Preface

This volume contains the extended abstracts selected for presentation at ESA 2020, the 28th European Symposium on Algorithms. Due to the COVID-19 pandemia, the symposium was organized as a virtual meeting during September 7–9 by the University of Pisa, Italy as part of ALGO 2020. Performing the switch from physical to virtual meeting was accompanied by many discussions about how to handle this situation. However, eventually, the scientific quality of the program as well as the process of selecting contributions was surprisingly little affected. In particular, the number of submissions as well as the acceptance rate was similar to previous years. The PC-chairs gave an exceptional five-day deadline extension to mitigate potential difficulties of authors in handling the situation. This proved an effective means of achieving a high turnout of good submissions.

The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions that also address real-world applications, engineering, and experimental analysis of algorithms. Information on past symposia, including locations and proceedings, is maintained at `http://esa-symposium.org`.

In response to the call for papers for ESA 2020, 313 papers were submitted, 262 for Track A and 51 for Track B (these are the counts after the removal of papers with invalid format and after withdrawals). Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews. The program committees selected 83 papers for inclusion in the program, 70 from track A and 13 from track B, yielding an acceptance rate of about 1/4.

The European Association for Theoretical Computer Science (EATCS) sponsored a best paper award and a best student paper award. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission. The best student paper award for track A was given to Hanrui Zhang for the paper *Improved Prophet Inequalities for Combinatorial Welfare Maximization with (Approximately) Subadditive Agents*. The best paper award for track A was given to Moritz Venzin and Friedrich Eisenbrand for the paper *Approximate CVP_p in time* $2^{0.802n}$. The best paper award for track B was given to Georg Osang, Mael Rouxel-Labbé and Monique Teillaud for the paper *Generalizing CGAL Periodic Delaunay Triangulations*. No best student paper award has been given this year for track B.

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and all the external reviewers who assisted the program committees in the evaluation process. Special thanks go to the organizing committee, who helped us with the organization of the conference. All of these people did a great job in keeping ESA a hoard of excellence in a difficult situation.

Abstract

Given a set P of n red and blue points in the plane, a *planar bichromatic spanning tree* of P is a geometric spanning tree of P, such that each edge connects between a red and a blue point, and no two edges intersect. In the bottleneck planar bichromatic spanning tree problem, the goal is to find a planar bichromatic spanning tree T, such that the length of the longest edge in T is minimized. In this paper, we show that this problem is NP-hard for points in general position. Our main contribution is a polynomial-time $(8\sqrt{2})$-approximation algorithm, by showing that any bichromatic spanning tree of bottleneck λ can be converted to a planar bichromatic spanning tree of bottleneck at most $8\sqrt{2}\lambda$.

2012 ACM Subject Classification Theory of computation → Computational geometry; Theory of computation → Design and analysis of algorithms

Keywords and phrases Approximation Algorithms, Bottleneck Spanning Tree, NP-Hardness

1 Introduction

Let P be a bi-colored set of red and blue points in the plane and let $n = |P|$. A *bichromatic spanning tree* of P is a spanning tree of P whose edges are straight-line segments connecting between points of different colors. A spanning tree is *planar* if its edges do not cross each other. Borgelt et al. [15] studied the problem of computing a minimum-weight planar bichromatic spanning tree, and showed that the problem is NP-hard. Moreover, for points in general position, they gave an $O(\sqrt{n})$-approximation algorithm, and for points in convex position, they gave an exact cubic-time algorithm. Biniaz et al. [11] studied the problem of computing a maximum-weight planar bichromatic spanning tree and gave a (1/4)-approximation algorithm for the problem.

Algorithmic problems on bichromatic geometric input have appeared in many problems, including, e.g., trees [1, 12, 15], matchings [13, 18], and partitionings [19]. Often the bichromatic input is referred to as "red-blue" input, e.g. in red-blue intersection [4, 23], red-blue separation [9, 14, 17, 20], and red-blue connection problems [5, 10]. For a survey of many geometric problems on bichromatic (red-blue) points, see Kaneko and Kano [21].

Many of the structures studied in computational geometry are planar, including minimum spanning trees, minimum weight matchings, Delaunay/Voronoi diagrams, etc. Therefore, the planarity requirement is quite natural, and indeed many researchers have considered geometric problems dealing with crossing-free configurations in the plane; see, e.g. [2, 3, 6, 7, 8].

In this paper, we study the problem of computing a bottleneck planar bichromatic spanning tree of P, in which we seek a planar bichromatic spanning tree that minimizes the bottleneck, i.e., the length of the longest edge. To the best of our knowledge, this problem has not been considered before.

Our results. In Section 2, we prove that the problem of computing a bottleneck planar bichromatic spanning tree is NP-hard. Our proof is based on a reduction from the planar 3-SAT problem, and is influenced by the proof of Borgelt et al. [15]. As a corollary we obtain that the problem does not admit a PTAS. Next, in Section 3, we present a polynomial-time algorithm for computing a planar bichromatic spanning tree of bottleneck at most $8\sqrt{2}$ times the bottleneck OPT of an optimal such planar bichromatic spanning tree. We first compute a bottleneck bichromatic spanning tree having bottleneck λ that may have crossings (so λ is a lower bound on OPT). Then, we use the length λ to define a partition of the plane into convex cells, and to partition P into subsets according to these cells. Next, we construct planar bichromatic trees for each subset, and we connect these trees to obtain a planar bichromatic spanning tree of P. We show that this tree has a bottleneck at most $8\sqrt{2}\lambda$.

2 Hardness Proof

In this section, we prove the NP-hardness (Theorem 1) of computing a bottleneck planar bichromatic spanning tree; our proof also shows (Corollary 2, below) that there is no approximation factor less than $\sqrt{2}$, unless $P = NP$.

▶ **Theorem 1.** *Let P be a set of n red and blue points in the plane. Computing a bottleneck planar bichromatic spanning tree of P is NP-hard.*

Proof. We adapt the proof of Borgelt et al. [15], making modifications necessary to address the bottleneck version. For completeness, we explain the ingredients required for the proof.

The proof is based on a reduction from the planar 3-SAT problem. Given a 3-CNF formula F with n variables $X = \{x_1, x_2, \ldots, x_n\}$ and m clauses $Y = \{C_1, C_2, \ldots, C_m\}$, let $G_F = (V, E)$ be the graph of F, i.e., $V = X \cup Y$ and $E = \{(x_i, C_j) : x_i \text{ or } \widetilde{x_i} \text{ appears in } C_j\}$. If G_F is planar, then F is called a planar 3-CNF formula. The planar 3-SAT problem is to determine whether a given planar 3-CNF formula F is satisfiable; the problem is NP-complete [22].

Let F be a planar 3-SAT formula. We construct, in polynomial time, a set P of red and blue points in the plane, such that F is satisfiable if and only if there exists a planar bichromatic spanning tree of P of bottleneck 1. Consider the graph G_F. It is well known that G_F can be embedded in the plane in polynomial time, using polynomial area, i.e., with the $n + m$ nodes of G_F placed at grid points of a regular square grid of size $O(n + m)$-by-$O(n + m)$ [16].

The construction is based on chains of pairs of red and blue points. We call the pairs in the chain *sites*. The distance between the two points comprising each site is less than 1, and the distance between two points of different colors in consecutive (along the chain) sites is exactly 1; see Figure 1(a). Now, for every two consecutive sites, there are two possible edges to connect them using edges of length at most 1: we either connect (with an edge

of length exactly 1) the blue point of the first site with the red point of the second site, or the other way around. Moreover, the chain is constructed in such a way that if we connect the blue point in the leftmost site to the red point in the next site, this forces the choice of connections in one direction along the chain; see Figure 1(b).

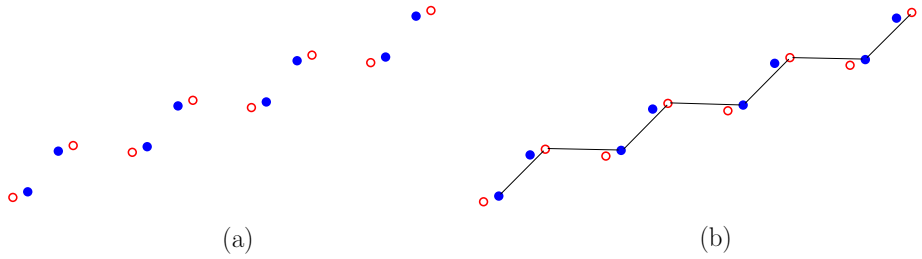

Figure 1 A chain of red-blue sites.

Variables. Each variable $x_i \in X$ is represented by a circular chain of $O(m)$ sites, a special red point r_i, and a red-blue path; see Figure 2. The addition of the red-blue path to the variable gadget of [15] is required, since without it the special red point r_i can be connected to both sides of the chain without increasing the bottleneck, which is not the case in the minimum weight version. The red-blue path forces r_i to be connected exactly to one side.

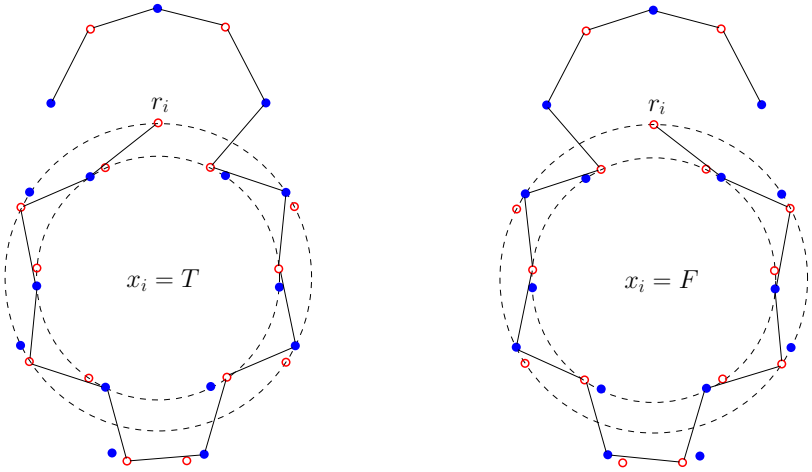

Figure 2 The trees corresponding to the true and the false assignments of x_i.

The sites on the circular chain are located on two circles, an inner circle and an outer circle. We locate the points in such a way that the (bichromatic) distances are 1 between consecutive sites on the circular chain, the distance is 1 between r_i and the blue points of its neighboring sites in the chain, and the distance is 1 between the endpoints of the red-blue path and the corresponding points of the chain. Moreover, the points are located such that there are only two possible optimal trees (i.e., planar bichromatic spanning trees of bottleneck 1) of the points, depending on the connection of r_i to the chain. In each of the two trees, r_i is connected to exactly one site of the chain. We associate (arbitrarily) one possibility with the assignment $x_i = T$, and the other with the assignment $x_i = F$; see Figure 2. Thus, the value of x_i will determine the tree of these points, and vice virsa. Moreover, if $x_i = T$ (resp., $x_i = F$), then the red points on the right (resp., left) of the inner circle are free to be connected to points outside the gadget, and the red points on the left (resp., right) of the inner circle cannot be connected to points outside the gadget without crossing, and vice versa.

Clauses. Each clause C_j is represented by a single red point r_j and three chains that are connected to the respective variables of C_j; see Figure 3(a). The distance between r_j and each chain is 1. In any optimal tree, r_j will be connected to at least one of the three chains. However, it cannot be connected to any chain if all the chains are connected to variables that are in the wrong state; see Figure 3(b).

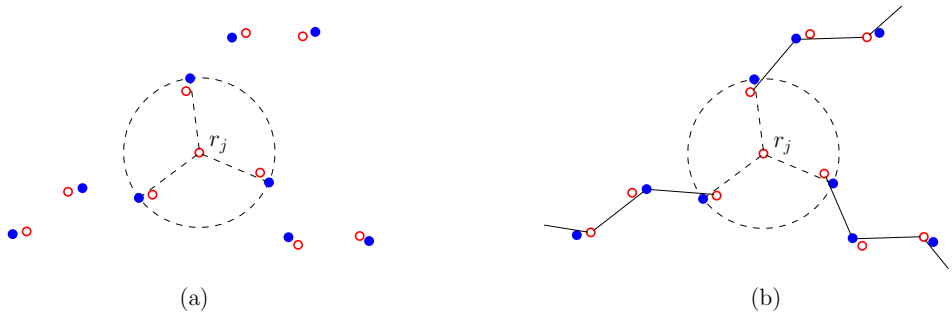

Figure 3 The gadget corresponding to the clause C_j.

We connect between the variables and the clauses such that, in any optimal tree, one of the three chains of the clause has to be connected to a red point on the inner circle of the corresponding variable. Assume that x_i appears unnegated in a clause C_j and negated in a clause C_k, i.e., $C_j = (x_i \vee \cdot \vee \cdot)$ and $C_k = (\widetilde{x_i} \vee \cdot \vee \cdot)$. We connect the chain of C_j that is respective to x_i to a site on the right of the inner circle of the gadget x_i, and we connect the chain of C_k that is respective to x_i to a site on the left of the inner circle of the gadget x_i; see Figure 4. This connection ensures that, if x_i is assigned T, then the red point on the right of the inner circle of x_i is free to be connected to the chain of C_j, and this connection can produce a path through the chain that ends at r_j. On the other hand, if x_i is assigned T, then the red point on the left of the inner circle of x_i cannot be connected to the chain of C_k, which does not allow a connection between the chain and r_k. The same argument holds when x_i is assigned F.

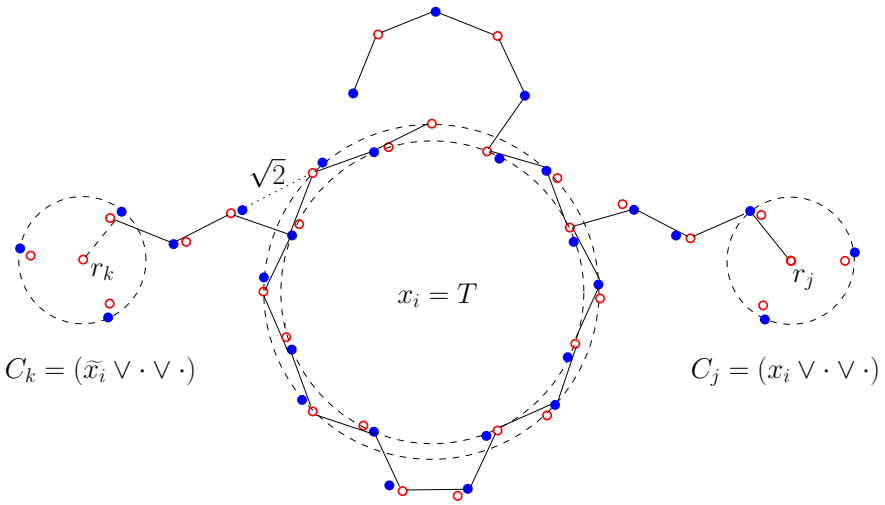

Figure 4 The connection between the variable x_i and the clauses C_j and C_k.

Finally we need to connect all variables to each other by some fixed part of the tree, because the whole construction needs to be a tree and not a forest. These connections can easily be made using red-blue chains having distance at most 1 between every two consecutive points in the path. Also, we need to make sure that the distance between different parts of the construction is large enough to avoid shortcuts.

Overall, the reduction is performed in polynomial (in n, m) time, since the planar graph G_F is drawn on a regular $O(n+m)$-by-$O(n+m)$ grid, and each of our variable gadgets is of size $O(m)$, resulting in overall polynomial area and a polynomial-size construction that is computed in polynomial (in n, m) time. ◀

Notice that in the reduction we proved that if the 3-SAT formula is not satisfiable, then any planar bichromatic spanning tree of P has an edge of length greater than 1. Actually, we can push the length of this edge to be closer to $\sqrt{2}$. That is, we can draw the connection between each clause and its corresponding variables, such that the distance between each chain of the clause and the corresponding site on the inner circle of the variable is 1, and the distance between each chain of the clause and the sites on the outer circle of the variable is at least $\sqrt{2}-\varepsilon$, for any $0 < \varepsilon < \sqrt{2}-1$; see Figure 4. This implies that the bottleneck planar bichromatic spanning tree problem cannot be approximated within a factor less than $\sqrt{2}$, unless $P = NP$.

▶ **Corollary 2.** *The bottleneck planar bichromatic spanning tree problem cannot be approximated within a factor less than $\sqrt{2}$, unless $P = NP$. In particular, there is no PTAS (unless $P = NP$).*

3 Approximation Algorithm

Let P be a set of red and blue points in the plane and let $n = |P|$. Let T be a bichromatic spanning tree of P of minimum bottleneck (T may have crossings and can be computed in $O(n \log n)$ time [12]). Let λ denote the bottleneck of T, i.e., the length of the longest edge in T. Notice that λ is the lower bound for any bichromatic spanning tree of P, in particular for any planar bottleneck bichromatic spanning tree of P. In this section, we show how to compute a planar bichromatic spanning tree of P, such that its bottleneck is at most $8\sqrt{2}\lambda$.

Our algorithm partitions the plane into disjoint cells satisfying the following properties:

1. Each cell is convex and contains points of both colors.
2. In each cell, the distance between any two points is at most $5\sqrt{2}\lambda$.
3. The cells are connected, i.e., if we consider the graph with the cells as its vertices and there is an edge between two cells if they are adjacent (sharing a common boundary), then this graph is connected.
4. We can construct a planar bichromatic spanning tree of the points in each cell and we can connect them without crossings.

Assume, w.l.o.g., that $\lambda = 1$. Consider an axis-parallel grid, with each (square) cell of edge length 3 and all points of P in the interior (not on the boundary) of these cells; see Figure 5. We say that a cell $C_{i,j}$ is bichromatic if it contains points of both colors and we say that $C_{i,j}$ is monochromatic (red or blue) if all of the points in $C_{i,j}$ have the same color, otherwise, we say that $C_{i,j}$ is an empty cell.

Our algorithm consists of two stages. In Stage 1, we modify the grid cells to satisfy properties (1)-(3), and, in Stage 2, we construct a planar bichromatic spanning tree of the points in each cell and connect between these trees to obtain a planar bichromatic spanning tree of P.

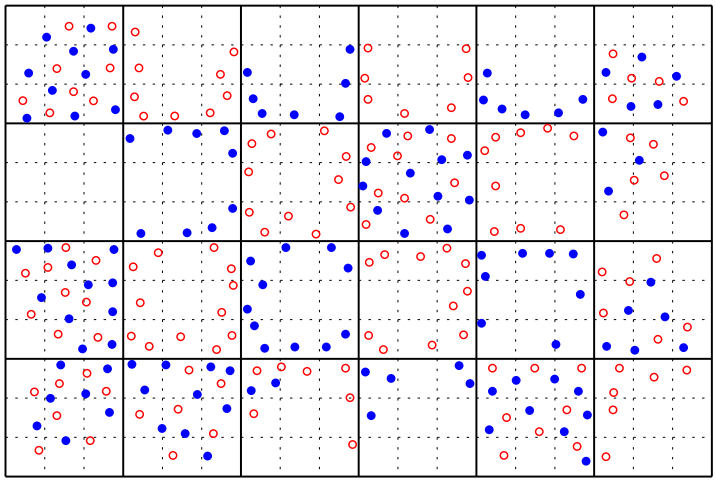

Figure 5 The grid partitioning the points of P.

Stage 1

In this stage, we consider the monochromatic cells and we partition and merge portions of them in order to obtain a subdivision in which all cells are convex and bichromatic. Let $C_{i,j}$ be a 3×3 cell of the grid. Since $C_{i,j}$ is a 3×3 cell, $C_{i,j}$ is the union of 9 unit sub-cells, labelled $C^k_{i,j}$, for $k = 1, 2, 3, \ldots, 9$, as shown in Figure 6(a). Notice that, since $C_{i,j}$ is a monochromatic cell, the points of $C_{i,j}$ are of distance at most 1 from the boundary of $C_{i,j}$, and therefore, $C^5_{i,j}$ is empty of points of P. The region $C_{i,j} \setminus C^5_{i,j}$ is the union of four trapezoids $\mathcal{T}^l_{i,j}$, $\mathcal{T}^r_{i,j}$, $\mathcal{T}^t_{i,j}$, and $\mathcal{T}^b_{i,j}$, such that $\mathcal{T}^l_{i,j}$ (resp., $\mathcal{T}^r_{i,j}$, $\mathcal{T}^t_{i,j}$, and $\mathcal{T}^b_{i,j}$) is the trapezoid obtained by connecting the left (resp., right, top, and bottom) corners of $C_{i,j}$ by diagonals to the left (resp., right, top, and bottom) corners of $C^5_{i,j}$; see Figure 6(b).

(a) (b)

Figure 6 (a) The 9 unit sub-cells of cell $C_{i,j}$. (b) The trapezoids $\mathcal{T}^l_{i,j}$, $\mathcal{T}^r_{i,j}$, $\mathcal{T}^t_{i,j}$, and $\mathcal{T}^b_{i,j}$.

Stage 1.1

In this stage, we introduce a directed graph G in which the vertices are the monochromatic cells and the edges are defined as follows. Let $C_{i,j}$ be a monochromatic cell, and let $\mathcal{N}(C_{i,j}) = \{C_{i,j-1}, C_{i,j+1}, C_{i-1,j}, C_{i+1,j}\}$ be the set of cells that share a grid edge with $C_{i,j}$. Let $C \in \mathcal{N}(C_{i,j})$ be a monochromatic cell and assume, w.l.o.g., that $C = C_{i,j+1}$. There is a directed edge from $C_{i,j}$ to $C_{i,j+1}$ if and only if $C_{i,j}$ and $C_{i,j+1}$ are of different colors and the trapezoid $\mathcal{T}^r_{i,j}$ is not empty of points of P; see Figure 7.

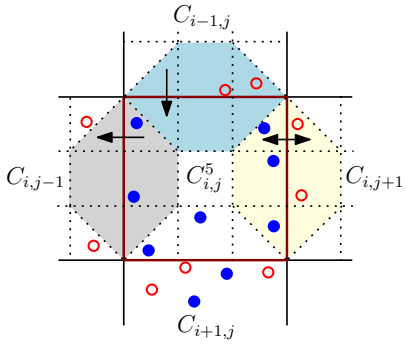

Figure 7 Directed edges between monochromatic cell $C_{i,j}$ and its monochromatic neighbors $(C_{i,j-1}, C_{i-1,j}, C_{i,j+1})$.

Stage 1.2

In this stage, we modify the grid cells by partitioning and merging some of the monochromatic cells with their neighbors, guided by the directed edges introduced in Stage 1.1. Before describing how to modify the grid cells, we describe the following *cell partition procedure* that we will apply in this stage to the empty and some of the monochromatic cells.

Cell partition procedure. For a monochromatic cell $C_{i,j}$, partition $C_{i,j} \setminus C^5_{i,j}$ into trapezoids $\mathcal{T}^l_{i,j}$, $\mathcal{T}^r_{i,j}$, $\mathcal{T}^t_{i,j}$, and $\mathcal{T}^b_{i,j}$, and merge them with the cells $C_{i,j-1}$, $C_{i,j+1}$, $C_{i-1,j}$, and $C_{i+1,j}$, respectively; see Figure 8(b).

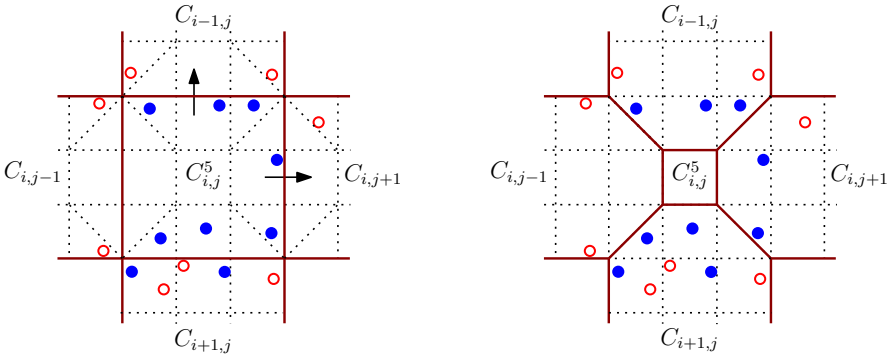

Figure 8 (a) $d_{in}(C_{i,j}) = 0$ and $d_{out}(C_{i,j}) > 0$. (b) Partitioning and merging $C_{i,j}$ with its neighbors.

Let $d_{in}(C_{i,j})$ (resp., $d_{out}(C_{i,j})$) denote the in-degree (resp., the out-degree) of the vertex corresponding to the monochromatic cell $C_{i,j}$ in the graph G. We apply the following three steps on the empty and monochromatic cells.

