Thus, we have to make sure that we do not contract cuts of value $\hat{\lambda}$, as they might be minimal and additionally make sure that we do not contract edges incident to vertices that could have a *trivial minimum cut*, i.e. a minimum cut, where one side contains only a single vertex. Figure 1 depicts the contraction routines and Lemma 2 gives a more formal definition of them.

▶ **Lemma 2.** *For an edge $e = (u, v) \in E$, e is not part of any minimum cut, if e fulfills at least one of the following criteria. Thus, all minimum cuts of G are still present in G/e and e can be contracted.*

1. *`HeavyEdge`:* $c(e) > \hat{\lambda}$
2. *`ImbalancedVertex`:*
   - $c(v) < 2c(e)$ *and* $c(v) > \hat{\lambda}$, *or*
   - $c(u) < 2c(e)$ *and* $c(u) > \hat{\lambda}$
3. *`ImbalancedTriangle`:*
   $\exists w \in V$ *with*
   - $c(v) < 2\{c(v, w) + c(e)\}$ *and* $c(v) > \hat{\lambda}$, *and*
   - $c(u) < 2\{c(u, w) + c(e)\}$ *and* $c(u) > \hat{\lambda}$
4. *`HeavyNeighborhood`:*
   $c(e) + \sum_{w \in V} min\{c(v, w), c(u, w)\} > \hat{\lambda}$

Proof.

1. If $c(e) > \hat{\lambda}$, every cut that contains e has capacity $> \hat{\lambda}$. Thus it can not be a minimal cut.
2. Without loss of generality let v be the vertex in question. The condition $c(v) < 2c(e)$ means that e is heavier than all other edges incident to v combined. Thus, for any non-trivial cut that contains e, we can find a lighter cut by replacing e with all other incident edges to v, i.e. moving v to the other side of the cut. As this is not true for the trivial minimum cut $(v, V \setminus v)$, we cannot contract an edge incident to a vertex that has weight $\leq \hat{\lambda}$.
3. This condition is similar to (2). Let there be a triangle u, v, w in the graph in which it holds for both u and v that the two incident triangle edges are heavier than the sum of all other incident edges. Then, every cut that separates u and v can be improved by moving u and v into the same side. As the cut could have vertex w on either side, both vertices need to fulfill this condition. To make sure that we do not contract any trivial minimum cut, we check that both v and u have weight $> \hat{\lambda}$ and thus can not represent a trivial minimum cut.
4. In this condition we check the whole shared neighborhood of vertices u and v. Every cut that separates u and v must contain e and for each shared neighbor w at least one of the edges connecting them to w. Thus, we sum over the lighter edge connecting them to the shared neighbors and have a lower bound of the minimum cut that separates u and v. If this is heavier than $\hat{\lambda}$, we know that no minimum cut separates u and v. ◀

The conditions `HeavyEdge` and `ImbalancedVertex` can both be checked for the whole graph in a single run in linear time. While we can check condition `ImbalancedTriangle` when summing up the lighter incident edges for condition `HeavyNeighborhood`, exhaustively checking all triangles incurs a strictly worse than linear runtime, as a graph can have up to $\Theta(m^{3/2})$ triangles [52]. Thus, we only perform linear-time runs as developed by Chekuri et al. [12] by marking the neighborhood of u and v while we check the conditions and do not perform the test on marked vertices.

3.1.3 Vertices with one Neighbor

Over the run of the algorithm, we occasionally encounter vertices that have only a single neighbor. Let v be this vertex with one neighbor and $e = (v, w)$ be the only incident edge. As we update $\hat{\lambda}$ to the minimum degree whenever we perform a bulk edge contraction, $c(e) \geq \hat{\lambda}$: for an edge whose weight is $> \hat{\lambda}$, condition `HeavyEdge` will contract it. For an edge whose weight is $\hat{\lambda}$, the edge represents a trivial minimum cut iff $\hat{\lambda} = \lambda$. This is the only minimum cut that contains e, as every non-trivial cut containing e has higher weight. Thus, we can contract e for now and remember that it was contracted. If $\hat{\lambda}$ is decreased, we can forget about these vertices as the cuts are not minimal. When we are finished, we can re-insert all contracted vertices that have a trivial minimum cut. We perform this reinsertion in a bottom-up fashion (i.e. in reverse order to how they were contracted), as the neighbor w could be contracted in a later contraction.

3.2 Finding all Minimum Cuts

We apply the reductions in the previous section exhaustively until they are not able to find a significant number of edges to contract. On the remaining graph we aim to find the cactus representation of all minimum cuts. Our algorithm for this purpose is based on the algorithm of Nagamochi, Nakao and Ibaraki [45]. While there is a multitude of algorithms for the problem of finding all minimum cuts, to the best of our knowledge there are no implementations accessible to the public and there is no practical experimentation on finding all minimum cuts. We base our algorithm on the algorithm of Nagamochi, Nakao and Ibaraki [45], as their algorithm allows us to run the reduction routines previously detailed in between recursion steps.

We give a quick sketch of their algorithm, for details we refer the reader to [45]. To find all minimum cuts in graph G, the algorithm chooses an edge $e = (s, t)$ in G and uses a maximum flow f to find the minimum s-t-cut $\lambda(s, t)$. If $\lambda(s, t) > \lambda$ there is no minimum cut that separates s and t and thus e can be contracted. If $\lambda(s, t) = \lambda$, the edge is part of at least one minimum cut. They show that the strongly connected components $(V_1, \ldots, V_k)$ of the residual graph G_f represent all minimum cuts that contain e (and potentially some more). For each connected component V_i, they build a graph C_i, in which all other connected components are contracted into a single vertex. We recurse on these component subgraphs and afterwards combine the minimum cut cactus graphs of the recursive calls to a cactus representation for G.

The combination of the cactus graphs begins by building a cactus graph C representing the set of strongly connected components, in which each V_i is represented by a single vertex v_i. Each cactus C_i is then merged with C by replacing v_i with C_i. For details we refer the reader to [45].

As the contraction routines in Section 3.1 usually mark a large amount of edges that can be contracted in bulk, we represent the graph in the compressed sparse row format [56]. This allows for fast and memory-efficient accesses to vertices and edges, however, we need to completely rebuild the graph in each bulk contraction and also keep vertex information about the whole graph hierarchy to be able to see which vertices in the original graph are encompassed in a vertex in a coarser vertex and to be able to re-introduce the cactus edges that were removed. While this is efficient for the bulk contractions performed in the previous section, in this section we often perform single-edge contractions or contract a small block of vertices. For fast running times these operations should not incur a complete rebuild of the graph data structure. We therefore use a mutable adjacency list data structure where

each vertex is represented by a dynamic array of edges to neighboring vertices. Each edge stores its weight, target and the ID of its reverse edge (as we look at undirected graphs). This allows us to contract edges and small blocks in time corresponding to the sum of vertex degrees. For each vertex in the original graph, we store information which vertex currently encompasses it and every vertex keeps a list of currently encompassed vertices of the original graph. This information is updated during each edge contraction. Inside this algorithm we re-run the contraction routines of Section 3.1. As they incur some computational cost and the graph does not change too much over different recursion steps, we only run the contraction routines every 10 recursion steps.

3.2.1 Edge Selection

The recursive algorithm of Nagamochi, Nakao and Ibaraki [45] selects an arbitrary edge for the maximum flow problem in each recursion step. If this edge has connectivity equal to the minimum cut, we create a recursive subproblem for each connected component of the residual graph. In order to reduce the graph size - and thus the amount of work necessary - quickly, we aim to select edges in which the largest connected component of the residual graph is as small as possible. The edge selection strategy `Heavy` searches for the highest degree vertex v and chooses the edge from v to its highest degree neighbor. The strategy `WeightedHeavy` does the same, but uses the vertices whose weighted degree is highest. The idea is that an edge between high-degree vertices is most likely 'central' to the graph and thus manages to separate sizable chunks from the graph. The edge selection strategy `Central` aims to find a central edge more directly: we aim to find two vertices u and v with a high distance and take the central edge in their shortest paths. We find those vertices by performing a breadth-first search from a random vertex w, afterwards performing a breadth-first search from the vertex encountered last. We then take the central edge in the shortest path (as defined from the second breadth-first search) from the two vertices encountered last in the two breadth-first searches. The edge selection strategy `Random` picks a random edge.

3.2.2 Degree-two Reductions

Over the course of this recursive contraction-based algorithm, we routinely encounter vertices with just two neighbors. Let v be the vertex in question, which is connected to u_0 by edge e_0 and to u_1 by edge e_1. We look at four cases, each looking at whether the weight of e_0 being equal to the weight of e_1 and $c(v)$ being equal to λ, both conditions that can be checked in constant time. In three out of four cases, we are able to contract an incident edge.

$c(e_0) \neq c(e_1)$ and $c(v) > \lambda$: Without loss of generality let e_0 be the heavier edge. As $c(v) > \lambda$, the trivial cut $(\{v\}, V \setminus \{v\})$ is not a minimum cut. As by definition no cut in G is smaller than λ, $\lambda(u_0, u_1) \geq \lambda$. Thus, excluding the path through v, they have a connectivity of $\geq \lambda - c(e_1)$ and any cut containing e_0 has weight $\geq \lambda - c(e_1) + c(e_0) > \lambda$ and can thus not be minimal. We therefore know that e_0 is not part of any minimum cuts and can be contracted according to Lemma 1.

$c(e_0) \neq c(e_1)$ and $c(v) = \lambda$: Without loss of generality let e_0 be the heavier edge. Analogously to the previous case we can show that no nontrivial cut contains e_0. In this case, where $c(v) = \lambda$, the trivial cut $(\{v\}, V \setminus \{v\})$ is minimal and therefore should be represented in the cactus graph. For all other minimum cuts that contain e_1, we know that v and u_0 will be in the same block (as $c(e_0) > c(e_1)$). Thus, v will be represented in the cactus as a leaf incident to u_0. We contract e_0 calling the resulting vertex u^* and store which vertices of the original graph are represented by v. Then we recurse. On return from the recursion we check which cactus vertex now encompasses u^* and add an edge from this vertex to a newly added vertex representing all vertices encompassed by v.

Algorithm 1 Algorithm to find all minimum cuts.

```
1: procedure FindAllMincuts(G = (V, E))
2:     λ̂ ← VieCut(G) [28]
3:     while not converged do
4:         (G, D_1, λ̂) ← contract degree-one vertices(G, λ̂)
5:         (G, λ̂) ← connectivity-based contraction(G, λ̂)
6:         (G, λ̂) ← local contraction(G, λ̂)
7:     λ ← FindMinimumCutValue(G)
8:     C ← RecursiveAllMincuts(G, λ) ([45])
9:     C ← reinsert vertices(C, D_1)
10:    return (C, λ)
```

$c(e_0) = c(e_1)$ and $c(v) > \lambda$: in this case we are not able to contract any edges without further connectivity information.

$c(e_0) = c(e_1)$ and $c(v) = \lambda$: as $c(v) = \lambda$, the trivial cut $(\{v\}, V \setminus \{v\})$ is minimal. If there are other minimum cuts that contain either e_0 or e_1 (e.g. that separate u_0 and u_1), we know that by replacing e_0 with e_1 (or vice-versa) the cut remains minimal. Such a minimum cut exists iff $\lambda(u_0, u_1) = \lambda$. We contract e_0 and remember this decision. As e_1 is still in the graph (merged with (u_0, u_1)), we are able to find each cut that separates u_0 and u_1. If none exists, $\lambda(u_0, u_1) > \lambda$ and u_0 and u_1 will be contracted into a single vertex later in the algorithm. When leaving the recursion, we can thus re-introduce vertex v as a leaf connected to the vertex encompassing u_0 and u_1. If u_0 and u_1 are in different vertices after leaving the recursion, there is at least one nontrivial cut that contains e_1. We thus re-introduce v as a cycle vertex connected to u_0 and u_1, each with weight $\frac{\lambda}{2}$, and subtract $\frac{\lambda}{2}$ from $c(u_0, u_1)$.

In three out of the four cases presented here, we are able to contract an edge incident to a degree-two vertex. We can check these conditions in total time $\mathcal{O}(n)$ for the whole graph. Over the course of the algorithm, we perform edge contractions and thus routinely encounter vertices whose neighborhood has been contracted and thus have a degree of two. Thus, these reductions are able to reduce the size of the graph significantly even if the initial graph is rather dense and does not have a lot of low degree vertices.

3.3 Putting it all together

Algorithm 1 gives an overview over our algorithm to find all minimum cuts. Over the course of the algorithm we keep an upper bound $\hat{\lambda}$ for the minimum cut, initially set to the result of the inexact variant of the `VieCut` minimum cut algorithm [28]. While the `VieCut` algorithm also offers an exact version [26], we use the inexact version, as it is considerably faster and gives a low upper bound for the minimum cut, usually equal to the minimum cut. As described in Section 3.1, we use this bound to contract degree-one vertices, high-connectivity edges and edges whose local neighborhood guarantees that they are not part of any minimum cut. We repeat this process until it is converged, as an edge contraction can cause other edges in the neighborhood to also become safely contractible. As this process often incurs a long tail of single edge contractions, we stop if the number of vertices was decreased by less than 1% over a run of all contraction routines.

We then use the minimum cut algorithm of Nagamochi, Ono and Ibaraki [43, 46] on the remaining graph, as the following steps need the correct minimum cut. To find all minimum cuts in the contracted graph, we call our optimized version of the algorithm of Nagamochi et al. [45], as sketched in Section 3.2, and afterwards re-insert all minimum cut edges that were

previously deleted. Before each recursive call of the algorithm of Nagamochi et al. [45], we contract edges incident to degree-one and eligible degree-two vertices. Every 10 recursion levels we additionally check for connectivity-based edge contractions and local contractions.

3.4 Shared-Memory Parallelism

Algorithm 1 employs shared-memory parallelism in every step. When we run the algorithm in parallel, we use the parallel variant of VieCut [28]. Local contraction and marking of degree one vertices are parallelized using OpenMP [13]. For the first round of connectivity-based contraction, we use the parallel connectivity certificate used in the shared-memory parallel minimum cut algorithm by Henzinger et al. [26]. This connectivity certificate is essentially a parallel version of the connectivity certificate of Nagamochi et al. [43, 46], in which the processors divide the work of computing the connectivity bounds for all edges of the graph. In subsequent iterations every processor runs an independent run of the connectivity certificate of Nagamochi et al. on the whole graph starting from different random vertices in the graph. As the connectivity bounds given by the algorithm heavily depend on the starting vertex, this allows us to find significantly more contractible edges per round than running the connectivity certificate only once.

We use the shared-memory parallel minimum cut algorithm of Henzinger et al. [26] to find the exact minimum cut of the graph. The algorithm of Nagamochi et al. [45] is not shared-memory parallel, however we usually manage to contract the graph to a size proportional to the minimum cut cactus before calling them. Unfortunately it is not beneficial to perform the recursive calls embarrassingly parallel, as in almost all cases one of the connected components of the residual graph contains the vast majority of vertices and thus also has the overwhelming majority of work.

4 Applications

We can use the minimum cut cactus C_G to find a minimum cut fulfilling certain balance criteria, such as a most balanced minimum cut, e.g. a minimum cut $(A, V \setminus A)$ that maximizes $\min(|A|, |V \setminus A|)$. Note that this is not equal to the most balanced s-t-cut problem, which is NP hard [9]. Following that we show how to modify the algorithm to find the optimal minimum cut for other optimization functions.

One can find a most balanced minimum cut trivially in time $\mathcal{O}\big((n^*)^3\big)$, as one can enumerate all $\mathcal{O}\big((n^*)^2\big)$ minimum cuts [33] and add up the number of vertices of the original graph G on either side. We now show how to find a most balanced minimum cut of a graph G in $\mathcal{O}(n^* + m^*)$ time, given the minimum cut cactus graph C_G.

For every cut $(A, V\setminus A)$, we define the balance $b(A)$ (or $b(V\setminus A)$) of the cut as the number of vertices of the original graph encompassed in the lighter side of the cut. Recall that for any node $v \in V_G$, $c(v)$ is the number of vertices of G represented by v. For a leaf $v \in V_G$, we set its weight $w(v) = c(v)$ and set the balance $b(v)$ to be the minimum of $w(v)$ and $n - w(v)$. We root C_G in an arbitrary vertex and depending on that root define $w(v)$ as the sum of vertex weights in the subcactus rooted in v; and $b(v)$ accordingly. For a cycle $C = \{c_1, \dots, c_i\}$, we define $b(c_j, \dots, c_{k \mod i})$ with $0 \geq j \geq k$ analogously as the balance of the minimum cut splitting the cycle so that the sub-cacti rooted in $c_j, \dots, c_{k \mod i}$ are on one side of the cut and the rest are on the other side (see blue line in Figure 2 for an example).

Let T_G be the tree representation of C_G where each cycle in C_G is contracted into a single vertex. We perform a depth-first search on T_G rooted on an arbitrary vertex and check the balance of every cut in T_G when backtracking.

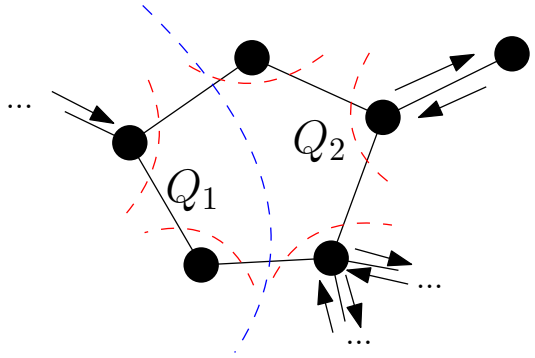

Figure 2 Cycle check in balanced cut algorithm.

As C_G is not necessarily a tree, we might encounter cycles and we explain next how to extend the depth first search to handle such cycles. Let $\mathcal{C} = \{c_0, \ldots, c_{i-1}\}$ be a cycle and c_0 be the vertex encountered first by the DFS. Due to the cactus graph structure of C_G, the depth-first search backtracks from a vertex v_{cy} in T_G that represents $\mathcal{C}$ only after all subtrees rooted in $\mathcal{C}$ are explored. Thus, we know the weight of all subtrees rooted in vertices $c_1, \ldots, c_{i-1}$ when backtracking. The weight of c_0 is equal to n minus the sum of these sub-cactus weights.

Examining all cuts in the cycle would take i^3 time, but as we only want to find the most balanced cut, we can check only a subset of them, as shown in Algorithm 2. Q_1 and Q_2 are *queues*, thus elements are ordered and the following operations are supported: *queue* adds an element to the back of the queue, called the *tail* of the queue, *dequeue* removes the element at the front of the queue, called the *head* of the queue. We implicitly use the fact that queues can only be appended to, thus an element q was added to the queue after all elements that are closer to the head of the queue and before all elements that are closer to its tail.

Algorithm 2 Algorithm to find most balanced cut in cycle $\{c_0, \ldots, c_{i-1}\}$.

```
1:  procedure BalanceInCycle(G = (V, E), C = {c_1, ..., c_i})
2:      b_OPT ← 0
3:      Q_1 = Queue({})
4:      Q_2 = Queue({c_0, c_1, ..., c_{i-1}})
5:      while c_0 not Q_1.head() for second time do
6:          b_OPT ← checkBalance(Q_1, Q_2)
7:          if w(Q_1) > w(Q_2) then
8:              Q_2.queue(Q_1.dequeue())
9:          else
10:             Q_1.queue(Q_2.dequeue())
11:     return b_OPT
```

The weight of a queue $w(Q)$ is denoted as the weight of its contents. For queue $Q = \{c_{j \bmod i}, \ldots, c_{k \bmod i}\}$ with $0 \leq j \leq k$, we use the notation $w_{j \bmod i, k \bmod i}$ to denote the weight of Q and $\overline{w_{j \bmod i, k \bmod i}}$ as the weight of the queue that contains all cycle vertices not in Q.

In every step of the algorithm, the cut represented by the current state of the queues consists of the two edges connecting the queue heads to the tails of the respective other queue. Initially Q_1 is empty and Q_2 contains all elements, in order from c_0 to c_{i-1}. In every

step of the algorithm, we dequeue one element and queue it in the other queue. Thus, at every step each cycle vertex is in exactly one queue. When we check the balance of a cut, we compute the weight of each queue at the current point in time; and update b_{OPT}, the best balance found so far, if (Q_1, Q_2) is more balanced. As we only move one cycle vertex in each step, we can check the balance of an adjacent cut in constant time by adding and subtracting the weight of the moved vertex to the weights of each set.

▶ **Lemma 3.** *Algorithm 2 terminates after $O(i)$ steps.*

Proof. In each step of Algorithm 2, one queue head is moved to the other queue. The algorithm terminates when c_0 is the head of Q_1 for the second time. In the first step, c_0 is moved to Q_1, as the empty queue Q_1 is the lighter one. The algorithm terminates after c_0 then performs a full round through both queues and is the head of Q_1 again. At termination, c_0 was thus moved a total of three times, twice from Q_2 to Q_1 and once the other way. As no element can 'overtake' c_0 in the queues, every vertex will be moved at most three times. Thus, we enter the loop at most $3i$ times, each time only using a constant amount of time. ◀

In Algorithm 2, we only check the balance of a subset of cuts represented by edges in the cycle C. Lemma 5 shows that none of the disregarded cuts can have balance better than b_{OPT} and we thus find the most balanced minimum cut. We call a cut disregarded if its balance was never checked (Line 6), and considered otherwise. In order to prove correctness of Algorithm 2, we first show the following Lemma:

▶ **Lemma 4.** *Each vertex in the cycle is dequeued from Q_1 at least once in the algorithm.*

Proof. The algorithm terminates when c_0 is the head of Q_1 for the second time. For this, it needs to be moved from Q_2 to Q_1 twice. As we queue elements to the back of a queue, all vertices are dequeued from Q_2 before c_0 is dequeued from it for the second time. In order for c_0 to become the head of Q_1 again, all elements that were added beforehand need to be dequeued from Q_1. ◀

▶ **Lemma 5.** *Algorithm 2 finds the most balanced minimum cut represented by cycle C.*

Proof. We now prove for each $c_l \in \mathcal{C}$ that all disregarded cuts containing the cycle edge separating c_l from $c_{(l-1) \bmod i}$ are not more balanced than the most balanced cut found so far. As no disregarded cut can be more balanced than the most balanced cut considered in the algorithm, the output of the algorithm is the most balanced minimum cut; or one of them if multiple cuts of equal balance exist.