Step 1. We apply this step as long as there exists a cell $C_{i,j}$ with $d_{in}(C_{i,j}) = 0$ and $d_{out}(C_{i,j}) > 0$. For each such cell, we apply the cell partition procedure on $C_{i,j}$ and remove the out-going edges from $C_{i,j}$ and from its neighbors $C_{i,j-1}$, $C_{i,j+1}$, $C_{i-1,j}$, and $C_{i+1,j}$; see Figure 8.

Step 2. We apply this step on the monochromatic cells $C_{i,j}$ with $d_{in}(C_{i,j}) > 0$. Consider the grid as an arbitrary white-black chessboard. For each white cell with $d_{in}(C_{i,j}) > 0$, we apply the cell partition procedure on $C_{i,j}$.

Step 3. We apply this step on the empty and the monochromatic cells $C_{i,j}$ with $d_{in}(C_{i,j}) = 0$ and $d_{out}(C_{i,j}) = 0$ (that are not considered in the previous steps). For each such cell, we apply the cell partition procedure on $C_{i,j}$.

We call a cell $C_{i,j}$ a *partitioned cell* if $C_{i,j}$ has been partitioned (using the cell partition procedure), and we call it an *extended cell* otherwise. If we have two adjacent partitioned cells $C_{i,j}$ and $C_{i,j+1}$, then we call the merged area of the two trapezoids $\mathcal{T}^r_{i,j}$ and $\mathcal{T}^l_{i,j+1}$ a *lune*; see Figure 9.

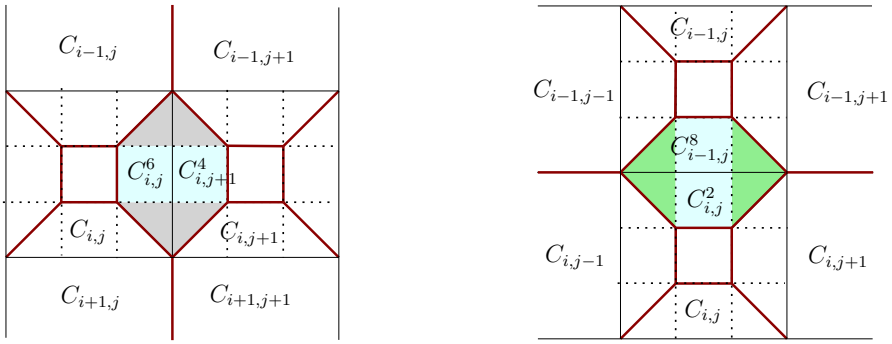

Figure 9 (a) vertical and (b) horizontal lunes.

At the end of this stage, we have three types of non-empty convex cells: original 3×3 cells, extended cells, and lunes. Clearly, each original cell is bichromatic, otherwise, it would have been partitioned or extended in Steps 1–3. Observe that each extended cell $C_{i,j}$ is bichromatic, since $d_{in}(C_{i,j}) > 0$. Observe also that each non-empty lune L is monochromatic. To see this, assume, w.l.o.g., that L was obtained by partitioning the cells $C_{i,j}$ and $C_{i,j+1}$ and merging the trapezoids $\mathcal{T}^r_{i,j}$ and $\mathcal{T}^l_{i,j+1}$. Thus, L cannot be bichromatic, since otherwise, there would be a directed edge from $C_{i,j}$ to $C_{i,j+1}$ and vice versa, which means that one of the cells $C_{i,j}$ and $C_{i,j+1}$ (the black one in the chessboard) is extended in Step 2.

Stage 1.3

In this stage, we get rid of the lunes, by partitioning each lune into sub-pieces and merging the sub-pieces with adjacent extended cells as follows. Let L_1 be a vertical lune obtained by merging two adjacent trapezoids $\mathcal{T}^r_{i,j}$ and $\mathcal{T}^l_{i,j+1}$; see Figure 9(a). (A horizontal lune will be treated analogously.) As observed above, L_1 is monochromatic (or empty) which means that the subregion $C^6_{i,j} \cup C^4_{i,j+1} \subseteq L_1$ is empty of points of P.

We consider the four triangles obtained by removing $C^6_{i,j}$ from $\mathcal{T}^r_{i,j}$ and removing $C^4_{i,j+1}$ from $\mathcal{T}^l_{i,j+1}$, and we merge them with the cells $C_{i-1,j}$, $C_{i-1,j+1}$, $C_{i+1,j}$, and $C_{i+1,j+1}$ according to the following cases. We describe how to merge the top triangles with $C_{i-1,j}$ and $C_{i-1,j+1}$. (Merging the bottom triangles with $C_{i+1,j}$, and $C_{i+1,j+1}$ is done analogously.) Let v_t be the top vertex of L_1; see Figure 10.

- If both $C_{i-1,j}$ and $C_{i-1,j+1}$ are extended cells, then we merge the top-left triangle with $C_{i-1,j}$ and the top-right triangle with $C_{i-1,j+1}$; see Figure 10(a).
- If $C_{i-1,j}$ is a partitioned cell and $C_{i-1,j+1}$ is an extended cell, then we have another horizontal lune L_2 between $C_{i-1,j}$ and $C_{i,j}$; see Figure 10(b). Notice that the union of the top-left triangle of L_1 and the right-bottom triangle of L_2 is exactly the sub-cell $C^3_{i,j}$.

Notice also that L_2 is monochromatic and has the same color as L_1. Thus, the points of P in $C^3_{i,j}$ are of distance 1 from v_t. In this case, we merge the top-right triangle of L_1 and the right-top triangle of L_2 with $C_{i-1,j+1}$. Moreover, we merge the region of $C^3_{i,j}$ intersecting the disk of radius 1 centered at v_t with $C_{i-1,j+1}$; see Figure 10(b).

- If $C_{i-1,j}$ is an extended cell and $C_{i-1,j+1}$ is a partitioned cell, then this case is symmetric to the previous case; see Figure 10(c).
- If both $C_{i-1,j}$ and $C_{i-1,j+1}$ are partitioned cells, then we have four lunes incident to v_t; see Figure 10(d). Since all of the lunes are monochromatic and have the same color, the triangles of these lunes that are incident to v_t are empty of points of P and, therefore, we remove these triangles from the division.

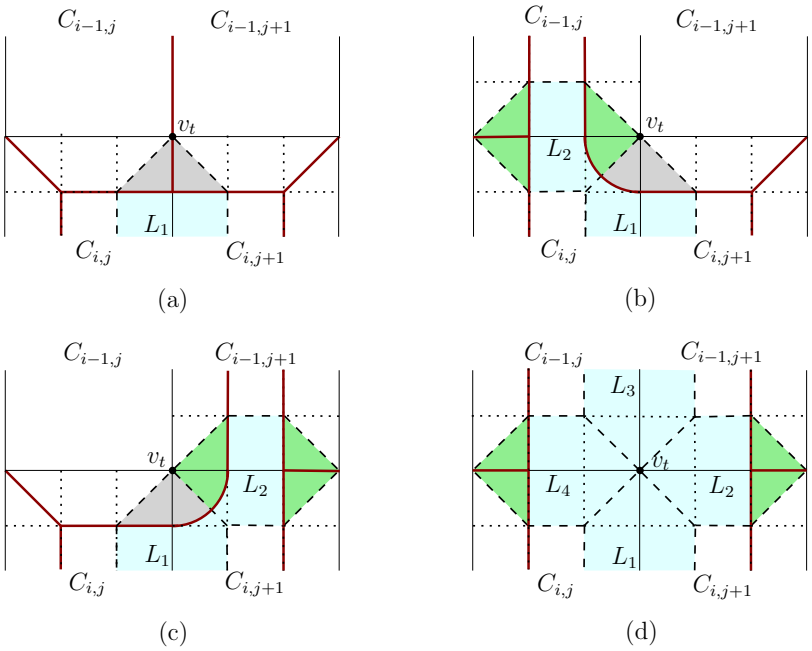

Figure 10 Merging the top triangles of L_1 with the cells $C_{i-1,j}$ and $C_{i-1,j+1}$. The gray and the green regions are part of vertical and horizontal lunes, respectively, and the light blue regions are empty of points of P.

Moreover, in each partitioned cell $C_{i,j}$ such that $i = 1$, $i = n$, $j = 1$, or $j = n$, we treat the trapezoids adjacent to the boundary of the grid as half-lunes and we merge them with their adjacent extended cells as in the lunes case.

Notice that, at the end of this stage, we have two types of non-empty cells: original 3×3 cells and extended cells, and both types are convex and bichromatic cells; see Figure 11. From now on, we refer to both types of these cells as extended cells and denote them by $\hat{C}$. That is, $\hat{C}_{i,j}$ is either an original 3×3 cell $C_{i,j}$ or an extended cell obtained by merging $C_{i,j}$ with trapezoids from its neighbors.

Stage 2

In this stage, we construct a planar bichromatic spanning tree in each (extended) cell and connect them to each other to obtain, overall, a planar bichromatic spanning tree of P. For each cell $\hat{C}_{i,j}$, we denote by $\hat{P}_{i,j}$ the set of points of P lying in $\hat{C}_{i,j}$. If $C_{i,j}$ has been partitioned, then we set $\hat{P}_{i,j} = \emptyset$.

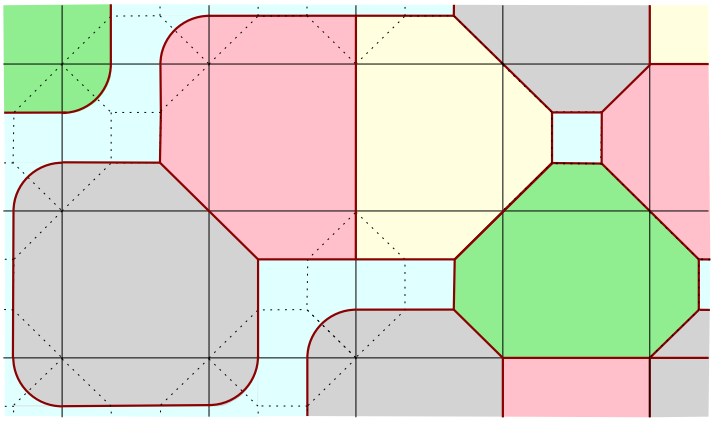

Figure 11 A subdivision obtained at the end of Stage 1. The light blue regions are empty of points of P.

Stage 2.1

In each cell $\hat{C}_{i,j}$, we construct a planar bichromatic spanning tree $T_{i,j}$ of $\hat{P}_{i,j}$ as follows. We select an arbitrary red point $s \in \hat{P}_{i,j}$ as a center of the tree and connect it to each blue point in the cell to produce a star. We extend the edges of the star to partition the cell into convex cones, possibly except one cone; see Figure 12. If we have a non-convex cone, then we divide it into two convex cones by adding its bisector, as shown in Figure 12(right). Then, we connect all the red points in each cone to one of the blue points on the lines bounding the cone.

Figure 12 Constructing a planar bichromatic spanning tree in a cell.

▶ **Lemma 3.** *Let $T_{i,j}$ be a tree constructed in Stage 2.1 in cell $\hat{C}_{i,j}$. Any (red or blue) point p in the plane can be connected to a point of opposite color of $T_{i,j}$ without crossing the edges of $T_{i,j}$.*

Proof. Let s be the center of $T_{i,j}$ and recall that its color is red. Consider the cones produced by the rays between s and the blue points of $T_{i,j}$. Let C be the cone containing p and let a and b be the two blue points defining C. By the way we constructed $T_{i,j}$, all the points in C are red and connected to exactly one of the points a and b, assume, w.l.o.g., a. We distinguish between two cases with respect to the color of p.

Case 1: p is a blue point. If the edge (s, p) does not cross the edges of $T_{i,j}$, then we connect p to s. Otherwise, we connect p to the endpoint of the first edge (from p) crossing (s, p); see Figure 13(a).

Case 2: p is a red point. In this case, we connect p to a; see Figure 13(b). ◀

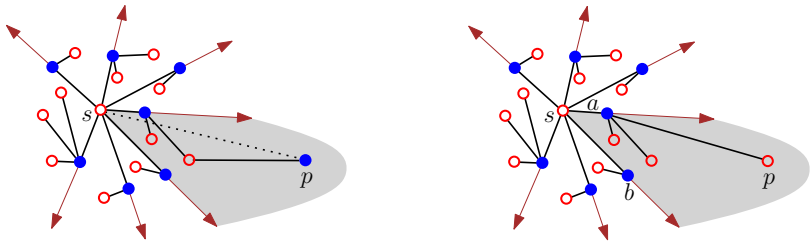

Figure 13 (a) p and s are of different colors. (b) p and s are of the same color.

Stage 2.2

In this stage, we connect between the trees that are constructed in Stage 2.1 to obtain a planar bichromatic spanning tree of P. Let $\hat{C}_{i,j}$ and $\hat{C}_{k,l}$ be two (extended) cells. We say that $\hat{C}_{k,l}$ is a *side* adjacent (or s-adjacent for short) cell of $\hat{C}_{i,j}$, if one of the following holds:

- $k = i + 1$ and $l = j$, or
- $k = i$ and $l = j + 1$,

and we say that $\hat{C}_{k,l}$ is a *diagonal* adjacent (or d-adjacent for short) cell of $\hat{C}_{i,j}$, if one of the following holds:

- $k = i - 1$, $l = j + 1$, and $C_{i-1,j}$ and $C_{i,j+1}$ have been partitioned, or
- $k = i - 1$, $l = j - 1$, and $C_{i,j-1}$ and $C_{i-1,j}$ have been partitioned.

We construct a bichromatic spanning tree T' of P by traversing the cells starting from an arbitrary (non-empty) cell (in breadth first search (BFS) manner). That is, we first initiate a tree T' by an arbitrary tree $T_{i,j}$ that is constructed in a cell $\hat{C}_{i,j}$. Then, we connect T' to all the trees constructed in the cells adjacent to $\hat{C}_{i,j}$, and proceed from these trees. More precisely, in each step, we consider a tree $T_{i,j}$, which is already connected to T', and we connect T' to all of the trees constructed in the cells adjacent to $\hat{C}_{i,j}$ via $T_{i,j}$ (if they are not connected yet to T'). In the following, we describe how to connect T' to all the trees constructed in the cells adjacent to $\hat{C}_{i,j}$.

Let $\hat{C}$ be a cell adjacent to $\hat{C}_{i,j}$, such that the tree T_C constructed in $\hat{C}$ is not connected yet to T'. Let v_{tr}, v_{tl}, v_{br}, and v_{bl} be the top-right, top-left, bottom-right, and bottom-left vertices of the grid incident to $C_{i,j}$, respectively; see Figure 14. We distinguish between two cases.

Case 1: $\hat{C}$ is a d-adjacent cell of $\hat{C}_{i,j}$. Assume, w.l.o.g., that $\hat{C} = \hat{C}_{i-1,j+1}$. Then, the boundaries of $\hat{C}_{i,j}$ and $\hat{C}_{i-1,j+1}$ share a common (diagonal) edge $\overline{ab}$; see Figure 14. Moreover, the convex hull of $\hat{C}_{i,j} \cup \hat{C}_{i-1,j+1}$ does not contain any point of $P \setminus (\hat{P}_{i,j} \cup \hat{P}_{i-1,j+1})$ (this can be seen clearly in Figure 11). Let $p \in \hat{P}_{i,j}$ be the closest point to the line passing through $\overline{ab}$, such that no edge of T' crosses the triangle Δpab. By Claim 4, such a point p exists. Then, any edge connecting p to any point of $T_{i-1,j+1}$ does not cross any non-empty cell except $\hat{C}_{i,j}$ and $\hat{C}_{i-1,j+1}$. Therefore, by Lemma 3, we can connect p to $T_{i-1,j+1}$ without crossing any other edge of T'.

Case 2: $\hat{C}$ is an s-adjacent cell of $\hat{C}_{i,j}$. Assume, w.l.o.g., that $\hat{C} = \hat{C}_{i,j+1}$. Let p be the rightmost point in $\hat{P}_{i,j}$, such that no edge of T' crosses the triangle $\Delta p v_{br} v_{tr}$; see Figure 15. By Claim 4, such a point p exists. Let H be the convex hull of $\hat{P}_{i,j+1} \cup \{p\}$. We consider two sub-cases.

Case 2.1: $H \cap (P \setminus (\hat{P}_{i,j} \cup \hat{P}_{i,j+1})) = \emptyset$ (i.e., H does not contain any point of P that is not in $\hat{P}_{i,j} \cup \hat{P}_{i,j+1}$); see Figure 15. Therefore, by Lemma 3, we can connect $T_{i,j+1}$ to $T_{i,j}$ via p, without crossing any other edge of T'.

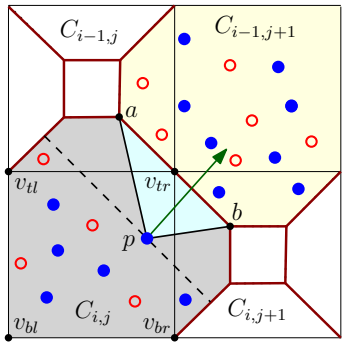

Figure 14 Illustration of Case 1. We connect $T_{i-1,j+1}$ to $T_{i,j}$ via p.

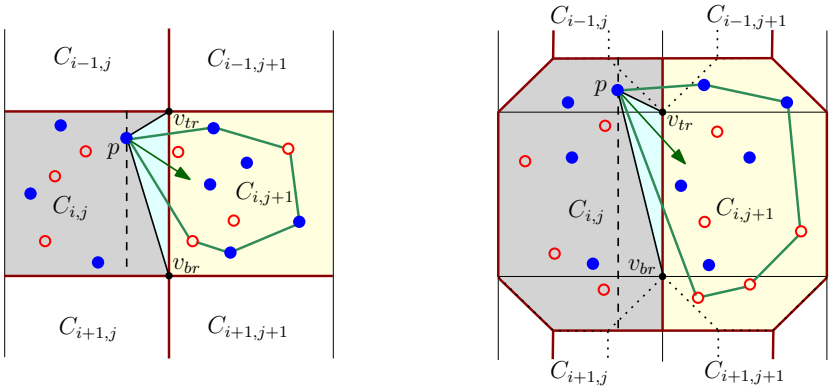

Figure 15 The convex hull H of $\hat{P}_{i,j+1} \cup \{p\}$ (consisting of green segments) does not contain any point of P that is not in $\hat{P}_{i,j} \cup \hat{P}_{i,j+1}$. We connect $T_{i,j+1}$ to $T_{i,j}$ via p.

Case 2.2: $H \cap (P \setminus (\hat{P}_{i,j} \cup \hat{P}_{i,j+1})) \neq \emptyset$ (i.e., H contains a point of P that is not in $\hat{P}_{i,j} \cup \hat{P}_{i,j+1}$). In this case, H contains a point in $\hat{P}_{i-1,j} \cup \hat{P}_{i-1,j+1}$ or in $\hat{P}_{i+1,j} \cup \hat{P}_{i+1,j+1}$. Assume, w.l.o.g., that H contains a point in $\hat{P}_{i-1,j} \cup \hat{P}_{i-1,j+1}$; see Figure 16. Notice that exactly one of the sets $\hat{P}_{i-1,j}$ or $\hat{P}_{i-1,j+1}$ is an empty set, since, in this case, exactly one of the cells $C_{i-1,j}$ or $C_{i-1,j+1}$ has been partitioned. We further distinguish between two cases.

1. $H \cap \hat{P}_{i-1,j} \neq \emptyset$; see Figure 16(a). In this case we first connect $T_{i,j+1}$ to $T_{i-1,j}$ as follows. Let $q \in \hat{P}_{i-1,j}$ be the closest point to the line passing through the boundary edge between $\hat{C}_{i-1,j}$ and $\hat{C}_{i,j+1}$. Then, the convex hull of $\hat{P}_{i,j+1} \cup \{q\}$ does not contain any point of P that is not in $\hat{P}_{i,j+1} \cup \{q\}$. Therefore, by Lemma 3, we can connect $T_{i,j+1}$ to $T_{i-1,j}$ via q, without crossing any other edge of T'.
   Moreover, if $T_{i-1,j}$ is not connected yet to T', then we apply Case 2 on $\hat{C}_{i-1,j}$ to connect $T_{i-1,j}$ to $T_{i,j}$.
2. $H \cap \hat{P}_{i-1,j+1} \neq \emptyset$. If $T_{i-1,j+1}$ is not connected yet to T', then we first connect $T_{i-1,j+1}$ to $T_{i,j}$ as follows. Let $q \in \hat{P}_{i,j}$ be the closest point to the line passing through the boundary edge between $\hat{C}_{i,j}$ and $\hat{C}_{i-1,j+1}$; see Figure 16(b). Then, the convex hull of $\hat{P}_{i-1,j+1} \cup \{q\}$ does not contain any point of P that is not in $\hat{P}_{i-1,j+1} \cup \{q\}$. Therefore, by Lemma 3, we can connect $T_{i-1,j+1}$ to $T_{i,j}$ via q, without crossing any other edge of T'.
   Moreover, we connect $T_{i,j+1}$ to $T_{i-1,j+1}$ as follows. Let a be the bottom-right corner of $C_{i-1,j+1}$. Thus, $\Delta p v_{tr} a \cap \hat{P}_{i-1,j+1} \neq \emptyset$ and $\Delta p v_{tr} a \cap (\hat{P}_{i,j} \setminus \{p\}) = \emptyset$. Let z be the bottommost point in $\Delta p v_{tr} a \cap \hat{P}_{i-1,j+1}$, such that no edge of T' crosses the triangle

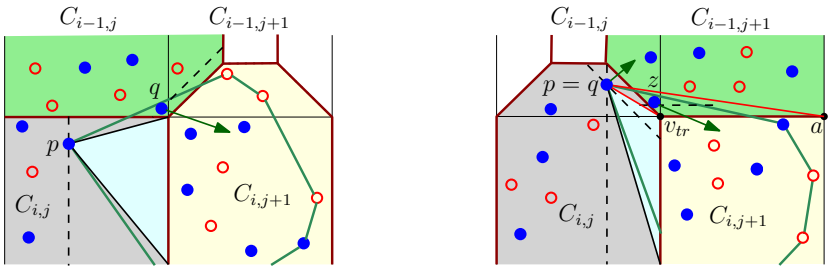

Figure 16 (a) H contains points from $\hat{P}_{i-1,j}$. We connect $T_{i,j+1}$ to $T_{i-1,j}$ via q. (b) H contains a point z from $\hat{P}_{i-1,j+1}$. We connect $T_{i-1,j+1}$ to $T_{i,j}$ via q and we connect $T_{i,j+1}$ to $T_{i-1,j+1}$ via z.

$\Delta z v_{tr} a$; see Figure 16(b). By Claim 4, such a point z exists. Then, the convex hull of $\hat{P}_{i,j+1} \cup \{z\}$ does not contain any point of P that is not in $\hat{P}_{i,j+1} \cup \{z\}$. Therefore, by Lemma 3, we can connect $T_{i,j+1}$ to $T_{i-1,j+1}$ via z, without crossing any other edge of T'. (Notice that the two edges added in this case do not cross each other.)

Correctness Proof

Recall that T is a bichromatic spanning tree of P of minimum bottleneck λ. In this section, we prove that T' is a planar bichromatic spanning tree of P of bottleneck at most $8\sqrt{2}\lambda$. Notice that every point $p \in P$ is contained in a bichromatic cell $\hat{C}_{i,j}$ and hence, it is connected to $T_{i,j}$, the tree constructed in Stage 2.1 in $\hat{C}_{i,j}$. Therefore, to show that T' is a bichromatic spanning tree of P, it is sufficient to show that each tree $T_{i,j}$ is connected to T'.

▷ Claim 4. Let T' be the tree constructed at some step during Stage 2.2 and assume that T' is planar. Let $T_{i,j}$ be a tree constructed in $\hat{C}_{i,j}$ and assume that $T_{i,j}$ is already connected to T'. Let $\hat{C}$ be an adjacent cell of $\hat{C}_{i,j}$ that shares an edge $\overline{ab}$ with $\hat{C}_{i,j}$ and let T_C be the tree constructed in $\hat{C}$, and assume that T_C is not connected yet to T'. Then, there exists a point p in $\hat{C}_{i,j}$, such that no edge of T' crosses the triangle Δpab.