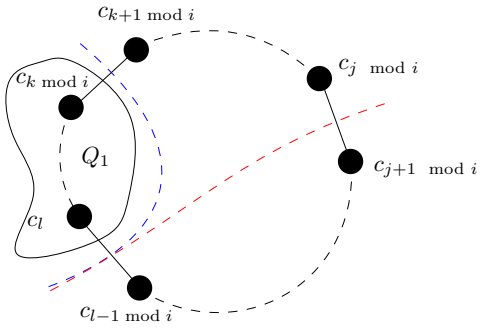

Figure 3 State of Q_1 at time t_l (cut in blue). Cut in red denotes cut considered at time t^*.

Let t_l be the time that c_l becomes the head of Q_1 for the first time. Figure 3 shows the state of Q_1 at that point in time. Let $c_{k \bmod i}$ be the tail of Q_1 at time t_l for some integer k. Right before t_l, $c_{l-1 \bmod i}$ was head of the heavier queue Q_1 and thus dequeued, i.e. $Q_1 = \{c_{l-1 \bmod i}, \ldots, c_{k \bmod i}\}$ has weight $w_{l-1 \bmod i, k \bmod i} \geq \overline{w_{l-1 \bmod i, k \bmod i}}$ and c_l is now head of Q_1.

From this point t_l the algorithm considers cuts that separate c_l from $c_{l-1 \bmod i}$. While Q_1 is not heavier than Q_2, we add more elements to the tail of Q_1 (and check the respective cuts) until Q_1 is the heavier queue. Let t^* be the time when this happens and $c_{j \bmod i}$ with $j \geq k$ be the tail of Q_1 at this point. Note that at time t^*, c_l is about to be dequeued from Q_1. The red cut in Figure 3 shows the cut at time t^*, where $w_{c_l, c_{j \bmod i}} > \overline{w_{c_l, c_{j \bmod i}}}$.

We now prove that all cuts in which c_l is the head of Q_1 and its tail is not between $c_{k \bmod i}$ and $c_{j \bmod i}$ cannot be more balanced than the most balanced cut considered so far.

For all cuts where c_l is head of Q_1 and Q_1 also contains $c_{j+1 \bmod i}$, Q_1 is heavier than $w_{l,j \bmod i}$, as it contains all elements in $c_l, \ldots, c_{j \bmod i}$ plus at least one more. As $w_{l,j \bmod i} > \overline{w_{l,j \bmod i}}$, i.e. Q_1 is already heavier when $c_{j \bmod i}$ is its tail, all of these cuts are less balanced than $(\{c_l, \ldots, c_{j \bmod i}\}, \mathcal{C} \backslash \{c_l, \ldots, c_{j \bmod i}\})$.

For the cuts in which $c_{k \bmod i}$ is in Q_2, i.e. Q_1 is lighter than at time t_l, we need to distinguish two cases, depending on whether $w_{l,k \bmod i}$ is larger than $\overline{w_{l,k \bmod i}}$ or not.

If $w_{l,k \bmod i} \leq \overline{w_{l,k \bmod i}}$, all cuts in which c_l is the head of Q_1 and $c_{k \bmod i}$ is in Q_2 are less balanced than $(\{c_l, \ldots, c_{k \bmod i}\}, \mathcal{C} \backslash \{c_l, \ldots, c_{k \bmod i}\})$, as Q_1 is lighter than it is at t_l, where it was already not the heavier queue.

If $w_{l,k \bmod i} > \overline{w_{l,k \bmod i}}$, there might be cuts in which c_l is the head of Q_1 that are more balanced than $(\{c_l, \ldots, c_{k \bmod i}\}, \mathcal{C} \backslash \{c_l, \ldots, c_{k \bmod i}\})$ in which Q_1 is lighter than at time t_l. Thus, consider time t' when $c_{k \bmod i}$ was added to Q_1. Such a time must exist, since Q_1 is initially empty. As $c_{k \bmod i}$ is already the tail of Q_1 at time t_l, $t' < t_l$. At that time Q_1 contained $c_{l-1 \bmod i}, \ldots, c_{k-1 \bmod i}$ and potentially more vertices.

Still, $w_{l-1 \bmod i, k-1 \bmod i} \leq \overline{w_{l-1 \bmod i, k-1 \bmod i}}$, as otherwise $c_{k \bmod i}$ would not have been added to Q_1. Obviously $w_{l-1 \bmod i, k-1 \bmod i} > w_{l, k-1 \bmod i}$, as Q_1 is even lighter when $c_{l-1 \bmod i}$ is dequeued. As $w_{l-1 \bmod i, k-1 \bmod i}$ is already not heavier than its complement, $(\{c_l, \ldots, c_{k-1 \bmod i}\}, \mathcal{C} \backslash \{c_l, \ldots, c_{k-1 \bmod i}\})$ is more imbalanced than the cut examined just before time t'. Thus, all cuts where c_l is the head of Q_1 and $c_{k-1 \bmod i}$ is in Q_2 are even more imbalanced, as Q_1 is even lighter.

Coming back to the outline shown in Figure 3, we showed that for all cuts in which c_l is head of Q_1 and Q_1 is lighter than at time t_l (left of blue cut) and all cuts where Q_1 is heavier than at time t^* (below red cut) can be safely disregarded, as a more balanced cut than any of them was considered at some point between t' and t^*. The algorithm considers next all cuts with c_l as head of Q_1 and the tail of Q_1 between $c_{k \bmod i}$ and $c_{j \bmod i}$. Thus, the algorithm will return a cut that is at least as balanced as the most balanced cut that separates c_l and $c_{l-1 \bmod i}$. This is true for every cycle vertex $v_l \in \mathcal{C}$, which concludes the proof. ◀

This allows us to perform the depth-first search and find the most balanced minimum cut in C_G in time $\mathcal{O}(n^* + m^*)$. This algorithm can be adapted to find the minimum cut of any other optimization function of a cut that only depends on the (weight of the) edges on the cut and the (weight of the) vertices on either side of the cut. In order to retain the linear running time of the algorithm, the function needs to be evaluable in constant time on a neighboring cut. For example, we can find the minimum cut of lowest conductance. The conductance of a cut $(S, V \setminus S)$ is defined as $\frac{\lambda(S,(V \setminus S))}{min(a(S),a(V \setminus S))}$, where $a(S)$ is the sum of degrees for all vertices in set S. Note that this is not the minimum conductance cut problem,

which is NP-hard [4], as we only look at the minimum cuts. To find the minimum cut of lowest conductance, we set the weight of a vertex $v_{C_G} \in C_G$ to the sum of vertex degrees encompassed in v_{C_G}. Otherwise the algorithm remains the same.

5 Experiments and Results

We now perform an experimental evaluation of the proposed algorithms. This is done in the following order: first analyze the impact of algorithmic components on our minimum cut algorithm in a non-parallel setting, i.e. we compare different variants for edge selection and see the impact of the various optimizations detailed in this work. Afterwards, we report parallel speedup on a variety of large graphs.

Experimental Setup and Methodology

We implemented the algorithms using C++-17 and compiled all code using g++ version 8.3.0 with full optimization (`-O3`). Our experiments are conducted on a machine with two Intel Xeon Gold 6130 processors with 2.1GHz with 16 CPU cores each and 256 GB RAM in total. We perform five repetitions per instance and report average running time. In this section we first describe our experimental methodology. Afterwards, we evaluate different algorithmic choices in our algorithm and then we compare our algorithm to the state of the art. When we report a mean result we give the geometric mean as problems differ significantly in cut size and time. Our code is freely available under the permissive MIT license [1].

Instances

We use a variety of graphs from the 10th DIMACS Implementation challenge [6] and the SuiteSparse Matrix Collection [15]. These are social graphs, web graphs, co-purchase matrices, cooperation networks and some generated instances. Table 2 shows a set of smaller instances and Table 3 shows a set of larger and harder to solve instances. All instances are undirected. If the original graph is directed, we generate an undirected graph by removing edge directions and then removing duplicate edges. If a network has multiple connected components, we run on the largest.

As most large real-world networks have cuts of size 1, finding all minimum cuts becomes essentially the same as finding all bridges, which can be solved in linear time using depth-first search [55]. However, usually there is usually one huge block that is connected by minimum cuts to a set of small and medium size blocks. Thus, we use our algorithm to generate a more balanced set of instances. We find all minimum cuts and contract each edge that does not connect two vertices of the largest block. Thus, the remaining graph only contains the huge block and is guaranteed to have a minimum cut value $> \lambda$. We use this method to generate multiple graphs with different minimum cuts for each instance.

5.1 Edge Selection

Figure 4 shows the results for the graphs in Table 2. We compute the cactus graph representing all minimum cuts using the edge selection variants `Random`, `Central`, `Heavy` and `HeavyWeighted`, as detailed in Section 3.2. As we want a majority of the running time in the recursive algorithm of Nagamochi et al. [45], where we actually select edges, we run a variant of our algorithm that only contracts edges using connectivity-based contraction and then runs the algorithm of Nagamochi et al. [45].

[1] `https://github.com/VieCut/VieCut`

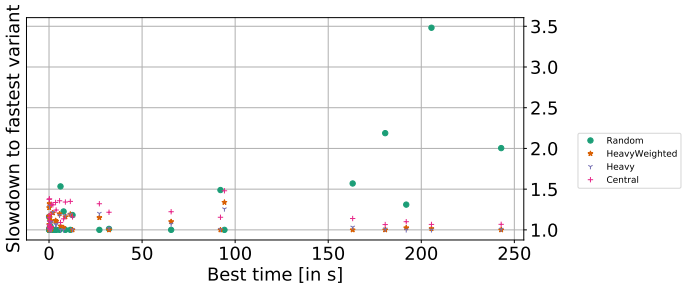

Figure 4 Effect of edge selection strategies.

We can see that in the graphs which cannot be contracted quickly, `Random` is significantly slower than all other variants. On `cnr-2000`, `Random` takes over 700 seconds in average, whereas all other variants finish in approximately 200 seconds. This happens independently of the random seed used, there is no large deviation in the running time on any of the graphs. On almost all graphs, the variants `Heavy` and `HeavyWeighted` are within 3% of each other, which is not surprising, as the variants are almost identical. While it optimizes for 'edge centrality' very directly, `Central` has two iterations of breadth-first search in each edge selection and thus a sizable overhead. For this reason it is usually $5-15\%$ slower than `Heavy` and is not the fastest algorithm on any graph. On graphs with large n^*, all three variants manage to shrink the graph significantly faster than `Random`.

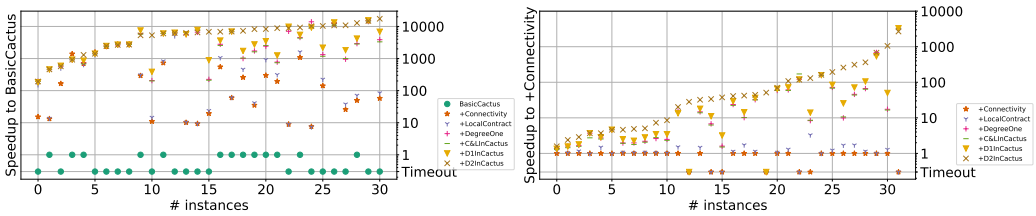
On graphs with a low value of n^*, we can see that `Random` is slightly faster than the other variants. There is no significant difference in the shrinking of the graph, as almost all selected edges have connectivity larger than λ and thus only trigger a single edge contraction anyway. Thus, not spending the extra work of finding a "good" edge results in a slightly lower running time. In the following we will use variant `Heavy`, which is the only variant that is never more than 30% slower than the fastest variant on any graph.

5.2 Optimization

We now examine the effect of the different optimizations. For this purpose, we benchmarks different variants on a variety of graphs. We hereby compare the following variants that build on one another: as a baseline, `BasicCactus` runs the algorithm of Nagamochi, Nakao and Ibaraki [45] on the input graph. `+Connectivity` additionally runs VieCut [28] to find an upper bound for the minimum cut and uses this to contract high-connectivity edges as described in Section 3.1.1. In addition to this, `+LocalContract` also contracts edges whose neighborhood guarantees that they are not part of any minimum cut, as described in Section 3.1.2 and Lemma 2. `+DegreeOne` runs also the last remaining contraction routine from Algorithm 1, contraction and re-insertion of degree-one vertices as described in Section 3.1.3.

`+C&LInCactus` additionally runs high-connectivity and local contraction in every tenth recursion step. `+D1InCactus` additionally contracts and re-inserts degree-one vertices in every recursion step. `FullAlgorithm` also runs the degree-two contraction as described in Section 3.2.2. We compare these variants on the graphs in Tables 2 and 3. We use a timeout of 30 minutes on these graphs. If the baseline algorithm does not finish in the allotted time, we report speedup to the timeout, so a lower bound for the actual speedup.

Figure 5a shows the speedup of all variants to the baseline variant `BasicCactus` on all graphs in Table 2. We can see that already just adding `+Connectivity` gives a speedup of more than an order of magnitude for each of the graphs in the dataset. Most of the



(a) Speedup to `BasicC` on small graphs (Table 2) **(b)** Speedup to `+Conn` on large graphs (Table 3)

Figure 5 Speedup to respective basic version.

other optimizations manage to improve the running time of at least some instances by a large margin. Especially `+DegreeOne`, which is the first contraction for edges that are in a minimum cut, has speedups of multiple orders of magnitude in some instances. This is the case as minimum cut edges that are incident to a degree-one vertex previously incur a flow problem on the whole graph each. However, it is very easy to see that the edge will be part of exactly one minimum cut, thus we can contract and re-insert it in constant time. Especially in graphs whose minimum cut is 1, all edges can be quickly contracted, as they will either be incident to a degree-one vertex or be quickly certified to have a connectivity value of > 1.

While rerunning `Connectivity` and `LocalContract` inside of the recursive algorithm of Nagamochi et al. [45] does usually not yield a large speedup, many graphs develop degree-one vertices by having their whole neighborhood contracted. Thus, `+D1InCactus` has a significant speedup for most graphs in which n^* is sufficiently large. `FullAlgorithm` has an even larger speedup on these graphs, even when the minimum cut is significantly higher than 2, as there are often cascading effects where the contraction of an edge incident to a degree-two vertex often lowers the degree of neighboring vertices to two.

Figure 5b shows the speedup of all variants. As variant `BasicCactus` is not able to solve any of these instances in 30 minutes, we use `+Connectivity` as a baseline. The results are similar to Figure 5a, but we can see even clearer how useful the contraction of degree-two vertices is in finding all minimum cuts: `FullAlgorithm` often has a speedup of more than an order of magnitude to all other variants and is the only variant that never times out.

5.3 Shared-memory Parallelism

Table 1 shows the average running times of our algorithm both sequential and with 16 threads on huge social and web graphs. Each of these graphs has more than a billion of edges and more than a million vertices in the cactus graph depicting all minimum cuts. On these graphs we have a parallel speedup factor of 5.7x to 9.1x using 16 threads. On all of these graphs, a large part of the running time is spent in the first iteration of the kernelization routines, which already manages to contract most dense blocks in the graph. Thus, all subsequent operations can be performed on significantly smaller problems and are therefore much faster.

Table 1 Huge social and web graphs. n^* denotes number of vertices in cactus graph, max n and max m denote size of smaller block in most balanced cut.

Name	n	m	n^*	λ	max. n	max. m	seq. t	par. t
friendster	65.6M	1.81B	13.99M	1	897	1 793	1266.35s	138.34s
twitter7	41.7M	1.20B	1.93M	1	47	1 893	524.86s	72.51s
uk-2007-05	104.3M	3.29B	9.66M	1	49 984	13.8M	229.18s	40.16s

6 Conclusion

We engineered an algorithm to find all minimum cuts in large undirected graphs. Our algorithm combines multiple kernelization routines with an engineered version of the algorithm of Nagamochi, Nakao and Ibaraki [45] to find all minimum cuts of the reduced graph. Our experiments show that our algorithm can find all minimum cuts of huge social networks with up to billions of edges and millions of minimum cuts in a few minutes on shared memory. We found that especially the contraction of high-connectivity edges and efficient handling of low-degree vertices can give huge speedups. Additionally we give a linear time algorithm to find the most balanced minimum cut given the cactus graph representation of all minimum cuts. Future work includes finding near-minimum cuts.

Abstract

We extend the notion of lossy kernelization, introduced by Lokshtanov et al. [STOC 2017], to approximate Turing kernelization. An α-approximate Turing kernel for a parameterized optimization problem is a polynomial-time algorithm that, when given access to an oracle that outputs c-approximate solutions in $\mathcal{O}(1)$ time, obtains an $\alpha \cdot c$-approximate solution to the considered problem, using calls to the oracle of size at most $f(k)$ for some function f that only depends on the parameter.

Using this definition, we show that Independent Set parameterized by treewidth ℓ has a $(1+\varepsilon)$-approximate Turing kernel with $\mathcal{O}(\frac{\ell^2}{\varepsilon})$ vertices, answering an open question posed by Lokshtanov et al. [STOC 2017]. Furthermore, we give $(1+\varepsilon)$-approximate Turing kernels for the following graph problems parameterized by treewidth: Vertex Cover, Edge Clique Cover, Edge-Disjoint Triangle Packing and Connected Vertex Cover.

We generalize the result for Independent Set and Vertex Cover, by showing that all graph problems that we will call *friendly* admit $(1+\varepsilon)$-approximate Turing kernels of polynomial size when parameterized by treewidth. We use this to obtain approximate Turing kernels for Vertex-Disjoint H-packing for connected graphs H, Clique Cover, Feedback Vertex Set and Edge Dominating Set.

1 Introduction

Many important computational problems are NP-hard and, thus, they do not have efficient algorithms unless P = NP. At the same time, it is well known that *efficient preprocessing* can greatly speed up (exponential-time) algorithms for solving NP-hard problems. The notion of a *kernelization* from parameterized complexity has allowed a rigorous and systematic study of this important paradigm. The central idea is to relate the effectiveness of preprocessing to the structure of the input instances, as quantified by suitable parameters.

A *parameterized problem* consists of any (classical) problem together with a choice of one or more parameters; we use (x, k) to denote an instance with input data x and parameter k. A *kernelization* is an efficient algorithm that on input of (x, k) returns an equivalent instance

(x', k') of size upper bounded by $f(k)$, where f is a computable function. For a polynomial kernelization we require that the size bound $f(k)$ is polynomially bounded in k. The study of which parameterized problems admit (polynomial) kernelizations has turned into a very active research area within parameterized complexity (see, e.g., [1, 5, 7, 8, 16, 23, 27, 28, 29, 31, 35] and the recent book [17]). An important catalyst for this development lies in the ability to prove lower bounds for kernelizations, e.g., to conditionally rule out polynomial kernels for a problem, which was initiated through work of Bodlaender et al. [4] and Fortnow and Santhanam [18].

Unfortunately, the lower bound tools have also revealed that many fundamental parameterized problems do not admit polynomial kernelizations (unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ and the polynomial hierarchy collapses). These include a variety of problems like Connected Vertex Cover [12], Disjoint Cycle Packing [6], Multicut [11], and k-Path [4] parameterized by solution size, but also essentially any NP-hard problem parameterized by width parameters such as treewidth. This has motivated the study of relaxed forms of kernelization, notably Turing kernelization [3] and lossy (or approximate) kernelization [30].

Given an input (x, k), a *Turing kernelization* may create $|x|^{\mathcal{O}(1)}$ many instances of size at most $f(k)$ each, and the answer for (x, k) may depend on solutions for all those instances. This is best formalized as an efficient algorithm that solves (x, k) while being allowed to ask questions of size at most $f(k)$ to an oracle. A priori, this is much more powerful than regular kernelization, which creates only a single output instance. Nevertheless, there are only few polynomial Turing kernelizations known for problems without (regular) polynomial kernelization (e.g., [3, 26, 25, 34]). Moreover, a hardness-based approach of Hermelin et al. [22] gives evidence that many problems are unlikely to admit polynomial Turing kernels.

More recently, Lokshtanov et al. [30] proposed a framework dedicated to the study of *lossy kernelization*. This relaxes the task of the kernelization by no longer requiring that an optimal solution to the output (x', k') yields an optimal solution for (x, k). Instead, for an α-approximate kernelization any c-approximate solution to (x', k') can be lifted to an $\alpha \cdot c$-approximate solution for (x, k). Amongst others, they show that Connected Vertex Cover and Disjoint Cycle Packing admit approximate kernelizations. In contrast, they were able to show, e.g., that k-Path has no α-approximate kernelization for any $\alpha \geq 1$ (unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$). Subsequent works have shown approximate kernelizations for other problems [13, 14, 32], in particular, further problems with connectivity constraints, which are often an obstruction for the existence of polynomial kernelizations.

Lokshtanov et al. [30] ask whether Independent Set parameterized by treewidth admits a polynomial-size approximate Turing kernelization with constant approximation ratio. In the present work, we answer this question affirmatively and in fact provide an efficient polynomial size approximate Turing kernelization scheme (EPSATKS). Moreover, extending the ideas for Independent Set, we provide similar results for a variety of other problems.

Our results. We prove that there is an EPSATKS for a wide variety of graph problems when parameterized by treewidth. The simplest problems we consider are the Vertex Cover and Independent Set problem. Observe that both problems parameterized by treewidth can be shown to be $\mathsf{MK}[2]$-hard, by a simple reduction from CNF-Sat with unbounded clause size.[1] As such, for both problems we indeed do not expect polynomial Turing kernels [22]. We show that Vertex Cover has a $(1+\varepsilon)$-approximate Turing kernel with $\mathcal{O}(\frac{\ell}{\varepsilon})$ vertices, and Independent Set has a kernel with $\mathcal{O}(\frac{\ell^2}{\varepsilon})$ vertices.

[1] A variant of the well-known NP-hardness proof of Independent Set (or Vertex Cover) suffices, where we add two vertices v_x and $v_{\bar{x}}$ for each variable x and connect them. Add a clique for each clause, that has a vertex u_ℓ for each literal ℓ in the clause. Connect u_ℓ to v_x if $\ell = \neg x$, connect u_ℓ to $v_{\bar{x}}$ if $\ell = x$. Observe that the treewidth is bounded by twice the number of variables.

Both approximate Turing kernels follow a similar strategy, based on using separators (originating from the tree decomposition) that separate a piece from the rest of the graph, such that the solution size in this piece is appropriately bounded. For this reason, we formulate a set of conditions on a graph problem and we call graph problems that satisfy these conditions *friendly*. We then show that all friendly graph optimization problems have polynomial-size $(1+\varepsilon)$-approximate Turing kernels for all $\varepsilon > 0$, when parameterized by treewidth. Precise bounds on the size of the obtained approximate Turing kernels depend on properties of the considered problem, such as the smallest-known (approximate) kernel when parameterized by solution size plus treewidth. In particular, applying the general result for Vertex Cover indeed shows that it has an EPSATKS of size $\mathcal{O}(\frac{\ell}{\varepsilon})$. Using this general technique, we obtain approximate Turing kernels for Clique Cover, Vertex-Disjoint H-Packing for connected graphs H, Feedback Vertex Set, and Edge Dominating Set.

Finally, we prove that Edge Clique Cover and Edge-Disjoint Triangle Packing have an EPSATKS and show that Connected Vertex Cover has a polynomial-size $(1+\varepsilon)$-approximate Turing kernel. These problems do not satisfy our definition of a friendly problem and require a more problem-specific approach. In particular, for Connected Vertex Cover we will need to consider subconnected tree decompositions [19] and carefully bound the size difference between locally optimal connected vertex covers, and intersections of (global) connected vertex covers with parts of the graph.

Overview. We start in Section 3 by illustrating the general technique using the Vertex Cover problem as an example. We continue by giving the approximate Turing kernels for Edge Clique Cover, Connected Vertex Cover, and Edge-Disjoint Triangle Packing. In Section 4 we state and prove our general theorem and then show that it allows us to give approximate Turing kernels for a number of different graph problems. For statements marked with a ★, the (full) proof can be found in the full version of the paper [24].

2 Preliminaries

We use $\mathbb{N}$ to denote the non-negative integers. Let $[n]$ be defined as the set containing the integers 1 to n. We assume that all graphs are simple and undirected, unless mentioned otherwise. A graph G has vertex set $V(G)$ and edge set $E(G)$. For $v \in V(G)$ we let $d_G(v)$ denote the degree of v. For $X \subseteq V(G)$, we use $G[X]$ to denote the graph induced by vertex set X, we use $G - X$ to denote $G[V(G) \setminus X]$. For $F \subseteq E(G)$, we use $G \setminus F$ to denote the graph resulting from deleting all edges in F from G.

We say that a set $X \subseteq V(G)$ *separates* vertex sets $A \subseteq V(G)$ and $B \subseteq V(G)$ if every path from some vertex in A to some vertex in B contains a vertex in X.

Treewidth. Recall the definition of treewidth.

▶ **Definition 1** ([10]). *A* tree decomposition *of a graph G is a tuple $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$, where T is a tree in which each node $t \in V(T)$ has an assigned set of vertices $X_t \subseteq V(G)$, also referred to as the* bag *of node t, such that the following three conditions hold:*

- $\bigcup_{t \in V(T)} X_t = V(G)$, *and*
- *for every edge $\{u, v\} \in E(G)$ there exists $t \in V(T)$ such that $u, v \in X_t$, and*
- *for all $v \in V(G)$ the set $T_v := \{t \in V(T) \mid v \in X_t\}$ induces a connected subtree of T.*

The width *of a tree decomposition of G is the size of its largest bag minus one. The* treewidth *of G is the minimum width of any tree decomposition of G.*

In the remainder of the paper, we will always assume that a tree decomposition is given on input, as treewidth is NP-hard to compute. If it is not, we may use the result below to obtain an approximation of the treewidth and a corresponding tree decomposition in polynomial time. Doing so will weaken any given size bounds in the paper, as it is not a constant-factor approximation. The theorem below is part of [15, Theorem 6.4].

▶ **Theorem 2** ([15, Theorem 6.4]). *There exists a polynomial time algorithm that finds a tree decomposition of width at most $\mathcal{O}(\sqrt{\log tw(G)} \cdot tw(G))$ for a general graph G.*

Let $\mathcal{T} = (T, \{X_t\}_{t \in V(T)})$ be a tree decomposition. Let $t \in V(T)$, we use V_t to denote the set of vertices from G that are contained in some bag of a node in the subtree of T that is rooted at t. It is well-known that for all $t \in V(T)$, the set X_t separates V_t from the rest of the graph. A rooted tree decomposition with root r is said to be *nice* if it satisfies the following properties (cf. [10]).

- **(i)** $X_r = \emptyset$ and $X_t = \emptyset$ for every leaf t of T.
- **(ii)** Every other node is of one of the following three types:
  - The node $t \in V(T)$ has exactly two children t_1 and t_2, and $X_t = X_{t_1} = X_{t_2}$. We call such a node a *join* node, or
  - the node $t \in V(T)$ has exactly one child t_1, and there exist $v \in V(G)$ such that $X_t = X_{t_1} \cup \{v\}$ (in this case t is an *introduce* node) or such that $X_{t_1} = X_t \cup \{v\}$ (in which case t is a *forget* node).

One can show that a tree decomposition of a graph G of width ℓ can be transformed in polynomial time into a nice tree decomposition of the same width and with $\mathcal{O}(\ell|V(G)|)$ nodes, see for example [10].

To deal with the Connected Vertex Cover problem we need the tree decomposition to preserve certain connectivity properties. Let a *subconnected tree decomposition* [19] be a tree decomposition where $G[V_t]$ is connected for all $t \in V(T)$. We observe the following.

▶ **Theorem 3** (cf. [19, Theorem 1]). *There is an $\mathcal{O}(n\ell^3)$-algorithm that, given a nice tree decomposition on n nodes of width ℓ of a connected graph G, returns an $\mathcal{O}(n \cdot \ell)$-node subconnected tree decomposition of G, of width at most ℓ such that each node in T has at most $2\ell + 2$ children.*

Proof. Without the additional bound on the degrees of nodes in T, the result is immediate from [19, Theorem 1]. We obtain a subconnected tree decomposition by only executing Phase 1 of Algorithm `make-it-connected` in [19]. Is is shown in [19, Claim 1] that this procedure results in a tree decomposition of width ℓ that is subconnected. It remains to analyze the maximum node degree. The only relevant step of the algorithm is the application of the `split` operation on nodes t from the original tree. Observe that every node in the original tree is visited at most once, and newly introduced nodes are never `split`. If t has parent s, the `split` operation only modifies the degree of s, and any newly introduced nodes. The newly introduced nodes will have degree at most $d_T(t)$. In particular, if s had degree a before the `split` operation on t, it will have degree $a - 1 + p$ after the `split` operation, where p is the number of connected components of $G[V_t]$. We will show that the number of connected components of $G[V_t]$ is bounded by $|X_t|$ if G is a connected graph. We do this by showing that each connected component contains at least one vertex from X_t. Suppose not. Let C be such a component. But since $C \cap X_t = \emptyset$, and X_t is a separator in G, it follows that there are no connections from C to $G[V(G) \setminus V_t]$. If $V_t = V(G)$, then $G[V_t]$ is connected and we are done, otherwise, vertices in $V(G) \setminus V_t$ are not connected to C in G, contradicting that G is connected. Thus, $p \leq |X_t| \leq \ell + 1$. Since in a nice tree decomposition every node has only two children, in the worst case `split` is applied to both these children. Thus, every node in T has degree at most $2\ell + 2$. ◀

Approximation, Kernelization, and Turing Kernelization. We recall the framework for approximate kernelization by Lokshtanov et al. [30] following Fomin et al. [17]. We then introduce suitable definitions for approximate Turing kernelization.

▶ **Definition 4** ([17]). *A* parameterized optimization problem $\mathcal{Q}$ *is a computable function*

$$\mathcal{Q}\colon \Sigma^* \times \mathbb{N} \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}.$$

The instances *of a parameterized optimization problem are pairs* (I, k) *where* k *is the parameter. A* solution *to* (I, k) *is simply a string* $s \in \Sigma^*$*, such that* $|s| \leq |I| + k$*. The* value *of a solution* s *is given by* $\mathcal{Q}(I, k, s)$*. Using this, we may define the optimal value for the problem as*

$$\mathrm{OPT}_{\mathcal{Q}}(I, k) = \min\{\mathcal{Q}(I, k, s) \mid s \in \Sigma^*, |s| \leq |I| + k\},$$

for minimization problems and as

$$\mathrm{OPT}_{\mathcal{Q}}(I, k) = \max\{\mathcal{Q}(I, k, s) \mid s \in \Sigma^*, |s| \leq |I| + k\},$$

for maximization problems.

An *optimization problem* $\mathcal{P}\colon \Sigma^* \times \Sigma^* \to \mathbb{R} \cup \{\pm\infty\}$ is defined similarly, but without the parameter. In both cases we will say that s is a *solution* for instance I, if its value is not ∞ (or $-\infty$, in case of maximization problems).

We say that an algorithm for a (regular) minimization problem $\mathcal{P}$ is a *c-approximation algorithm* if for all inputs x it returns a solution s such that the value of s is at most $c \cdot \mathrm{OPT}_{\mathcal{P}}(x)$. Similarly, for a maximization problem we require that s has value at least $\frac{1}{c}\mathrm{OPT}_{\mathcal{P}}(x)$.

When a problem is parameterized by the value of the optimal solution, the definitions of parameterized optimization problems and lossy kernels will cause problems. As such, we use the following interpretation [30, p.229]. Given an optimization problem $\mathcal{P}$ that we want to parameterize by a sum of (potentially multiple) parameters, one of which is the solution value, we define the following corresponding parameterized optimization problem:

$$\mathcal{P}^{\perp}(I, k, s) := \min\{\mathcal{P}(I, s), k + 1\}.$$

In cases where we consider $\mathcal{P}$ parameterized by the treewidth of the input graph, we simply use

$$\mathcal{P}^{\perp}(I, k, s) := \mathcal{P}(I, s).$$

▶ **Definition 5** (α-Approximate kernelization [17]). *Let* $\alpha \geq 1$ *be a real number, let* g *be a computable function and let* $\mathcal{Q}$ *be a parameterized optimization problem. An* α-approximate kernelization $\mathcal{A}$ *of size* g *for* $\mathcal{Q}$ *is a pair of polynomial-time algorithms. The first one is called the* reduction algorithm *and computes a map* $\mathcal{R}_{\mathcal{A}}\colon \Sigma^* \times \mathbb{N} \to \Sigma^* \times \mathbb{N}$*. Given as input an instance* (I, k) *of* $\mathcal{Q}$*, the reduction algorithm computes another instance* $(I', k') = \mathcal{R}_{\mathcal{A}}(I, k)$ *such that* $|I'|, k' \leq g(k)$*.*

The second is called the solution-lifting algorithm*. This algorithm takes as input an instance* $(I, k) \in \Sigma^* \times \mathbb{N}$ *of* $\mathcal{Q}$*, together with* $(I', k') := \mathcal{R}_{\mathcal{A}}(I, k)$ *and a solution* s' *to* (I', k')*. In time polynomial in* $|I| + |I'| + k + k' + |s|$*, it outputs a solution* s *to* (I, k) *such that if* $\mathcal{Q}$ *is a minimization problem, then*

$$\frac{\mathcal{Q}(I, k, s)}{\mathrm{OPT}_{\mathcal{Q}}(I, k)} \leq \alpha \cdot \frac{\mathcal{Q}(I', k', s')}{\mathrm{OPT}_{\mathcal{Q}}(I', k')}.$$

For maximization problems we require

$$\frac{\mathcal{Q}(I, k, s)}{\mathrm{OPT}_{\mathcal{Q}}(I, k)} \geq \frac{1}{\alpha} \cdot \frac{\mathcal{Q}(I', k', s')}{\mathrm{OPT}_{\mathcal{Q}}(I', k')}.$$

We say that a problem admits a *Polynomial Size Approximate Kernelization Scheme (PSAKS)* [30] if it admits an α-approximate polynomial kernel for all $\alpha > 1$.

We recall the definition of a Turing kernel, so that we can show how to naturally generalize the notion of approximate kernelization to Turing kernels.

▶ **Definition 6** (Turing kernelization [17]). *Let $\mathcal{Q}$ be a parameterized problem and let $f : \mathbb{N} \to \mathbb{N}$ be a computable function. A* Turing kernelization *for $\mathcal{Q}$ of size f is an algorithm that decides whether a given instance $(x, k) \in \Sigma^* \times \mathbb{N}$ belongs to $\mathcal{Q}$ in time polynomial in $|x|+k$, when given access to an oracle that decides membership of $\mathcal{Q}$ for any instance (x', k') with $|x'|, k' \leq f(k)$ in a single step.*

In the following definition, we combine the notions of lossy kernelization and Turing kernelization into one, as follows.

▶ **Definition 7** (Approximate Turing kernelization). *Let $\alpha \geq 1$ be a real number, let f be a computable function and let $\mathcal{Q}$ be a parameterized optimization problem. An* α-approximate Turing kernel of size f *for $\mathcal{Q}$ is an algorithm that, when given access to an oracle that computes a c-approximate solution for instances of $\mathcal{Q}$ in a single step, satisfies the following.*

- *It runs in time polynomial in $|I| + k$, and*
- *given instance (I, k), outputs a solution s such that $\mathcal{Q}(I, k, s) \leq \alpha \cdot c \cdot \mathrm{OPT}_{\mathcal{Q}}(I, k)$ if $\mathcal{Q}$ is a minimization problem and $\mathcal{Q}(I, k, s) \cdot \alpha \cdot c \geq \mathrm{OPT}_{\mathcal{Q}}(I, k)$ is $\mathcal{Q}$ is a minimization problem, and*
- *it only uses oracle-queries of size bounded by $f(k)$.*

Note that, in the definition above, the algorithm does not depend on c, just like in lossy kernelization. We say that a parameterized optimization problem $\mathcal{Q}$ has an *EPSATKS* when it has a polynomial-size $(1 + \varepsilon)$-approximate Turing kernel for every $\varepsilon > 0$, of size $f(\varepsilon) \cdot \mathrm{poly}(k)$ where f is a function that depends only on ε.

3 Approximate Turing kernels for specific problems

In this section we will give approximate Turing kernels for a number of graph problems parameterized by treewidth. We start by discussing the Vertex Cover problem, since the approximate Turing kernels for all other problems will follow the same overall structure.

3.1 Vertex Cover

In this section we discuss an approximate Turing kernel for Vertex Cover parameterized by treewidth ℓ. The overall idea will be to use the treewidth decomposition of the graph, and find a subtree rooted at a node t such that $G[V_t \setminus X_t]$ has a large (but not too large) vertex cover. A vertex cover of the entire graph will then be obtained by taking a vertex cover of $G[V_t \setminus X_t]$, adding all vertices in X_t, and recursing on the graph that remains after removing V_t. This produces a correct vertex cover because X_t is a separator in the graph. Furthermore, taking all of X_t into the vertex cover is not problematic as X_t is ensured to be comparatively small. To obtain a vertex cover of $G[V_t \setminus X_t]$, we will use the following lemma.

▶ **Lemma 8** (★). *Let G be a graph with $OPT_{VC}(G) \leq k$. Then there is a polynomial-time algorithm returning vertex cover of G of size at most $c \cdot \mathrm{OPT}_{VC}(G)$, when given access to c-approximate oracle that solves vertex cover on graphs with at most $\mathcal{O}(k)$ vertices.*

Proof sketch. First apply the LP-based kernel [9] for Vertex Cover parameterized by solution size to (G, k). This gives an instance G' with at most $2k$ vertices. We can then apply the oracle to obtain a c-approximate vertex cover of G'. We show in the complete proof that it is straightforward to lift this solution to a c-approximate vertex cover of the original graph G, concluding the proof. ◀

Using this, we can now give the $(1+\varepsilon)$-approximate Turing kernel for Vertex Cover. While the theorem statement requires $\varepsilon \leq 1$, this does not really impose a restriction: if $\varepsilon > 1$ one may simply reset it to be 1. It simply shows that the bounds do not continue improving indefinitely as ε grows larger than 1. Note however that Vertex Cover is 2-approximable in polynomial time, such that choosing ε larger than one is likely not useful.

▶ **Theorem 9.** *For every $0 < \varepsilon \leq 1$, Vertex Cover parameterized by treewidth ℓ has a $(1+\varepsilon)$-approximate Turing kernel with $\mathcal{O}(\frac{\ell}{\varepsilon})$ vertices.*

Proof. Consider Algorithm 1, we use the well-known 2-approximation algorithm for Vertex Cover. First of all, we show how to do Step 8 of the algorithm efficiently.

Algorithm 1 An approximate Turing kernel for Vertex Cover.

```
1: procedure ApproxVC(G, T, ε)
2:     Turn T into a nice tree decomposition of G
3:     Obtain a 2-approximate solution S̃ for VC in G
4:     if |S̃| ≤ 8(ℓ+1)/ε then
5:         Determine a c-approximate solution S to VC in G using Lemma 8
6:         return S
7:     else
8:         Find t ∈ V(T) s.t. (ℓ+1)/ε ≤ OPT_VC(G[V_t \ X_t]) ≤ 8(ℓ+1)/ε
9:         Determine a c-approximate solution S_t to VC in G[V_t \ X_t] using Lemma 8
10:        G' ← G − V_t
11:        Let T' be T after removing the subtree rooted at t and all vertices in X_t
12:        S' ← ApproxVC(G', T', ε)
13:        return S_t ∪ X_t ∪ S'
14:    end if
15: end procedure
```

▷ Claim. There is a polynomial-time algorithm that, given graph G such that $\mathrm{OPT}_{\mathrm{VC}}(G) \geq \frac{(\ell+1)}{\varepsilon}$, with a nice tree decomposition $\mathcal{T}$ of width at most ℓ, outputs a node $t \in V(T)$ such that $\frac{(\ell+1)}{\varepsilon} \leq \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) \leq \frac{8(\ell+1)}{\varepsilon}$.

Proof. Let $\mathcal{T}$ be a nice tree decomposition with root r. We start from $t := r$, maintaining that $\mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) \geq \frac{\ell+1}{\varepsilon}$. Note that this is initially true since $G_r = G$.

Check whether the 2-approximation returns a vertex cover of size at most $\frac{8(\ell+1)}{\varepsilon}$ for $G[V_t \setminus X_t]$. If yes, we are done. If not, then $\mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) > \frac{4(\ell+1)}{\varepsilon}$. We show that t has a child on which we will recurse. We do a case distinction on the type of node of t.

- t is a leaf node. In this case, $|V_t \setminus X_t| = 0$, contradicting that $\mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) > \frac{4(\ell+1)}{\varepsilon} \geq 0$.
- t is a forget or introduce node. This implies t has one child t_1 and the size of $V_t \setminus X_t$ and $V_{t_1} \setminus X_{t_1}$ differs by at most one. Therefore, $\mathrm{OPT}_{\mathrm{VC}}(G[V_{t_1} \setminus X_{t_1}]) \geq \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) - 1 \geq \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t])/2$.

- t is a join node with children t_1 and t_2. Observe that $G[V_t \setminus X_t]$ is the disjoint union of the graphs $G[V_{t_1} \setminus X_{t_1}]$ and $G[V_{t_2} \setminus X_{t_2}]$ (note $X_t = X_{t_1} = X_{t_2}$). As such, for one of the two children, without loss of generality let this be t_1, running the 2-approximation algorithm for vertex cover returns a value of at least $\mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t])/2$, meaning that $\mathrm{OPT}_{\mathrm{VC}}(G[V_{t_1} \setminus X_{t_1}]) \geq \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t])/4$.

Thus, there is a child t_1 such that $\mathrm{OPT}_{\mathrm{VC}}(G[V_{t_1} \setminus X_{t_1}]) \geq \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t])/4 \geq \frac{\ell+1}{\varepsilon}$. Continue with $t := t_1$. ◁

We will now show the correctness of the algorithm by induction on $|V(G)|$. Let G be a graph with nice tree decomposition $\mathcal{T}$. If the algorithm returns a Vertex Cover in Step 5, the result is immediate. If not, then it follows that the algorithm returns in Step 13, and that $\mathrm{OPT}_{\mathrm{VC}}(G) > \frac{4(\ell+1)}{\varepsilon}$. The algorithm then returns a vertex cover S_t for $G[V_t \setminus X_t]$ together with X_t and a vertex cover $S' = \textsc{ApproxVC}(G', \mathcal{T}', \varepsilon)$ in the remainder of the graph. It is easy to see that the returned set is indeed a vertex cover of the graph. Furthermore, one may verify that the oracle is only used for graphs with at most $\mathcal{O}(\frac{\ell}{\varepsilon})$ vertices. It remains to verify the approximation ratio. Recall that $G' := G - V_t$. Then

$$\begin{aligned}|S_t| + |S'| + |X_t| &\leq c \cdot \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) + c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{VC}}(G') + \ell + 1 \\ &\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{VC}}(G[V_t \setminus X_t]) + c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{VC}}(G') \\ &\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{VC}}(G).\end{aligned}$$ ◀

3.2 Edge Clique Cover

In this section, we obtain an approximate Turing kernel for Edge Clique Cover, which is defined as follows.

Edge Clique Cover (ECC) **Parameter:** ℓ
Input: A graph G with tree decomposition $\mathcal{T}$ of width ℓ.
Output: The minimum value for $k \in \mathbb{N}$ such that there exists a family S of subsets of $V(G)$ such that $\lvert S\rvert \leq k$, $G[C]$ is a clique for all $C \in S$, and for all $\{u, v\} \in E(G)$ there exists $C \in S$ such that $u, v \in S$?