Proof. Assume, w.l.o.g., that $\hat{C} = \hat{C}_{i,j+1}$, $a = v_{tr}$, and $b = v_{br}$; see Figure 17. The following procedure shows the existence of such a point p. We sweep leftwards in $\hat{C}_{i,j}$ with a vertical line l, starting from $\overline{v_{tr}v_{br}}$ until we meet a point, or an edge of T'. If we first meet a point, then this point satisfies the claim. Otherwise, we first meet an edge (p', q') of T'; see Figure 17. This could only be when exactly one of the endpoints p' or q' is outside $\hat{C}_{i,j}$. Let C_l and C_r be the two sub-cells obtained by partitioning $\hat{C}_{i,j}$ with the line that goes through the points p' and q'. Let C_r be the sub-cell containing v_{tr} and v_{br}. We keep sweeping leftwards only inside C_r. As before, if we first meet a point, then this point satisfies the claim. Otherwise, we meet an edge (p'', q'') of T' before we meet a point. Then, one of the endpoints p'' or q'' is outside $\hat{C}_{i,j}$. Let C_{rl} and C_{rr} be the two sub-cells obtained by partitioning C_r with the line that goes through the points p'' and q''. Let C_{rr} be the sub-cell containing v_{tr} and v_{br}. We keep sweeping leftwards only inside C_{rr}, until we meet a point, and this point satisfies the claim. Notice that, in the last sweep we meet a point before we meet an edge of T'. This follows from the planarity of T'. ◁

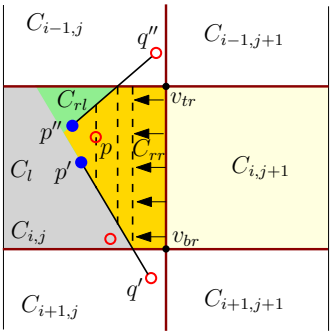

Figure 17 Illustration of the proof of Claim 4.

▶ **Lemma 5.** *Let $T_{i,j}$ be a tree constructed in $\hat{C}_{i,j}$ in Stage 2.1 and assume that $T_{i,j}$ is already connected to T'. Then, at the end of Stage 2.2, all the trees that are constructed in the cells adjacent to $\hat{C}_{i,j}$ are connected to T' as well.*

Proof. Let $\hat{C}$ be an adjacent cell of $\hat{C}_{i,j}$. We distinguish between two cases.

Case 1: $\hat{C}$ is a d-adjacent cell of $\hat{C}_{i,j}$. Assume, w.l.o.g., that $\hat{C} = \hat{C}_{i-1,j+1}$. Then, in Stage 2.2, Case 1, we connect between $T_{i,j}$ and $T_{i-1,j+1}$.

Case 2: $\hat{C}$ is an s-adjacent cell of $\hat{C}_{i,j}$. Assume, w.l.o.g., that $\hat{C} = \hat{C}_{i,j+1}$. As described in Stage 2.2, we select a point $p \in \hat{C}_{i,j}$ and compute the convex hull H of $\{p\} \cup \hat{P}_{i,j+1}$. Then, we consider two cases. In Case 2.1, when H does not contain any point of $P \setminus (\hat{P}_{i,j} \cup \hat{P}_{i,j+1})$, we connect $T_{i,j}$ directly to $T_{i,j+1}$ (via p). And, in Case 2.2, when H contains a point of $P \setminus (\hat{P}_{i,j} \cup \hat{P}_{i,j+1})$, we connect $T_{i,j+1}$ to $T_{i,j}$ via the tree $T_{i-1,j+1}$, in case that H contains a point of $\hat{P}_{i-1,j+1}$ (or via the tree $T_{i+1,j+1}$, in case that H contains a point of $\hat{P}_{i+1,j+1}$). In the case that H contains a point of $\hat{P}_{i-1,j}$ (symmetrically, H contains a point of $\hat{P}_{i+1,j}$), we connect $T_{i,j+1}$ to $T_{i,j}$ via the tree $T_{i-1,j}$. If $T_{i-1,j}$ is already connected to $T_{i,j}$, then we are done. Otherwise, since $\hat{C}_{i-1,j}$ is an s-adjacent cell of $\hat{C}_{i,j}$, we will try to connect $T_{i-1,j}$ to $T_{i,j}$ in the next iteration in Stage 2.2 (by applying Case 2 once again). In the next iteration, either we connect $T_{i-1,j}$ to $T_{i,j}$ in one of the cases described above or we end up by connecting $T_{i,j-1}$ to $T_{i-1,j}$. In the latter case, if $T_{i,j-1}$ is already connected to $T_{i,j}$, then we are done. otherwise, $T_{i+1,j}$ is already connected to $T_{i,j}$. In this case, we connect $T_{i,j-1}$ to $T_{i,j}$ either directly or via $T_{i+1,j}$, and we are done. ◀

▶ **Lemma 6.** *Let p and q be two points of P, such that p and q are of different colors, $|pq| \leq \lambda$ and p belongs to T'. Then, q also belongs to T'.*

Proof. Since $|pq| \leq \lambda$, either p and q are in the same cell or they are in adjacent cells. If they are in the same cell $\hat{C}_{i,j}$, then, after Stage 2.1, they are connected in $T_{i,j}$, and the lemma holds. Otherwise, assume, w.l.o.g., that $p \in \hat{C}_{i,j}$ and $q \in \hat{C}$, where $\hat{C}$ is adjacent to $\hat{C}_{i,j}$. Then, after Stage 2.1, p belongs to $T_{i,j}$ and q belongs to T_C, the tree constructed in $\hat{C}$. Since $T_{i,j}$ is part of T' and $\hat{C}$ is adjacent to $\hat{C}_{i,j}$, by Lemma 5, $T_{i,j}$ is connected to T_C and therefore q belongs to T'. ◀

▶ **Lemma 7.** *Let $T_{i,j}$ be a tree constructed in $\hat{C}_{i,j}$. Then, $T_{i,j}$ is connected to T'.*

Proof. Assume by contradiction that $T_{i,j}$ is not connected to T'. Let a be a point from T' and let b be a point from $T_{i,j}$. Since T is a bottleneck bichromatic spanning tree of P, there is a path Π between a and b in T. Let p be the last point (from a) on Π that belongs to T', i.e., no point of T' appears on the sub-path of Π between p and b. Since b does not belong

to T', such a point p exists. Let q be the point between p and b on Π that is connected to p. By the selection of p, q does not belong to T'. Since the bottleneck of T is λ, we have $|pq| \leq \lambda$. Therefore, by Lemma 6, p and q are connected in T', which contradicts that q does not belong to T'. ◀

▶ **Lemma 8.** *T' is planar.*

Proof. Each $T_{i,j}$ is planar. We start with $T' = T_{i,j}$, where $T_{i,j}$ is an arbitrary tree constructed in $\hat{C}_{i,j}$, and in each step, we extend T' by connecting it to the trees corresponding to the cells adjacent to the current cell. We connect T' to a "new" tree $T_{i,j}$ by picking a point p in T', such that the convex hull H of $\{p\} \cup \hat{P}_{i,j}$ is empty of any other points and no edge of T' crosses H. In Claim 4, we showed that such a point p always exists. Thus, connecting p to any point of $T_{i,j}$ will not cross any other edge of T' nor of any other tree. Moreover, in Lemma 3, we show that we can always connect p to $T_{i,j}$ without crossing any of the edges of $T_{i,j}$. Therefore, connecting T' to $T_{i,j}$ does not produce any crossing. ◀

▶ **Lemma 9.** *The bottleneck of T' is at most $8\sqrt{2}\lambda$.*

Proof. Consider Figure 11. After Stage 1, each extended cell is contained in a square of size $5\lambda \times 5\lambda$, and hence the bottleneck of each tree constructed in Stage 2.1 is at most $5\sqrt{2}\lambda$. Moreover, every two d-adjacent cells are contained in a square of size $8\lambda \times 8\lambda$ and every two s-adjacent cells are contained in a square of size $8\lambda \times 5\lambda$. Thus, each edge added in Stage 2.2 is of length at most $8\sqrt{2}\lambda$. Therefore, each edge in T' is of length at most $8\sqrt{2}\lambda$. ◀

The algorithm consists of two main stages, and each one of them can be implemented in polynomial time. Therefore, the total running time of the algorithm is polynomial. The following theorem summarizes the result of this section.

▶ **Theorem 10.** *Let P be a set of n red and blue points in the plane. One can compute in polynomial time a planar bichromatic spanning tree of P of bottleneck at most $8\sqrt{2}$ times the bottleneck of an optimal bichromatic spanning tree of P.*

Abstract

The dynamic trees problem is to maintain a forest subject to edge insertions and deletions while facilitating queries such as connectivity, path weights, and subtree weights. Dynamic trees are a fundamental building block of a large number of graph algorithms. Although traditionally studied in the single-update setting, dynamic algorithms capable of supporting batches of updates are increasingly relevant today due to the emergence of rapidly evolving dynamic datasets. Since processing updates on a single processor is often unrealistic for large batches of updates, designing parallel batch-dynamic algorithms that achieve provably low span is important for many applications.

In this work, we design the first work-efficient parallel batch-dynamic algorithm for dynamic trees that is capable of supporting both path queries and subtree queries, as well as a variety of nonlocal queries. Previous work-efficient dynamic trees of Tseng et al. were only capable of handling subtree queries [*ALENEX'19*, (2019), pp. 92–106]. To achieve this, we propose a framework for algorithmically dynamizing static round-synchronous algorithms to obtain parallel batch-dynamic algorithms. In our framework, the algorithm designer can apply the technique to any suitably defined static algorithm. We then obtain theoretical guarantees for algorithms in our framework by defining the notion of a computation distance between two executions of the underlying algorithm.

Our dynamic trees algorithm is obtained by applying our dynamization framework to the parallel tree contraction algorithm of Miller and Reif [*FOCS'85*, (1985), pp. 478–489], and then performing a novel analysis of the computation distance of this algorithm under batch updates. We show that k updates can be performed in $O(k \log(1 + n/k))$ work in expectation, which matches the algorithm of Tseng et al. while providing support for a substantially larger number of queries and applications.

1 Introduction

The dynamic trees problem, first posed by Sleator and Tarjan [27] is to maintain a forest of trees subject to the insertion and deletion of edges, also known as *links* and *cuts*. Dynamic trees are used as a building block in a multitude of applications, including maximum flows [27], dynamic connectivity and minimum spanning trees [11], and minimum cuts [19], making them a fruitful line of work with a rich history. There are a number of established sequential dynamic tree algorithms, including link-cut trees [27], top trees [28], Euler-tour trees [15], and rake-compress trees [5], all of which achieve $O(\log(n))$ time per operation.

Since they already perform such little work, there is often little to gain by processing single updates in parallel, hence parallel applications often process *batches* of updates. We are therefore concerned with the design of parallel *batch-dynamic* algorithms. Parallel batch-dynamic algorithms have been developed for several graph problems including incremental connectivity [26], Euler-Tour trees [29], and for fully dynamic connectivity [1]. Parallel batch-dynamic algorithms have also been recently studied in the MPC model [16, 10].

By applying batches it is often possible to obtain significant parallelism while preserving work efficiency. However, designing and implementing dynamic algorithms is difficult, and arguably even more so in the parallel setting.

The goals of this paper are twofold. First and foremost, we are interested in designing a parallel batch-dynamic algorithm for dynamic trees that supports a wide range of applications. On another level, based on the observation that parallel dynamic algorithms are usually quite complex and difficult to design, we are also interested in easing the design process of parallel batch-dynamic algorithms as a whole. To this end, we propose a framework for algorithmically dynamizing static parallel algorithms to obtain efficient parallel batch-dynamic algorithms. We then define a cost model that captures the *computation distance* between two executions of the static algorithm which allows us to bound the runtime of dynamic updates. There are several benefits of using algorithmic dynamization, some more theoretical some practical:

1. Proving correctness of a batch dynamized algorithm relies simply on the correctness of the parallel algorithm, which presumably has already been proven.
2. It is easy to implement different classes of updates. For example, for dynamic trees, in addition to links and cuts, it is very easy to update edge weights or vertex weights for supporting queries such as path length, subtree sums, or weighted diameter. One need only change the values of the weights and propagate.
3. Due to the simplicity of our approach, we believe it is likely to make it easier to program parallel batch-dynamic algorithms, and also result in practical implementations.

Using our algorithmic dynamization framework, we obtain a parallel batch-dynamic algorithm for rake-compress trees that generalizes the sequential data structure work efficiently without loss of generality. Specifically, our main contribution is the following theorem.

▶ **Theorem 1.** *The following operations can be supported on a bounded-degree dynamic tree of size n using the CRCW* PRAM*:*

- *Batch insertions and deletions of k edges in $O(k \log(1 + n/k))$ work in expectation and $O(\log(n) \log^*(n))$ span w.h.p.*
- *Batch connectivity, subtree sum, and path sum queries for batches of size k in $O(k \log(1 + n/k))$ work in expectation and $O(\log(n))$ span w.h.p.*
- *Independent parallel connectivity, subtree sum, path sum, diameter, lowest common ancestor, center, and median queries in $O(\log n)$ time per query w.h.p.*

Arbitrary-degree trees can be handled by transforming them into bounded degree trees using known techniques. We compare the capabilities of parallel rake-compress trees with other dynamic tree algorithms in Table 1. In summary, they support more operations than existing

Table 1 The known capabilities of various dynamic tree algorithms. Nonlocal queries are operations such as computing centers and medians. Our work extends rake-compress trees [5], which were previously only sequential, to also support parallel operations.

	Parallel Operations		Queries Supported		
	Updates	Queries	Path	Subtree	Nonlocal

(Parallel) Euler-tour trees [15, 29]	✓	✓		✓	
Top trees [28]		✓	✓	✓	✓
Rake-compress trees [5]		✓	✓	✓	✓
Parallel rake-compress trees (this paper)	✓	✓	✓	✓	✓

parallel data structures, and support the same broad set of operations as existing non-parallel data structures. Theorem 1 is obtained by dynamizing the parallel tree contraction algorithm of Miller and Reif [20] and performing a novel analysis of the computation distance.

Standalone algorithms for dynamic parallel tree contraction have previously been proposed, but are inefficient and not fully general. In particular, Reif and Tate [25] give an algorithm for parallel dynamic tree contraction that can process a batch of k leaf insertions or deletions in $O(k \log(n))$ work. Unlike our algorithm, theirs is not work efficient, as it performs $\Omega(n \log(n))$ work for batches of size $\Omega(n)$, and it can only modify the tree at the leaves.

Lastly, as some evidence of the applicability of algorithmic dynamization, in the full version of this paper [2], we demonstrate two other applications of the technique. Specifically, we consider map-reduce based computations, and dynamic sequences with splitting and joining. To summarize, the main contributions of this paper are:

1. An algorithmic framework for dynamizing round-synchronous parallel algorithms, and a cost model for analyzing the performance of algorithms resulting from the framework
2. An analysis of the computation distance of Miller and Reif's tree contraction algorithm under batch edge insertions and deletions, which shows that it can be efficiently dynamized
3. The first work-efficient parallel algorithm for batch-dynamic trees that supports subtree queries, path queries, and nonlocal queries such as centers and medians.

Technical overview

A *round-synchronous* algorithm consists of a sequence of rounds, where a round executes in parallel across a set of processes, and each process runs a sequencial *round computation* reading and writing from shared memory and doing local computation. The round synchronous model is similar to Valiant's well-known Bulk Synchronous Parallel (BSP) model [30], except that communication is done via shared memory. Algorithmic dynamization works by running the round-synchronous algorithm while tracking all write-read dependences – i.e., a dependence from a write in one round to a read in a later round. Then, whenever a batch of changes are made to the input, *change propagation* propagates the changes through the original computation, only rerunning round computations if the values they read have changed. We note that depending on the algorithm, changes to the input could drastically change the underlying computation, introducing new dependencies, or invalidating old ones. Part of the novelty of this paper is bounding the work and span of this update process.

The idea of change propagation has been applied in the sequential setting and used to generate efficient dynamic algorithms [3, 4]. The general idea of parallel change propagation has also been used in various practical systems [9, 14, 7, 23, 24] but none of them have been analyzed theoretically.

To capture the cost of running the change propagation algorithm for a particular parallel algorithm and class of updates we define a *computational distance* between two computations, which corresponds to the total work of the round computations that differ in the two computations. The *input configuration* for a computation consists of the input I, stored in shared memory, and an initial set of processes P. We show the following bounds, where the *work* is the sum of the time of all round computations, and *span* is the sum over rounds of the maximum time of any round computation in that round.

▶ **Theorem 2.** *Given a round-synchronous algorithm A that with input configuration (I, P) does W work in R rounds and S span, then, on the CRCW* PRAM*,*

1. *the initial run of the algorithm with tracking takes $O(W)$ work in expectation and $O(S + R \log W)$ time w.h.p.,*
2. *running change propagation from input configuration (I, P) to configuration (I', P') takes $O(W_\Delta + R')$ work in expectation and $O(S' + R' \log W')$ time w.h.p., where W_Δ is the computation distance between the two configurations, and S',R',W' are the maximum span, rounds and work for the two configurations.*

We show that the work can be reduced to $O(W_\Delta)$, and that the $\log W$ and $\log W'$ terms can be reduced to $\log^* W$ when the round-synchronous algorithms have certain restrictions that are satisfied by all of our example algorithms, including our main result on dynamic trees. We also present similar results in other parallel models of computation.

With our dynamization framework and cost model, we develop an algorithm for dynamic trees that support a broad set of queries including subtree sums, path queries, lowest common ancestors, diameter, center, and median queries. This significantly improves over previous work on batch-dynamic Euler tour trees [29], which only support subtree sums.

Our dynamic trees algorithm is a parallel version of the sequential rake-compress tree (RC tree) data structure. Previous work showed that in the sequential setting, one can generate an RC tree (or forest) as a byproduct of Miller and Reif's tree contraction process, which supports the wide collection of queries mentioned above, all in logarithmic time, w.h.p. [5]. Our approach generalizes this sequential algorithm to allow for batches of edge insertions or deletions, work efficiently in parallel. The challenge is in analyzing the computation distance incurred by batch updates in the parallel batch-dynamic setting. In Section 4 we do just that, and obtain the following result:

▶ **Theorem 3.** *In the round synchronous model, Miller and Reif's tree contraction algorithm does $O(n)$ work in expectation and has $O(\log n)$ rounds and span w.h.p. Furthermore, given forests T with n vertices, and T' with k modifications to the edge list of T, the computation distance of the algorithm on the two inputs is $O(k \log(1 + n/k))$ in expectation.*

The bounds can then be plugged into Theorem 2 to show that a set of k edges can be inserted or deleted in a batch in $O(k \log(1 + n/k))$ work in expectation and $O(\log^2 n)$ span w.h.p. We show that the span can be improved to $O(\log n \log^* n)$ w.h.p. on the CRCW PRAM model. The last step in obtaining our dynamic trees framework is to plug the dynamized tree contraction algorithm into the RC trees framework [5] (see Section 5).

2 Preliminaries

2.1 Parallel Models

The parallel random access machine (PRAM) model is a classic parallel model with p processors that work in lock-step, connected by a parallel shared-memory [17]. In this paper we primarily consider the Concurrent-Read Concurrent-Write model (CRCW PRAM), where

memory locations are allowed to be concurrently read and concurrently written to. If multiple writers write to the same location concurrently, we assume that an arbitrary writer wins. We analyze algorithms on the CRCW PRAM in terms of their *work* and *span*. The span (or parallel time) of an algorithm is the minimum running time achievable when arbitrarily many processors are available. The work is the product of the span and the number of processors.

The threaded random access machine (TRAM) is closely related to the PRAM, but more closely models current machines and programming paradigms [8]. In the binary forking TRAM (binary forking model for short), a process can *fork* another process to run in parallel, and can *join* to wait for all forked calls to complete. In the binary forking model, the *work* of an algorithm is the total number of instructions it performs, and the *span* is the longest chain of sequentially dependent instructions.

2.2 Parallel Primitives

The following parallel procedures are used throughout the paper. *Scan* takes as input an array A of length n, an associative binary operator $\oplus$, and an identity element $\perp$ such that $\perp \oplus x = x$ for any x, and returns the array $(\perp, \perp \oplus A[0], \perp \oplus A[0] \oplus A[1], \ldots, \perp \oplus_{i=0}^{n-2} A[i])$ as well as the overall sum, $\perp \oplus_{i=0}^{n-1} A[i]$. Scan takes $O(n)$ work and $O(\log n)$ span (assuming $\oplus$ takes $O(1)$ work) [17] on the CRCW PRAM, and in the binary forking model.

Filter takes an array A and a predicate f and returns a new array containing $a \in A$ for which $f(a)$ is true, in the same order as in A. Filter can be done in $O(n)$ work and $O(\log n)$ span on the CRCW PRAM (assuming f takes $O(1)$ work) [17], and in the binary forking model. The *Approximate Compaction* problem is similar to a Filter. It takes an array A and a predicate f and returns a new array containing $a \in A$ for which $f(a)$ is true where some of the entries in the returned array can have a null value. The total size of the returned array is at most a constant factor larger than the number of non-null elements. Gil et al. [12] describe a parallel approximate compaction algorithm that uses linear space and achieves $O(n)$ work and $O(\log^*(n))$ span w.h.p. on the CRCW PRAM.

A *semisort* takes an input array of elements, where each element has an associated key and reorders the elements so that elements with equal keys are contiguous. The purpose is to collect equal keys together, rather than sort them. Semisorting a sequence of length n can be performed in $O(n)$ expected work and $O(\log n)$ depth w.h.p. on the CRCW PRAM [13] and in the binary forking model [8], assuming access to a uniformly random hash function mapping keys to integers in the range $[1, n^{O(1)}]$.

3 Dynamization Framework

3.1 Round-synchronous algorithms

In this framework, we consider dynamizing algorithms that are *round synchronous*. The round synchronous framework encompasses a range of classic BSP [30] and PRAM algorithms. A round-synchronous algorithm consists of M *processes*, with process IDs bounded by $O(M)$. The algorithm performs sequential rounds in which each active process executes, in parallel, a *round computation*. At the end of a round, any processes can decide to *retire*, in which case they will no longer execute in any future round. The algorithm terminates once there are no remaining active processes – i.e., they have all retired. Given a fixed input, round-synchronous algorithms must perform deterministically. Note that this does not preclude us from implementing randomized algorithms (indeed, our dynamic trees algorithm is randomized), it just requires that we provide the source of randomness as an input to

the algorithm, so that its behavior is identical if re-executed. An algorithm in the round synchronous framework is defined in terms of a procedure ComputeRound(r, p), which performs the computation of process p in round r. The initial run of a round-synchronous algorithm must specify the set P of initial process IDs.

Memory model

Processes in a round-synchronous algorithm may read and write to local memory that is not persisted across rounds. They also have access to a *shared memory*. The input to a round-synchronous algorithm is the initial contents of the shared memory. Round computations can read and write to shared memory with the condition that writes do not become visible until the end of the round. Reads can only access shared locations that have been written to, and shared locations can only be written to once, hence concurrent writes are not permitted. The contents of the shared memory at termination is considered to be the algorithm's output. Change propagation is driven by tracking all reads and writes to shared memory.

Pseudocode

We describe round-synchronous algorithms using the following primitives:

1. The **read** instruction reads the given shared memory locations and returns their values,
2. The **write** instruction writes the given value to the given shared memory location.
3. Processes may retire by invoking the **retire process** instruction.

Measures

The following measures will help us to analyse the efficiency of round-synchronous algorithms. For convenience, we define the *input configuration* of a round-synchronous algorithm as the pair (I, P), where I is the input to the algorithm (i.e. the initial state of shared memory) and P is the set of initial process IDs.

▶ **Definition 4** (Initial work, Round complexity, and Span)**.** *The* initial work *of a round-synchronous algorithm on some input configuration (I, P) is the sum of the work performed by all of the computations of each processes over all rounds when given that input. Its* round complexity *is the number of rounds that it performs, and its* span *is the sum of the maximum costs per round of the computations performed by each process.*

3.2 Change propagation

Given a round-synchronous algorithm, a *dynamic update* consists of a change to the input configuration, i.e. changing the contents of shared memory, and/or adding or deleting processes. The initial run and change propagation algorithms maintain the following data:

1. $R_{r,p}$, the memory locations read by process p in round r
2. $W_{r,p}$, the memory locations written by process p in round r
3. S_m, the set of round, process pairs that read memory location m
4. $X_{r,p}$, which is **true** if process p retired in round r

Algorithm 1 depicts the procedure for executing the initial run of a round-synchronous algorithm before making any dynamic updates.