To obtain an approximate Turing kernel, we will separate suitably-sized subtrees from the graph using the tree decomposition, as we did in the approximate Turing kernel for Vertex Cover. To show that this results in the desired approximation bound, we will need the following lemma. It basically shows that if we find a node t of the tree decomposition such that X_t is "small" compared to $\mathrm{OPT}(V_t)$, we will be able to combine an edge clique cover in $G[V_t]$ with one in $G - (V_t \setminus X_t)$ to obtain a clique cover of the entire graph that is not too far from optimal.

▶ **Lemma 10.** *Let G be a graph, let $X_1, X_2 \subseteq V(G)$ such that $X_1 \cup X_2 = V(G)$ and $X = X_1 \cap X_2$ separates X_1 from X_2 in G. Then*

$$OPT_{ECC}(G) \geq OPT_{ECC}(G[X_1]) + OPT_{ECC}(G[X_2]) - \binom{|X|}{2}.$$

Proof. Let S be an edge clique cover of G. We show how to obtain clique covers S_1 and S_2 for $G[X_1]$ and $G[X_2]$ such that $|S_1| + |S_2| \leq |S| + \binom{|X|}{2}$. First define

$$S_1' := \{C \mid C \cap (X_1 \setminus X) \neq \emptyset, C \in S\} \cup \{C \mid C \subseteq X, C \in S\},$$

similarly, define

$$S_2' := \{C \mid C \cap (X_2 \setminus X) \neq \emptyset, C \in S\}.$$

For $j \in [2]$, define $S_j := S_j' \cup S_j''$, where $S_j'' := \{\{u,v\} \in E(G[X]) \mid \{u,v\} \text{ not covered by } S_j'\}$.

We start by showing that S_j is an edge clique cover of $G[X_j]$ for $i \in [2]$. First of all, we will verify that $C \subseteq X_j$ and that C forms a clique in $G[X_j]$ for all $C \in S_j$. For $C \in S_j''$ this is trivial, for $C \in S_j'$, observe that C is a clique in G and any clique in G containing a vertex from $X_j \setminus X$ cannot contain a vertex from $V(G) \setminus X_j$, since X is a separator. Thus $C \subseteq X_j$. The fact that C is a clique in $G[X_j]$ is immediate from C being a clique in G.

It remains to show that S_j covers all edges in $G[X_j]$. Let $\{u,v\} \in E(G[X_j])$. If $u,v \in X$, then the edge is covered by definition. Without loss of generality, suppose $u \in X_j \setminus X$. Let $C \in S$ be a clique that covered edge $\{u,v\}$. Then clearly $u \in C \cap (X_j \setminus X)$ and thus $C \cap (X_j \setminus X) \neq \emptyset$, implying $C \in S_j$. Thus, the edge $\{u,v\}$ is indeed covered by S_j.

It remains to show that $|S_1| + |S_2| \leq |S| + \binom{|X|}{2}$. Start by observing that $|S_1'| + |S_2'| \leq |S|$, since a clique cannot contain both a vertex from $X_1 \setminus X$ and $X_2 \setminus X$. Since every edge $\{u,v\} \in E(G[X])$ is covered by S, it is easy to observe from the definition that $\{u,v\}$ is covered by S_1' or S_2'. As such, $S_1'' \cap S_2'' = \emptyset$. Since $G[X]$ has at most $\binom{|X|}{2}$ edges, it follows that $|S_1''| + |S_2''| \leq \binom{|X|}{2}$ and indeed $|S_1| + |S_2| \leq |S_1'| + |S_1''| + |S_2'| + |S_2''| \leq |S| + \binom{|X|}{2}$. ◀

Before giving the approximate Turing kernel, we show that there exists a node t in the tree decomposition such that the size of the subtree rooted at t falls within certain size bounds. We use this to split off subtrees, similar to the strategy we used for Vertex Cover earlier.

▶ **Lemma 11 (★).** *There is a polynomial-time algorithm that, given a graph G with $|V(G)| \geq 2\frac{1+\varepsilon}{\varepsilon}(\ell+1)^4$, a nice tree decomposition $\mathcal{T}$ of width ℓ, and $\varepsilon > 0$, outputs a node $t \in V(T)$ such that $2\frac{1+\varepsilon}{\varepsilon}(\ell+1)^4 \leq |V_t \setminus X_t| \leq 4\frac{1+\varepsilon}{\varepsilon}(\ell+1)^4$.*

Using the lemma above, we can now give the approximate Turing kernel for Edge Clique Cover.

▶ **Theorem 12.** *For every $0 < \varepsilon \leq 1$, Edge Clique Cover parameterized by treewidth ℓ has a $(1+\varepsilon)$-approximate Turing kernel with $\mathcal{O}(\frac{\ell^4}{\varepsilon})$ vertices.*

Proof. Consider Algorithm 2, we show that it is a $(1+\varepsilon)$-approximate Turing kernel for ECC. Observe that Step 2 can be done efficiently while maintaining a valid tree decomposition, as one may simply restrict the bags of the decomposition to the relevant connected component of G. It is easy to verify that the procedure runs in polynomial time, using that $|V_t \setminus X_t|$ is always non-empty and thus the recursive call is on a strictly smaller graph. Finally, we can verify the size-bound, as the oracle is only applied to G if $|V(G)| \leq \mathcal{O}(\frac{\ell^4}{\varepsilon})$ or to $G[V_t]$ when $|V_t \setminus X_t| \leq \mathcal{O}(\frac{\ell^4}{\varepsilon})$, implying that $|V_t| \leq |V_t \setminus X_t| + \ell + 1 = \mathcal{O}(\frac{\ell^4}{\varepsilon})$.

We continue by showing that Algorithm 2 returns an edge clique cover of G. If the algorithm returns in Step 6, this is immediate. Otherwise, observe that since X_t separates V_t and $V(G')$ in G, it follows that any edge in G is in $E(G[V_t])$ or in $E(G')$. Thus, such an edge is covered by S_t or S', implying that $S = S_t \cup S'$ is an edge clique cover of G. We now bound $|S_t| + |S'|$, to show that the algorithm indeed approximates the optimum ECC.

$$\begin{aligned} |S_t| + |S'| &\leq c \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) + |S'| \\ &= c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) - c \cdot \varepsilon \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) + |S'| \end{aligned}$$

Algorithm 2 An approximate Turing Kernel for Edge Clique Cover.

procedure ApproxECC($G, \mathcal{T}, \varepsilon$)
  If G is not connected, split G into its connected components and treat them separately.
  Turn $\mathcal{T}$ into a nice tree decomposition.
  if $|V(G)| \leq \frac{2(1+\varepsilon)}{\varepsilon}(\ell+1)^4$ **then**
    Apply the c-approximate oracle to obtain an ECC S of G
    return S
  else
    Find $t \in V(T)$ s.t. $2\frac{(1+\varepsilon)}{\varepsilon}(\ell+1)^4 \leq |V_t \setminus X_t| \leq \frac{4(1+\varepsilon)}{\varepsilon}(\ell+1)^4$ (by Lemma 11)
    Determine a c-approximate solution S_t to ECC in $G[V_t]$ using the oracle
    $G' \leftarrow G - (V_t \setminus X_t)$
    Let $\mathcal{T}'$ be $\mathcal{T}$ after removing the subtree rooted at t except for t
    $S' \leftarrow$ ApproxECC($G', \mathcal{T}', \varepsilon$)
    return $S_t \cup S'$
  end if
end procedure

Observe that every clique covers at most $\binom{\ell+1}{2}$ edges, since it has at most $\ell+1$ vertices, since the treewidth of G is bounded by ℓ. Thus $\mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) \geq |E(G[V_t])|/\binom{\ell+1}{2}$.

$$\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) - c \cdot \varepsilon \cdot |E(G[V_t])|/\binom{\ell+1}{2} + |S'|$$

Observe that $V_t \setminus X_t$ cannot contain vertices that are isolated in $G[V_t]$, since G is connected and X_t separates V_t from the remainder of G. Thus, $|E(G[V_t])| \geq |V_t \setminus X_t|/2$.

$$\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) - c \cdot \varepsilon \cdot \frac{|V_t \setminus X_t|}{2(\ell+1)^2} + |S'|$$
$$\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) - c \cdot (1+\varepsilon) \cdot (\ell+1)^2 + |S'|$$

using $\ell + 1 \geq |X_t|$

$$\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) - c \cdot (1+\varepsilon) \cdot \binom{|X_t|}{2} + |S'|$$
$$\leq c \cdot (1+\varepsilon) \cdot (\mathrm{OPT}_{\mathrm{ECC}}(G[V_t]) + \mathrm{OPT}_{\mathrm{ECC}}(G') - \binom{|X_t|}{2})$$

By Lemma 10

$$\leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{ECC}}(G). \quad \blacktriangleleft$$

3.3 Edge-Disjoint Triangle Packing

In this section we give an approximate Turing kernel for the Edge-Disjoint Triangle Packing problem, defined as follows.

Edge-Disjoint Triangle Packing (ETP) **Parameter:** ℓ

Input: A graph G with tree decomposition $\mathcal{T}$ of width ℓ.

Output: The maximum value for $k \in \mathbb{N}$ such that there exists a family S of size-3 subsets of $V(G)$ such that $|S| \geq k$, $G[X]$ is a triangle for all $X \in S$, and X and Y are edge-disjoint for all $X, Y \in S$?

Observe that the problem has a 3-approximation by taking any maximal edge-disjoint triangle packing S, which can be greedily constructed. This packing then uses $3|S|$ edges. If there is a solution S' with $|S'| > 3|S|$, then there is a triangle in S' that contains no edge covered by S, contradicting that S is maximal. We now give the approximate Turing kernel.

▶ **Theorem 13.** *For every $0 \leq \varepsilon \leq 1$, Edge-Disjoint Triangle Packing parameterized by treewidth ℓ, has a $(1+\varepsilon)$-approximate Turing kernel with $\mathcal{O}(\frac{\ell^2}{\varepsilon})$ vertices.*

Proof. We will use the following claim.

▷ Claim 14 (★). Let G be a graph with $\mathrm{OPT}_{\mathrm{ETP}}(G) \leq k$. There is a polynomial-time algorithm that when given access to a c-approximate oracle, outputs a c-approximate solution for G using calls to the oracle with at most $\mathcal{O}(k)$ vertices.

We now describe the algorithm. Start by computing a 3-approximate solution $\tilde{S}$ to Edge-Disjoint Triangle Packing in G. If $|\tilde{S}| \leq 18\frac{(\ell+1)^2}{\varepsilon}$, we obtain an approximate solution to triangle packing using Claim 14.

Otherwise, for $t \in V(T)$ define G_t as $G[V_t] \setminus E(G[X_t])$, i.e., the graph $G[V_t]$ from which the edges between vertices in X_t have been removed. We show how to find $t \in T$ such that

$$\frac{(\ell+1)^2}{\varepsilon} \leq \mathrm{OPT}_{\mathrm{ETP}}(G_t) \leq 18\frac{(\ell+1)^2}{\varepsilon},$$

together with an approximate solution S_t in G_t. Start with $t := r$, observe that initially $\mathrm{OPT}_{\mathrm{ETP}}(G_t) > \frac{18(\ell+1)^2}{\varepsilon}$ since $G_r = G$ and $\mathrm{OPT}_{\mathrm{ETP}}(G_t) \geq |\tilde{S}|$. So suppose we are at some node t with $\mathrm{OPT}_{\mathrm{ETP}}(G_t) \geq \frac{(\ell+1)^2}{\varepsilon}$. Compute a 3-approximate solution in G_t. If this solution has value at most $\frac{6(\ell+1)^2}{\varepsilon}$, we obtain an approximate solution S_t to triangle packing in G_t using Claim 14. Otherwise, we will recurse on a child t_1 of t for which $\mathrm{OPT}_{\mathrm{ETP}}(G_{t_1}) \geq \frac{(\ell+1)^2}{\varepsilon}$, we show how to find such a child by doing a case distinction on the type of node of t.

- t is a leaf node. This is a contradiction with the assumption that $\mathrm{OPT}_{\mathrm{ETP}}(G_t) > 6\frac{(\ell+1)^2}{\varepsilon}$, since G_t is empty.
- t has exactly one child t_1 and $X_t = X_{t_1} \cup \{v\}$ for some $v \in V(G)$. This means in particular that $G_{t_1} = G_t - \{v\}$. Furthermore, we can show that v is isolated in G_t. After all, there are no edges between vertices in X_t and v by definition of G_t. Furthermore, there are no edges between v and vertices not in X_t, by correctness of the tree decomposition. Therefore, trivially, $\mathrm{OPT}_{\mathrm{ETP}}(G_t) = \mathrm{OPT}_{\mathrm{ETP}}(G_{t_1})$ and we continue with $t \leftarrow t_1$.
- t has exactly one child t_1 and $X_t = X_{t_1} \setminus \{v\}$ for some $v \in V(G)$. In this case G_{t_1} can be obtained by G_t by removing all edges between vertices in v and vertices in X_t. This removes at most $(\ell+1)$ edges from the graph, and thus $\mathrm{OPT}_{\mathrm{ETP}}(G_{t_1}) \geq \mathrm{OPT}_{\mathrm{ETP}}(G_t) - \ell \geq \frac{(\ell+1)^2}{\varepsilon}$, and we continue with $t \leftarrow t_1$.
- t is a join node with children t_1 and t_2. Observe that X_t separates G_t and that $\mathrm{OPT}_{\mathrm{ETP}}(G_t) = \mathrm{OPT}_{\mathrm{ETP}}(G_{t_1}) + \mathrm{OPT}_{\mathrm{ETP}}(G_{t_2})$. As such, there is a child of G_t, w.l.o.g. let this be t_1, such that $\mathrm{OPT}_{\mathrm{ETP}}(G_{t_1}) \geq \mathrm{OPT}_{\mathrm{ETP}}(G_t)/2 \geq \frac{3(\ell+1)^2}{\varepsilon}$. Using the 3-approximation on both children, find a child where the returned solution size is at least $\frac{3(\ell+1)^2}{3\varepsilon} = \frac{(\ell+1)^2}{\varepsilon}$. Continue with this child.

Using t and the obtained solution S_t in G_t, we now do the following. Let $G' := G - (V_t \setminus X_t)$. Obtain a solution S' in G' using the algorithm above on the smaller graph G'. Output $S := S_t \cup S'$. Since G' and G_t are edge-disjoint subgraphs of G, it is easy to observe that S is an edge-disjoint triangle packing in G.

It remains to show that S has the desired size. Observe that the size of an edge-disjoint triangle packing in G can be bounded by considering the triangles whose edges are in G_t, those whose edges are in G', and those with at least one edge with both endpoints in X_t. Using that there are at most $\binom{X_t}{2}$ edges between vertices in X_t, we get

$$\begin{aligned}\mathrm{OPT}_{\mathrm{ETP}}(G) &\leq \mathrm{OPT}_{\mathrm{ETP}}(G_t) + \mathrm{OPT}_{\mathrm{ETP}}(G') + \binom{X_t}{2} \\ &\leq (1+\varepsilon)\mathrm{OPT}_{\mathrm{ETP}}(G_t) + \mathrm{OPT}_{\mathrm{ETP}}(G') \\ &\leq c \cdot (1+\varepsilon)|S_t| + c \cdot (1+\varepsilon)|S'| \\ &\leq c \cdot (1+\varepsilon)|S|.\end{aligned}$$

◀

The strategy used to obtain a kernel for Edge-Disjoint Triangle Packing can be generalized to packing larger cliques, as long as these problems have polynomial kernels when parameterized by solution size. Generalizing to the more general question of packing edge-disjoint copies of some other graph H may be more difficult. In this case, there can be copies of H that have vertices in both sides of the graph after removing the edges within a separator, and one needs to be careful to not discard too many of these.

3.4 Connected Vertex Cover

The Connected Vertex Cover (CVC) problem asks, given a graph G and tree decomposition $\mathcal{T}$, for the minimum size of a vertex cover S in G such that $G[S]$ is connected. It is known that CVC has a $(1+\varepsilon)$-approximate kernel of polynomial size [30].

▶ **Theorem 15** ([30]). *Connected Vertex Cover parameterized by solution size k admits a strict time efficient PSAKS with $\mathcal{O}(k^{\lceil \frac{\alpha}{\alpha-1} \rceil} + k^2)$ vertices.*

To obtain an approximate Turing kernel, we will use a similar strategy to the Turing kernel for Vertex Cover described in Theorem 9. However, the connectivity constraint makes this kernel somewhat more complicated. We deal with this by changing the procedure in two places. First of all, we will use a subconnected tree decomposition, to ensure that $G[V_t]$ is connected for any node t. We will then again find a subtree with a suitably-sized solution. In this case however, we will contract the separator between the subtree and the rest of the graph to a single vertex. The next lemma shows that this does not reduce the connected vertex cover size in the subtree by more than twice the size of the separator.

▶ **Lemma 16.** *Let G be a connected graph and let $X \subseteq V(G)$. Given a connected vertex cover S of G_X where G_X is obtained from X by identifying all vertices from X into a single vertex z, there is a polynomial-time algorithm that finds a connected vertex cover S' of size at most $|S| + 2|X|$ of G.*

Proof. Let S be a connected vertex cover of G_X. Let $S'' := S \cup X \setminus \{z\}$. Observe that S'' is a vertex cover of G, such that every connected component of $G[S'']$ contains at least one vertex from X; thus, there are at most $|X|$ connected components. If $G[S'']$ is connected, we are done. Otherwise, we show that there is a single vertex $v \in V(G)$ such that $G[S'' \cup \{v\}]$ has strictly fewer connected components than $G[S'']$. It is then straightforward to obtain S' by repeatedly adding such a vertex, until $G[S'']$ is connected. For any vertex $u \in S''$ define C_u as the connected component of vertex u in $G[S'']$.

Let x and x' be in two distinct components in $G[S'']$, consider the shortest path P from x to x' in G. Refer to Figure 1 for a sketch of the situation. By this definition, $C_x \neq C_{x'}$. Let y be the first vertex in P such that $y \in S''$ but $y \notin C_x$, let y' be the vertex on P before

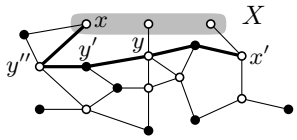

Figure 1 A graph with a vertex cover S'' (indicated in white) that is connected when all vertices in X are identified into a single vertex. Shown are x, x',y,y',y'', and P (indicated in bold) as used in the proof of Lemma 16.

y, observe that $y' \notin S''$ since otherwise $y' \in S''$ and $y' \notin C_x$ which is a contradiction with the fact that y is the first such vertex in P. Let y'' be the vertex on the path before y', such that $P = (x, \ldots, y'', y', y, \ldots, x')$, where possibly $x = y''$ or $y = x'$. Observe that $y'' \in S''$ as otherwise edge $\{y'', y'\}$ is not covered, and therefore $y'' \in C_x$ since y is the first vertex on P that is in S'' but not in C_x. Therefore, adding vertex y' to S'' will merge connected components C_x and C_y, such that the number of connected components in $G[S'' \cup \{y'\}]$ is strictly smaller than the number of connected components in $G[S'']$. In total, we add less than $|X|$ vertices to S'' obtain a connected vertex cover S' and thus $|S'| \leq |S| + |X|$. ◀

We now prove the main result of this section.

▶ **Theorem 17.** *For every $0 < \varepsilon \leq 1$, Connected Vertex Cover parameterized by treewidth ℓ has a $(1+\varepsilon)$-approximate Turing Kernel with $\mathcal{O}((\frac{\ell^2}{\varepsilon})^{\lceil \frac{3+\varepsilon}{\varepsilon} \rceil})$ vertices.*

Proof. We will use the PSAKS for Connected Vertex Cover from Theorem 15. Recall that such a PSAKS consists of a reduction algorithm $R_{\mathcal{A}}$ together with a solution lifting algorithm $S_{\mathcal{A}}$. We will use the following claim.

▷ Claim 18. Given $0 < \delta \leq 1$ and a connected graph G with tree decomposition of width ℓ, there is a polynomial-time algorithm to determine a d-approximate solution for CVC or correctly decide that $\mathrm{OPT}_{\mathrm{CVC}}(G) > \frac{100\ell^2}{\delta}$, when given access to a c-approximate CVC-oracle that allows calls using graphs with at most $\mathcal{O}((\frac{\ell^2}{\delta})^{\lceil \frac{1+\delta}{\delta} \rceil})$ vertices, where $d = \min(c \cdot (1+\delta), 2)$.

Proof. Using the fact that CVC is 2-approximable in polynomial time [33], obtain a 2-approximate solution $\tilde{S}$ in G. If $|\tilde{S}| > 200\ell^2/\delta$, return NO and halt. Otherwise, continue by running $R_{\mathcal{A}}$ on $(G, |\tilde{S}|)$ to obtain (G', k'). Observe that G' has at most $\mathcal{O}((\frac{\ell^2}{\delta})^{\lceil \frac{1+\delta}{\delta} \rceil})$ many vertices. Apply the c-approximate oracle on G' to obtain CVC S' in G'. Obtain an approximate solution S in G by using the solution lifting algorithm on G' and S'. Output the smallest solution of S and $\tilde{S}$, let this be $\hat{S}$. We show that this has the desired approximation factor, which requires an argument since the PSAKS works for $\mathrm{CVC}^{\perp}$ instead of CVC (recall $\mathrm{CVC}^{\perp}(G, k, S) = \min\{k+1, \mathrm{CVC}(G, S)\}$). Observe that $|\hat{S}| \leq |\tilde{S}|$, by definition. Therefore, $|\hat{S}| \leq \mathrm{CVC}^{\perp}(G, |\tilde{S}|, S)$. Thus

$$\frac{|\hat{S}|}{\mathrm{OPT}_{\mathrm{CVC}}(G)} \leq \frac{\mathrm{CVC}^{\perp}(G, |\tilde{S}|, S)}{\mathrm{OPT}_{\mathrm{CVC}}(G)} \leq \frac{\mathrm{CVC}^{\perp}(G, |\tilde{S}|, S)}{\mathrm{OPT}_{\mathrm{CVC}^{\perp}}(G, |\tilde{S}|)}.$$

By correctness of the solution lifting algorithm, we get

$$\frac{\mathrm{CVC}^{\perp}(G, |\tilde{S}|, S)}{\mathrm{OPT}_{\mathrm{CVC}^{\perp}}(G, |\tilde{S}|)} \leq (1+\delta)\frac{\mathrm{CVC}^{\perp}(G', k', S')}{\mathrm{OPT}_{\mathrm{CVC}^{\perp}}(G', k')} \leq (1+\delta)\frac{|S'|}{\mathrm{OPT}_{\mathrm{CVC}}(G')} \leq c \cdot (1+\delta),$$

by correctness of the oracle. ◁

Algorithm. The algorithm now proceeds as follows. Our goal is to find a subtree of T for which on the one hand, the local optimum CVC is small enough to find an approximate solution using Claim 18, but also large enough to be able to (among other things) add the entire set X_t to the solution, without introducing a too large error. Let $\delta := \varepsilon/3$.

For any vertex $t \in V(T)$, let G_t be the graph given by $G[V_t]$ after identifying all vertices from X_t into a single vertex z_t. Apply Claim 18 to G, if it returns an approximate connected vertex cover of G, we are done. Otherwise, $\mathrm{OPT}_{\mathrm{CVC}}(G) > \frac{100\ell^2}{\delta}$. We now aim to find a vertex t such that Claim 18 returns an approximate solution in G_t of size at least $\frac{10\ell}{\delta}$.

▷ Claim 19. There is a polynomial-time algorithm that, given G with tree decomposition $\mathcal{T}$ of width ℓ such that $\mathrm{OPT}_{\mathrm{CVC}}(G) > \frac{100\ell^2}{\delta}$, finds $t \in V(T)$ for which Claim 18 returns an approximate solution S_t with $|S_t| \geq \frac{10\ell}{\delta}$, using calls to a c-approximate oracle of size at most $\mathcal{O}((\frac{\ell^2}{\delta})^{\lceil \frac{1+\delta}{\delta} \rceil})$.

Proof. Start with $t := r$, note that since $\mathrm{OPT}_{\mathrm{CVC}}(G) > \frac{100\ell^2}{\delta}$ and $G_r = G$, we have that $\mathrm{OPT}_{\mathrm{CVC}}(G_r) > \frac{100\ell^2}{\delta}$, where r is the root of T. We search through the graph maintaining $\mathrm{OPT}_{\mathrm{CVC}}(G_t) > \frac{100\ell^2}{\delta}$. Let $t_1, \ldots, t_m$ be the children of t, recall that we may assume $m \leq 2\ell + 2$ by Theorem 3. For each t_i, apply Claim 18. Consider the following possibilities.

- There exists $i \in [m]$ such that the claim determines $\mathrm{OPT}_{\mathrm{CVC}}(G_{t_i}) > \frac{100\ell^2}{\delta}$, in this case, recurse with this t_i.
- There exists $i \in [m]$ such that the claim returns a $\min\{2, (1+\delta)\cdot c\}$-approximate solution S_{t_i} of size at least $\frac{10\ell}{\delta}$ for CVC. In this case, return $t := t_i$.
- Otherwise. Thus, for every $i \in [m]$, the algorithm returns a connected vertex cover S_i of size at most $\frac{10\ell}{\delta}$ for CVC in G_{t_i}. Obtain a connected vertex cover S'_i of $G[V_{t_i}]$ of size at most $|S_i| + 2(\ell+1)$ using Lemma 16. We will argue that in this case $CVC(G_t) < \frac{55\ell^2}{\delta}$, which is a contradiction. We obtain a connected vertex cover of G_t as follows. Let $\hat{S}_t := \bigcup_{i\in[m]}(S'_i) \cup \{z_t\}$. Observe that $\hat{S}_t$ has size at most $(2\ell+2)\cdot\frac{13\ell}{\delta} + 1 \leq \frac{55\ell^2}{\delta}$. It is easy to observe that $\hat{S}_t$ is indeed a connected vertex cover of G_t.

Observe that from the steps above, we always get a connected vertex cover S_t of G_t, that is a $(1+\delta)\cdot c$-approximation of $\mathrm{OPT}_{\mathrm{CVC}}(G_t)$ and has size at least $\frac{10\ell}{\delta}$. ◁

Using Claim 19, we obtain a node t and a connected vertex cover S_t of G_t, that is a $\min\{(1+\delta)\cdot c, 2\}$-approximation of $\mathrm{OPT}_{\mathrm{CVC}}(G_t)$ and has size at least $\frac{10\ell}{\delta}$. Use Lemma 16 to obtain a connected vertex cover S'_t of $G[V_t]$ of size at most $|S_t| + 2(\ell+1)$, containing X_t.

We now obtain graph G' by removing all vertices in $V_t \setminus X_t$ from G and then contracting all vertices in X_t to a single vertex z_t. Let $\mathcal{T}'$ to be a tree decomposition of G', one may obtain $\mathcal{T}'$ by replacing occurrences of vertices in V_t by z_t in $\mathcal{T}$. Since G' is strictly smaller than G, we may use the algorithm described above to obtain a $c\cdot(1+\varepsilon)$-approximate solution S' for $\mathrm{OPT}_{\mathrm{CVC}}(G')$, using $\mathcal{T}'$. Output $S := S' \cup S'_t \setminus \{z_t\}$.

Correctness. We start by showing that S is a connected vertex cover. Verify that it is indeed a vertex cover of G: any edge within G' is covered as $S' \subseteq S$, any edge in G_t is covered since $S'_t \subseteq S$ and any other edge has at least one endpoint in $X_t \subseteq S$ and is thereby covered. It remains to verify that $G[S]$ is connected. Clearly, $G[V_t \cap S]$ is connected since it corresponds to $G[S'_t]$. Let $\tilde{G} := G - (V_t \setminus X_t)$. We show that every connected component of $\tilde{G}[S]$ contains at least one vertex from X_t, such that the entire graph is connected as $X_t \subseteq S$ and the vertices in X_t are in the same connected component as observed earlier. Suppose not, let C be such a component not containing any vertex in X_t. Consider $G'[S']$. Observe that C is also a connected component of $G'[S']$. Furthermore, vertex z_t is not adjacent to

any vertex in C, as otherwise there is an edge from some vertex in C to some vertex in X_t in $\tilde{G}$, since $X_t \subseteq S$ this contradicts that C contains no vertex from X_t. Since G' is connected however, z_t has an incident edge $\{z_t, u\}$ for some $u \in V(G')$ and thus $u \in S'$ or $z_t \in S'$. In both cases there is a vertex in S' that is not in connected component C, a contradiction with the assumption that S' is a connected vertex cover of G'.

We now show that we indeed achieve the desired approximation factor.

▷ Claim 20. $|S| \leq c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{CVC}}(G)$

Proof. Let S^* be a minimum connected vertex cover of G. Assume for now $|S^* \cap V(G_t)| \geq 4/\delta$.

$$\begin{aligned}|S| &\leq |S'_t| + |S'| \\ &\leq |S_t| + 2(\ell+1) + c \cdot (1+\varepsilon)\mathrm{OPT}_{\mathrm{CVC}}(G')\end{aligned}$$

Using $|S_t| \geq \frac{10\ell}{\delta}$

$$\begin{aligned}&\leq |S_t| + \frac{\delta}{2}|S_t| + c \cdot (1+\varepsilon)\mathrm{OPT}_{\mathrm{CVC}}(G') \\ &\leq c \cdot (1+\delta)(1+\delta/2)\mathrm{OPT}_{\mathrm{CVC}}(G_t) + c \cdot (1+\varepsilon)|(S^* \cap V(G')) \cup \{z_t\}| \\ &\leq c \cdot (1+\delta)(1+\delta/2)|(S^* \cap V(G_t)) \cup \{z_t\}| + c \cdot (1+\varepsilon)|(S^* \cap V(G')) \cup \{z_t\}| \\ &\leq c \cdot (1+\delta)(1+\delta/2)(|S^* \cap V(G_t)| + 1) + c \cdot (1+\varepsilon)|(S^* \cap V(G')) \cup \{z_t\}|\end{aligned}$$

By assuming $|S^* \cap V(G_t)| \geq 4/\delta$, and then using $\delta = \varepsilon/3$

$$\begin{aligned}&\leq c \cdot (1+\delta)(1+\delta/2)(1+\delta/4)(|S^* \cap V(G_t)|) + c \cdot (1+\varepsilon)|(S^* \cap V(G')) \cup \{z_t\}| \\ &\leq c \cdot (1+\varepsilon)(|S^* \cap V(G_t)|) + c \cdot (1+\varepsilon)|(S^* \cap V(G')) \cup \{z_t\}|\end{aligned}$$

Observe that since G_t and G' are non-empty, S^* must contain a vertex from X_t

$$\leq c \cdot (1+\varepsilon)|S^*| = c \cdot (1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{CVC}}(G).$$

It remains to observe that $|S^* \cap V(G_t)| \geq 4/\delta$ is a reasonable assumption. Suppose not, then $\mathrm{OPT}_{\mathrm{CVC}}(G_t) \leq |S^* \cap V(G_t)| + 1 \leq 4/\delta + 1$. However, $S_t \geq \frac{10\ell}{\delta} \geq 2 \cdot \mathrm{OPT}_{\mathrm{CVC}}(G_t)$, meaning that S_t is not a 2-approximation in G_t, which is a contradiction. ◁

Having shown the correctness of the procedure, it remains to argue the size of this Turing kernel. Observe that the oracle is only used when applying Claim 18. As such, we may bound the size of the kernel by $\mathcal{O}((\frac{\ell^2}{\delta})^{\lceil \frac{1+\delta}{\delta} \rceil}) = \mathcal{O}((\frac{\ell^2}{\varepsilon})^{\lceil \frac{3+\varepsilon}{\varepsilon} \rceil})$, recall that $\delta = \frac{\varepsilon}{3}$. ◀

4 Meta result

In this section we will describe a wide range of graph problems for which approximate Turing kernels can be obtained. The problems we will consider satisfy certain additional constraints, such that the general strategy already described for the Vertex Cover problem can be applied. Informally speaking, we need the following requirements. First of all, the problems should behave nicely with respect to taking the disjoint union of graphs. Secondly, we want to look at what happens for induced subgraphs. We will only consider problems whose value cannot increase when taking an induced subgraph. Furthermore, we restrict how much the optimal value can decrease when taking an induced subgraph. Finally, we require existence of a PSAKS and an approximation algorithm for the problem. We use the following definitions.

▶ **Definition 21.** *Let $\varphi\colon \mathbb{R}\times\mathbb{N}\to\mathbb{R}$ be a function. A* φ-approximation algorithm *for a problem $\mathcal{P}$ is a polynomial-time algorithm that, given an instance G with tree decomposition $\mathcal{T}$ of width ℓ, outputs a solution S such that (for minimization problems) $\mathcal{P}(G,S)\leq\varphi(\mathrm{OPT}_{\mathcal{P}}(G),\ell)$, and (for maximization problems) $\varphi(\mathcal{P}(G,S),\ell)\geq\mathrm{OPT}_{\mathcal{P}}(G)$.*

▶ **Definition 22.** *Let $\mathcal{P}$ be an optimization problem whose input is a graph. We will say that it is* friendly *if it satisfies the following conditions.*

1. *For all graphs G, G_1, and G_2 such that G is the disjoint union of graphs G_1 and G_2, $\mathrm{OPT}_{\mathcal{P}}(G)=\mathrm{OPT}_{\mathcal{P}}(G_1)+\mathrm{OPT}_{\mathcal{P}}(G_2)$. In particular, if S_1 is a solution for G_1 and S_2 is a solution for G_2, then $S_1\cup S_2$ is a solution for G and*

$$\mathcal{P}(G,S_1\cup S_2)=\mathcal{P}(G_1,S_1)+\mathcal{P}(G_2,S_2).$$

   In the other direction, given solution S in G it can efficiently be split into solutions S_1 in G_1 and S_2 in G_2 satisfying the above. For consistency, we require that the size of the optimal solution in the empty graph is zero.
2. *There exists a non-decreasing polynomial function f such that for all graphs G, for all $X\subseteq V(G)$:*

$$\mathrm{OPT}_{\mathcal{P}}(G)\leq\mathrm{OPT}_{\mathcal{P}}(G-X)+f(|X|),\text{ and }\mathrm{OPT}_{\mathcal{P}}(G-X)\leq\mathrm{OPT}_{\mathcal{P}}(G).$$

   In particular, for minimization problems there is a polynomial-time algorithm $\mathcal{A}$ that, given a solution S' in $G-X$, outputs a solution S for G such that $\mathcal{P}(G,S)\leq\mathcal{P}(G-X,S')+f(|X|)$. For maximization problems we require that any solution S for $G-X$ is also a solution for G and $\mathcal{P}(G,S)=\mathcal{P}(G-X,S)$.
3. *$\mathcal{P}^{\perp}$ parameterized by $k+\ell$, where k is the solution value and ℓ is the treewidth, has a $(1+\delta)$-approximate kernel for all $\delta>0$, that has $h(\delta,k+\ell)$ vertices for some function h that is polynomial in its second parameter.*
4. *$\mathcal{P}$ has a φ-approximation algorithm for some polynomial function φ such that $\alpha\cdot\varphi(k,\ell)<\varphi(\alpha\cdot k,\ell)$ for all $\alpha>1$, and φ is non-decreasing in its first parameter.*

Observe that many well-known vertex subset problems fit in this framework. As an example, let us verify them for the Vertex Cover problem. The first point is immediate. For the second point, let $\mathcal{A}(G,X,S)$ output $S':=S\cup X$. Verify that indeed this satisfies the conditions with $f(|X|)=|X|$. The third point follows with some extra work from the fact that Vertex Cover has a kernel with $2k$ vertices, this kernel can then be shown to be 1-approximate. For the last point, it is well-known that Vertex Cover has a 2-approximation algorithm.

▶ **Lemma 23 (★).** *Let $\mathcal{P}$ be a friendly graph optimization problem. There is a polynomial-time algorithm $\mathcal{B}$ with access to a c-approximate oracle. It takes as input a graph G with nice tree decomposition $\mathcal{T}$ of width ℓ and a number $0<\delta\leq 1$, and outputs either*

- *a node t such that $\mathrm{OPT}_{\mathcal{P}}(G[V_t\setminus X_t])\geq\frac{f(\ell+1)}{\delta}$ together with a $(c\cdot(1+\delta))$-approximate solution S_t to $\mathcal{P}$ in $G[V_t\setminus X_t]$, or*
- *a $c\cdot(1+\delta)$-approximate solution for G,*

using calls to the oracle on graphs with at most $h(\delta,\varphi(k,\ell)+\ell)$ vertices, where $k=\frac{2f(\ell+1)}{\delta}+f(1)$.

We will prove the result separately for maximization and minimization problems (see [24, Lemma 25] for the minimization case).

Proof of Lemma 23: Maximization problems. Let r be the root of $\mathcal{T}$, and observe that $G = G[V_r \setminus X_r]$ since $X_r = \emptyset$. Let $k := \frac{2f(\ell+1)}{\delta} + f(1)$. Compute a φ-approximate solution $\tilde{S}$ in G. We do a case distinction on the value of this solution.

If $\mathcal{P}(G, \tilde{S}) \leq k$, then apply the PSAKS with approximation ratio $1+\delta$ to $(G, \varphi(k,\ell)+\ell)$ and obtain instance (G', k') with at most $h(\delta, \varphi(k,\ell)+\ell)$ vertices. Obtain solution S' by applying the c-approximate oracle on G'. Apply the solution lifting algorithm to S' to obtain a solution S for G. We start by showing that S is the desired approximate solution. Clearly, $\mathcal{P}(G', S') \geq \frac{1}{c} \cdot \mathrm{OPT}_{\mathcal{P}}(G')$ by correctness of the oracle. If $\mathcal{P}(G', S') > k'$, then $\mathcal{P}^{\perp}(G', k', S') = k' + 1$ and thus $\mathcal{P}^{\perp}(G', k', S') \geq \mathrm{OPT}_{\mathcal{P}^{\perp}}(G', k')$. Otherwise, we have $\mathcal{P}^{\perp}(G', k', S') = \mathcal{P}(G', S') \geq \frac{1}{c} \cdot \mathrm{OPT}_{\mathcal{P}}(G') \geq \frac{1}{c} \cdot \mathrm{OPT}_{\mathcal{P}^{\perp}}(G', k')$. From the properties of the solution lifting algorithm, it now follows that $\mathcal{P}^{\perp}(G, \varphi(k,\ell)+\ell, S) \geq \frac{1}{c(1+\delta)}\mathrm{OPT}_{\mathcal{P}^{\perp}}(G, \varphi(k,\ell)+\ell)$. Observe that since $\mathcal{P}(G, \tilde{S}) \leq k$ and φ non-decreasing in its first parameter, we get that $\mathrm{OPT}_{\mathcal{P}}(G) \leq \varphi(\mathcal{P}(G, \tilde{S}), \ell) \leq \varphi(k, \ell)$ and thereby $\mathrm{OPT}_{\mathcal{P}}(G) = \mathrm{OPT}_{\mathcal{P}^{\perp}}(G, \varphi(k,\ell)+\ell)$. It follows that $\mathcal{P}(G, S) \geq \mathcal{P}^{\perp}(G, \varphi(k,\ell)+\ell, S) \geq \frac{1}{c(1+\delta)}\mathrm{OPT}_{\mathcal{P}^{\perp}}(G, \varphi(k,\ell)+\ell) = \frac{1}{c(\delta+1)}\mathrm{OPT}_{\mathcal{P}}(G)$.

Suppose $\mathcal{P}(G, \tilde{S}) > k$. For every node $t \in T$, compute a φ-approximate solution $\tilde{S}_t$ for graph $G[V_t \setminus X_t]$. We start by showing how to find a node $t \in V(T)$ such that both $\mathcal{P}(G[V_t \setminus X_t], \tilde{S}_t) \leq k$, and $\mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) \geq \frac{f(\ell+1)}{\delta}$. Start by observing that for the leaf vertices, it holds that $\mathcal{P}(G[V_t \setminus X_t], \tilde{S}_t) = 0 \leq k$. On the other hand, for the root, we found that $\mathcal{P}(G[V_r \setminus X_r], \tilde{S}_r) = \mathcal{P}(G, \tilde{S}) > k$. As such, we can find a node p such that $\mathcal{P}(G[V_p \setminus X_p], \tilde{S}_p) > k$, while for all of its children t it holds that $\mathcal{P}(G[V_t \setminus X_t], \tilde{S}_t) \leq k$. We show that one of the children of p has the desired properties. The result that $\mathcal{P}(G[V_t \setminus X_t], \tilde{S}_t) \leq k$ for all children of p is immediate. On the other hand, observe that $\mathrm{OPT}_{\mathcal{P}}(G[V_p \setminus X_p]) \geq \mathcal{P}(G[V_p \setminus X_p], \tilde{S}_p) \geq k \geq \frac{2f(\ell+1)}{\delta}$, by assumption. We do a case distinction on the type of node that p is in the nice tree decomposition.

- p is an introduce or forget node. In this case, p has exactly one child t and $V_t \setminus X_t = V_p \setminus X_p$, or $V_t \setminus X_t = (V_p \setminus X_p) \setminus \{v\}$ for some $v \in V(G)$. Since $\mathcal{P}$ is friendly, we get that $\mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) \geq \mathrm{OPT}_{\mathcal{P}}(G[V_p \setminus X_p]) - f(1) \geq \frac{f(\ell+1)}{\delta}$.
- p is a join node. In this case, p has exactly two children t_1 and t_2 and $G[V_p \setminus X_p]$ is the disjoint union of $G[V_{t_1} \setminus X_{t_1}]$ and $G[V_{t_2} \setminus X_{t_2}]$. Obtain S_1 and S_2 such that $\tilde{S}_p = S_1 \cup S_2$ and S_1 is a solution in $G[V_{t_1} \setminus X_{t_1}]$, S_2 in $G[V_{t_2} \setminus X_{t_2}]$, and $\mathcal{P}(G[V_p \setminus X_p], \tilde{S}_p) = \mathcal{P}(G[V_{t_1} \setminus X_{t_1}], S_1) + \mathcal{P}(G[V_{t_2} \setminus X_{t_2}], S_2)$. This can be done since $\mathcal{P}$ is friendly.
  Therefore, there is $i \in [2]$ such that $\mathrm{OPT}_{\mathcal{P}}(G[V_{t_i} \setminus X_{t_i}]) \geq \mathcal{P}(G[V_{t_i} \setminus X_{t_i}], S_i) \geq \mathcal{P}(G[V_p \setminus X_p], \tilde{S}_p)/2 \geq \frac{f(\ell+1)}{\delta}$.

So, we have obtained a node t such that $\mathcal{P}(G[V_t \setminus X_t], \tilde{S}_t) \leq k$, and $\mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) \geq \frac{f(\ell+1)}{\delta}$. We now show how to obtain S_t. Apply the PSAKS with ratio $1+\delta$ to $(G[V_t \setminus X_t], \varphi(k,\ell)+\ell)$ and obtain instance (G', k'). Apply the c-approximate oracle on G' to obtain a solution S''. Apply the solution lifting algorithm to S'' to obtain solution S_t in $G[V_t \setminus X_t]$. With similar arguments as before, S_t is a $c(1+\delta)$-approximate solution in $G[V_t \setminus X_t]$. Output t and S_t. ◀

The next theorem gives a polynomial-size $(1+\varepsilon)$-approximate Turing kernel with parameter treewidth for any friendly optimization problem $\mathcal{P}$. The Turing kernel follows the same ideas as the Turing kernels presented earlier in this paper, using Lemma 23 to find a node in the tree decomposition where we can split the graph.

▶ **Theorem 24 (★).** *Let $\mathcal{P}$ be a friendly optimization problem on graphs. Then $\mathcal{P}$ parameterized by treewidth has a $(1+\varepsilon)$-approximate Turing kernel with $h(\frac{\varepsilon}{3}, \varphi(\frac{6f(\ell+1)}{\varepsilon} + f(1), \ell) + \ell)$ vertices, for all $0 < \varepsilon \leq 1$.*

While the description of the Turing kernel is mostly the same for maximization and minimization problems, the correctness proof will differ quite significantly. Therefore, these cases will be proven separately, the proof for minimization problems can be found in the full version of the paper.