To help formalize change propagation, we define the notion of an *affected computation*. The task of change propagation is to identify the affected computations and rerun them.

Algorithm 1 Initial run.

```
1:  procedure RUN(P)
2:    local r ← 0
3:    while P ≠ ∅ do
4:      for each process p ∈ P do in parallel
5:        COMPUTEROUND(r, p)
6:        R_{r,p} ← {memory locations read by p in round r}
7:        W_{r,p} ← {memory locations written to by p in round r}
8:        X_{r,p} ← (true if p retired in round r else false)
9:      for each  m ∈ ∪_{p∈P} R_{r,p} do in parallel
10:       S_m ←  S_m ∪ {(r, p) | m ∈ R_{r,p} ∧  p ∈ P}
11:     P ← P \ {p ∈ P : X_{r,p} = true}
12:     r ← r + 1
```

▶ **Definition 5** (Affected computation)**.** *Given a round-synchronous algorithm A and two input configurations (I, P) and (I', P'), the* affected computations *are the round and process pairs (r, p) such that either:*

1. *process p runs in round r on one input configuration but not the other*
2. *process p runs in round r on both input configurations, but reads a variable from shared memory that has a different value in one configuration than the other*

The change propagation algorithm is depicted in Algorithm 2. It works by maintaining the affected computations as three disjoint sets, P, the set of processes that read a memory location that was rewritten, L, processes that outlived their previous self, i.e. that retired the last time they ran, but did not retire when re-executed, and D, processes that retired earlier than their previous self. First, at each round, the algorithm determines the set of computations that should become affected because of shared memory locations that were rewritten in the previous round (Lines 12–14). These are used to determine P, the set of affected computations to rerun this round (Line 15). To ensure correctness, the algorithm must then reset the reads that were performed by the computations that are no longer alive, or that will be reran, since the set of locations that they read may differ from last time (Lines 18–19). Lines 22–26 perform the re-execution of all processes that read a changed memory location, or that lived longer (did not retire) than in the previous configuration. The algorithm then subscribes the reads of these computations to the memory locations that they read (Lines 28–29). Finally, on Lines 32–36, the algorithm updates the set of changed memory locations (U), the set of computations that lived longer than their previous self (L) and the set of computations that retired earlier then their previous self (D).

3.3 Correctness

In this section, we sketch a proof of correctness of the change propagation algorithm (Algorithm 2). Intuitively, correctness is assured because of the write-once condition on global shared memory, which ensures that computations can not have their output overwritten, and hence do not need to be re-executed unless data that they depend on is modified.

▶ **Lemma 6.** *Given a dynamic update, re-executing only the affected computations for each round will result in the same output as re-executing all computations on the new input.*

Proof. Since by definition they read the same values, computations that are not affected, if re-executed, would produce the same output as they did the first time. Since all shared memory locations can only be written to once, values written by processes that are not

Algorithm 2 Change propagation.

```
1: // U = sequence of memory locations that have been modified
2: // P+ = sequence of new process IDs to create
3: // P− = sequence of process IDs to remove
4: procedure PROPAGATE(U, P+, P−)
5:   local D ← P−                                  // Processes that died earlier than before
6:   local L ← P+                                  // Processes that lived longer than before
7:   local A ← ∅                                   // Affected computations at each round
8:   local r ← 0
9:   while U ≠ ∅ ∨ D ≠ ∅ ∨ L ≠ ∅ ∨ ∃r' ≥ r : (A_r' ≠ ∅) do
10:    // Determine the computations that become affected
11:    // due to the newly updated memory locations U
12:    local A' ← ∪_{m∈U} S_m
13:    for each r' ∈ ∪_{(r',p)∈A'} {r'} do in parallel
14:      A_r' ← A_r' ∪ {p | (r', p) ∈ A'}
15:    local P ← A_r \ D                           // Processes to rerun
16:    // Forget the prior reads of all processes that are
17:    // now dead or will be rerun on this round
18:    for each m ∈ ∪_{p∈P∪D} R_{r,p} do in parallel
19:      S_m ← S_m \ {(r, p) | m ∈ R_{r,p} ∧ p ∈ P ∪ D}
20:    local X^prev = {p ↦ X_{r,p} | p ∈ P}
21:    // (Re)run all changed or newly live processes
22:    for each process p in P ∪ L do in parallel
23:      COMPUTEROUND(r, p)
24:      R_{r,p} ← {memory locations read by p in round r}
25:      W_{r,p} ← {memory locations written to by p in round r}
26:      X_{r,p} ← (true if p retired in round r else false)
27:    // Remember the reads performed by processes on this round
28:    for each m ∈ ∪_{p∈P∪L} R_{r,p} do in parallel
29:      S_m ← S_m ∪ {(r, p) | m ∈ R_{r,p} ∧ p ∈ P ∪ L}
30:    // Update the sets of changed memory locations,
31:    // newly live processes, and newly dead processes
32:    U ← ∪_{p∈(P∪L)} W_{r,p}
33:    L' ← {p ∈ P | X_p^prev = true ∧ X_{r,p} = false}
34:    L ← L ∪ L' \ {p ∈ L | X_{r,p} = true}
35:    D' ← {p ∈ P | X_p^prev = false ∧ X_{r,p} = true}
36:    D ← D ∪ D' \ {p ∈ D | X_p^prev = true}
37:    r ← r + 1
```

re-executed can not have been overwritten, and hence it is safe to not re-execute them, as their output is preserved. Therefore re-executing only the affected computations will produce the same output as re-executing all computations. ◀

▶ **Theorem 7** (Consistency). *Given a dynamic update, change propagation correctly updates the output of the algorithm.*

Proof sketch. Follows from Lemma 6 and the fact that all reads and writes to global shared memory are tracked in Algorithm 2, and since global shared memory is the only method by which processes communicate, all affected computations are identified. ◀

3.4 Cost analysis

To analyze the work of change propagation, we need to formalize a notion of *computation distance*. Intuitively, the computation distance between two computations is the work performed by one and not the other. We then show that change propagation can efficiently re-execute the affected computations in work proportional to the computation distance.

▶ **Definition 8** (Computation distance)**.** *Given a round-synchronous algorithm A and two input configurations, the* computation distance W_Δ *between them is the sum of the work performed by all of the affected computations with respect to both input configurations.*

▶ **Theorem 9.** *Given a round-synchronous algorithm A with input configuration (I, P) that does W work in R rounds and S span, then*

1. *the initial run of the algorithm with tracking takes $O(W)$ work in expectation and $O(S + R \cdot \log(W))$ span w.h.p.,*
2. *running change propagation on a dynamic update to the input configuration (I', P') takes $O(W_\Delta + R')$ work in expectation and $O(S' + R' \log(W'))$ span w.h.p., where S', R', W' are the maximum span, rounds, and work of the algorithm on the two input configurations,*

These bounds hold on the CRCW PRAM *and in the binary forking* TRAM *model.*

Proof. We begin by analyzing the initial run. By definition, all executions of the round computations, ComputeRound, take $O(W)$ work and $O(S)$ span in total, with at most an additional $O(\log(M)) = O(\log(W))$ span to perform the parallel for loop. We will show that all additional work can be charged to the round computations, and that at most an additional $O(\log(W))$ span overhead is incurred.

We observe that $R_{r,p}, W_{r,p}$ and $X_{r,p}$ are at most the size of the work performed by the corresponding computations, hence the cost of Lines 6 – 8 can be charged to the computation. The reader sets S_m can be implemented as dynamic arrays with lazy deletion (this will be discussed during change propagation). To append new elements to S_m (Line 10), we can use a semisort performing linear work in expectation to first bucket the shared memory locations in $\cup_{p \in P} R_{r,p}$, whose work can be charged to the corresponding computations that performed the reads. This adds an additional $O(\log(W))$ span w.h.p. since the number of reads is no more than W in total. Finally, removing retired computations from P (Line 11) requires a compaction operation. Since compaction takes linear work, it can be charged to the execution of the corresponding processes. The span of compaction is at most $O(\log(W))$.

Summing up, we showed that all additional work can be charged to the round computations, and the algorithm incurs at most $O(\log(W))$ additional span per round w.h.p. Hence the cost of the initial run is $O(W)$ work in expectation and $O(S + R \cdot \log(W))$ span w.h.p.

We now analyze the change propagation procedure (Algorithm 2). The core of the work is the re-execution of the affected readers on Line 23, which, by definition takes $O(W_\Delta)$ work, and $O(S')$ span, with at most $O(\log(W'))$ additional span to perform the parallel for loop. Since some rounds may have no affected computations, the algorithm could perform up to $O(R')$ additional work to process these rounds. We will show that all additional work can be charged to the affected computations, incurring at most an additional $O(\log(W'))$ span.

Lines 12 – 14 bucket the newly affected computations by round. This can be achieved with an expected linear work semisort and by maintaining the A_r sets as dynamic arrays. The work is chargeable to the affected computations and the span is at most $O(\log(W'))$ w.h.p. Computing the current set of affected computations (Line 15) requires a filter/compaction operation, whose work is charged to the affected computations and span is at most $O(\log(W'))$.

Updating the reader sets S_m (Line 19) can be done as follows. We maintain S_m as dynamic arrays with lazy deletion, meaning that we delete by marking the corresponding slot as empty. When more than half of the slots have been marked empty, we perform compaction,

whose work is charged to the updates and whose span is at most $O(\log(W'))$. In order to perform deletions in constant time, we augment the set $R_{r,p}$ so that it remembers, for each entry m, the location of (r,p) in S_m. Therefore these updates take constant amortized work each (using a dynamic array), charged to the corresponding affected computations, and at most $O(\log(W'))$ span if a resize/compaction is triggered.

X^{prev} can be implemented as an array of size $|P|$, with work charged to the affected computations in P. As in the initial run, the cost of updating $R_{r,p}, W_{r,p}$ and $X_{r,p}$ can also be charged to the work performed by the affected computations.

Updating the reader sets S_m (Line 29) is a matter of appending to dynamic arrays, and, as mentioned earlier, remembering for each $m \in R_{r,p}$, the location of (r,p) in S_m. The work can be charged to the affected computations, and the span is at most $O(\log(W'))$.

Collecting the updated locations U (Line 32) can similarly be charged to the affected computations, and incurs no more than $O(\log(W'))$ span. On Lines 33 – 36, the sets L' and D' are computed by a compaction over P, whose work is charged to the affected computations in P. Updating L and D correspondingly requires a compaction operation, whose work is charged to the affected computations in L and D respectively. Each of these compactions costs $O(\log(W'))$ span.

We can finally conclude that all additional work performed by change propagation can be charged to the affected computations, and hence to the computation distance W_Δ, while incurring at most $O(\log(W'))$ additional span per round w.h.p. Therefore the total work performed by change propagation is $O(W_\Delta + R')$ in expectation and the span is $O(S' + R' \cdot \log(W'))$ w.h.p. ◀

We now show that for a special class of round-synchronous algorithms, the span overhead can be reduced. Our dynamic trees algorithm falls into this special case.

▶ **Definition 10.** *A* restricted round-synchronous *algorithm is a round-synchronous algorithm such that each round computation performs only a constant number of reads and writes, and each shared memory location is read only by a constant number of computations, and only in the round directly after it was written.*

▶ **Theorem 11.** *Given a restricted round-synchronous algorithm A with input configuration (I,P) that does W work in R rounds and S span, then*

1. *the initial run of the algorithm with tracking takes $O(W)$ work and $O(S + R\log^*(W))$ span w.h.p. on the CRCW* PRAM *and $O(S + R\log(W))$ span in the binary forking model,*
2. *change propagation on a dynamic update to the input configuration (I', P') takes $O(W_\Delta)$ work (in expectation on the CRCW* PRAM*), and $O(S' + R'\log^*(W'))$ span w.h.p. on the CRCW* PRAM *and $O(S' + R'\log(W'))$ span in the binary forking model, where S', R', W' are the maximum span, rounds, and work of the algorithm on the two input configurations.*

Proof sketch. Rather than recreate the entirety of the proof of Theorem 9, we simply sketch the differences. In essence, we obtain the result by removing the uses of scans, and semisorts, which were the main cause of the $O(\log(W'))$ span overhead and the randomized work. Instead, we rely only on (possibly approximate) compaction, which is only randomized on the CRCW PRAM. We also lose the R' term in the work since computations can only read from locations written in the previous round, and hence the set of rounds on which there exists an affected computation must be contiguous.

The main technique that we will make use of is the sparse array plus compaction technique. In situations where we wish to collect a set of items from each executed process, we would, in the unrestricted model, require a scan, which costs $O(\log(W'))$ span on the CRCW PRAM.

If each executed process, however, only produces a constant number of these items, we can allocate an array that is a constant size larger than the number of processes, and each process can write its set of items to a designated offset. We can then perform (possibly approximate) compaction on this array to obtain the desired set, with at most a constant factor additional blank entries. This takes $O(\log^*(W'))$ span w.h.p. on the CRCW PRAM, and $O(\log(W'))$ span in the binary forking model.

Maintaining S_m in the initial run and during change propagation is the first bottleneck, originally requiring a semisort. Since each computation performs a constant number of writes, we can collect the writes using the sparse array plus compaction technique. Since, in the restricted model, each modifiable will only be read by a constant number of readers, we can update S_m in constant time.

To compute the affected computations A_r also originally required a semisort, but in the restricted model, since all reads happen on the round directly after the write, no semisort is needed, since they will all have the same value of r. Collecting the affected computations from the written modifiables can also be achieved using the sparse array and compaction technique, using the fact that each computation wrote to a constant number of modifiables, and each modifiable is subsequently read by a constant number of computations. Additionally, A_r will be empty at the beginning of round r, so computing P requires only a compaction.

Lastly, collecting the updated locations U can also be performed using the sparse array and compaction technique. In summary, we can replace all originally $O(\log(W'))$ span operations with (approximate) compaction in the restricted setting, and hence we obtain the given span bounds since this takes $O(\log^*(W'))$ span w.h.p. on the CRCW PRAM, and $O(\log(W'))$ span in the binary forking model. ◀

▶ Remark 12 (Space usage). We do not formally specify an implementation of the memory model, but one simple way to achieve good space bounds is to use hashtables to implement global shared memory. Each write to a particular global shared memory location maps to an entry in the hashtable. When a round computation is invalidated during a dynamic update, its writes can be purged from the hashtable to free up space, preventing unbounded space blow up. Since the algorithm must also track the reads of each global shared memory location, using this implementation, the space usage is proportional to the number of shared memory reads and writes. In the restricted round-synchronous model, the number of reads must be proportional to the number of writes, and hence the space usage is proportional to the number of writes.

4 Dynamizing Tree Contraction

In this section, we show how to obtain a dynamic tree contraction algorithm by applying our dynamization technique to the static tree contraction algorithm of Miller and Reif [20]. In Section 5, we will show how to use this to obtain a parallel batch-dynamic trees framework.

Tree contraction

Tree contraction is the process of shrinking a tree down to a single vertex by repeatedly performing local contractions. Each local contraction deletes a vertex and merges its adjacent edges if it had degree two. Tree contraction has a number of useful applications, studied extensively in [21, 22, 5]. It can be used to perform various computations by associating data with edges and vertices and defining how data is accumulated during local contractions.

Various versions of tree contraction have been proposed depending on the specifics of local contractions. We consider an undirected variant of the randomized version proposed by Miller and Reif [20], which makes use of two operations: *rake* and *compress*. The former

removes all nodes of degree one from the tree, except in the case of a pair of adjacent degree one vertices, in which case only one of them is removed by tiebreaking on the vertex IDs. The latter operation, compress, removes an independent set of vertices of degree two that are not adjacent to any vertex of degree one. Compressions are randomized with coin flips to break symmetry. Miller and Reif showed that it takes $O(\log n)$ rounds w.h.p. to fully contract a tree of n vertices in this manner.

Input forests

The algorithms described here operate on undirected forests $F = (V, E)$, where V is a set of vertices, and E is a set of undirected edges. If $(u, v) \in E$, we say that u and v are *adjacent*, or that they are *neighbors*. A vertex with no neighbors is said to be *isolated*, and a vertex with one neighbor is called a *leaf*.

We assume that the forests given as input have bounded degree. That is, there exists some constant t such that each vertex has at most t neighbors. We will explain how to handle arbitrary-degree trees momentarily.

The static algorithm

The static tree contraction algorithm (Algorithm 3) works in rounds, each of which takes a forest from the previous round as input and produces a new forest for the next round. On each round, some vertices may be *deleted*, in which case they are removed from the forest and are not present in all remaining rounds. Let $F^i = (V^i, E^i)$ be the forest after i rounds of contraction, and thus $F^0 = F$ is the input forest. We say that a vertex v is *alive* at round i if $v \in V^i$, and is *dead* at round i if $v \notin V^i$. If $v \in V^i$ but $v \notin V^{i+1}$ then v was deleted in round i. There are three ways for a vertex to be deleted: it either *finalizes* (Line 32), *rakes* (Line 21), or *compresses* (Line 26). Finalization removes isolated vertices. Rake removes all leaves from the tree, with one special exception. If two leaves are adjacent, then to break symmetry and ensure that only one of them rakes, the one with the lower identifier rakes into the other (Line 8). Finally, compression removes an independent set of degree two vertices that are not adjacent to any degree one vertices, as in Miller and Reif's algorithm. The choice of which vertices are deleted in each round is made locally for each vertex based upon its own degree, the degrees of its neighbors, and coin flips for itself and its neighbors (Line 13). For coin flips, we assume a function $\textsc{Heads}(i, v)$ which indicates whether or not vertex v flipped heaps on round i. It is important that $\textsc{Heads}(i, v)$ is a function of both the vertex and the round number, as coin flips must be repeatable for change propagation to be correct.

The algorithm produces a *contraction data structure* which serves as a record of the contraction process. The contraction data structure is a tuple, (A, D), where $A[i][u]$ is a list of pairs containing the vertices adjacent to u in round i, and the positions of u in the adjacency lists of the adjacent vertices. $D[u]$ stores the round on which vertex u contracted. The algorithm also records $\text{leaf}[i][u]$, which is true if vertex u is a leaf at round i. An implementation of the tree contraction algorithm in our framework is shown in Algorithm 3.

Updates

We consider update operations that implement the interface of a batch-dynamic tree data structure. This requires supporting batches of links and cuts. A *link (insertion)* connects two trees in the forest by a newly inserted edge. A *cut (deletion)* deletes an edge from the forest, separating a single tree into two trees. We formally specify the interface for batch-dynamic trees and give a sample implementation of their operations in terms of the tree contraction data structure in the full version of this paper [2].

Algorithm 3 Tree contraction algorithm.

```
1: procedure ComputeRound(i, u)
2:   local ((v_1, p_1), ..., (v_t, p_t)), ℓ ← read(A[i][u], leaf[i][u])
3:   if v_i = ⊥ ∀i then                                  // A vertex with no neighbors finalizes
4:     DoFinalize(i, u)
5:   else if ℓ then                                      // A leaf vertex rakes if its neighbor is
6:     local (v, p) ← (v_i, p_i) such that v_i ≠ ⊥       // not a leaf, or if it has the lower ID
7:     local ℓ' ← read(leaf[i][v])
8:     if ¬ℓ' ∨ u < v then DoRake(i, u, (v, p))
9:     else DoAlive(i, u, ((v_1, p_1), ..., (v_t, p_t)))
10:  else                                                // If the vertex has exactly two
11:    if ∃(v, p), (v', p') : {v_1, ..., v_t} \ {⊥} = {v, v'} then   //  neighbors, it will compress
12:      local ℓ', ℓ'' ← read(leaf[i][v], leaf[i][v'])   // if neither of them are
13:      local c ← Heads(i, u) ∧ ¬Heads(i, v) ∧ ¬Heads(i, v')   // leaves and it flips heads
14:      if (¬ℓ' ∧ ¬ℓ'' ∧ c) then                        // and they both flip tails
15:        DoCompress(i, u, (v, p), (v', p'))
16:      else
17:        DoAlive(i, u, ((v_1, p_1), ..., (v_t, p_t)))
18:    else
19:      DoAlive(i, u, ((v_1, p_1), ..., (v_t, p_t)))
20:
21: procedure DoRake(i, u, (v, p))                       // When a vertex rakes, it replaces itself with
22:   write(A[i + 1][v][p], ⊥)                           // null (⊥) in its neighbor's adjacency list in
23:   write(D[u], i)                                     // in the next round
24:   retire process
25:
26: procedure DoCompress(i, u, (v, p), (v', p'))         // When a vertex compresses, it replaces itself
27:   write(A[i + 1][v][p], (v', p'))                    // with its opposite neighbors in each neighbor's
28:   write(A[i + 1][v'][p'], (v, p))                    // adjacency list in the next round
29:   write(D[u], i)
30:   retire process
31:
32: procedure DoFinalize(i, u)
33:   write(D[u], i)
34:   retire process
35:
36: procedure DoAlive(i, u, ((v_1, p_1), ..., (v_t, p_t)))   // If a vertex remains alive, it writes itself into
37:   local nonleaves ← 0                                // its neighbors' adjacency lists in the next
38:   for j ← 1 to t do                                  // round. It must also determine whether it
39:     if v_j ≠ ⊥ then                                  // it will be a leaf in the next round
40:       write(A[i + 1][v_j][p_j], (u, j))
41:       nonleaves += 1 - read(leaf[i][v_j])
42:     else
43:       write(A[i + 1][u][j], ⊥)
44:   write(leaf[i + 1][u], nonleaves = 1)
```

Handling trees of arbitrary degree

To handle trees of arbitrary degree, we can split each vertex into a path of vertices, one for each of its neighbors. This technique is standard and has been described in [18], for example. This results in a tree of degree 3, with at most $O(n + m)$ vertices and $O(m)$ edges for an initial tree of n vertices and m edges. For edge-weighted trees, the additional edges can be

given a suitable identity weight to preserve query values. It is simple to maintain such a transformation dynamically. For a batch insertion, a work-efficient semisort can be used to group each new neighbor by their endpoints, and then for each vertex, an appropriate number of new vertices can be added to the path. Batch deletion can be handled similarly.

4.1 Analysis

We now analyse the initial work, round, complexity, span, and computation distance of the tree contraction algorithm. This section is dedicated to proving the following theorem.

▶ **Theorem 13.** *Given a forest of n vertices, the initial work of tree contraction is $O(n)$ in expectation, the round complexity and the span is $O(\log(n))$ w.h.p. and the computation distance induced by updating k edges is $O(k \log(1 + n/k))$ in expectation.*

Let $F = (V, E)$ be the set of initial vertices and edges of the input tree, and denote by $F^i = (V^i, E^i)$, the set of remaining (alive) vertices and edges at round i. We use the term *at round i* to denote the beginning of round i, and *in round i* to denote an event that occurs during round i. For some vertex v at round i, we denote the set of its adjacent vertices by $A^i(v)$, and its degree with $\delta^i(v) = \left|A^i(v)\right|$. A vertex is *isolated* at round i if $\delta^i(v) = 0$. When multiple forests are in play, it will be necessary to disambiguate which is in focus. For this, we will use subscripts: for example, $\delta^i_F(v)$ is the degree of v in the forest F^i, and E^i_F is the set of edges in the forest F^i.

4.1.1 Analysis of construction

We first show that the static tree contraction algorithm is efficient. This argument is similar to Miller and Reif's argument in Theorem 2.1 of [21].