Proof of Theorem 24: Maximization problems. Let $\mathcal{P}$ be a friendly maximization problem. We show that Algorithm 3 is the desired approximate Turing kernel, where we let $\mathcal{A}(G, X_t, S' \cup S_t)$ return $S' \cup S_t$.

Algorithm 3 An approximate Turing kernel for friendly optimization problems $\mathcal{P}$.

procedure ApproxP$(G, \mathcal{T}, \varepsilon)$
  Turn $\mathcal{T}$ into a nice tree decomposition
  Apply Lemma 23 for $\delta := \varepsilon/3$
  if this outputs an approximate solution S for G **then**
    return S
  else // *We obtained $t \in V(T)$, $c(1+\delta)$-approximate solution S_t for $\mathcal{P}$ in $G[V_t \setminus X_t]$ such that* $\mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) \geq \frac{f(\ell+1)}{\delta}$
    Let $G' := G - V_t$.
    Obtain $\mathcal{T}'$ from $\mathcal{T}$ by removing the subtree rooted at t and all vertices in X_t
    Let $S' :=$ ApproxP$(G', \mathcal{T}', \varepsilon)$
    return $S := \mathcal{A}(G, X_t, S' \cup S_t)$
  end if
end procedure

It is easy to see that since $\mathcal{P}$ is friendly, the algorithm indeed returns a correct solution for $\mathcal{P}$ in G, it remains to prove the size bound.

$$\begin{aligned}
\mathrm{OPT}_{\mathcal{P}}(G) &\leq \mathrm{OPT}_{\mathcal{P}}(G - X_t) + f(\ell+1) \\
&= \mathrm{OPT}_{\mathcal{P}}(G - V_t) + \mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) + f(\ell+1) \\
&\leq \mathrm{OPT}_{\mathcal{P}}(G - V_t) + (1+\delta) \cdot \mathrm{OPT}_{\mathcal{P}}(G[V_t \setminus X_t]) \\
&\leq c \cdot (1+\varepsilon) \cdot \mathcal{P}(G - V_t, S') + c \cdot (1+\delta)^2 \cdot \mathcal{P}(G[V_t \setminus X_t], S_t) \\
&\leq c \cdot (1+\varepsilon) \cdot (\mathcal{P}(G - V_t, S') + \mathcal{P}(G[V_t \setminus X_t], S_t)) \\
&= c \cdot (1+\varepsilon) \cdot (\mathcal{P}(G - X_t, S' \cup S_t)) = c \cdot (1+\varepsilon) \cdot (\mathcal{P}(G, S' \cup S_t)).
\end{aligned}$$

◀

4.1 Consequences

We show that a number of considered problems are friendly in the next lemma.

▶ **Lemma 25.** *The following problems are friendly (with respect to the following bounds).*

- Independent Set *with* $f(x) = x$, $h(\delta, m) = (m+1)^2$, $\varphi(s, \ell) = (\ell+1) \cdot s$.
- Vertex-Disjoint H-packing *for connected graphs* H, *with* $|V(H)|$ *constant, with* $f(x) = x$, $h(\delta, k) = \mathcal{O}(k^{|V(H)|-1})$, $\varphi(s, \ell) = |V(H)| \cdot s$.
- Vertex Cover *with* $f(x) = x$, $h(\delta, k) = 2k$, $\varphi(s, \ell) = 2s$.
- Clique Cover *with* $f(x) = x$, $h(\delta, m) = m(m+1)$, $\varphi(s, \ell) = (\ell+1) \cdot s$
- Feedback Vertex Set *with* $f(x) = x$, $h(\delta, k) = 4k^2$, $\varphi(s, \ell) = 2s$.
- Edge Dominating Set *with* $f(x) = x$, $h(\delta, k) = 4k^2 + 4k$, $\varphi(s, \ell) = 2s$.

Proof.

Independent Set. Clearly, if G is the disjoint union of two graphs G_1 and G_2, then the union of an independent set in G_1 and an independent set in G_2 forms an independent set in G. Conversely, restricting an independent set in G to $V(G_1)$ (respectively $V(G_2)$) results in an independent set in G_1 (respectively, G_2). Furthermore, if X is a subset of G it is easy to verify that $\mathrm{OPT}_{\mathrm{IS}}(G) \leq \mathrm{OPT}_{\mathrm{IS}}(G-X) + |X|$ and that $\mathrm{OPT}_{\mathrm{IS}}(G-X) \leq \mathrm{OPT}_{\mathrm{IS}}(G)$ as any independent set in $G-X$ is an independent set in G. The PSAKS parameterized by $m := k+\ell$ is as follows. It is known that any graph of treewidth ℓ has an independent set of size at least $|V(G)|/(\ell+1)$. This can be seen from the fact that such graphs are ℓ-degenerate, meaning that there is an order of the vertices $v_1, \ldots, v_n$ such that v_i has degree at most ℓ in $G[v_1, \ldots, v_i]$. As such, an independent set of size $|V(G)|/(\ell+1)$ can be greedily constructed.

Thus, if $|V(G)| > (m+1)^2$, we simply let G' be the graph consisting of an independent set of size $m+1$. The solution lifting algorithm can then simply find a size-$(m+1)$ independent set and output it. This is always an optimal solution for $\mathcal{P}^{\perp}$, since it does not distinguish between solutions of size larger than m. Otherwise, we obtain that $|V(G)| \leq (m+1)^2$ and the PSAKS will not modify G. In both cases, we output a graph on at most $(m+1)^2$ vertices.

It remains to show that there is an approximation algorithm, the idea is equivalent to the PSAKS. Return an independent set in G of size at least $|V(G)|/(\ell+1)$. Then indeed $\varphi(|V(G)|/(\ell+1), \ell) = |V(G)| \geq \mathrm{OPT}_{\mathrm{IS}}(G)$.

Vertex-Disjoint H-Packing. Requirements 1 and 2 are easily verified for $f(|X|) = |X|$, as any vertex in X could be contained in at most one graph in any copy of H.

A simple approximation algorithm for Vertex-Disjoint H-Packing is to simply return any maximal H-packing S. We show that $|S| \geq \frac{1}{|V(H)|}\mathrm{OPT}_{\mathcal{P}}(G)$, such that this is an φ-approximation algorithm with $\varphi(s,\ell) = |V(H)| \cdot s$. Suppose there is an optimal solution S^* with $|S^*| > |V(H)| \cdot |S|$. Since the copies of H in S are vertex-disjoint, S uses exactly $|V(H)| \cdot |S|$ vertices. Since S^* contains more than $|V(H)| \cdot |S|$ elements, it follows that there is $s \in S^*$ that uses no vertices used by S, contradicting that S is maximal.

The existence of a PSAKS is shown in [24, Lemma 31, Appendix A].

Vertex Cover. Requirements 1 and 2 are easily verified for vertex cover, let algorithm $\mathcal{A}$ simply output the union of the given solution with set X. As (implicitly) observed in the proof of Lemma 8, Vertex Cover has a 1-approximate kernel of size $2k$. Furthermore, it is well-known to be 2-approximable.

Clique Cover. Requirement 1 is easy to verify. We show Requirement 2. Let $X \subseteq V(G)$. Let S be a clique cover of G, it is easy to see that $\{s \setminus X \mid s \in S\}$ is a clique cover of $G-X$, of size at most $|S|$. Therefore, $\mathrm{OPT}_{\mathcal{P}}(G) \geq \mathrm{OPT}_{\mathcal{P}}(G-X)$. Furthermore, let algorithm $\mathcal{A}$ when given G, clique cover S of $G-X$ and X output the clique cover $S \cup \{\{x\} \mid x \in X\}$. Then this is a clique cover of G and it has size at most $|S| + |X| \leq |S| + f(|X|)$.

To show Requirement 3, we obtain a 1-approximate kernel for Clique Cover in a somewhat similar way as for Independent Set. Observe that any n-vertex graph with treewidth ℓ has a minimum clique cover of size at least $\frac{n}{\ell+1}$. So, given G and parameter $m := k+\ell$, if $n > m(m+1) \geq k \cdot (\ell+1)$, we know for sure that G does not have a minimum clique cover of size k. The reduction algorithm reduces G to an independent set of size $m+1$. The solution lifting algorithm (irrespective of the solution given for G') outputs $V(G)$. Otherwise, if $n \leq m(m+1)$ we simply let G be the output of the reduction algorithm. Since the graph does not change, the solution lifting algorithm simply outputs the solution it is given. In both cases, the reduced instance has size at most $m(m+1)$.

It remains to verify that there is a φ-approximation algorithm for Clique Cover. Given a graph G of treewidth ℓ, we simply output $\{\{v\} \mid v \in V(G)\}$. Clearly, this is a valid clique cover of G of size $|V(G)|$. Observe that since G has treewidth ℓ, G contains no cliques of size larger than $\ell+1$, thus any clique in the optimal clique cover of G covers at most $\ell+1$ vertices. As such, the optimal solution contains at least $\frac{|V(G)|}{\ell+1}$ cliques, and thus $|S| \leq (\ell+1)\mathrm{OPT}_{\mathcal{P}}(G)$.

Feedback Vertex Set. Requirements 1 and 2 are straightforward to verify. The problem has a 1-approximate kernel with $4k^2$ vertices and therefore a PSAKS by [24, Lemma 29, Appendix A], showing Requirement 3. It is also known that the Feedback Vertex Set problem has a 2-approximation algorithm [2], showing Requirement 4.

Edge Dominating Set. Requirement 1 is again straightforward. For the second requirement, let G be a graph and let $X \subseteq V(G)$. We start by showing that $\mathrm{OPT}_{\mathcal{P}}(G) \geq \mathrm{OPT}_{\mathcal{P}}(G-X)$. Let S be an edge-dominating set in G. We obtain an edge-dominating set S' for $G-X$ as follows. Initialize S' as the set of edges with both endpoints in $V(G) \setminus X$, so $S' := \{e \in S \mid e \cap X = \emptyset\}$. For every edge $\{x,v\} \in S$ with $x \in X, v \notin X$, choose one arbitrary edge $\{u,v\} \in E(G-X)$ and add $\{u,v\}$ to S'. If no such edge exists, do nothing. Clearly, $|S'| \leq |S|$. Furthermore, we show that S' is indeed an edge dominating set. Suppose for contradiction that $e = \{u,v\}$ is not dominated in $G-X$ by S'. Let $\{w,v\} \in S$ be the edge dominating $\{u,v\}$ in G. Then, since $\{w,v\} \notin S'$, we have $w \in X$. But then some edge with endpoint v was added to S', a contradiction.

We continue by showing that $\mathrm{OPT}_{\mathcal{P}}(G) \leq \mathrm{OPT}_{\mathcal{P}}(G-X) + |X|$ and that algorithm $\mathcal{A}$ exists. Let S be a solution for $G-X$, then algorithm $\mathcal{A}$ will output S together with one edge $\{x,v\} \in E(G)$ for all $x \in X$. In the case that $x \in X$ is isolated in G, no edge is added for this vertex. By this definition, the output has size at most $|S|+|X|$. Furthermore, any edge with vertices in $V(G-X)$ is dominated by S. Any edge with at least one endpoint in X is dominated by the additional edges.

Edge Dominating Set has a kernel that outputs a graph G' of size at most $4k^2+4k$ such that G' is an induced subgraph of G and any size-k edge dominating set in G' is also an edge dominating set in G [21]. We can see that this is a 1-approximate kernel. Let the solution lifting algorithm simply output the solution for G' as a solution for G. Since any solution of size at most k in G' is a solution in G, and obviously any solution in G is a solution for G', it is clear that $\mathrm{OPT}_{\mathcal{P}^\perp}(G',k) = \mathrm{OPT}_{\mathcal{P}^\perp}(G,k)$. As such, the approximation ratio is preserved by the solution lifting algorithm.

It is known that even the weighted version of Edge Dominating Set can be 2-approximated [20], such that the problem has a φ-approximation for $\varphi(s,\ell) = 2s$. ◀

As an immediate consequence of Lemma 25 and Theorem 24, we obtain approximate Turing kernels for a large number of graph problems. These results are summarized in the corollary below, the size bounds are obtained by substituting the relevant bounds given by Lemma 25 into Theorem 24.

▶ **Corollary 26.** *The following problems have a polynomial $(1+\varepsilon)$-approximate Turing kernel for all $0 < \varepsilon \leq 1$, of the given size (in number of vertices), when parameterized by treewidth ℓ.*

- *Independent Set, of size $\mathcal{O}(\frac{\ell^4}{\varepsilon^2})$.*
- *Vertex-Disjoint H-packing for connected graphs H, of size $\mathcal{O}((\frac{\ell}{\varepsilon})^{|V(H)|-1})$.*
- *Vertex Cover of size $\mathcal{O}(\frac{\ell}{\varepsilon})$.*
- *Clique Cover of size $\mathcal{O}(\frac{\ell^4}{\varepsilon^2})$.*
- *Feedback Vertex Set of size $\mathcal{O}((\frac{\ell}{\varepsilon})^2)$.*
- *Edge Dominating Set of size $\mathcal{O}((\frac{\ell}{\varepsilon})^2)$.*

We observe that the bounds for Independent Set and Clique Cover can be improved to $\mathcal{O}(\frac{\ell^2}{\varepsilon})$ by a more careful analysis. Instead of using that the problem is friendly and applying Lemma 23, one may simply find t such that the number of vertices in $G[V_t \setminus X_t]$ is between $\frac{(\ell+1)^2}{\delta}$ and $\frac{10(\ell+1)^2}{\delta}$, and use that an optimal solution has size at least $|V(G)|/(\ell+1)$ for graphs of treewidth ℓ. There is no need to apply a kernelization in this case.

5 Conclusion

In this paper we have provided approximate Turing kernels for various graph problems when parameterized by treewidth. Furthermore, we give a general result that can be used to obtain approximate Turing kernels for all friendly graph problems parameterized by treewidth.

While the notion of being friendly captures many known graph problems, some interesting problems do not fit this definition. In particular, it is not clear whether the Dominating Set problem has a polynomial-size constant-factor approximate Turing kernel when parameterized by treewidth. We leave this as an open problem.

Abstract

We present the first fine-grained complexity results on two classic problems on strings. The first one is the k-Median-Edit-Distance problem, where the input is a collection of k strings, each of length at most n, and the task is to find a new string that minimizes the sum of the edit distances from itself to all other strings in the input. Arising frequently in computational biology, this problem provides an important generalization of edit distance to multiple strings and is similar to the multiple sequence alignment problem in bioinformatics. We demonstrate that for any $\varepsilon > 0$ and $k \geq 2$, an $O(n^{k-\varepsilon})$ time solution for the k-Median-Edit-Distance problem over an alphabet of size $O(k)$ refutes the Strong Exponential Time Hypothesis (SETH). This provides the first matching conditional lower bound for the $O(n^k)$ time algorithm established in 1975 by Sankoff.

The second problem we study is the k-Center-Edit-Distance problem. Here also, the input is a collection of k strings, each of length at most n. The task is to find a new string that minimizes the maximum edit distance from itself to any other string in the input. We prove that the same conditional lower bound as before holds. Our results also imply new conditional lower bounds for the k-Tree-Alignment and the k-Bottleneck-Tree-Alignment problems studied in phylogenetics.

1 Introduction

Recent years have seen a remarkable increase in our understanding of the hardness of problems in the complexity class P. By establishing conditional lower bounds based on popular conjectures, researchers have been able to identify which problems are unlikely to yield algorithms significantly faster than what is known, at least not without solving other long-standing open questions. We contribute to this growing body of research here by establishing tight conditional hardness results for the k-Median-Edit-Distance problem. This generalizes the seminal work by Backurs and Indyk in STOC 2015, which showed that conditioned on the Strong Exponential Time Hypothesis (SETH), there does not exist a strongly subquadratic algorithm for computing the edit distance between two strings [10].

▶ **Problem 1** (k-Median-Edit-Distance). *Given a set $\mathcal{S}$ of k strings, each of length at most n, find a string s^* (called a median string) that minimizes the sum of edit distances from the strings in $\mathcal{S}$ to s^*. This sum is called the median edit distance.*

When $k = 2$ this problem is equivalent to the well-known edit distance problem, whose famous dynamic programming solution was first given in 1965 by Vintsyuk [44]. An algorithm for solving this problem on k strings in time $O(n^k)$ was then given by Sankoff in 1975 [41] in the more general context of tree alignment (mutation trees). Since Sankoff's solution, no algorithms with significantly better time complexity have been developed. This is despite the problem being of practical importance as well as the subject of extensive study [29, 30, 33, 38]. Compelling reasons for this were finally given 25 years later by Higuera and Casacuberta in 2000 who showed the NP-completeness of the problem over unbounded alphabets [20]. This result was later strengthened to finite alphabets in [42] and then even to binary alphabets in [39]. In [39] it was also shown that the problem is W[1]-hard in k. This last result implies it is highly unlikely to find an algorithm with time complexity of the form $f(k) \cdot N^{O(1)}$, where N is the sum of the lengths of the k strings. None of these hardness results, however, rule out the possibility of algorithms where the time complexity is of the form $O(n^{k-\varepsilon})$. Nearly five decades after its creation, this paper gives a convincing argument as to why a significant improvement over Sankoff's algorithm is unlikely. Specifically, we show that an $O(n^{k-\varepsilon})$ time algorithm for any $\varepsilon > 0$ would refute SETH. We also prove that the same lower bound holds for a related problem known as the k-Center-Edit-Distance.

▶ **Problem 2** (k-Center-Edit-Distance). *Given a set $\mathcal{S}$ of k strings, each of length at most n, find a string s^* (called a center string) that minimizes the maximum of edit distances from the strings in $\mathcal{S}$ to s^*. The maximum edit distance from s^* to any string in $\mathcal{S}$ is called the center edit distance.*

Like k-Median-Edit-Distance, the k-Center-Edit-Distance problem is known to be NP-complete and W[1]-hard in k [39]. Additionally, k-Center-Edit-Distance has been shown to have an $O(n^{2k})$ time solution [39]. However, ours are the first fine-grained complexity results for both these problems. Finally, we note that our results imply similar conditional lower bounds for two classic tree alignment problems from phylogenetics called k-Tree-Alignment and k-Bottleneck-Tree-Alignment [18, 28, 43, 45]. The k-Tree-Alignment (resp. k-Bottleneck-Tree-Alignment) problem is defined as follows: given a tree $\mathcal{T}$ with k leaves where each leaf is labeled with a string of length n, find an assignment of strings to all internal vertices of $\mathcal{T}$ such that the sum (resp. max) of edit distances between adjacent strings/vertices over all edges is minimal. Note that the median (resp. center) edit distance problem on k strings is a special case of the k-Tree-Alignment (resp. k-Bottleneck-Tree-Alignment) problem, specifically when the tree has only one internal vertex.

1.1 Related Work

Recent progress in the field of fine-grained complexity has given us conditional hardness results for many popular problems. The list of problems includes those related to graphs, computational geometry, and strings [1, 3, 4, 6, 7, 8, 10, 15, 17, 19, 21, 24, 23, 31, 32]. Reductions based on SETH, such as the one considered here, tend to have a very similar structure. The Orthogonal Vectors problem [46] is typically used as an intermediate step in the reduction. The proof we provide here works off a generalized variant of the Orthogonal Vectors problem as used in [2]. Our work contributes to a growing list of conditional lower bounds for string problems which we describe in more detail below.

Along with the SETH-based lower bound for edit distance by Backurs and Indyk in [10], there has been a number of newly appearing conditional lower bounds for string related problems [9, 12, 14, 16]. Bringmann and Künnemann created a framework by which any string problem which allowed for a particular gadget construction has similar SETH-based lower bounds proven for it [13]. This framework includes the problems of the longest common subsequence, dynamic time warping, and edit distance under a binary alphabet (less than the four symbols used in the original reduction by Backurs and Indyk). Further work to extend these types of lower bounds to more than two strings was undertaken in [2], where it was shown that an algorithm which could find the longest common subsequence on k strings in time $O(n^{k-\varepsilon})$ for any $\varepsilon > 0$ would refute SETH. The study of conditional hardness of problems on k strings also includes [22], where the longest common increasing subsequence on k strings, k-LCIS, was studied. Likewise in [7] the local alignment problem on k strings under sum of pairs was considered. In both of the last two works mentioned, it was shown that an $O(n^{k-\varepsilon})$ algorithm would refute SETH.

Another notable achievement in this direction is in [5], where it was shown that it is possible to weaken the assumptions used to achieve many of these results. They showed that under much weaker conjectures than SETH regarding circuit complexity, many of the same hardness results still hold. In fact, for any problem where the gadgetry of Bringmann and Künnemann can be applied, having a strongly sub-quadratic time algorithm would have drastic implications for our ability to solve satisfiability problems on Boolean circuits much more complex than those required for 3-SAT. Furthermore, their work also demonstrated that if one could shave off arbitrarily large logarithmic factors, it would have drastic implications in the field of circuit complexity. In this same work, they showed that their reduction from branching programs to string problems can be adapted to k-LCS, implying circuit-based hardness results apply for LCS on k strings.

There exists a close relationship between LCS and edit distance on two strings. Namely, on two strings of lengths n and m, the edit distance with only the insertion and deletion operations is equal to $n + m - 2\ell$, where ℓ is the length of the strings' longest common subsequence. For more than two strings, such a clear relationship (in terms of just lengths and number of edits) seems unlikely. In fact, there exist collections of k strings where the lengths of the longest common subsequences are equal, but the median edit distances are not, e.g., with $k = 3$ and $n \geq 1$, the sets $\{a^n, a^n, b^n\}$ and $\{a^n, b^n, c^n\}$ both have a longest common subsequence of length zero, while the first has median edit distance n and the second has median edit distance $2n$. Because of this, it seems difficult to parlay the hardness results proven for k-LCS into hardness results for k-Median-Edit-Distance, even under only insertions and deletions. Hence, the hardness of k-Median-Edit-Distance was left open. On the other hand, a 2-approximation for k-Median-Edit-Distance can be easily obtained in $O(k^2n^2)$ time: simply choose the string within the collection that minimizes the sum of edit distances from itself to the other strings.