▶ **Lemma 14.** *For any forest (V, E), there exists $\beta \in (0, 1)$ such that $\mathbf{E}\left[\left|V^i\right|\right] \leq \beta^i |V|$, where V^i is the set of vertices remaining after i rounds of contraction.*

Proof. We begin by considering trees, and then extend the argument to forests. Given a tree (V, E), consider the set V' of vertices after one round of contraction. We would like to show there exists $\beta \in (0, 1)$ such that $\mathbf{E}[|V'|] \leq \beta |V|$. If $|V| = 1$, then this is trivial since the vertex finalizes (it is deleted with probability 1). For $|V| \geq 2$, Consider the following sets, which partition the vertex set:

$H = \{v : \delta(v) \geq 3\}$
$L = \{v : \delta(v) = 1\}$
$C = \{v : \delta(v) = 2 \wedge \forall u \in A(v), u \notin L\}$
$C' = \{v : \delta(v) = 2\} \setminus C$

Note that at least half of the vertices in L must be deleted, since all leaves are deleted, except those that are adjacent to another leaf, in which case exactly one of the two is deleted. Also, in expectation, $1/8$ of the vertices in C are deleted. Vertices in H and C' necessarily do not get deleted. Now, observe that $|C'| \leq |L|$, since each vertex in C' is adjacent to a distinct leaf. Finally, we also have $|H| < |L|$, which follows from standard arguments about compact trees. Therefore in expectation,

$$\frac{1}{2}|L| + \frac{1}{8}|C| \geq \frac{1}{4}|L| + \frac{1}{8}|H| + \frac{1}{8}|C'| + \frac{1}{8}|C| \geq \frac{1}{8}|V|$$

vertices are deleted, and hence

$$\mathbf{E}[|V'|] \leq \frac{7}{8}|V|.$$

Equivalently, for $\beta = \frac{7}{8}$, for every i, we have $\mathbf{E}\left[\left|V^{i+1}\right| \mid V_i\right] \leq \beta \left|V^i\right|$, where V^i is the set of vertices after i rounds of contraction. Therefore $\mathbf{E}\left[\left|V^{i+1}\right|\right] \leq \beta\, \mathbf{E}\left[\left|V^i\right|\right]$. Expanding this recurrence, we have $\mathbf{E}\left[\left|V^i\right|\right] \leq \beta^i |V|$. To extend the proof to forests, simply partition the forest into its constituent trees and apply the same argument to each tree individually. Due to linearity of expectation, summing over all trees yields the desired bounds. ◀

▶ **Lemma 15.** *On a forest of n vertices, after $O(\log n)$ rounds of contraction, there are no vertices remaining w.h.p.*

Proof. For any $c > 0$, consider round $r = (c+1) \cdot \log_{1/\beta}(n)$. By Lemma 14 and Markov's inequality, we have

$$\mathbf{P}\left[|V^r| \geq 1\right] \leq \beta^r n = n^{-c}.$$ ◀

Proof of initial work, rounds, and span in Theorem 13

Proof. At each round, the construction algorithm performs $O\left(\left|V^i\right|\right)$ work, and so the total work is $O\left(\sum_i \mathbf{E}\left[\left|V^i\right|\right]\right)$ in expectation. By Lemma 14, this is $O(|V|) = O(n)$. The round complexity and the span follow from Lemma 15. ◀

4.1.2 Analysis of dynamic updates

Intuitively, tree contraction is efficiently dynamizable due to the observation that, when a vertex locally makes a choice about whether or not to delete, it only needs to know who its neighbors are, and whether or not its neighbors are leaves. This motivates the definition of the *configuration* of a vertex v at round i, denoted $\kappa_F^i(v)$, defined as

$$\kappa_F^i(v) = \begin{cases} (\{(u, \ell_F^i(u)) : u \in A_F^i(v)\}), & \text{if } v \in V_F^i \\ \text{dead}, & \text{if } v \notin V_F^i, \end{cases}$$

where $\ell_F^i(u)$ indicates whether $\delta_F^i(u) = 1$ (the *leaf status* of u). Consider some input forest $F = (V, E)$, and let $F' = (V, (E \setminus E^-) \cup E^+)$ be the newly desired input after a batch cut with edges E^- and/or a batch-link with edges E^+. We say that a vertex v is *affected* at round i if $\kappa_F^i(v) \neq \kappa_{F'}^i(v)$.

▶ **Lemma 16.** *The execution in the tree contraction algorithm of process p at round r is an affected computation if and only if p is an affected vertex at round r.*

Proof. The code for ComputeRound for tree contraction reads only the neighbors, and corresponding leaf statuses, which are precisely the values encoded by the configuration. Hence if vertex p is alive in both forests the computation p is affected if and only if vertex p is affected. If instead p is dead in one forest but not the other, vertex p is affected, and the process p will have retired in one computation but not the other, and hence it will be an affected computation. Otherwise, if vertex p is dead in both forests, then the process p will have retired in both computations, and hence be unaffected. ◀

This means that we can bound the computation distance by bounding the number of affected vertices. First, we show that vertices that are not affected at round i have nice properties.

▶ **Lemma 17.** *If v is unaffected at round i, then either v is dead at round i in both F and F', or v is adjacent to the same set of vertices in both.*

Proof. Follows directly from $\kappa_F^i(v) = \kappa_{F'}^i(v)$. ◀

▶ **Lemma 18.** *If v is unaffected at round i, then v is deleted in round i of F if and only if v is also deleted in round i of F', and in the same manner (finalize, rake, or compress).*

Proof. Suppose that v is unaffected at round i. Then by definition it has the same neighbors at round i in both F and F'. The contraction process depends only on the neighbors of the vertex, and hence proceeds identically in both cases. ◀

If a vertex v is not affected at round i but is affected at round $i+1$, then we say that v *becomes affected in round* i. A vertex can become affected in many ways.

▶ **Lemma 19.** *If v becomes affected in round i, then at least one of the following holds:*
1. *v has an affected neighbor u at round i which was deleted in either F^i or $(F')^i$.*
2. *v has an affected neighbor u at round $i+1$ where $\ell_F^{i+1}(u) \neq \ell_{F'}^{i+1}(u)$.*

Proof. First, note that since v becomes affected, we know v does not get deleted, and furthermore that v has at least one child at round i. If v were to be deleted, then by Lemma 18 it would do so in both forests, leading it to being dead in both forests at the next round and therefore unaffected. If v were to have no children, then v would rake, but we just argued that v cannot be deleted.

Suppose that the only neighbors of v which are deleted in round i are unaffected at round i. Then v's set of children in round $i+1$ is the same in both forests. If all of these are unaffected at round $i+1$, then their leaf statuses are also the same in both forests at round $i+1$, and hence v is unaffected, which is a contradiction. Thus case 2 of the lemma must hold. In any other scenario, case 1 of the lemma holds. ◀

▶ **Lemma 20.** *If v is not deleted in either forest in round i and $\ell_F^{i+1}(v) \neq \ell_{F'}^{i+1}(v)$, then v is affected at round i.*

Proof. Suppose v is not affected at round i. If none of v's neighbors are deleted in this round in either forest, then $\ell_F^{i+1}(v) = \ell_{F'}^{i+1}(v)$, a contradiction. Otherwise, if the only neighbors that are deleted do so via a compression, since compression preserves the degree of its endpoints, we will also have $\ell_F^{i+1}(v) = \ell_{F'}^{i+1}(v)$ and thus a contradiction. So, we consider the case of one of v's children raking. However, since v is unaffected, we know $\ell_F^i(u) = \ell_{F'}^i(u)$ for each child u of v. Thus if one of them rakes in round i in one forest, it will also do so in the other, and we will have $\ell_F^{i+1}(v) = \ell_{F'}^{i+1}(v)$. Therefore v must be affected at round i. ◀

Lemmas 19 and 20 give us tools to bound the number of affected vertices for a consecutive round of contraction: each affected vertex that is deleted affects its neighbors, and each affected vertex whose leaf status is different in the two forests at the next round affects its neighbor. This strategy actually overestimates which vertices are affected, since case 1 of Lemma 19 does not necessarily imply that v is affected at the next round. We wish to show that the number of affected vertices at each round is not large. Intuitively, we will show that the number of affected vertices grows only arithmetically in each round, while shrinking geometrically, which implies that their total number can never grow too large. Let A^i denote the set of affected vertices at round i. We begin by bounding the size of $|A^0|$.

▶ **Lemma 21.** *For a batch update of size k, we have $|A^0| \leq 3k$.*

Proof. The computation for a given vertex u at most reads its neighbors, and if it has a single neighbor, its neighbor's leaf status. Therefore, the addition/deletion of a single edge affects at most 3 vertices at round 0. Hence $|A^0| \leq 3k$. ◀

We say that an affected vertex u *spreads to* v in round i, if v was unaffected at round i and v becomes affected in round i in either of the following ways:

1. v is a neighbor of u at round i and u is deleted in round i in either F or F', or
2. v is a neighbor of u at round $i+1$ and the leaf status of u changes in round i, i.e., $\ell_F^{i+1}(v) \neq \ell_{F'}^{i+1}(v)$.

Let $s = |A^0|$. For each of F and F', we now inductively construct s disjoint sets for each round i, labeled $A_1^i, A_2^i, \ldots A_s^i$. These sets will form a partition of A^i. First, arbitrarily partition A^0 into s singleton sets, and let $A_1^0, \ldots, A_s^0$ be these singleton sets. In other words, each affected vertex in A^0 is assigned a unique number $1 \leq j \leq s$, and is then placed in A_j^0.

Given sets $A_1^i, \ldots, A_s^i$, we construct sets $A_1^{i+1}, \ldots, A_s^{i+1}$ as follows. Consider some $v \in A^{i+1} \setminus A^i$. By Lemmas 19 and 20, there must exist at least one $u \in A^i$ such that u spreads to v. Since there could be many of these, let $S^i(v)$ be the set of vertices which spread to v in round i. Define

$$j^i(v) = \begin{cases} j, & \text{if } v \in A_j^i \\ \min_{u \in S^i(v)} \left(j \text{ where } u \in A_j^i\right), & \text{otherwise} \end{cases}$$

In other words, $j^i(v)$ is v's set identifier if v is affected at round i, or otherwise the minimum set identifier j such that a vertex from A_j^i spread to v in round i. We can then produce the following for each $1 \leq j \leq k$:

$$A_j^{i+1} = \{v \in A^{i+1} \mid j^i(v) = j\}$$

Informally, each affected vertex from round i which stays affected also stays in the same place, and each newly affected vertex picks a set to join based on which vertices spread to it.

We say that a vertex v is a *frontier* at round i if v is affected at round i and at least one of its neighbors in either F or F' is unaffected at round i. It is easy to show that any frontier at any round is alive in both forests and has the same set of unaffected neighbors in both at that round, and thus, the set of frontier vertices at any round is the same in both forests. It is also easy to show that if a vertex v spreads to some other vertex in round i, then v is a frontier at round i. We show next that the number of frontier vertices within each A_j^i is bounded.

▶ **Lemma 22.** *For any i, j, each of the following statements hold:*

1. *The subforests induced by A_j^i in each of F^i and $(F')^i$ are trees.*
2. *A_j^i contains at most 2 frontier vertices.*
3. *$|A_j^{i+1} \setminus A_j^i| \leq 2$.*

Proof. Statement 1 follows from rake and compress preserving connectedness, and the fact that if u spreads to v then u and v are neighbors in both forests either at round i or round $i+1$. We prove statement 2 by induction on i, and conclude statement 3 in the process. At round 0, each A_j^0 contains at most 1 frontier. We now consider some A_j^i. Suppose there is a single frontier vertex v in A_j^i. If v compresses in one of the forests, then v will not be a frontier in A_j^{i+1}, but it will spread to at most two newly affected vertices which may be frontiers at round $i+1$. Thus the number of frontiers in A_j^{i+1} will be at most 2, and $|A_j^{i+1} \setminus A_j^i| \leq 2$.

If v rakes in one of the forests, then v must also rake in the other forest (if not, then v could not be a frontier, since its neighbor would be affected). It spreads to one newly affected vertex (its neighbor) which may be a frontier at round $i+1$. Thus the number of frontiers in A_j^{i+1} will be at most 1, and $|A_j^{i+1} \setminus A_j^i| \leq 1$.

Now suppose there are two frontiers u and v in A_j^i. Due to statement 1 of the Lemma, each of these must have at least one affected neighbor at round i. Thus if either is deleted, it will cease to be a frontier and may add at most one newly affected vertex to A_j^{i+1}, and this newly affected vertex might be a frontier at round $i+1$. The same can be said if either u or v spreads to a neighbor due to a leaf status change. Thus the number of frontiers either remains the same or decreases, and there are at most 2 newly affected vertices. Hence statements 2 and 3 of the Lemma hold. ◀

Now define $A_{F,j}^i = A_j^i \cap V_F^i$, that is, the set of vertices from A_j^i which are alive in F at round i. We define $A_{F',j}^i$ similarly for forest F'.

▶ **Lemma 23.** *For every i, j, we have*

$$\mathbf{E}\left[\left|A_{F,j}^i\right|\right] \leq \frac{6}{1-\beta},$$

and similarly for $A_{F',j}^i$.

Proof. Let $F_{A,j}^i$ denote the subforest induced by $A_{F,j}^i$ in F^i. By Lemma 22, this subforest is a tree, and has at most 2 frontier vertices. By Lemma 14, if we applied one round of contraction to $F_{A,j}^i$, the expected number of vertices remaining would be at most $\beta \cdot \mathbf{E}[|A_{F,j}^i|]$. However, some of the vertices that are deleted in $F_{A,j}^i$ may not be deleted in F^i. Specifically, any vertex in $A_{F,j}^i$ which is a frontier or is the neighbor that spread to a frontier might not be deleted. There are at most two frontier vertices and two associated neighbors. By Lemma 22, two newly affected vertices might also be added. We also have $|A_{F,j}^0| = 1$. Therefore we conclude the following, which similarly holds for forest F':

$$\mathbf{E}\left[\left|A_{F,j}^{i+1}\right|\right] \leq \beta\, \mathbf{E}\left[\left|A_{F,j}^i\right|\right] + 6 \leq 6\sum_{r=0}^{\infty} \beta^r = \frac{6}{1-\beta}.$$ ◀

▶ **Lemma 24.** *For a batch update of size k, we have for every i,*

$$\mathbf{E}\left[\left|A^i\right|\right] \leq \frac{36}{1-\beta}k.$$

Proof. Follows from Lemmas 21 and 23, and the fact that

$$\left|A^i\right| \leq \sum_{j=1}^{s} \left(\left|A_{F,j}^i\right| + \left|A_{F',j}^i\right|\right).$$ ◀

Proof of computation distance in Theorem 13

Proof. Let F be the given forest and F' be the desired forest. Since each process of tree contraction does constant work each round, Lemma 16 implies that the algorithm does $O\left(\left|A^i\right|\right)$ work at each round i, so $W_\Delta = \sum_i \left|A^i\right|$.

Since at least one vertex is either raked or finalized each round, we know that there are at most n rounds. Consider round $r = \log_{1/\beta}(1 + n/k)$, using the β given in Lemma 14. We now split the rounds into two groups: those that come before r and those that come after.

For $i < r$, we bound $\mathbf{E}\left[\left|A^i\right|\right]$ according to Lemma 24, yielding

$$\sum_{i<r} \mathbf{E}\left[\left|A^i\right|\right] = O(rk) = O\left(k \log\left(1 + \frac{n}{k}\right)\right)$$

work. Now consider $r \leq i < n$. For any i we know $\left|A^i\right| \leq \left|V_F^i\right| + \left|V_{F'}^i\right|$, because each affected vertex must be alive in at least one of the two forests at that round. We can then apply the bound given in Lemma 14, and so

$$\begin{aligned}\sum_{r \leq i < n} \mathbf{E}\left[\left|A^i\right|\right] &\leq \sum_{r \leq i < n} \left(\mathbf{E}\left[\left|V_F^i\right|\right] + \mathbf{E}\left[\left|V_{F'}^i\right|\right]\right) \\ &\leq \sum_{r \leq i < n} \left(\beta^i n + \beta^i n\right) \\ &= O(n\beta^r) \\ &= O\left(\frac{nk}{n+k}\right) \\ &= O(k),\end{aligned}$$

and thus

$$\mathbf{E}\left[W_\Delta\right] = O\left(k \log\left(1 + \frac{n}{k}\right)\right) + O(k) = O\left(k \log\left(1 + \frac{n}{k}\right)\right). \quad \blacktriangleleft$$

5 Parallel Rake-compress Trees

Dynamic trees typically provide support for dynamic connectivity queries. Most dynamic tree data structures also support some form of augmented value query. For example, Link-cut trees [27] support root-to-vertex path queries, and Euler-tour trees [15] support subtree sum queries. Top trees [28, 6] support both path and subtree queries, as well as nonlocal queries such as centers and medians, but no parallelization of them is known. The only existing parallel batch-dynamic tree data structure is that of Tseng et al. [29], which is based on Euler-tour trees, and hence only handles subtree queries.

Rake-compress trees [5] (RC trees) are another sequential dynamic trees data structure, based on tree contraction, and have also been shown to be capable of handling both path and subtree queries, as well as nonlocal queries, all in $O(\log(n))$ time. In this section, we will explain how our parallel batch-dynamic algorithm for tree contraction can be used to derive a parallel batch-dynamic version of RC trees, leading to the first work-efficient algorithm for batch-dynamic trees that can handle this wide range of queries. We use a slightly different set of definitions than the original presentation of RC trees in [5], which correct some subtle corner cases and simplify the exposition, although the resulting data structure is equivalent. All of the query algorithms for sequential RC trees therefore work on our parallel version.

Contraction and clusters

RC trees are based on the idea that the tree contraction process can be interpreted as a recursive clustering of the original tree. Formally, a *cluster* is a connected subset of vertices and edges of the original tree. Note, importantly, that a cluster may contain an edge without containing both of its endpoints. The *boundary* vertices of a cluster C are the vertices $v \notin C$ that are adjacent to an edge $e \in C$. The *degree* of a cluster is the number of boundary vertices of that cluster. The vertices and edges of the original tree form the base clusters. Clusters are merged using the following simple rule: Whenever a vertex v is deleted, all of the clusters that have v as a boundary vertex are merged with the base cluster containing v. This implies that all clusters formed will have degree at most two. A cluster of degree zero is called a *nullary* cluster, a cluster of degree one a *unary* cluster, and a cluster of degree two a

binary cluster. All non-base clusters have a unique *representative vertex*, which corresponds to the vertex that was deleted to form it. The full version of this paper [2] provides additional details and some diagrams that explain what each kind of cluster looks like.

5.1 Building and maintaining RC trees

Given a tree and an execution of the tree contraction algorithm, the RC tree consists of *nodes* which correspond to the clusters formed by the contraction process. The children of a node are the nodes corresponding to the clusters that merged together to form it. An example tree, a clustering, and the corresponding RC tree are depicted in Figure 1. Note that in the case of a disconnected forest, the RC tree will have multiple roots.

We will sketch here how to maintain an RC tree subject to batch-dynamic updates in parallel using our algorithm for parallel batch-dynamic tree contraction. This requires just two simple augmentations to the tree contraction algorithm. Recall that tree contraction (Algorithm 3) maintains an adjacency list for each vertex at each round. Whenever a neighbor u of a vertex v rakes into v, the process u writes a null value into the corresponding position in v's adjacency list. This process can be augmented to also write, in addition to the null value, the identity of the vertex that just raked. Second, when storing the data for a neighboring edge in a vertex's adjacency list, we additionally write the name of the representative vertex if that edge corresponds to a compression, or null if the edge is an edge of the original tree. The RC tree can then be inferred using this augmented data as follows.

1. Given any cluster C with representative v, its unary children can be determined by looking at the vertices that raked into v. The children are precisely the unary clusters represented by these vertices. For the final cluster, these are its only children.
2. Given a binary or unary cluster C with representative v, its binary children can be determined by inspecting v's adjacency list at the moment it was deleted. The binary clusters corresponding to the edges adjacent to v at its time of death are the binary children of the cluster C.

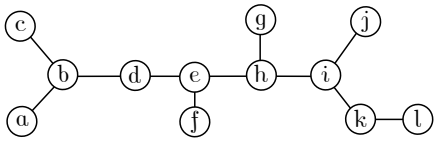
It then suffices to observe that this information about the clusters can be recorded during the contraction process. By employing change propagation, the RC tree can therefore be maintained subject to batch-dynamic updates. Since each cluster consists of a constant amount of information, this can be done in the same work and span bounds as the tree contraction algorithm. We therefore have the following result.

▶ **Theorem 25.** *We can maintain a rake-compress tree of a tree on n vertices subject to batch insertions and batch deletions of size k in $O(k \log(1 + n/k))$ work in expectation and $O(\log^2(n))$ span per update w.h.p. The span can be improved to $O(\log(n) \log^*(n))$ w.h.p. on the CRCW* PRAM*.*

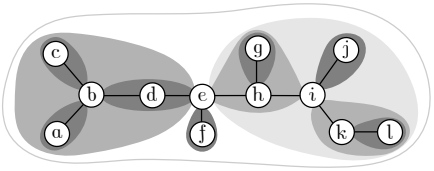
5.2 Applications

Most kinds of queries assume that the vertices and/or edges of the input tree are annotated with data, such as weights or labels. In order to support queries, each cluster is annotated with some additional information. The algorithm must then specify how to combine the data from multiple constituent clusters whenever a set of clusters merge. These annotations are generated during the tree contraction algorithm, and are therefore available for querying immediately after performing an update.

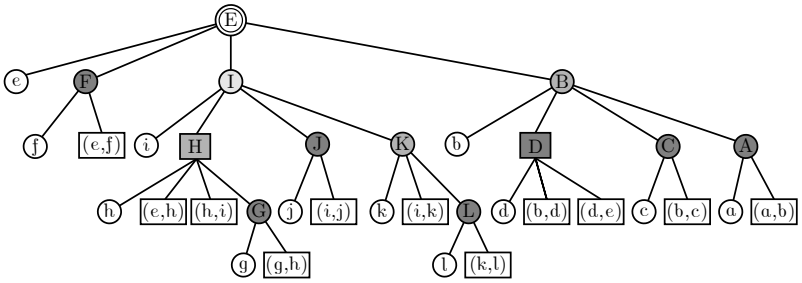
Once the clusters are annotated with the necessary data, the queries themselves typically perform a bottom-up or top-down traversal of the RC tree, or possibly in the case of more complicated queries, a combination of both. A variety of queries is described in [5].



(a) A tree.



(b) A recursive clustering of the tree produced by tree contraction. Clusters produced in earlier rounds are depicted in a darker color.



(c) The corresponding RC tree. (Non-base) unary clusters are shown as circles, binary clusters as rectangles, and the finalize (nullary) cluster at the root with two concentric circles. The base clusters (the leaves) are labeled in lowercase, and the composite clusters are labeled with the uppercase label of their representative vertex.

Figure 1 A tree, a clustering, and the corresponding RC tree.

Batch queries

We can also implement *batch queries*, in which we answer k queries simultaneously in $O(k \log(1 + n/k))$ work in expectation and $O(\log(n))$ span w.h.p. This improves upon the work bound of $O(k \log(n))$ obtained by simply running independent queries in parallel. The idea is to detect when multiple traversals would intersect, and to eliminate redundant work that they would perform. An example in which this technique is applicable is finding a representative vertex of a connected component. When traversing upwards, if multiple query paths intersect, then only one proceeds up the tree and subsequently brings the answer back down for the other ones. The following theorem is the main tool that we can use for analyzing batch queries. The proof is similar to that of the computation distance in Theorem 13, and can be found in the full version of this paper [2].

▶ **Theorem 26.** *Given a tree on n vertices and a corresponding RC tree, k root-to-leaf paths in the RC tree touch $O(k \log(1 + n/k))$ distinct RC tree nodes in expectation.*

In the full version of this paper [2], we will show that batch connectivity, subtree sum, and path sum queries given batches of size k can be answered in $O(k \log(1 + n/k))$ work in expectation and $O(\log(n))$ span w.h.p.

6 Conclusion

In this paper we showed that we can obtain work-efficient parallel batch-dynamic algorithms by applying an algorithmic dynamization technique to corresponding static algorithms. Using this technique, we obtained the first work-efficient parallel algorithm for batch-dynamic trees that supports more than just subtree queries. Our framework also demonstrates the

broad benefits of algorithmic dynamization; much of the complexity of designing parallel batch-dynamic algorithms by hand is removed, since the static algorithms are usually simpler than their dynamic counterparts. We note that although the round synchronous model captures a very broad class of algorithms, the breadth of algorithms suitable for dynamization is less clear. To be suitable for dynamization, an algorithm additionally needs to have small computational distance between small input changes. As some evidence of broad applicability, however, the practical systems mentioned in the technical overview of the introduction have been applied broadly and successfully – again without any theoretical justification, yet.

Abstract

In this paper, we study the parallel query complexity of reconstructing biological and digital phylogenetic trees from simple queries involving their nodes. This is motivated from computational biology, data protection, and computer security settings, which can be abstracted in terms of two parties, a ***responder***, Alice, who must correctly answer queries of a given type regarding a degree-d tree, T, and a ***querier***, Bob, who issues batches of queries, with each query in a batch being independent of the others, so as to eventually infer the structure of T. We show that a querier can efficiently reconstruct an n-node degree-d tree, T, with a logarithmic number of rounds and quasilinear number of queries, with high probability, for various types of queries, including ***relative-distance queries*** and ***path queries***. Our results are all asymptotically optimal and improve the asymptotic (sequential) query complexity for one of the problems we study. Moreover, through an experimental analysis using both real-world and synthetic data, we provide empirical evidence that our algorithms provide significant parallel speedups while also improving the total query complexities for the problems we study.