The problem of finding the center string of a set of k strings, the string which minimizes the maximum distance from itself to any string in the set, has more often been studied under the Hamming distance metric than the edit distance metric. In this context the problem is typically called the closest string problem [25, 27, 35, 36]. The problem under the Hamming distance metric is NP-complete [34], whereas the median version under Hamming distance can be easily solved in polynomial time. In the cases where this problem has been studied under the edit distance metric, it has made use of a parameter d, the maximum distance any solution is allowed to have from an input string. The problem is fixed parameter tractable in d, which is the basis of many solutions [11, 26, 37].

2 Hardness for k-Median-Edit-Distance

Our reduction will be from the k-Most-Orthogonal-Vectors problem, which was first introduced in [2]. It was shown that if it could be solved in $\mathcal{O}(n^{k-\varepsilon})$ time for some constant $\varepsilon > 0$, it would imply new upper bounds for MAX-CNF-SAT that would violate SETH.

▶ **Problem 3** (k-Most-Orthogonal-Vectors). *Given $k \geq 2$ sets $S_1, S_2, \ldots, S_k$ each containing n binary vectors $v \in \{0,1\}^d$, and an integer $r < d$, are there k vectors $v_1, v_2, \ldots, v_k$ with $v_i \in S_i$ such that their inner product, defined as $\sum_{h=1}^{d} \prod_{t\in[1,k]} v_t[h]$, is at most r? A collection of vectors that satisfies this property will be called r-far, and otherwise called r-close.*

Modifying the Vectors. In our reduction we apply a modification to the vectors in our input sets $S_1, S_2, \ldots, S_k$. We prepend $(r+1)$ 0's to each vector $v \in S_1$ and $(r+1)$ 1's to each vector $v \in S_i$ where $i > 1$. Every vector is now of dimension $d + r + 1 \leq 2d$ and the k-Most-Orthogonal-Vectors problem is identical on the original and modified sets.

2.1 Technical Overview

Given sets $S_1, S_2, \ldots, S_k$ of binary vectors, we will design strings $T_1, T_2, \ldots, T_k$ such that if there exists a collection of r-far vectors in the input, then their median edit distance will be at most a constant E^-. Otherwise, if there does not exist any collection of r-far vectors in the input, their median edit distance will be equal to E^+, where $E^- < E^+$. Our strings will be constructed in three levels of increasing scope: coordinate level, vector level, and set level. We use $\text{EDIT}(x_1, x_2, \ldots, x_k)$ to denote the *median edit distance* of k strings $x_1, x_2, \ldots, x_k$.

- **Coordinate Level:** Given k bits $b_1, b_2, \ldots, b_k$, we construct *coordinate gadget* strings $\text{CG}_i(b_i)$ that can distinguish between the case when $b_1 b_2 \cdots b_k = 0$ and $b_1 b_2 \cdots b_k = 1$. Specifically, we will show that there exist constants C^- and C^+ with $C^- < C^+$ such that if $b_1 b_2 \cdots b_k = 0$, then $\text{EDIT}(\text{CG}_1(b_1), \text{CG}_2(b_2), \ldots, \text{CG}_k(b_k)) = C^-$, and else if $b_1 b_2 \cdots b_k = 1$, then $\text{EDIT}(\text{CG}_1(b_1), \text{CG}_2(b_2), \ldots, \text{CG}_k(b_k)) = C^+$.
- **Vector Level:** Given vectors $v_1, v_2, \ldots, v_k \in \{0,1\}^{d+r+1}$, we construct *vector gadget* strings $\text{VG}_i(v_i)$ for $i \in [2,k]$ and a slightly more complicated *decision gadget* string $\text{DG}_1(v_1)$ out of our coordinate gadgets. Together these gadgets can determine if the k vectors are r-far or not. Specifically, we will show that if $v_1, v_2, \ldots, v_k$ are r-far, then $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)) \leq D^-$ and else if $v_1, v_2, \ldots, v_k$ are r-close, then $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)) = D^+$, where D^+ and $D^- < D^+$ are constants. Our construction here is a generalization of the work in [10] to k strings.
- **Set Level:** In the set level step of the reduction, we will build our final strings $T_1, T_2, \ldots, T_k$ by concatenating our vector level gadgets and adding special $\$_i$ symbols. Our final strings will be designed so that if there is an r-far collection of vectors $v_1, v_2, \ldots, v_k$ with $v_i \in S_i$, then the corresponding gadgets $\text{DG}_1(v_1), \text{VG}_2(v_2), \text{VG}_3(v_3), \ldots, \text{VG}_k(v_k)$ will align in an optimal edit sequence of our strings. These vector gadgets will have a lower median edit distance, resulting in $\text{EDIT}(T_1, T_2, \ldots, T_k) \leq E^-$. Otherwise, $\text{EDIT}(T_1, T_2, \ldots, T_k) = E^+$, where $E^- < E^+$.

We now present a definition and an associated fact.

▶ **Definition 4** (Alignment). *Given a particular edit sequence (a sequence of insertions, substitutions, and deletions) on strings $x_1, x_2, \ldots, x_k$, we say symbol α in x_i is aligned with symbol β in another string x_j if neither α nor β is deleted but are instead preserved or substituted to correspond to the same symbol. We say a substring s of x_i is aligned with substring t of x_j, if there exists a pair of aligned characters in s and t.*

The following observation will be used implicitly throughout.

▶ **Fact 5** (No criss-crossed alignments). *Consider an edit sequence on a set of strings containing strings x and y. Let $i_1 < j_1$ and $i_2 < j_2$ be indices on these strings. If $x[i_1]$ is aligned with $y[j_2]$, then $x[i_2]$ cannot be aligned with $y[j_1]$.*

2.2 Coordinate level reduction

For $i \in [1, k]$, we define coordinate gadget strings CG_i over the alphabet $\Sigma = \{2_1, 2_2, \ldots, 2_k, 3, 4\}$. Let $\ell_1 = 10k^2$. For bits $b_1, b_2, \ldots, b_k \in \{0, 1\}$, we define

$$\mathrm{CG}_i(b_i) \coloneqq f_i(b_i) \circ 4^{\ell_1} \circ g_i(b_i) \circ 4^{\ell_1} \circ h_i(b_i) \quad \text{for } i \in [1, k], \text{ where}$$

$$f_i(b_i) = \begin{cases} 2_{i+1}^{k-1} & \text{if } b_i = 1, i < k \\ 2_1^{k-1} & \text{if } b_i = 1, i = k \\ 2_i^{k-1} & \text{if } b_i = 0 \end{cases} \quad g_i(b_i) = \begin{cases} 3^{k-1} & \text{if } b_i = 1 \\ 2_i^{k-1} & \text{if } b_i = 0 \end{cases} \quad h_i(b_i) = \begin{cases} 2_i^k & \text{if } b_i = 1 \\ \bigcirc_{j=1}^{k} 2_j & \text{if } b_i = 0 \end{cases}$$

We present the following examples on $k = 3$ to aid in the understanding of our $\mathrm{CG}_i(b_i)$.

b_1, b_2, b_3	$f_1(b_1), f_2(b_2), f_3(b_3)$	$g_1(b_1), g_2(b_2), g_3(b_3)$	$h_1(b_1), h_2(b_2), h_3(b_3)$	$\mathrm{EDIT}(\mathrm{CG}_1(b_1), \cdot, \cdot)$
$1, 1, 1$	$2_2 2_2, 2_3 2_3, 2_1 2_1$	$33, 33, 33$	$2_1 2_1 2_1, 2_2 2_2 2_2, 2_3 2_3 2_3$	$4 + 0 + 6 = 10$
$0, 1, 1$	$2_1 2_1, 2_3 2_3, 2_1 2_1$	$2_1 2_1, 33, 33$	$2_1 2_2 2_3, 2_2 2_2 2_2, 2_3 2_3 2_3$	$2 + 2 + 4 = 8$
$0, 0, 0$	$2_1 2_1, 2_2 2_2, 2_3 2_3$	$2_1 2_1, 2_2 2_2, 2_3 2_3$	$2_1 2_2 2_3, 2_1 2_2 2_3, 2_1 2_2 2_3$	$4 + 4 + 0 = 8$

▶ **Lemma 6.** *Let $C^- = 2(k-1)^2$ and let $C^+ = C^- + (k-1) = (2k-1)(k-1)$. Then*

$$\mathrm{EDIT}(\mathrm{CG}_1(b_1), \mathrm{CG}_2(b_2), \ldots, \mathrm{CG}_k(b_k)) = \begin{cases} C^+ & \text{if } b_1 b_2 \cdots b_k = 1 \\ C^- & \text{otherwise} \end{cases}$$

Proof. For the remainder of this proof, let $\pi = b_1 + b_2 + \cdots + b_k \in [0, k]$.

▷ Claim 7. The median edit distance of our f_i gadgets is

$$\mathrm{EDIT}(f_1(b_1), \ldots, f_k(b_k)) = \begin{cases} (k-1)^2 & \text{if } \pi = 0 \text{ or } k \\ (k-1)(k-2) & \text{otherwise} \end{cases}$$

▷ Claim 8. The median edit distance of our g_i gadgets is

$$\mathrm{EDIT}(g_1(b_1), \ldots, g_k(b_k)) = \begin{cases} (k-1)^2 & \text{if } \pi = 0 \\ (k-1)(k-\pi) & \text{otherwise} \end{cases}$$

▷ Claim 9. The median edit distance of our h_i gadgets is $\mathrm{EDIT}(h_1(b_1), \ldots, h_k(b_k)) = (k-1)\pi$.

We have chosen ℓ_1 to be sufficiently large that all f_i, g_i, and h_i gadgets align only with gadgets of their own type. Therefore,

$$\mathrm{EDIT}(\mathrm{CG}_1(b_1), \ldots, \mathrm{CG}_k(b_k)) = \begin{cases} (k-1)^2 + (k-1)^2 + 0 & \pi = 0 \\ (k-1)(k-2) + (k-1)(k-\pi) + (k-1)\pi & 0 < \pi < k \\ (k-1)^2 + 0 + (k-1)k & \pi = k \end{cases}$$

A simple calculation will show that $\mathrm{EDIT}(\mathrm{CG}_1(b_1), \ldots, \mathrm{CG}_k(b_k))$ is C^- when $\pi < k$ (and hence $b_1 b_2 \cdots b_k = 0$) and is C^+ when $\pi = k$ (and hence $b_1 b_2 \cdots b_k = 1$). ◀

2.3 Vector level reduction

At this step of the reduction we are given binary vectors $v_1, v_2, \ldots, v_k \in \{0,1\}^{d+r+1}$ and we want to determine whether or not they are r-far. We accomplish this by constructing vector level gadgets that will have a "lower" median edit distance if the vectors are r-far. Let integer parameters $\ell_2 = 10d\ell_1$ and $\ell_3 = (10\ell_2)^2$. For vectors $v_1, v_2, \ldots, v_k$, we define

$$\mathrm{VG}_i(v_i) \coloneqq 6^{\ell_3} \circ M_i(v_i) \circ 6^{\ell_3} \qquad \text{where} \qquad M_i(v_i) \qquad \coloneqq \bigcirc_{j\in[1,d+r+1]}(5^{\ell_2} \circ \mathrm{CG}_i(v_i[j]) \circ 5^{\ell_2})$$

Observe that the vector gadget of a vector v_i is just the concatenation of the coordinate gadgets corresponding to each coordinate in v_i, along with some additional padding symbols. It follows that the median edit distance of $\mathrm{VG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)$ will be proportional to the inner product of $v_1, v_2, \ldots, v_k$. This is promising because we can now argue about whether or not $v_1, v_2, \ldots, v_k$ are r-far based on the median edit distance of the $\mathrm{VG}_i(v_i)$'s (a "lower" distance implies the vectors are r-far and a "higher" distance implies the vectors are r-close). Unfortunately, vectors with a very large inner product will result in a large median edit distance, which could interfere with our ability to detect r-far vectors in the next step of our reduction. What is desired here is to have vector level gadgets with a fixed "higher" median edit distance when the vectors are r-close. We achieve this by replacing $\mathrm{VG}_1(v_1)$ with a decision gadget $\mathrm{DG}_1(v_1)$ that will ensure that no matter how large the inner product of a collection of r-close vectors, the median edit distance of their corresponding gadgets will be a constant D^+. For vector v_1, we define

$$\mathrm{DG}_1(v_1) \coloneqq 7^{\ell_3} \circ M_1(v_1) \circ 6^{\ell_3} \circ M_1(\theta) \circ 7^{\ell_3}, \quad \theta \in \{0,1\}^{d+r+1} \text{ and } \theta[i] = \begin{cases} 1 & i \le r+1 \\ 0 & \text{else} \end{cases}$$

The key properties of our vector level gadgets are captured in Lemma 10 and Lemma 11. In both proofs we let $m = |M_i| = (d+r+1)(2\ell_2 + 2\ell_1 + 3k - 2)$, and we define $D^- = 2\ell_3 + m + (d+1)C^- + rC^+$ and $D^+ = D^- + (k-1)$.

▶ **Lemma 10.** *For any given r-far vectors $v_1, v_2, \ldots, v_k \in \{0,1\}^{d+r+1}$,* $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \mathrm{VG}_3(v_3), \ldots, \mathrm{VG}_k(v_k)) \le D^-$.

Proof. To upper bound the median edit distance of our k strings by D^-, we must give a complete edit sequence of our strings that requires D^- or fewer edits. Let $v_1, v_2, \ldots, v_k$ be r-far vectors. We decide to align $\mathrm{VG}_2(v_2), \mathrm{VG}_3(v_3), \ldots, \mathrm{VG}_k(v_k)$ with the $7^{\ell_3} \circ M_1(v_1) \circ 6^{\ell_3}$ substring of $\mathrm{DG}_1(v_1)$ as in Figure 1.

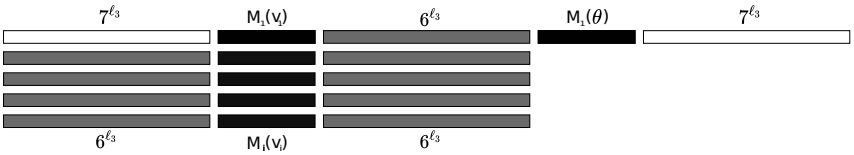

Figure 1 An optimal alignment of $\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)$ when $v_1, v_2, \ldots, v_k$ are r-far.

First we delete $M_1(\theta) \circ 7^{\ell_3}$ from $\mathrm{DG}_1(v_1)$ in $m + \ell_3$ edits. Then we substitute all the 7 symbols in the 7^{ℓ_3} prefix of $\mathrm{DG}_1(v_1)$ to 6 symbols in ℓ_3 edits. Finally, we must edit substrings $M_1(v_1), M_2(v_2), \ldots, M_k(v_k)$ to be the same. Each $M_i(v_i)$ contains $d+r+1$ coordinate gadgets, and for $j \in [1, d+r+1]$, we choose to align the jth leftmost coordinate gadgets of all $M_i(v_i)$ for $i \in [1,k]$. Note that the inner product of $v_1, v_2, \ldots, v_k$ is less than or equal to

r because the vectors are r-far. It follows that we will have no more than r alignments of coordinate gadgets with cost C^+ and at least $d+1$ alignments with cost C^- (recall Lemma 6). Then $\text{EDIT}(M_1(v_1), M_2(v_2), \ldots, M_k(v_k)) \leq (d+1)C^- + rC^+$. The total number of edits performed in this edit sequence is at most $2\ell_3 + m + (d+1)C^- + rC^+ = D^-$. ◀

We note that if $v_1, v_2, \ldots, v_k$ are r-close and as a result have an inner product greater than r, the optimal edit sequence of $\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)$ will align strings $\text{VG}_2(v_2), \text{VG}_3(v_3), \ldots, \text{VG}_k(v_k)$ with the $6^{\ell_3} \circ M_1(\theta) \circ 7^{\ell_3}$ substring of $\text{DG}_1(v_1)$ as in Fig. 2.

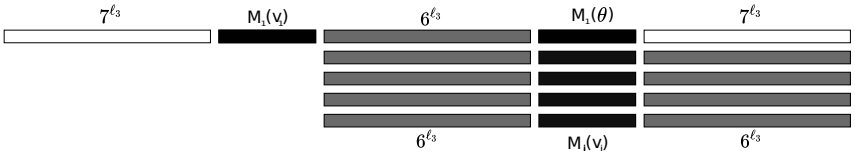

Figure 2 An optimal alignment of $\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)$ when $v_1, v_2, \ldots, v_k$ are r-close.

▶ **Lemma 11.** *For any given r-close vectors $v_1, v_2, \ldots, v_k \in \{0,1\}^{d+r+1}$,* $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \text{VG}_3(v_3), \ldots, \text{VG}_k(v_k)) = D^+$.

Proof. The proof of Lemma 11 is a straightforward generalization of the vector gadget proof in [10] to k strings. In the course of this proof we will make use of the fact that for any subset $x_{i_1}, x_{i_2}, \ldots, x_{i_j}$ of strings $x_1, x_2, \ldots, x_k$, $\text{EDIT}(x_{i_1}, x_{i_2}, \ldots, x_{i_j}) \leq \text{EDIT}(x_1, x_2, \ldots, x_k)$.

▷ Claim 12. $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \text{VG}_3(v_3) \ldots, \text{VG}_k(v_k)) \leq D^+$

Subproof. Note that the inner product of $\theta, v_2, v_3, \ldots, v_k$ is equal to $r+1$ by the definition of θ and our modifications to the input vectors. Then we can align $\text{VG}_2(v_2), \text{VG}_3(v_3), \ldots, \text{VG}_k(v_k)$ with the $6^{\ell_3} \circ M_1(\theta) \circ 7^{\ell_3}$ substring of $\text{DG}_1(v_1)$ in a manner analogous to our edit sequence in Lemma 10. ◁

Now we "just" need to prove that $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)) \geq D^+$. We proceed by cases on the alignments of the $M_i(v_i)$ substrings.

▷ Claim 13. $\text{EDIT}(\text{DG}_1(v_1), \text{VG}_2(v_2), \text{VG}_3(v_3) \ldots, \text{VG}_k(v_k)) \geq D^+$

Subproof. We have the following cases to consider.

- **Case 1:** The $M_i(v_i)$ substring of some $\text{VG}_i(v_i)$ gadget with $i > 1$ has alignments with both substrings $7^{\ell_3} \circ M_1(v_1)$ and $M_1(\theta) \circ 7^{\ell_3}$ of $\text{DG}_1(v_1)$. In this case, the cost induced by the symbols in the 7^{ℓ_3} prefix and suffix of $\text{DG}_1(v_1)$ and the 6^{ℓ_3} substring of $\text{DG}_1(v_1)$ is ℓ_3 each, so $\text{EDIT}(\text{VG}_i(v_i), \text{DG}_1(v_1)) \geq 3\ell_3 > D^+$. Our lower bound is satisfied. Note that since the inequality is strict, this case will not occur in an optimal edit sequence.
- **Case 2:** The $M_i(v_i)$ substring of some $\text{VG}_i(v_i)$ gadget with $i > 1$ does not have any alignments with the $7^{\ell_3} \circ M_1(v_1)$ substring of $\text{DG}_1(v_1)$.
- **Case 2.1:** The $M_j(v_j)$ substring of some $\text{VG}_j(v_j)$ gadget with $j > 1$ does not have any alignments with substring $M_1(\theta) \circ 7^{\ell_3}$ of $\text{DG}_1(v_1)$. We will consider $\text{EDIT}(\text{VG}_i(v_i), \text{VG}_j(v_j), \text{DG}_1(v_1))$, which is the same as $\text{EDIT}(\text{VG}_i(v_i), \text{DG}_1(v_1))$ when $i = j$. The $M_i(v_i)$ substring of $\text{VG}_i(v_i)$ has no alignments with the $7^{\ell_3} \circ M_1(v_1)$ substring of $\text{DG}_1(v_1)$. Therefore at least $D_1 = \ell_3 + m$ edits need to be performed between the 6^{ℓ_3} prefix of $\text{VG}_i(v_i)$ and the $7^{\ell_3} \circ M_1(v_1)$ prefix of $\text{VG}_1(v_1)$. Likewise, the $M_j(v_j)$ substring of $\text{VG}_j(v_j)$ has no alignments with the $M_1(\theta) \circ 7^{\ell_3}$ substring of $\text{DG}_1(v_1)$, and so at least D_1 edits need to be performed between the 6^{ℓ_3} suffix of $\text{VG}_j(v_j)$ and the $M_1(\theta) \circ 7^{\ell_3}$ suffix of $\text{DG}_1(v_1)$. The above edit costs are disjoint, and it follows that $\text{EDIT}(\text{VG}_i(v_i), \text{VG}_j(v_j), \text{DG}_1(v_1)) \geq 2D_1 > D^+$. Our lower bound is satisfied.

- **Case 2.2:** We consider the complement of Case 2.1: the $M_i(v_i)$ substrings of all $\mathrm{VG}_i(v_i)$ gadgets with $i > 1$ have alignments with the substring $M_1(\theta) \circ 7^{\ell_3}$ of $\mathrm{DG}_1(v_1)$. By our analysis in Case 1, we may now assume that the $M_i(v_i)$ substrings of all $\mathrm{VG}_i(v_i)$ gadgets with $i > 1$ do not have alignments with the $7^{\ell_3} \circ M_1(v_1)$ substring of $\mathrm{DG}_1(v_1)$. Then by our argument in Case 2.1, at least D_1 edits must be performed on the 6^{ℓ_3} prefix of $\mathrm{VG}_i(v_i)$ and the $7^{\ell_3} \circ M_1(v_1)$ prefix of $\mathrm{VG}_1(v_1)$. Additionally, note that all $\mathrm{VG}_i(v_i)$ share the suffix 6^{ℓ_3}, whereas $\mathrm{DG}_1(v_1)$ has suffix 7^{ℓ_3}. It follows that at least $D_2 = \ell_3$ edits are needed to edit $\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)$ to have the same suffix. Furthermore, these edits are disjoint from the D_1 edits performed on the prefixes of $\mathrm{DG}_1(v_1)$ and the $\mathrm{VG}_i(v_i)$. We have shown that at least $D_1 + D_2 = 2\ell_3 + m$ edits are required to align $\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)$. Now all we must do is lower bound the edits internal to our $M_i(v_i)$ substrings. Recall that our $M_i(v_i)$ substrings are composed of $d + r + 1$ coordinate gadgets $\mathrm{CG}_i(v_i[j])$.
  - **Case 2.2.1:** There is some $\mathrm{VG}_i(v_i)$ gadget with $i > 1$ such that there are some $j, \ell \in [1, d + r + 1]$ with $j \neq \ell$ such that the jth leftmost coordinate gadget of $M_i(v_i)$ is aligned with the ℓth leftmost coordinate gadget of the $M_1(\theta)$ in $\mathrm{VG}_1(v_1)$. Then we incur an edit cost of at least $2\ell_2$ from the 5 symbols between the coordinate gadgets. It follows that $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)) \geq D_1 + D_2 + 2\ell_2 > D^+$. Our lower bound is satisfied.
  - **Case 2.2.2:** We now consider the complement of Case 2.2.1. For all $i \in [1, d + r + 1]$, the ith leftmost coordinate gadget of $M_j(v_j)$ for all $j > 1$ is either aligned with the ith leftmost coordinate gadget of $M_1(\theta)$ or it's not aligned with any coordinate gadget of $M_1(\theta)$.
    - For all $i \in [1, d + r + 1]$ we analyze the edit costs of the ith leftmost coordinate gadgets in $M_1(\theta), M_2(v_2), \ldots, M_k(v_k)$. If the ith leftmost coordinate gadgets of all $M_j(v_j)$ for $j > 1$ are aligned with the ith leftmost coordinate gadget of $M_1(\theta)$. Then by the transitivity of the alignment relation, we have that the ith coordinate gadgets of $M_1(\theta), M_2(v_2), \ldots, M_k(v_k)$ are aligned. By our analysis of the coordinate gadgets in Lemma 6, this alignment of coordinate gadgets will incur cost at least C^- if $\theta[i]v_2[i]v_3[i] \ldots v_k[i] = 0$, and else incur cost at least C^+ if $\theta[i]v_2[i]v_3[i] \ldots v_k[i] = 1$.
    - Else for some $M_j(v_j)$ with $j > 1$, the ith leftmost coordinate gadget $\mathrm{CG}_j(v_j[i])$ is not aligned with any coordinate gadget of $M_1(\theta)$, then it incurs cost $|\mathrm{CG}_j(v_j[i])| \geq C^+$.

    Combining our case analysis for all $d + r + 1$ coordinate gadgets, we see that they collectively incur a cost of at least $D_3 = (r + 1)C^+ + dC^-$, since the inner product of vectors $\theta, v_2, v_3, \ldots, v_k$ is $r + 1$ (follows from our modification of the input vectors and our definition of θ). Then $D_1 + D_2 + D_3 = D^+$, and since the edits from D_1, D_2, and D_3 are all necessarily disjoint, we have that $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)) \geq D^+$.
- **Case 3:** The $M_i(v_i)$ substring of some $\mathrm{VG}_i(v_i)$ with $i > 1$ does not have alignments with the $M_1(\theta) \circ 7^{\ell_3}$ substring of $\mathrm{DG}_1(v_1)$. This case is symmetric to Case 2, with the only difference being that we have substring $M_1(v_1)$ as opposed to $M_1(\theta)$. Since we assumed that $v_1, v_2, \ldots, v_k$ are r-close and hence have an inner product greater than or equal to $r + 1$, it must be the case that $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)) \geq D^+$.

We have shown in every case that $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)) \geq D^+$, so we conclude that $\mathrm{EDIT}(\mathrm{DG}_1(v_1), \mathrm{VG}_2(v_2), \ldots, \mathrm{VG}_k(v_k)) = D^+$. ◁

This completes the proof of Lemma 11. ◀

2.4 Set level reduction

In this step of the reduction we will construct our final strings $T_1, T_2, \ldots, T_k$ that can detect r-far vectors in our input sets $S_1, S_2, \ldots, S_k$. We will accomplish this by embedding in string T_i the vector level gadgets of the vectors belonging to set S_i for $i \in [1, k]$. Then if an r-far collection of vectors exists, we can align their corresponding vector gadgets and give our strings $T_1, T_2, \ldots, T_k$ a "lower" median edit distance.

We will construct our final strings in several steps. We start by padding our vector level gadgets to discourage them from aligning with more than one vector level gadget in any given string. We define integer parameter $\ell_4 = 10000k^4 d\ell_3$, and we add a new padding symbol 8 to our alphabet. For all $v \in \{0,1\}^{d+r+1}$, let

$$\mathrm{DG}'_1(v) \coloneqq 8^{\ell_4} \circ \mathrm{DG}_1(v) \circ 8^{\ell_4} \quad \text{and} \quad \mathrm{VG}'_i(v) \coloneqq 8^{\ell_4} \circ \mathrm{VG}_i(v) \circ 8^{\ell_4} \quad \text{for } i \in [1, k]$$

We now concatenate our vector level gadgets DG'_1 and VG'_i. Define

$$P_1 \coloneqq \bigcirc_{v \in S_1} \mathrm{DG}'_1(v) \quad \text{and} \quad P_i \coloneqq \bigcirc_{v \in S_i} \mathrm{VG}'_i(v) \quad \text{for } i \in [2, k]$$

Strings $P_1, P_2, \ldots, P_k$ now contain all the vectors from our input sets. However, they are not sufficient to complete the reduction. To solve k-Most-Orthogonal-Vectors we must be able to check all n^k collections of vectors in $S_1 \times S_2 \times \cdots \times S_k$ for r-far-ness. Likewise, we must be able to align all n^k corresponding vector level gadgets in our final strings. In $P_1, P_2, \ldots, P_k$ this is not always possible without incurring a large additional edit cost. For example, there is no optimal edit sequence of $P_1, P_2, \ldots, P_k$ that aligns the leftmost vector level gadget of a string P_i with the rightmost vector level gadget of another string P_j – the number of insertions or deletions necessary would be too high.

Our strings $P_1, P_2, \ldots, P_k$ are rigid, but we can give them the freedom to slide around by making the lengths of all strings distinct. Specifically, we will add a varying number of vector level gadgets to each string so that P_{i+1} will have more vector level gadgets than P_i for all $i \in [1, k-1]$. We define the *dummy vector* ϕ to be a vector of all ones of length $d+r+1$. Let

$$L_1 \coloneqq \mathrm{VG}'_1(\phi)^{(50k+1)n} \circ \mathrm{DG}'_1(\phi)^{50kn} \quad \text{and} \quad R_1 \coloneqq \mathrm{DG}'_1(\phi)^{50kn} \circ \mathrm{VG}'_1(\phi)^{(50k+1)n}$$
$$L_i \coloneqq \mathrm{VG}'_i(\phi)^{(100k+i)n} \quad \text{and} \quad R_i \coloneqq \mathrm{VG}'_i(\phi)^{(100k+i)n} \quad \text{for } i \in [2, k]$$

Strings L_i and R_i will pad the left side and the right side of our P_i.

$$P'_i \coloneqq L_i \circ P_i \circ R_i \text{ for } i \in [1, k]$$

Observe that string P'_{i+1} has $2n$ more (dummy) vector level gadgets than P'_i for $i \in [1, k-1]$. This gives $P'_1, P'_2, \ldots, P'_k$ a pyramid-like shape as in Figure 3. We will see that this allows the sort of sliding between strings necessary to complete our reduction.

Figure 3 Final strings $T_1, T_2, \ldots, T_k$ when $k = 5$ shown from top to bottom. The vector gadgets corresponding to vectors from our input sets are shown in black, whereas the vector gadgets corresponding to dummy vectors ϕ are shown in gray. The special $\$_i$ symbols are shown in white.

However, because our strings $P'_1, P'_2, \ldots, P'_k$ are of different lengths, any complete edit sequence will require inserting or deleting vector level gadgets. This is problematic because it is difficult to reason about the edit costs of our vector level gadgets if they are inserted or

deleted in the optimal edit sequence. To solve this problem we add special $\$_i$ symbols to our strings. We will see that the $\$_i$ symbols "absorb" all the edits needed to make the lengths of the final strings equal and that no vector level gadgets will be inserted or deleted in the optimal edit sequence. We add $\$_1, \$_2, \ldots, \$_{k-1}$ to our alphabet, and we let $\ell_5 = 1000kn\ell_4$. Define

$$T_i \coloneqq \$_i^{\ell_5} \circ P'_i \circ \$_i^{\ell_5} \quad \text{for } i \in [1, k-1] \qquad \text{and} \qquad T_k \coloneqq P'_k$$

This completes the construction of our final strings $T_1, T_2, \ldots, T_k$. The length of each string as well as the time for their construction is $\mathcal{O}(nd^{O(1)})$. Their properties are summarized in Lemma 14 and Lemma 15 (proofs are deferred to Section 2.5 and Section 2.6, respectively).

▶ **Lemma 14.** *For any given sets $S_1, \ldots, S_k$ such that there is some collection $v_1, v_2, \ldots, v_k$ of r-far vectors with $v_i \in S_i$ for $i \in [1, k]$, $\text{EDIT}(T_1, T_2, \ldots, T_k) \leq E^-$, where $E^- = D^- + (100kn + n - 1)D^+ + 101k(k-1)(2k-1)(d+r+1)n + 2(k-1)\ell_5$.*

▶ **Lemma 15.** *For any given sets $S_1, S_2, \ldots, S_k$ such that there is no collection $v_1, v_2, \ldots, v_k$ of r-far vectors with $v_i \in S_i$ for $i \in [1, k]$, $\text{EDIT}(T_1, T_2, \ldots, T_k) = E^+$, where $E^+ = E^- + (k-1)$.*

▶ **Theorem 16.** *If there is an $\varepsilon > 0$, an integer $k \geq 2$, and an algorithm that can solve k-Median-Edit-Distance on strings, each of length at most n, over an alphabet of size $\mathcal{O}(k)$ in $O(n^{k-\varepsilon})$ time, then* SETH *is false.*

Proof. Follows from Lemma 14 and Lemma 15. ◀

2.5 Proof of Lemma 14

Statement: *For any given sets $S_1, S_2, \ldots, S_k$ such that there is some collection $v_1, v_2, \ldots, v_k$ of r-far vectors with $v_i \in S_i$ for $i \in [1, k]$, $\text{EDIT}(T_1, T_2, \ldots, T_k) \leq E^-$, where $E^- = D^- + (100kn + n - 1)D^+ + 101k(k-1)(2k-1)(d+r+1)n + 2(k-1)\ell_5$.*

To upper bound the median edit distance of $T_1, T_2, \ldots, T_k$ by E^-, we must give an edit sequence of at most E^- edits. Initially, we will only edit the substrings $P'_1, P'_2, \ldots, P'_k$ and thus exclude the $\$_i$ symbols from consideration. We start by aligning the vector level gadgets.

Vector Level Gadget Alignment. We have assumed vectors $v_1, v_2, \ldots, v_k$ are r-far, and we choose to align their corresponding vector level gadgets $\text{DG}_1(v_1), \text{VG}_2(v_2), \ldots, \text{VG}_k(v_k)$. We then align the rest of our vector level gadgets using the following rules:

1. Each vector level gadget in T_i aligns to exactly one vector level gadget in T_j for $j > i$.
2. If two vector level gadgets are adjacent in T_i, then they will be aligned to adjacent vector level gadgets in T_j for $j > i$.

Feasibility. We must demonstrate that this alignment is always achievable no matter how the vector level gadgets of $v_1, v_2, \ldots, v_k$ are embedded in strings $T_1, T_2, \ldots, T_k$. Recall that the vector level gadgets corresponding to vectors from our input sets are located in substrings P_i of T_i for all $i \in [1, k]$. Our construction gives paddings L_{i+1} and R_{i+1} exactly n more dummy vector level gadgets than L_i and R_i respectively for $i \in [1, k-1]$. It follows that even if the leftmost (resp. rightmost) vector level gadget in P_i is aligned with the rightmost (resp. leftmost) vector level gadget in P_{i+1}, the rules above remain satisfied.

Edit Cost for Vector Level Gadgets. There are $100kn + n$ decision gadgets DG_1 in T_1, so our edit sequence will yield $100kn + n$ alignments of $\mathrm{DG}_1, \mathrm{VG}_2, \ldots, \mathrm{VG}_k$, of which at least one such alignment will have cost D^- and the rest at most D^+. This gives an edit cost of at most $E_1^- = D^- + (100kn + n - 1)D^+$. At this point, all vector level gadgets in $P_1, P_2, \ldots, P_k$ have been edited (refer to Figure 4).

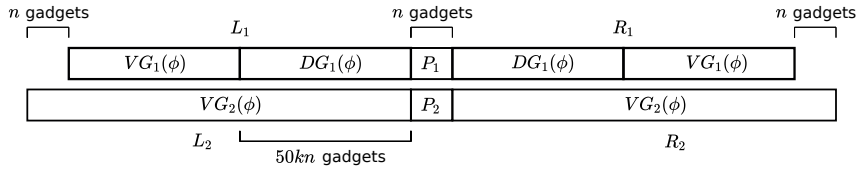

Figure 4 Strings P_1' and P_2'. All vector gadgets in P_2 align with decision gadgets DG_1 in P_1'.

Then there are exactly $2(50k + 1)n$ alignments of $\mathrm{VG}_1(\phi), \mathrm{VG}_2(\phi), \ldots, \mathrm{VG}_k(\phi)$ gadgets, and for all $i \in [2, k]$ there are exactly $2n$ alignments containing precisely the gadgets $\mathrm{VG}_i(\phi), \mathrm{VG}_{i+1}(\phi), \ldots, \mathrm{VG}_k(\phi)$. We will count the minimal number of edits needed to make these dummy vector gadgets identical. Let $F_i = (d + r + 1)(2k - 1)(k - i)$.

▷ Claim 17. For all $i \in [1, k]$, $\mathrm{EDIT}(\mathrm{VG}_i(\phi), \mathrm{VG}_{i+1}(\phi), \ldots, \mathrm{VG}_k(\phi)) = F_i$.

Proof. Each dummy vector gadget $\mathrm{VG}_j(\phi)$ is composed of $d + r + 1$ coordinate gadgets. Each alignment of the coordinate gadgets $\mathrm{CG}_i(1), \mathrm{CG}_{i+1}(1), \ldots, \mathrm{CG}_k(1)$ will incur $(2k - 1)(k - i)$ total edits, with $(k - 1)(k - i)$ edits from f gadgets and $k(k - i)$ edits from h gadgets. ◁

Denote the sum of the internal edit costs of all alignments of $\mathrm{VG}_i, \mathrm{VG}_{i+1}, \ldots, \mathrm{VG}_k$ gadgets for $i \in [1, k]$ by

$$E_2^- = 2(50k + 1)n \cdot F_1 + \sum_{i \in [2,k]} 2n \cdot F_i = 101k(k - 1)(2k - 1)(d + r + 1)n$$

This completes our edits on all vector level gadgets.

Total Edit Cost. All substrings $P_1', P_2', \ldots, P_k'$ have been edited to $P_1^*, P_2^*, \ldots, P_k^*$, respectively, so that P_i^* is a substring of P_j^* for all $i < j$. We will now edit the $\$_i$ symbols in order to complete the edit sequence of $T_1, T_2, \ldots, T_k$. In particular, we will edit all k strings to be equal to P_k^* by substituting and deleting $\$_i$ symbols. For the ith string, we will perform substitutions on $|P_k^*| - |P_i^*|$ of the $\$_i$ symbols in T_i and delete the remaining $\$_i$ symbols. Since we substitute or delete every $\$_i$ symbol, this will incur an edit cost of $E_3^- = 2(k - 1)\ell_5$. The total number of edits performed in our edit sequence is no more than $E_1^- + E_2^- + E_3^- = E^-$. This completes the proof.

2.6 Proof of Lemma 15

Statement: *For any given sets $S_1, S_2, \ldots, S_k$ such that there is no collection $v_1, v_2, \ldots, v_k$ of r-far vectors with $v_i \in S_i$ for $i \in [1, k]$,* $\mathrm{EDIT}(T_1, T_2, \ldots, T_k) = E^+ = E^- + (k - 1)$.

▷ Claim 18. $\mathrm{EDIT}(T_1, T_2, \ldots, T_k) \leq E^+$

Proof. We can achieve this upper bound by giving an edit sequence identical to the edit sequence in Lemma 14. Note that the only difference now is that there is no longer an r-far collection of vectors, so the edit cost of D^- in Lemma 14 is now D^+. This yields a complete edit sequence with $E^- + (D^+ - D^-) = E^+$ edits, so our inequality holds. ◁

We must now prove that $\text{EDIT}(T_1, T_2, \ldots, T_k) \geq E^+$. Our lower bound on the number of edits comes from two disjoint sources: the edits incurred by the $\$_i$ symbols and the edits incurred by alignments between vector level gadgets.

▷ Claim 19. The $\$_i$ symbols for $i \in [1, k-1]$ incur a cost of at least $E_1^+ = 2(k-1)\ell_5$ edits in a complete edit sequence of $T_1, T_2, \ldots, T_k$.

Proof. First note that symbols $\$_i$ for $i \in [1, k-1]$ have $E_1^+ = 2(k-1)\ell_5$ occurrences in $T_1, T_2, \ldots, T_k$. We will show that each of these $\$_i$ symbols incurs one edit and that this edit is disjoint from the edits of any other $\$_j$ symbol. If a $\$_i$ symbol is deleted or substituted, then it certainly incurs one edit. Furthermore, these deletions and substitutions are necessarily disjoint. Otherwise, suppose that a $\$_i$ symbol is not substituted or deleted, but remains unmodified in the edit sequence. Then because there are no $\$_i$ symbols in string T_k, we must incur at least one edit in T_k. This edit must be disjoint from any other edits incurred by other $\$_i$ symbols. ◁

Now we will reason about the lower bound on the edits incurred by vector level gadgets by considering every possible configuration of alignments between vector level gadgets. In order to do this, we define a graph G whose vertices correspond to vector level gadgets. More specifically, for the jth leftmost vector level gadget in T_i, we add a vertex x_i^j to G for $i \in [1, k]$. Thus vertices $x_i^1, x_i^2, \ldots, x_i^{(200k+2i+1)n}$ correspond to the $2(100k+i)n + n$ vector level gadgets in T_i from left to right. Now for a particular edit sequence, we define G to have an unordered edge $(x_{i_1}^{j_1}, x_{i_2}^{j_2})$ if the j_1th vector level gadget of T_{i_1} is aligned with the j_2th vector level gadget of T_{i_2} in the edit sequence. Also, we say that $x_{i_1}^{j_1}$ and $x_{i_2}^{j_2}$ are from the same row if $i_1 = i_2$.

Every edit sequence now corresponds to a graph G. This graph can be decomposed into a set of connected components $\mathcal{C}$. For a component $c \in \mathcal{C}$, we define $\#(c, i)$ as the number of vertices belonging to string T_i in c. We say that $\text{width}(c)$ of a component c is $\max_{i \in [1,k]} \#(c, i)$. We let $|c|$ denote the number of vertices in a component c. We now partition $\mathcal{C}$ into the following sets:

- $\mathcal{C}_1$ is the set of all components c with $\text{width}(c) > 1$
- $\mathcal{C}_2$ is the set of all components c with $\text{width}(c) = 1$ and $\#(c, k) = 0$
- $\mathcal{C}_3$ is the set of all components c with $\text{width}(c) = 1$ and $\#(c, k) = 1$

We now lower bound the edit costs of components in $\mathcal{C}_1$, $\mathcal{C}_2$, and $\mathcal{C}_3$. Let $Q = 10kd\ell_3$.

▶ **Lemma 20.** *Every component c in $\mathcal{C}_1$ incurs at least $Q \cdot \text{width}(c)$ edits.*

Proof. Because our component c is connected, the case illustrated in Figure 5 must occur at least $\text{width}(c) - 1$ times. Then at least $2\ell_4(\text{width}(c) - 1)$ edits must be performed on the padding 8 symbols between the vector level gadgets of c. Observe that because $\ell_4 > Q$, this cost is greater than $Q \cdot \text{width}(c)$. These edits are disjoint from the edits of the $\$_i$ symbols. ◀

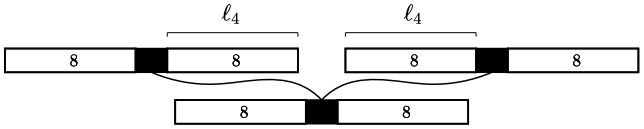

Figure 5 Case: one vector gadget in a string T_i is aligned with two vector gadgets in a string T_j. This alignment requires $2\ell_4$ edits of 8 symbols.

▶ **Lemma 21.** *Every component c in $\mathcal{C}_2$ incurs at least Q edits.*

Proof. By definition, the vector level gadgets in component c have no alignments with any vector level gadget VG_k in T_k. It follows that we incur a cost of at least $|\mathrm{VG}_k| > Q$. Furthermore, this edit cost is disjoint from the E_1^+ edit cost of our $\$_i$ symbols because there are no $\$_i$ symbols in T_k. ◀

We have given lower bounds for the edit costs of every component in $\mathcal{C}_1$ and $\mathcal{C}_2$, and these edit costs are disjoint by nature. Now we bound the costs of every component in $\mathcal{C}_3$. It will be useful to partition the components in $\mathcal{C}_3$ into the following sets:

- $\mathcal{C}_{3.1}$ is the set of all components c containing a vertex corresponding to a DG_1 gadget
- $\mathcal{C}_{3.2}$ is the remaining components in $\mathcal{C}_3$.

▶ **Lemma 22.** *All components c in $\mathcal{C}_{3.1}$ incur an edit cost of D^+.*

Proof. Our proof makes use of the following claim.

▷ Claim 23. No optimal edit sequence aligns a decision gadget DG_1 with any $\$_i$ symbol.