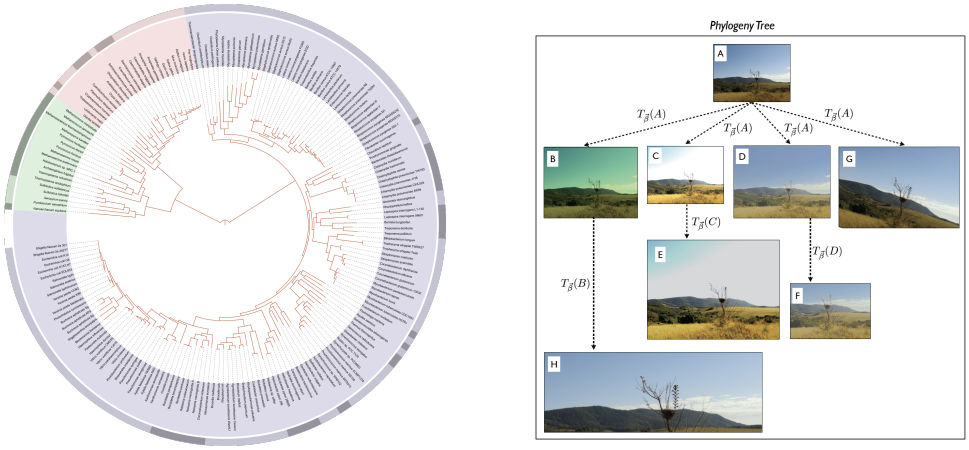
1 Introduction

Phylogenetic trees represent evolutionary relationships among a group of objects. For instance, each node in a biological phylogenetic tree represents a biological entity, such as a species, bacteria, or virus, and the branching represents how the entities are believed to have evolved from common ancestors [29, 8, 34]. (See Figure 1a.) In a digital phylogenetic tree,



(a) (b)

(a) A biological phylogenetic tree of life, showing relationships between species whose genomes had been sequenced as of 2006; public domain image by Ivica Letunic, retraced by Mariana Ruiz Villarreal. (b) A digital phylogenetic tree of images, from Dias et al. [14].

on the other hand, each node represents a data object, such as a computer virus [22, 35], a source-code file [27], a text file or document [32, 40], or a multimedia object (such as an image or video) [6, 16, 15, 14] and the branching represents how these objects are believed to have evolved through edits or data compression/corruption. (See Figure 1b.)

In this paper, we are interested in studying efficient methods for reconstructing phylogenetic trees from queries regarding their structure, noting that there are differences in the types of queries one may perform on the two types of phylogenetic trees. In particular, with some exceptions,[1] in a biological phylogenetic tree we can only perform queries involving the leaves of the tree, since these typically represent living biological entities and internal nodes represent ancestors that are likely to be extinct. In digital phylogenetic trees, on the other hand, we can perform queries involving any of the nodes in the tree, including internal nodes, since these represent digital artifacts, which are often archived. The former type of phylogenetic tree has also received attention in the context of *hierarchical clustering*, where the goal is to provide a hierarchical grouping structure of items according to their similarity [18]. To support reconstruction of both biological and digital phylogenetic trees, therefore, we study both types of querying regimes in this paper.

More specifically, with respect to biological phylogenetic trees, we focus on ***relative-distance*** queries, where one is given three leaf nodes (corresponding to species), x, y, and z, and the response is a determination of which pair, (x, y), (x, z), or (y, z), is a closest pair, hence, has the most-recent common ancestor [29]. With respect to digital phylogenetic trees, we instead focus on ***path queries***, where one is given two nodes, v and w, in the tree and the response is "true" if and only if v is an ancestor of w.

The motivation for reconstructing phylogenetic trees comes from a desire to better understand the evolution of the objects represented in a given phylogenetic tree. For example, understanding how biological species evolved is useful for understanding and

[1] One notable exception to this restriction of only being able to ask queries involving leaves in a biological phylogenetic tree is for phylogenetic trees of biological viruses, for which genetic sequencing may be known for all instances; hence, ancestor-descendant path queries might also be appropriate for reconstructing some biological phylogenetic trees.

categorizing the fossil record and understanding when species are close relatives [29, 18]. Similarly, understanding how digital objects have been edited and transformed can be useful for data protection, computer security, privacy, copyright disputes, and plariarism detection [22, 35, 27, 32, 40, 6, 16, 15, 14]. For instance, understanding the evolutionary process of a computer virus can provide insights into its ancestry, characteristics of the attacker, and where future attacks might come from and what they might look like [35].

The efficiency of a tree reconstruction algorithm can be characterized in terms of its ***query-complexity*** measure, $Q(n)$, which is the total number of queries of a certain type needed to reconstruct a given tree. This parameter comes from machine-learning and complexity theory, e.g., see [1, 9, 17, 42], where it is also known as "decision-tree complexity," e.g., see [48, 5]. Previous work on tree reconstruction has focused on sequential methods, where queries are issued and answered one at a time. For example, in pioneering work for this research area, Kannan et al. [29] show that an n-node biological phylogenetic tree can be reconstructed sequentially from $O(n \log n)$ three-node relative-distance queries.

Indeed, their reconstruction algorithms are inherently sequential and involve incrementally inserting leaf nodes into the phylogenetic tree reconstructed for the previously-inserted nodes.

In many tree reconstruction applications, queries are expensive [29, 18, 22, 35, 27, 32, 40, 6, 16, 15, 14], but can be issued in batches. For example, there is nothing preventing the biological experiments [29] that are represented in three-node relative-distance queries from being issued in parallel. Thus, in order to speed up tree reconstruction, in this paper we are interested in parallel tree reconstruction. To this end, we also use a ***round-complexity*** parameter, $R(n)$, which measures the number of rounds of queries needed to reconstruct a tree such that the queries issued in any round comprise a batch of independent queries. That is, no query issued in a given round can depend on the outcome of another query issued in that round, although both can depend on answers to queries issued in previous rounds. Roughly speaking, $R(n)$ corresponds to the span of a parallel reconstruction algorithm and $Q(n)$ corresponds to its work. In this paper, we are interested in studying complexities for $R(n)$ and $Q(n)$ with respect to biological and digital phylogenetic trees with fixed maximum degree, d.

1.1 Related Work

The general problem of reconstructing graphs from distance queries was studied by Kannan et al. [30], who provide a randomized algorithm for reconstructing a graph of n vertices using $\tilde{O}(n^{3/2})$ distance queries.[2]

Previous parallel work has focused on inferring phylogenetic trees through Bayesian estimation [4]. However, we are not aware of previous parallel work using a similar query models to ours. With respect to previous work on sequential tree reconstruction, Culberson and Rudnicki [13] provide the first sub-quadratic algorithms for reconstructing a weighted undirected tree with n vertices and bounded degree d from additive queries, where each query returns the sum of the weights of the edges of the path between a given pair of vertices. Reyzin and Srivastava [38] show that the Culberson-Rudnicki algorithm uses $O(n^{3/2} \cdot \sqrt{d})$ queries.

Waterman et al. [47] introduce the problem of reconstructing biological phylogenetic trees, using additive queries, which are more powerful than relative-distance queries. Hein [24] shows that this problem has a solution that uses $O(dn \log_d n)$ additive queries, when the

[2] The $\tilde{O}(\cdot)$ notation hides poly-logarithmic factors.

tree has maximum degree d, which is asymptotically optimal [31]. Kannan et al. [29] show that an n-node binary phylogenetic tree can be reconstructed from $O(n \log n)$ three-node relative-distance queries. Their method appears inherently sequential, however, as it is based on an incremental approach that mimics insertion-sort. Similarly, Emamjomeh-Zadeh and Kempe [18] also give a sequential method using relative-distance queries that has a query complexity of $O(n \log n)$. Their algorithm, however, was designed for a different context, namely, hierarchical clustering.

Additionally, there exists some work (e.g. [28, 7, 25]) in an alternative perspective of the problem reconstructing phylogenetic trees, in which the goal is to find the best tree explaining the similarity and the relationship between a given fixed (or dynamic) set of data sequences (e.g. of species), using Maximum Parsimony [19, 21, 39] or Maximum Likelihood [20, 10]. This contrasts with our approach of recovering the "ground truth" tree known only to an oracle, which is consistent with its answers about the tree.

With respect to digital phylogenetic tree reconstruction, there are a number of sequential algorithms with $O(n^2)$ query complexities, including the use of what we are calling path queries, where the queries are also individually expensive, e.g., see [22, 35, 27, 32, 40, 6, 16, 15, 14]. Jagadish and Sen [26] consider reconstructing undirected unweighted degree-d trees, giving a deterministic algorithm that requires $O(dn^{1.5} \log n)$ separator queries, which answer if a vertex lies on the path between two vertices. They also give a randomized algorithm using an expected $O(d^2 n \log^2 n)$ number of separator queries, and they give an $\Omega(dn)$ lower bound for any deterministic algorithm. Wang and Honorio [46] consider the problem of reconstructing bounded-degree rooted trees, giving a randomized algorithm that uses expected $O(dn \log^2 n)$ path queries. They also prove that any randomized algorithm requires $\Omega(n \log n)$ path queries.

Our Contributions. In this paper, we study the parallel phylogenetic tree reconstruction problem with respect to the two different types of queries mentioned above:

- We show that an n-node rooted biological (binary) phylogenetic tree can be reconstructed from three-node ***relative-distance queries*** with $R(n)$ that is $O(\log n)$ and $Q(n)$ that is $O(n \log n)$, with high probability (w.h.p.)[3]. Both bounds are asymptotically optimal.
- We show that an n-node fixed-degree digital phylogenetic tree can be reconstructed from ***path queries***, which ask whether a given node, u, is an ancestor of a given node, w, with $R(n)$ that is $O(\log n)$ and $Q(n)$ that is $O(n \log n)$, w.h.p. We also provide an $\Omega(dn + n \log n)$ lower bound for any randomized or deterministic algorithm suggesting that our algorithm is optimal in terms of query complexity and round complexity. Further, this asymptotically-optimal $Q(n)$ bound actually improves the sequential complexity for this problem, as the previous best bound for $Q(n)$, due to Wang and Honorio [46], had a $Q(n)$ bound of $O(n \log^2 n)$ for reconstructing fixed-degree rooted trees using path queries. Of course, our method also applies to biological phylogenetic trees that support path queries.

A preliminary announcement of some of this paper's results, restricted to binary trees, was presented in [3]. Most of our algorithms are quite simple, although their analyses are at times nontrivial. Moreover, given the many applications of biological and digital phylogenetic tree reconstruction, we feel that our algorithms have real-world applications. Thus, we

[3] We say that an event occurs with high probability if it occurs with probability at least $1 - 1/n^c$, for some constant $c \geq 1$.

have done an extensive experimental analysis of our algorithms, using both real-world and synthetic data for biological and digital phylogenetic trees. Our experimental results provide empirical evidence that our methods achieve significant parallel speedups while also providing improved query complexities in practice.

2 Preliminaries

In graph theory, an ***arborescence*** is a directed graph, T, with a distinguished vertex, r, called the ***root***, such that, for any vertex v in T that is not the root, there is exactly one path from r to v, e.g., see Tutte [43]. That is, an arborescence is a graph-theoretic way of describing a rooted tree, so that all the edges are going away from the root. In this paper, when we refer to a "rooted tree" it should be understood formally to be an arborescence.

We represent a rooted tree as $T = (V, E, r)$, with a vertex set V, edge set E, and root $r \in V$. The ***degree*** of a vertex in such a tree is the sum of its in-degree and out-degree, and the degree of a tree, T, is the maximum degree of all vertices in T. So, an arborescence representing a binary tree would have degree 3. Because of the motivating applications, e.g., from computational biology, we assume in this paper that the trees we want to reconstruct have maximum degree that is bounded by a fixed constant, d.

Let us review a few terms regarding rooted trees.

▶ **Definition 1** (ancestry). *Given a rooted tree, $T = (V, E, r)$, we say u is **parent** of v (and v is a **child** of u) if there exists a directed edge (u, v) in E. The **ancestor** relation is the transitive closure of the parent relation, and the **descendant** relation is the transitive closure of the child relation. We denote the number of descendants of vertex s by $D(s)$. A node without any children is called a **leaf**. Given two leaf nodes, u and v in T, their **lowest common ancestor**, $lca(u, v)$, is the node, w in T, that is an ancestor of both u and v and has no child that is also an ancestor of u and v.*

We next define the types of queries we consider in this paper for reconstructing a rooted tree, $T = (V, E, r)$.

▶ **Definition 2.** *A **relative-distance query** for T is a function, closer, which takes three leaf nodes, u, v, and w in T, as input and returns the pair of nodes from the set, $\{u, v, w\}$, that has the lower lowest common ancestor. That is, $closer(u, v, w) = (u, v)$ if $lca(u, v)$ is a descendant of $lca(u, w) = lca(v, w)$. Likewise, we also have that $closer(u, v, w) = (u, w)$ if $lca(u, w)$ is a descendant of $lca(u, v) = lca(v, w)$, and $closer(u, v, w) = (v, w)$ if $lca(v, w)$ is a descendant of $lca(u, v) = lca(u, w)$.*

Definition 2 assumes T is a binary tree (of degree 3). Note that in this paper we restrict relative-distance queries to leaves, since these represent, e.g., current species in the application of reconstructing biological phylogenetic trees.

▶ **Definition 3.** *A **path query** for T is a function, path, that takes two nodes, u and v in T, as input and returns 1 if there is a (directed) path from vertex u to v, and otherwise returns 0. Also, for $u \in V$ and $W \subseteq V$, we define $count(u, W) = \sum_{v \in W} path(u, v)$, which is the number of descendants of u in W.*

We next study some preliminaries involving the structure of degree-d rooted trees that will prove useful for our parallel algorithms.

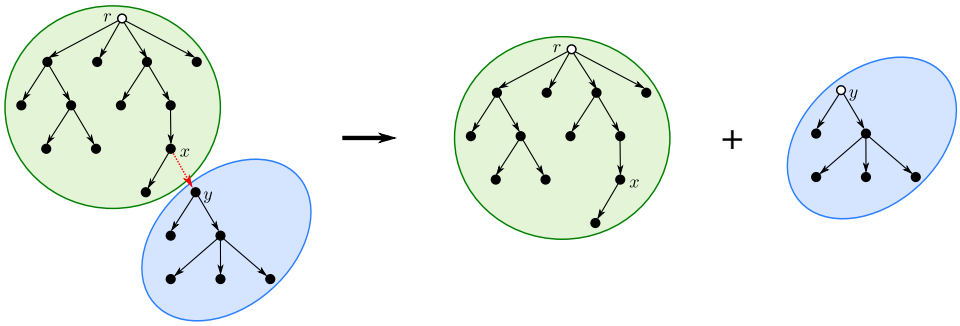


Figure 2 Illustration of a divide-conquer approach for trees. The edge (x, y) is an even-edge-separator. Note that the root of T'' is r, while y becomes root of T'.

▶ **Definition 4.** *Let $T = (V, E, r)$ be a degree-d rooted tree. We say that an edge $e = (x, y) \in E$ is an **even-edge-separator** if removing e from T partitions it into two rooted trees, $T' = (V', E', y)$ and $T'' = (V'', E'', r)$, such that $\frac{|V|}{d} \leq |V'| \leq \frac{|V|(d-1)}{d}$ and $\frac{|V|}{d} \leq |V''| \leq \frac{|V|(d-1)}{d}$. (See Figure 2.)*

▶ **Lemma 5.** *Every rooted tree of degree-d has an even-edge-separator.*

Proof. This follows from a result by Valiant [45, Lemma 2]. ◀

As we will see, this fact is useful for designing simple parallel divide-and-conquer algorithms. Namely, if we can find an even-edge-separator, then we can cut the tree in two by removing that edge and recurse on the two remaining subtrees in parallel (see Figure 2).

3 Reconstructing Biological Phylogenetic Trees in Parallel

Relative-distance queries model an experimental approach to constructing a biological phylogenetic tree, e.g., where DNA sequences are compared to determine which samples are the most similar [29]. In simple terms, pairs of DNA sequences that are closer to one another than to a third sequence are assumed to be from two species with a common ancestor that is more recent than the common ancestor of all three. In this section, for the sake of tree reconstruction, we assume the ***responder*** has knowledge of the absolute structure of a rooted binary phylogenetic tree; hence, each response to a $closer(u, v, w)$ query is assumed accurate with respect to an unknown rooted binary tree, T. As in the pioneering work of Kannan et al. [29], we assume the distance comparisons are accurate and consistent. The novel dimension here is that we consider parallel algorithms for phylogenetic tree reconstruction.

As mentioned above, we consider relative-distance queries to occur between leaves of a rooted binary tree, T. That is, in our query model, the ***querier*** has no knowledge of the internal nodes of T and can only perform queries using leaves. Because T is a binary phylogenetic tree, we may assume it is a ***proper*** binary tree, where each internal node in T has exactly two children.

3.1 Algorithm

At a high level, our parallel reconstruction algorithm (detailed in Algorithm 1) uses a randomized divide-and-conquer approach, similar to Figure 2. In our case, however, the division process is random three-way split through a vertex separator, rather than an edge-separator-based binary split. Initially, all leaves belong to a single partition, L. Then two

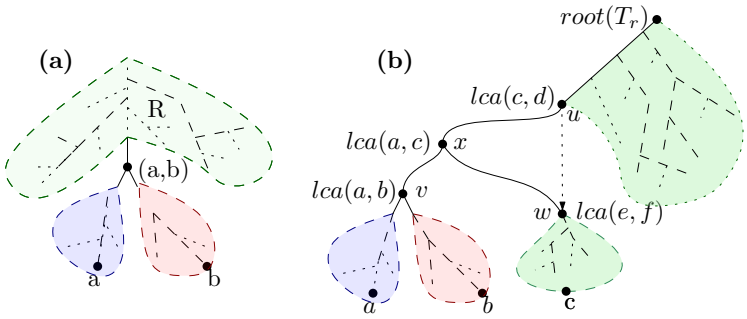

Figure 3 **(a)** The subgroups leaves are split into. **(b)** The linking step attaching T_a, T_b and T_r.

Algorithm 1 Reconstruct a binary tree of a set of leaves, L.

Function reconstruct-phylogenetic(L)**:**
  if $|L| \leq 3$ **then return** the tree formed by querying L
  Pick two leaves, $a, b \in L$, uniformly at random
  for ***each*** $c \in L$ ***s.t.*** $c \neq a, b$ **do in parallel**
    Perform query $closer(a, b, c)$
  Split the leaves in L into R, A, and B based on results
  parallel do
    $T_a \leftarrow$ reconstruct-phylogenetic$(A \cup \{a\})$
    $T_b \leftarrow$ reconstruct-phylogenetic$(B \cup \{b\})$
    $T_r \leftarrow$ reconstruct-phylogenetic(R)
  Let v be a new node, labeled "$lca(a, b)$"
  Set v's left child to $root(T_a)$ and the right to $root(T_b)$
  if $R = \emptyset$ **then return** tree, T_v, rooted at v
  else return link(v, T_r)

leaves, a and b, are chosen uniformly at random from L and each remaining leaf, c, is queried in parallel against them using relative-distance queries. Notice that the lowest common ancestor of a and b splits the tree into three parts. Given a and b, the other leaves are split into three subsets (R, A, and B) according to their query result (as shown in Figure 3(a)):

- A: leaves close to a, i.e., for which $closer(a, b, c) = (a, c)$
- B: leaves close to b, i.e., for which $closer(a, b, c) = (b, c)$
- R: remaining leaves, i.e., for which $closer(a, b, c) = (a, b)$

We then recursively construct the trees in parallel: T_a, for $A \cup \{a\}$; T_b, for $B \cup \{b\}$; and T_r, for R. The remaining challenge, of course, is to merge these trees to reconstruct the complete tree, T. The subtree of T formed by subset $A \cup B$ is rooted at an internal node, $v = lca(a, b)$; hence, we can create a new node, v, label it "$lca(a, b)$" and let T_a and T_b be v's children. If $R = \emptyset$, then we are done. Otherwise, we need to determine the parent of v in T; that is, we need to link v into T_r using function link(v, T_r).

To identify the parent of v, in T, let us assume inductively that each internal node $u \in T_r$ has a label "$lca(c, d)$", since we have already recursively labeled each internal node in T. Recall that v is labeled with "$lca(a, b)$". The crucial observation is to note if there exists an edge $(u \to w)$ in T_r, such that u is labeled "$lca(c, d)$" and $closer(a, c, d) = (a, z)$ for $z \in \{c, d\}$, and w is either leaf z or an ancestor of z labeled "$lca(e, f)$" with $closer(a, e, f) = (e, f)$, (See Figure 3(b)), then edge $(u \to w)$ must be where the parent of v belongs in T, and if

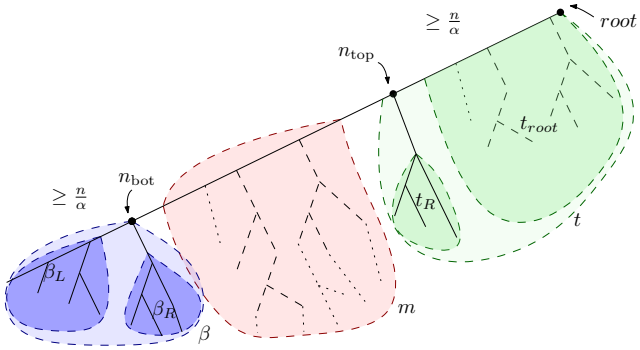

Figure 4 A left-heavy tree drawing displaying node n_{top}, node n_{bot} and the relevant partitions.

there is no such edge, the parent of v is the root of T and the sibling of v is the root of T_r. We can determine the edge $(u \to w)$ in a single parallel round by performing the query, $closer(a, c, d)$, for each each internal node $u \in T$ (where the label of u is "$lca(c, d)$"). The full pseudo-code of function $\mathsf{link}(v, T_r)$ is provided in the full version of the paper [2]. It is also worth noting that if the oracle can identify cases where all three leaves share a single lca, simple modifications to Algorithm 1 would enable it to handle trees of higher degree.

3.2 Analysis

The correctness of our algorithm follows from the way relative-distance queries always return a label for the lowest common ancestor for the two closest leaves among the three input nodes. Furthermore, executing the three recursive calls can be done in parallel, because $A \cup \{a\}$, $B \cup \{b\}$, and R form a partition of the set of leaves, L, and at every stage we only perform relative-distance queries relevant to the respective partition.

▶ **Theorem 6.** *Given a set, L, of n leaves in a proper binary tree, T, such as a biological phylogenetic tree, we can reconstruct T using relative-distance queries with a round complexity, $R(n)$, that is $O(\log n)$ and a query complexity, $Q(n)$, that is $O(n \log n)$, with high probability.*

Proof. Because the recursive calls we perform in each call to the reconstruct algorithm are done in parallel on a partition of the leaf nodes in L, we perform $\Theta(n)$ work per round. Thus, showing that the number of rounds, $R(n)$, is $O(\log n)$ w.h.p. also implies that $Q(n)$ is $O(n \log n)$ w.h.p. To prove this, we show that each round in Algorithm 1 has a constant probability of decreasing the problem size by at least a constant factor for each of its recursive calls. For analysis purposes, we consider the left-heavy representation of each tree, in which the tree rooted at the left child of any node is always at least as big as the tree rooted at its right child. (See Figure 4.) Using this view, we can characterize when a partition determines a "good split" and provide bounds on the sizes of the partitions, as follows.

▶ **Lemma 7.** *With probability of at least $\frac{\alpha-5}{2\alpha^2}$, a round of Algorithm 1 decreases the problem size of any recursive call by at least a factor of $\frac{\alpha-1}{\alpha}$, for a constant $\alpha > 5$, thus experiencing a **good split**.*

Proof. Define the ***spine*** to be all nodes on the path from the root to its left-most leaf in a left-heavy drawing. Let n_{bot} be the bottom-most node on the spine that has at least n/α of the nodes in its sub-tree. Conversely, let n_{top} be the parent of the top-most spine node that has at most $(1 - 1/\alpha) \cdot n$ descendants. (See Figure 4.) Consider the three resulting trees obtained from separating at the incoming edge to n_{bot} and the outgoing edge from n_{top} to

its left child. As shown in Figure 4, let t be the resulting tree retaining the root, β the tree rooted at n_{bot} and m the tree between n_{top} and n_{bot}. Within β let β_L and β_R be the trees rooted at the left and right child of n_{bot}. Similarly, for t, let t_R be the tree rooted at the right child of n_{top}. Finally, let t_{root} be the remaining tree when cut at n_{top}.

Consider the size of tree β, $|\beta|$, since this is the first tree rooted in the spine with over n/α nodes, then β_L must have had strictly under n/α nodes. Since the trees are in left-heavy order, β_R can have at most as many nodes as β_L so $\frac{n}{\alpha} \leq |\beta| < \frac{2n}{\alpha}$. Furthermore, we know that $|\beta|+|m|+|t_R|+|t_{root}|+1 = n$. Due to the left-heavy order, $|t_R| \leq |\beta|+|m|$. By definition of n_{top}, it's necessary that $|t_{root}| < \frac{n}{\alpha}$, thus $2(|\beta|+|m|)+1 > n-\frac{n}{\alpha}$ and $|\beta|+|m| > \left(\frac{\alpha-1}{2\alpha}\right)n-\frac{1}{2}$. Using the previous inequality and $|t| = n-|\beta|-|m|$, we find $|t| < \left(\frac{\alpha+1}{2\alpha}\right)n+\frac{1}{2}$. Also, $|m| = n-|t|-|\beta|$, so $|m| > n-\frac{5n+\alpha n}{2\alpha}$.

$$\frac{n}{\alpha} \leq |\beta| < \frac{2n}{\alpha}, \qquad \frac{n}{\alpha} \leq |t| < \left(\frac{\alpha+1}{2\alpha}\right)n+\frac{1}{2}, \qquad \left(\frac{\alpha-5}{2\alpha}\right)n < |m| \leq \left(\frac{\alpha-2}{\alpha}\right)n \quad (1)$$

Picking a leaf from β and another from m guarantees that $\beta \subseteq (A \cup \{a\})$ and $t \subseteq R$. Thus, using Equation (1), each of the three sub-problem sizes, $|A \cup \{a\}|$, $|B \cup \{b\}|$, and $|R|$, will be at most $\left(\frac{\alpha-1}{\alpha}\right)n$, when $\alpha > 5$. $Pr[\text{good split}] \geq Pr[\text{leaf in } \beta] \cdot Pr[\text{leaf in } m]$. Asymptotically, $Pr[\text{leaf in } \beta] \approx Pr[\text{node in } \beta]$, thus $Pr[\text{good split}] > \frac{\alpha-5}{2\alpha^2}$, which established the lemma. ◀

Returning to the proof of Theorem 6, let $p = \frac{\alpha-5}{2\alpha^2}$. From Lemma 7, we expect it will take $1/p$ rounds to obtain a good split. Every good split will reduce the problem-size by at least a constant factor, $\frac{\alpha-1}{\alpha}$. Thus, we are guaranteed to have just a single node left after we get $N_{\text{SPLITS}} = \log_{\frac{\alpha}{\alpha-1}}(n)$ good splits. Consider the geometric random variable, X_i, describing the number of rounds required to obtain the i-th good split, then $X = X_1 + \ldots + X_{N_{\text{SPLITS}}}$ describes the total number of rounds required by the algorithm. By linearity of expectation, $E[X] = \frac{2\alpha^2}{(\alpha-5)} \cdot N_{\text{SPLITS}} = \frac{2\alpha^2}{(\alpha-5)} \cdot \log_{\frac{\alpha}{\alpha-1}}(n)$. Therefore, since $\alpha > 5$ is a constant, this already implies an expected $O(\log n)$ rounds for Algorithm 1. Moreover, by a Chernoff bound for the sum of independent geometric random variables (see [23, 33]), $Pr\left[X > C \cdot E[X]\right] \leq e^{\frac{-(C-1)\cdot p \cdot N_{\text{SPLITS}}}{5}}$ for any constant $C \geq 3$ and constant $\alpha > 5$. Thus, the probability that we take over $C \cdot E[X]$ rounds is $O(1/n^{C-1})$. Therefore, by a union bound across the n leaves, our algorithm completes in $O(\log n)$ rounds w.h.p. ◀

▶ **Corollary 8.** *Algorithm 1 is optimal when asking $\theta(n)$ queries per round.*

The query complexity of Algorithm 1 matches an $\Omega(n \log n)$ lower bound for $Q(n)$, due to Kannan et al. [29]. Besides, we need $\Omega(\log n)$ rounds if we have $\theta(n)$ processors; hence, the round complexity of Algorithm 1 is also optimal.

4 Reconstructing Phylogenetic Trees from Path Queries

Let $T = (V, E, r)$ be a rooted (biological or digital) phylogenetic tree with fixed degree, d. In this section, we show how a querier can reconstruct T by issuing $Q(n) \in O(n \log n)$ path queries in $R(n) \in O(\log n)$ rounds, w.h.p., where $n = |V|$. We provide a lower bound to prove that our algorithm is optimal in terms of query complexity and round complexity. At the outset, the only thing we assume the querier knows is n and V, that is, the vertex set for T, and that the names of the nodes in V are unique, i.e., we may assume, w.l.o.g., that $V = \{1, 2, \ldots, n\}$. The querier doesn't know E or r – learning these is his goal.

4.1 Algorithms

We start by learning r, which we show can be done via any maximum-finding algorithm in Valiant's parallel model [44], which only counts parallel steps involving comparisons. The challenge, of course, is that the ancestor relationship in T is, in general, not a total order, as required by a maximum-finding algorithm. This does not actually pose a problem, however.

▶ **Lemma 9.** *Let A be a parallel maximum-finding algorithm in Valiant's model, with $O(f(n))$ span and $O(g(n))$ work. We can use A to find the root, r in a rooted tree $T = (V, E, r)$, using $R(n) \in O(f(n))$ rounds and $Q(n) \in O(g(n) + n)$ total queries.*

Proof. We pick an arbitrary vertex $v \in T$. In the first round, we perform queries $path(u, v)$ in parallel for every other vertex $u \in V$ to find S, the ancestor set for v. If $S = \emptyset$, then v is the root. Otherwise, we know all the vertices in a path from root to the parent of v, albeit unsorted. Still, note that for S the ancestor relation is a total order; hence, we can simulate A with path queries to resolve the comparisons made by A. We have just a single round and $O(n)$ queries more than what it takes for A to find the maximum. Thus, we can find the root in $O(f(n))$ rounds and $O(g(n) + n)$ queries. ◀

Thus, by well-known maximum-finding algorithms, e.g., see [11, 41, 44]:

▶ **Corollary 10.** *We can find r of a rooted tree $T = (V, E, r)$ deterministically in $O(\log \log n)$ rounds and $O(n)$ queries.*

Determining the rest of the structure of T is more challenging, however. At a high level, our approach to solving this challenge is to use a separator-based divide-and-conquer strategy, that is, find a "near" edge-separator in T, divide T using this edge, and recurse on the two remaining subtrees in parallel. The difficulty, of course, is that the querier has no knowledge of the edges of T; hence, the very first step, finding a "near" edge-separator, is a bottleneck computation. Fortunately, as we show in Lemma 11, if v is a randomly-chosen vertex, then, with probability depending on d, the path from root r to v includes an edge-separator.

▶ **Lemma 11.** *Let $T = (V, E, r)$ be a rooted tree of degree d and let v be a vertex chosen uniformly at random from V. Then, with probability at least $\frac{1}{d}$, an even-edge-separator is one of the edges on the path from r to v.*

Proof. By Lemma 5, T has an even-edge-separator. Let $e = (x, y)$ be an even-edge-separator for $T = (V, E, r)$ and let $T' = (V', E', y)$ be the subtree rooted at y when we remove e. Then, every path from r to each $v \in V'$ must contain e. By Definition 4, T' has at least $|V|/d$ vertices. Therefore, if we choose v uniformly at random from V, then with probability $\frac{|V'|}{|V|} \geq \frac{1}{d}$, the path from r to v contains e. ◀

▶ **Definition 12** (splitting-edge)**.** *In a degree-d rooted tree, an edge $(parent(s), s)$ is a splitting-edge if $\frac{|V|}{d+2} \leq D(s) \leq \frac{|V|(d+1)}{d+2}$, where $D(s)$ is the number of descendants of s.*

Note that a degree-d rooted tree T always has a splitting-edge, as every even-edge-separator is also a splitting-edge and by Lemma 5, it always has an even-edge-separator – a fact we use in our tree-reconstruction algorithm, which we describe next. This recursive algorithm (given in pseudo-code in Algorithm 2), assumes the existence of a randomized method, find-splitting-edge, which returns a splitting-edge in T, with probability $\Omega(1/d)$, and otherwise returns *Null*. Our reconstruction algorithm is therefore a randomized recursive algorithm that takes as input a set of vertices, V, with a (known) root vertex $r \in V$, and

returns the edge set, E, for V. At a high level, our algorithm is to repeatedly call the method, find-splitting-edge, until it returns a splitting-edge, at which point we divide the set of vertices using this edge and recurse on the two resulting subtrees.

Algorithm 2 Reconstruct a rooted tree with path queries.

```
1  Function reconstruct-rooted-tree(V, r):
2      E ← ∅
3      if |V| ≤ g then // g is a chosen constant
4          return edges found by a quadratic brute-force algorithm
5      while true do
6          Pick a vertex v ∈ V uniformly at random
7          for z ∈ V do in parallel
8              Perform query path(z, v)
9          Let Y be the vertex set of the path from r to v
10         splitting-edge ← find-splitting-edge(v, Y, V)
11         if splitting-edge ≠ Null then
12             (u, w) ← splitting-edge
13             E ← E ∪ {(u, w)}
14             for z ∈ V do in parallel
15                 Perform query path(w, z)
16             split V into V1, V2 at (u, w) using query results
17             parallel do
18                 E ← E ∪ reconstruct-rooted-tree(V1, w)
19                 E ← E ∪ reconstruct-rooted-tree(V2, r)
20             return E
```

In more detail, during each iteration of a repeating **while** loop, we choose a vertex $v \in V$ uniformly at random. Then, we find the vertices on the path from r to v and store them in a set, Y, using the fact that a vertex, z, is on the path from r to v if and only if $path(z, v) = 1$. Then, we attempt to find a splitting-edge using the function find-splitting-edge (shown in pseudo-code in Algorithm 3). If find-splitting-edge is unsuccessful, we give up on vertex v, and restart the **while** loop with a new choice for v. Otherwise, find-splitting-edge succeeded and we cut the tree at the returned splitting-edge, (u, w). All vertices, $z \in V$, where $path(w, z) = 1$ belong to the subtree rooted at w, thus belonging to V_1, whereas the remaining vertices belong to V_2 and the partition containing both u and rooted at r. Thus, after cutting the tree we recursively reconstruct-rooted-tree on V_1 and V_2.

The main idea for our efficient tree reconstruction algorithm lies in our find-splitting-edge method (see Algorithm 3), which we describe next. This method takes as input the vertex v, the vertex set Y, (comprising the vertices on the path from r to v), and the vertex set V. As we show, with probability depending on d, the output of this method is a splitting-edge; otherwise, the output is *Null*. Our algorithm performs a type of "noisy" search in Y to either locate a likely splitting-edge or return *Null* as an indication of failure.

Our find-splitting-edge algorithm consists of two phases. We enter **Phase 1** if the size of path Y is too big, i.e., $|Y| > |V|/K = \frac{|V|}{C_2 \log |V|}$, where C_2 is a predetermined constant and $K = C_2 \log |V|$. The purpose of this phase is either to pass a shorter path including an even-edge-separator to the second phase or to find a splitting-edge in this iteration. The search on the set Y is noisy, because it involves random sampling. In particular, we take a random sample S of size $m = C_1\sqrt{|V|}$ from path Y (where C_1 is a predetermined

Algorithm 3 Finding a splitting-edge from vertex set, Y, on the path from vertex v to the root r.

Function find-splitting-edge(v, Y, V)**:**
  splitting-edge $\leftarrow$ *Null*
  $m = C_1\sqrt{|V|}$, $K = C_2 \log |V|$
  Phase 1:
    if $|Y| > |V|/K$ **then**
      $S \leftarrow$ subset of m random elements from Y
      $S \leftarrow S \cup \{v, r\}$
      for *each* $s \in S$ **do in parallel**
        $X_s \leftarrow$ subset of K random elements from V
        Perform queries to find $count(s, X_s)$
      if $\forall s \in S : count(s, X_s) < \frac{K}{d+1}$ **then return** *Null*
      if $\forall s \in S : count(s, X_s) > \frac{Kd}{d+1}$ **then return** *Null*
      if $\exists s \in S : \frac{K}{d+1} \leq count(s, X_s) \leq \frac{Kd}{d+1}$ **then**
        return verify-splitting-edge(s, V)
      for *each* $\{a, b\} \in S$ **do in parallel**
        perform query $path(a, b)$
      Find w, z such that they are two consecutive nodes in the sorted order of S such that $count(w, X_w) > \frac{Kd}{d+1}$ and $count(z, X_z) < \frac{K}{d+1}$
      $Y \leftarrow$ nodes from Y in the path from w to z
    Phase 2:
      if $|Y| > |V|/K$ **then return** *Null*
      for *each* $s \in Y$ **do in parallel**
        $X_s \leftarrow$ subset of K random elements from V
        Perform queries to find $count(s, X_s)$
      if $\exists s \in Y$ s.t. $\frac{K}{d+1} \leq count(s, X_s) \leq \frac{Kd}{d+1}$ **then**
        return verify-splitting-edge(s, V)
  return *Null*

constant). We include r and v, the two endpoints of the path Y, to S. Then, we estimate the number of descendants of s, $D(s)$, for each $s \in S$. To estimate this number for each $s \in S$, we take a random sample X_s of K elements from V and we perform queries to find $count(s, X_s)$. Here, we use $m \cdot K \in O(\sqrt{|V|} \log |V|)$ queries in a single round. Then, if all the estimates were less than $K/(d+1)$, we return *Null* as an indication of failure (we guess that all the nodes on the path Y have too few descendants to be a separator). Similarly, if all the estimates were greater than $\frac{Kd}{d+1}$, we return *Null* (we guess that all the nodes on the path Y have too many descendants to be a separator). If there exists a node s such that $\frac{K}{d+1} \leq count(s, X_s) \leq \frac{Kd}{d+1}$, we check if s is a splitting-edge by counting its descendants using a function, verify-splitting-edge. This function takes vertex s and the full vertex set V to return edge (find-parent$(s, V), s$) if $\frac{|V|}{d+2} \leq count(s, V) \leq |V| \cdot \frac{d+1}{d+2}$ and return *Null* otherwise.

If neither of these three cases happens, we perform queries to sort elements of S using a trivial quadratic work parallel sort which takes $O(m^2) \in O(|V|)$ queries in a single round. We know that two consecutive nodes w and z exist on the sorted order of S, where $count(w, X_w) > \frac{Kd}{d+1}$ and $count(z, X_z) < \frac{K}{d+1}$. We find all the nodes on Y starting at w and ending at z, and use this as our new path Y.

Function find-parent(s, V).

find Y, ancestor set of s from V using $|V|$ queries in parallel
$m = C_1\sqrt{|V|}$
for $i \leftarrow 1$ ***to*** 2 & $|Y| > m$ **do**
    $S \leftarrow$ random subset of Y with m elements
    sort S as $x_1 < ... < x_m$ using $O(m^2)$ queries in parallel
    find $Y' = \{u \in Y \mid u \leq x_1\}$ using $O(|Y|)$ queries in parallel, replace Y with Y'
if $|Y| \leq m$ **then**
    sort Y using $O(m^2)$ queries in parallel
    return (minimum of this path)
return *Null*

In **Phase 2**, we expect a path of size under $|Y|/K$, we will later prove this is true with high probability. Otherwise, we just return *Null*. In this phase, we estimate the number of descendants much like we did in the previous phase, except the only difference is that we estimate the number of descendants for all the nodes on our new path Y. If there exists a node $s \in Y$ such that $\frac{K}{d+1} \leq count(s, X_s) \leq \frac{Kd}{d+1}$, we verify if it is a splitting-edge, as described earlier.

Finally, let us describe how we find the parent of a node s in V. We first find, Y, the set of ancestors of v in V in parallel using $|V|$ queries. Let $x \succ y$ describe the total order of nodes in path Y, where for any $x, y \in Y : x \succ y$ if and only if $path(x, y) = 1$. The parent of s is the lowest vertex on the path. Then, the key idea is that if $|Y| \in O(\sqrt{|V|})$, we can sort them using $O(|V|)$ queries. If the path is greater than this amount, we instead use S, a sample of size $O(\sqrt{|V|})$ from the path. Next, we sort the sample to obtain $x_1 < \ldots < x_m$ for S and then find all of the nodes in Y which are less than the smallest sample x_1. Finally, we replace Y with these descendants of x_1 and repeat the whole procedure again. We later prove that with high probability after two iterations of this sampling, the size of the path is $O(\sqrt{|V|})$, allowing us to sort all nodes in Y to return the minimum (see Function find-parent).

4.2 Analysis

The correctness of the algorithm follows from the fact that our method first finds the root, r, of T and then finds the parent of each other node, v in T.

▶ **Theorem 13.** *Given a set, V, of nodes of a rooted tree, T, such as a biological or digital phylogenetic tree, with degree bounded by a fixed constant, d, we can construct T using path queries with round complexity, $R(n)$, that is $O(\log n)$ and query complexity, $Q(n)$, that is $O(n \log n)$, with high probability.*

Our proof of Theorem 13 begins with Lemma 14.

▶ **Lemma 14.** *In a rooted tree, $T = (V, E, r)$, let Y be a (directed) path, where $|Y| > m = C_1\sqrt{|V|}$. If we take a sample, S, of m elements from Y, then with probability $1 - \frac{1}{|V|}$, every two consecutive nodes of S in the sorted order of S are within distance $O\left(\frac{|Y| \log |V|}{\sqrt{|V|}}\right)$ from each other in Y.*

Proof. Note that some nodes of Y may be picked more than once as we pick S in parallel. Divide the path Y into $\frac{\sqrt{|V|}}{\log |V|}$ equal size sections (the difference between the size of any two sections is at most 1). For each $1 \leq i \leq \frac{\sqrt{|V|}}{\log |V|}$, let A_i be the subset of S lying in the i^{th}

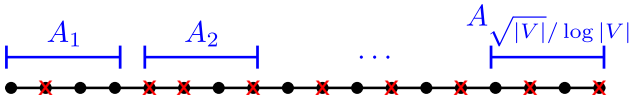

Figure 5 Illustration of how scattered sample S is on path Y. The i^{th} blue interval represents the i^{th} section of Y, the black dots correspond to the nodes on the path Y, and red crossed marks represent elements of S.

section of Y. (See Figure 5.) It is clear that each node $s \in S$ ends up in section i with probability $\frac{\log|V|}{\sqrt{|V|}}$, and therefore, for each $1 \le i \le \frac{\sqrt{|V|}}{\log|V|}$, $E[|A_i|] = C_1 \log|V|$. Thus, using standard a Chernoff bound, $\Pr[|A_i| = 0] < \frac{1}{|V|^2}$ for any constant $C_1 > 6\ln 10$. Using a union bound, all the sections are non-empty with probability at least $1 - \frac{1}{|V|}$. Hence, the distance between any two consecutive nodes of S from each other in Y is at most $\frac{2|Y|\log|V|}{\sqrt{|V|}}$. ◀

Lemma 14 allows us to analyze the find-parent method, as follows.

▶ **Lemma 15.** *The find-parent(s, V) method outputs the parent of s with probability at least $1 - 2/|V|$, with $Q(n) \in O(n)$ and $R(n) \in O(1)$.*

Proof. The find-parent method succeeds if, after the **for** loop, the size of the set of remaining ancestors of s, Y, is $|Y| \le m$, so it is enough to show that this occurs with probability at least $1 - 2/|V|$. By Lemma 14, the size of Y at the end of the first iteration is $|Y| \in O(m \log|V|)$, with probability at least $1 - 1/|V|$. Similarly, a second iteration, if required, further reduces the size of Y into $|Y| \in o(m)$, with probability at least $1 - 1/|V|$. Thus, by a union bound, the probability of success is at least $1 - 2/|V|$.

The query complexity can be broken down as follows, where $m \in O(\sqrt{|V|})$:

1. $O(|V|)$ queries in 1 round to determine the ancestor set, Y, of s.
2. $O(m^2) + O(|Y|) \in O(|V|)$ queries in 2 rounds for each of the (at most) 2 iterations performed in find-parent, whose purpose is to discard non-parent ancestors of s in Y.
3. $O(m^2) \in O(|V|)$ to find, in 1 round, the minimum among the remaining ancestors of Y (at most m w.h.p.). If $|Y| > m$, then no further queries are issued.

In total, the above amounts to $Q(n) \in O(n)$ and $R(n) \in O(1)$. ◀

We next analyze the find-splitting-edge method.

▶ **Lemma 16.** *Any call to find-splitting-edge returns true with probability $\frac{1}{2d}$; hence Algorithm 2 calls find-splitting-edge $O(d)$ times in expectation.*

Proof. By Lemma 11, we know that if we pick a vertex v, uniformly at random, then with probability $\frac{1}{d}$, an even-edge-separator lies on the path from r to v. We show that if there is such an even-edge-separator (Definition 4) on that path, find-splitting-edge(v, Y, V) returns a splitting-edge (Definition 12) with probability at least $\frac{1}{2}$, and otherwise returns *Null*. Using an intricate Chernoff-bound analysis (see full version for details [2]), we can prove that there exists a constant $C_2 > 0$, as used in line 3 of Algorithm 3 such that the following probability bounds always hold:

$$\begin{cases} \Pr\left(count(s, X_s) \ge \frac{K}{d+1}\right) \ge 1 - \frac{1}{|V|^2} & \text{if } count(s, V) \ge \frac{|V|}{d}, \\ \Pr\left(count(s, X_s) \le K\frac{d}{d+1}\right) \ge 1 - \frac{1}{|V|^2} & \text{if } count(s, V) \le |V|\frac{d-1}{d}, \end{cases} \tag{2}$$

$$\begin{cases} \Pr\left(count(s, X_s) < \frac{K}{d+1}\right) \geq 1 - \frac{1}{|V|^2} & \text{if } count(s, V) < \frac{|V|}{d+2}, \\ \Pr\left(count(s, X_s) > K\frac{d}{d+1}\right) \geq 1 - \frac{1}{|V|^2} & \text{if } count(s, V) > |V|\frac{d+1}{d+2} \end{cases} \tag{3}$$

It is clear that we either return a splitting-edge or *Null* when passing through verify-splitting-edge. We break the probability of returning *Null* according to the phases. We call a vertex v **ineligible** if $count(v, V) < \frac{|V|}{d+2}$ or $count(v, V) > \frac{|V|(d+1)}{d+2}$ ($(parent(v), v)$ is not a splitting-edge). On the other hand, we call vertex v **candidate** if after estimating the number of its descendants: $\frac{K}{d+1} \leq count(v, X) \leq \frac{Kd}{d+1}$. Let (a, b) be an even-edge-separator on path Y.

Phase 1:

- lines 10,11: By Definition 4, $\frac{|V|}{d} \leq count(b, V) \leq \frac{|V|(d-1)}{d}$. We add $\{r, v\}$ to S in line 6 of the algorithm (the two endpoints of path Y). Notice that $\frac{|V|}{d} \leq count(b, V) \leq count(r, V)$ and that $count(v, V) \leq count(b, V) \leq \frac{|V|(d-1)}{d}$. So, by Equation (2), with probability at least $1 - \frac{2}{|V|^2}$, $count(r, X_r) \geq \frac{K}{d+1}$ and $count(v, X_v) \leq \frac{Kd}{d+1}$, and consequently, we don't return *Null* in lines 10,11 of the algorithm.
- line 12: Equation (3) shows that an ineligible node is not a candidate with probability $1 - \frac{1}{|V|^2}$. Thus, by a union bound, none of our candidates is ineligible in line 12 with probability at least $1 - \frac{|S|}{|V|^2}$. Moreover, if there exists a candidate s in S, the algorithm outputs a splitting-edge $(parent(s), s)$ with probability at least $1 - \frac{2}{|V|}$, by Lemma 15.
- lines 15,16: Let us partition S into S_l and S_r (see Figure 6), as follows:

  $$S_l = \{s \in S \mid count(s, V) > count(b, V)\}, \qquad S_r = \{s \in S \mid count(s, V) < count(b, V)\}$$

  Then, by definition of b:

  $$\forall s \in S_l : \quad count(s, V) > |V|/d, \qquad \forall s \in S_r : \quad count(s, V) < |V|(d-1)/d.$$

  and thus, by Equation (2) and a union bound, we have with probability at least $1 - \frac{|S|}{|V|^2}$:

  $$\forall s \in S_l : \quad count(s, X_s) \geq K/(d+1), \qquad \forall s \in S_r : \quad count(s, X_s) \leq Kd/(d+1).$$

  Finally, since S does not contain any candidate nodes (otherwise we would have picked them in line 12), the above inequalities imply that:

  $$\forall s \in S_l : \quad count(s, X_s) > Kd/(d+1), \qquad \forall s \in S_r : \quad count(s, X_s) < K/(d+1).$$

  Therefore, $w \in S_l$ and $z \in S_r$, which implies that the subpath from w to z in Y must include vertex b. This means that with probability $1 - O(\frac{1}{|V|})$, we either find a splitting-edge in this phase or pass b to the next phase.

Now, consider **Phase 2:**

- line 17: Here, if $|Y| > |V|/K$, then we have passed through Phase 1. Using Lemma 14, we know that since S was a sample of size $C_1\sqrt{|V|}$ from Y, with probability $1 - \frac{1}{|V|}$ the distance between any two consecutive nodes of S in Y was $O(|Y|\frac{\log|V|}{\sqrt{|V|}}) \in O(\sqrt{|V|}\log|V|)$. Thus, the size of path Y after passing through line 15 is at most $O(\sqrt{|V|}\log|V|)$. Thus, the probability of returning *Null* in line 17 is at most $\frac{2}{|V|}$.

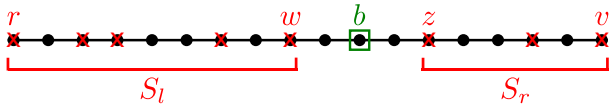

Figure 6 Illustration of the path reduction in Phase 1 of find-splitting-edge. At the end of this phase, the path Y is trimmed down into the subpath consisting of the nodes between w and z, which contains b w.h.p.

- line 21: By Equation (3), with probability at least $1 - \frac{|V|}{|V|^2}$, no ineligible node is between candidate set. Besides, for a candidate node s, the algorithm outputs a splitting-edge $(parent(s), s)$ with probability at least $1 - \frac{2}{|V|}$, by Lemma 15.
- line 22: The probability that we return *Null* here is equal to the probability that our candidate set in line 21 is empty. By Equation (2), with probability at least $1 - \frac{2}{|V|^2}$, b is between candidates at line 21 and candidate set is non-empty. Thus, the total probability of failing to return a splitting-edge in this phase is at most $O(\frac{1}{|V|})$.

Therefore, for $|V|$ greater than the chosen constant g, the probability of returning *Null* in the existence of an even-edge-separator is at most $O(\frac{1}{|V|}) \leq 1/2$. Thus, the probability of returning a splitting-edge in any call to find-splitting-edge is at least $\frac{1}{2d}$. ◀

▶ **Lemma 17.** *The subroutine find-splitting-edge(v, Y, V) has query complexity, $Q(n)$, that is $O(|V|)$, and round complexity, $R(n)$, that is $O(1)$.*

Proof. The queries done by find-splitting-edge(v, Y, V), in the worst case, can be broken down as follows, where $m = O(\sqrt{|V|})$:

Phase 1: A total of $O(|V|)$ queries in $O(1)$ rounds, consisting of:
- $O(mK) \in O(\sqrt{|V|}\log|V|)$ queries in one round for estimating the number of descendants for the m samples.
- $O(m^2) \in O(|V|)$ queries in one round for sorting the m samples.
- $O(|Y|) \in O(|V|)$ queries in a round to find the subpath of Y that is the input for Phase 2.
- $O(|V|)$ queries in $O(1)$ rounds for determining the parent of s (see Lemma 15).

Phase 2: If we enter this phase, it spends $O(|V|)$ queries in $O(1)$ rounds:
- $|Y| \cdot K \in O(|V|)$ queries in one round to evaluate count(s, X_s) for each $s \in Y$.
- $O(|V|)$ queries in one round to find the number of descendants of node s.
- $O(|V|)$ queries in $O(1)$ rounds to determine the parent of s (see Lemma 15).

Overall, the above break down amounts to $Q(n) \in O(n)$ and $R(n) \in O(1)$. ◀

Now, recall Theorem 13: *Given a set, V, of nodes of a rooted tree, T, such as a biological or digital phylogenetic tree, with degree bounded by a fixed constant, d, we can construct T using path queries with round complexity, $R(n)$, that is $O(\log n)$ and query complexity, $Q(n)$, that is $O(n \log n)$, with high probability.*

Proof. The expected query complexity $Q(n)$ of Algorithm 2 is dominated by the two recursive calls $\left(Q\left(\frac{n}{d+2}\right)\right.$ and $\left.Q\left(\frac{n(d+1)}{d+2}\right)\right)$ and the calls to find-splitting-edge. By Lemma 16, we call find-splitting-edge an expected $O(d)$ times, incurring a cost of $O(dn) \in O(n)$ path queries in $O(d) \in O(1)$ rounds (see Lemma 17). Thus, $Q(n)$ and $R(n)$ are:

$$Q(n) = Q\left(\frac{n}{d+2}\right) + Q\left(\frac{n(d+1)}{d+2}\right) + O(n),$$

$$R(n) = \max\left(R\left(\frac{n}{d+2}\right), R\left(\frac{n(d+1)}{d+2}\right)\right) + O(1)$$

which shows it needs $Q(n) \in O(n \log n)$ and $R(n) \in O(\log n)$ in expectation. To prove the high probability results, note that the main algorithm is a divide-and-conquer algorithm with two recursive calls per call; hence, it can be modeled with a recursion tree that is a binary tree, B, with height $h = O(\log_{\frac{d+2}{d+1}} n) = O(\log n)$. For any root-to-leaf path in B, the time taken can modeled as a sum of independent random variables, $X = X_1 + X_2 + \cdots + X_h$, where each X_i is the number of calls to find-splitting-edge (each of which uses $O(|V|)$ queries in $O(1)$ rounds) required before it returns true, which is a geometric random variable with parameter $p = \frac{1}{2d}$. Thus, by a Chernoff bound for sums of independent geometric random variables (e.g., see [23, 33]), the probability that X is more than $O(d \log_{\frac{d+2}{d+1}} n)$ is at most $1/n^{c+1}$, for any given constant $c \geq 1$. The theorem follows, then, by a union bound for the n root-to-leaf paths in B. ◀

4.3 Lower Bound

We establish the following simple lower bound, which extends and corrects lower-bound proofs of Wang and Honorio [46].

▶ **Theorem 18.** *Reconstructing an n-node, degree-d tree requires $\Omega(dn + n \log n)$ path queries. This lower bound holds for the worst case of a deterministic algorithm and for the expected value of a randomized algorithm.*

Proof. Consider an n-node, degree-d tree, T, as shown in Figure 7, which consists of a root, r, with d children, each of which is the root of a chain, T_i, of at least one node rooted at a child of r. Since a querier, Bob, can determine the root, r, in $O(n)$ queries anyway, let us assume for the sake of a lower bound that r is known; hence, no additional information is gained by path queries involving the root. Let us denote the vertices in chain T_i as V_i. In order to reconstruct T, Bob must determine the nodes in each V_i and must also determine their order in T_i. For a given path query, $path(u, v)$, say this query is ***internal*** if $u, v \in V_i$, for some $i \in [1, d]$, and this query is ***external*** otherwise. Note that even if Bob knows the full structure of T except for a given node, v, he must perform at least $d - 1$ external queries in the worst case, for a deterministic algorithm, or $\Omega(d)$ external queries in expectation, for a randomized algorithm, in order to determine the chain, T_i, to which v belongs. Furthermore, the result of an (internal or external) query, $path(u, v)$, provides no additional information for a vertex w distinct from u and v regarding the set, V_i, to which w belongs. Thus, Bob must perform $\Omega(d)$ external queries for each vertex $v \neq r$, i.e., he must perform $\Omega(dn)$ external queries in total. Moreover, note that the results of external queries involving a vertex, v,

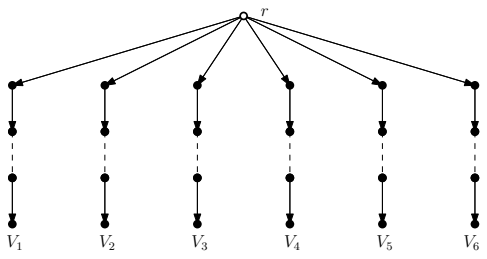

Figure 7 Illustration of the $\Omega(dn + n \log n)$ lower bound for path queries in directed rooted trees (shown for $d = 6$).

provide no information regarding the location of v in its chain, T_i. Even if Bob knows all the vertices that comprise each V_i, he must determine the ordering of these vertices in the chain, T_i, in order to reconstruct T. That is, Bob must ***sort*** the vertices in V_i using a comparison-based algorithm, where each comparison is an internal query involving two vertices, $u, v \in V_i$. By well-known sorting lower bounds (which also hold in expectation for randomized algorithms), e.g., see [23, 12], determining the order of the vertices in each T_i requires $\Omega(|V_i| \log |V_i|)$, as one of the chain can be as great as $n - d$ vertices, then he needs $\Omega(n \log n)$ internal queries. ◀

▶ **Corollary 19.** *Algorithm 2 is optimal for bounded-degree trees when asking $\theta(n)$ queries per round.*

The query complexity of Algorithm 2 matches the lower bound provided by Theorem 18 when d is constant. Besides, we need $\Omega(d + \log n)$ rounds if we have $\theta(n)$ processors; hence, the round complexity of Algorithm 2 is also optimal.

5 Experiments

Given that both of our algorithms are randomized and perform optimally with high probability, we carried out experiments to analyze the practicality of our algorithms and compare their performance with the best known algorithms for reconstructing rooted trees. [4]

5.1 Reconstructing Biological Phylogenetic Trees

In order to assess the practical performance of Algorithm 1, we performed experiments using synthetic phylogenetic trees and real-world biological phylogenetic trees from the phylogenetic library TreeBase [36], which is a database of biological phylogenetic trees, comprising over 100,000 distinct taxa in total.

[4] The complete source code for our experiments, including the implementation of our algorithms and the algorithms we compared against, is available at github.com/UC-Irvine-Theory/ParallelTreeReconstruction.

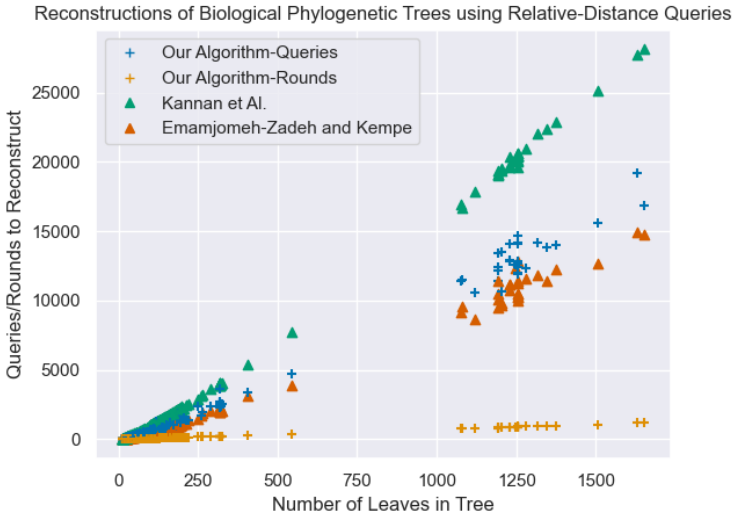

Figure 8 A scatter plot showing the number of queries and rounds for each of the three tree reconstruction algorithms for real trees from TreeBase. Since our algorithm is parallel, we include round complexity to serve as a comparison for the sequential complexity.

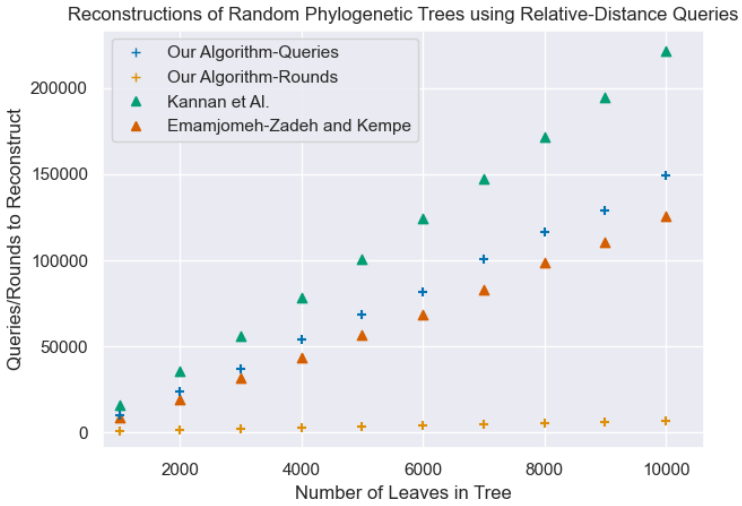

Figure 9 A plot showing the average number of queries and rounds for each of the three tree reconstruction algorithms. Each data point represents the average for 10 randomly generated trees.

We implemented an oracle interface, instantiated it with the relevant trees, and implemented our algorithm along with two other phylogenetic tree reconstruction algorithms that use relative-distance queries. The first is by Emamjomeh-Zadeh and Kempe [18], which is a randomized sequential divide-and-conquer algorithm. The second is by Kannan et al. [29], where they use a sequential deterministic procedure reminiscent of insertion-sort. All three algorithms achieve the optimal asymptotic query complexity of $\Theta(n \log n)$ in expectation.

Real Data. We instantiated our oracles with 1,220 biological phylogenetic trees from the TreeBase collection and used them to run all three algorithms. The results, shown in Figure 8, suggest that our algorithm outperforms the algorithm by Kannan et al., both in terms of its round complexity and query complexity. However our algorithm almost matches Emamjomeh-Zadeh and Kempe's in terms of total queries and we believe the small difference is a direct result of the cost incurred while parallelizing the link step of Algorithm 1. It remains clear that Algorithm 1 outperforms the two other algorithms when considering the parallel speed-up.

Synthetic Data. We also tested this algorithm using synthetic data and found similar results, detailed in Figure 9. We detail the method used to generate these random tree instances in Section 5.2, however, given our algorithm's strict focus on biological phylogenetic trees, we use only full binary trees, where each internal node has exactly two children.

5.2 Reconstructing Phylogenetic Trees from Path Queries

To assess the practical performance of our method for reconstructing (biological and digital) phylogenetic trees from path queries, we performed experiments using both synthetic and real data to compare our algorithm with the algorithm by Wang and Honorio [46], which is the best known reconstruction algorithm for phylogenetic trees from path queries. Our experimental results provide evidence that Algorithm 2 provides significant parallel speedup, while simultaneously improving the total number of queries.

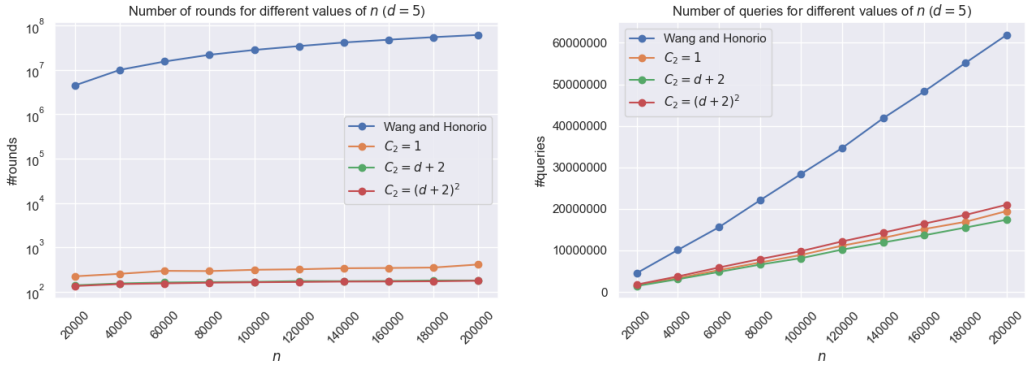

Figure 10 Comparing Our Algorithm's number of rounds (left) and total queries (right) with Wang and Honorio's [46], for fixed $d = 5$ and varying n.

Synthetic Data. In order to generate random instances of trees with maximum degree, d, we synthesized a data set of random degree-d trees of n nodes for different values of n and d. To generate a random tree, T, for a given n and d, we first generated a random Prüfer sequence [37] of a labeled tree, which defines a unique sequence associated with that tree, and converted it to its associated tree. In particular, each n-node tree $T = (V, E)$ has a unique code sequence $s_1, s_2, \ldots, s_{n-2}$, where $s_i \in V$ for all $1 \leq i \leq n-2$ and every node $v_i \in V$ of degree d_i appears exactly $d_i - 1$ times in this sequence. Therefore, in order to generate random degree-d rooted trees we generate a random Prüfer sequence while imposing conditions that: (i) all vertices appear at most $d-1$ times in the code and (ii) there is at least one node such that it appears exactly $d-1$ times. Converting each such sequence to its associated tree gave us a random degree-d tree instance that we used in our experiments.

Since our parallel reconstruction algorithm using path queries is parameterized by a constant, C_2, we ran our algorithm using different values for C_2. The constant C_2 controls sample size from V used to estimate the number of descendants of a node. Furthermore, to reduce noise from randomization, each data-point will be averaged for 3 runs on 10 randomly generated trees. In Figure 10, we compare our algorithm's rounds and total number of queries with the one by Wang and Honorio [46], for fixed degree trees $d = 5$ and varying tree-sizes. These results provide empirical evidence that our algorithm provides a noticeable speedup in parallel round complexity while also outperforming the algorithm by Wang and Honorio [46] in total number of queries.

In Figure 11, we compare Algorithm 2 with the one by Wang and Honorio [46] for fixed size and varying values of d. Again, this supports our theoretical findings that our algorithm achieves both a significant parallel speedup and a simultaneous improvement in the number of total queries.

In Figure 12, we study the behavior of Algorithm 2 under different values of C_2, so as to experimentally find the best value for C_2. While our high probability analysis requires $C_2 \approx (d+2)^4$, Figure 12 suggests that we do not need that high probability reassurance in practice, and we can use smaller sample to reduce the total number of queries.

Real Data. Our experiments on real-world biological phylogenetic trees also confirm the superiority of our algorithm in terms of performance as compared to the one by Wang and Honorio [46]. Similar to our experiments using relative-distance queries, we used a dataset comprised of trees from the phylogenetic library TreeBase [36]. Figure 13 summarizes our experimental results, where each data point corresponds to an average performance of 3 runs

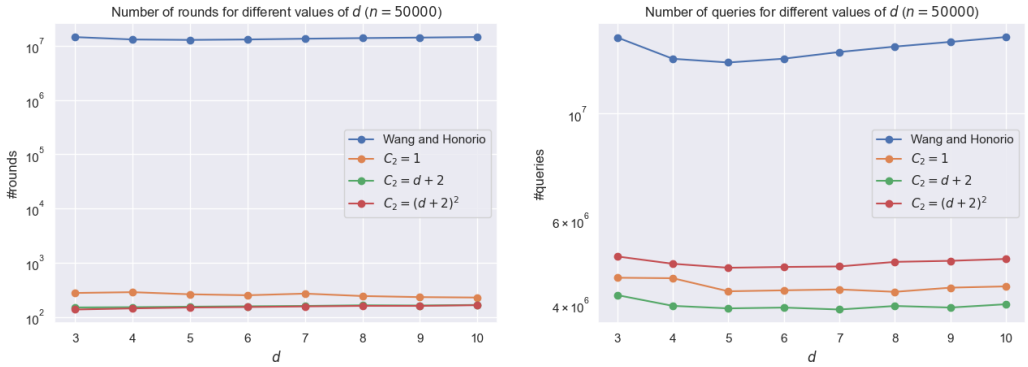

Figure 11 Comparing our algorithm's number of rounds (left) and total queries (right) with Wang and Honorio's [46], for $n = 50000$ and varying values for d.

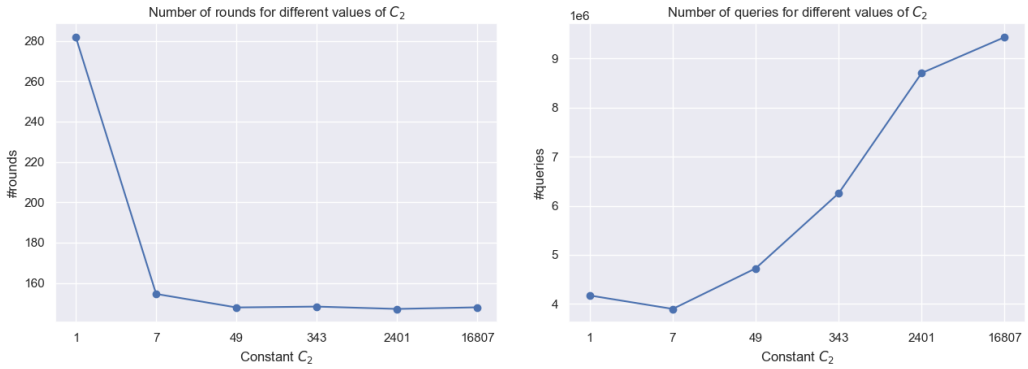

Figure 12 Change in the total number of rounds (left) and total number of queries (right) when running our algorithm for varying values of C_2 ($n = 50000$, $d = 5$).

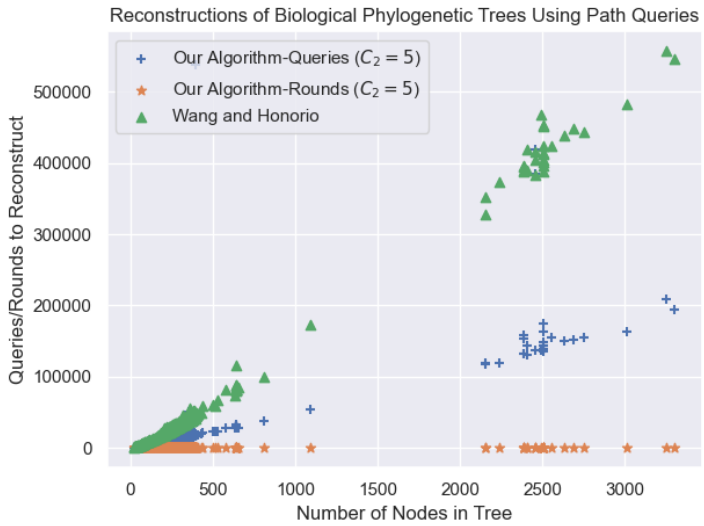

Figure 13 A scatter plot comparing the number of queries and rounds of our algorithm and with the one by Wang and Honorio [46] for real-world trees from TreeBase [36]. Since our algorithm is parallel, we include round complexity to serve as a comparison for the sequential complexity.

on the same tree. Our algorithm is superior in both queries and rounds for all the values of C_2 we tried: $C_2 \in \{1, d+2, (d+2)^2\}$. The best performance corresponds to $C_2 = d+2 = 5$, which is the one illustrated in Figure 13.

Abstract

We study the multi-level Steiner tree problem: a generalization of the Steiner tree problem in graphs where terminals T require varying priority, level, or quality of service. In this problem, we seek to find a minimum cost tree containing edges of varying rates such that any two terminals u, v with priorities $P(u)$, $P(v)$ are connected using edges of rate $\min\{P(u), P(v)\}$ or better. The case where edge costs are proportional to their rate is approximable to within a constant factor of the optimal solution. For the more general case of non-proportional costs, this problem is hard to approximate with ratio $c \log \log n$, where n is the number of vertices in the graph. A simple greedy algorithm by Charikar et al., however, provides a $\min\{2(\ln |T| + 1), \ell\rho\}$-approximation in this setting, where ρ is an approximation ratio for a heuristic solver for the Steiner tree problem and ℓ is the number of priorities or levels (Byrka et al. give a Steiner tree algorithm with $\rho \approx 1.39$, for example).

In this paper, we describe a natural generalization to the multi-level case of the classical (single-level) Steiner tree approximation algorithm based on Kruskal's minimum spanning tree algorithm. We prove that this algorithm achieves an approximation ratio at least as good as Charikar et al., and experimentally performs better with respect to the optimum solution. We develop an integer linear programming formulation to compute an exact solution for the multi-level Steiner tree problem with non-proportional edge costs and use it to evaluate the performance of our algorithm on both random graphs and multi-level instances derived from SteinLib.

1 Introduction

We study the following generalization of the Steiner tree problem where terminals have priorities, levels, or quality of service (QoS) requirements. Variants of this problem are known in the literature under different names including multi-level network design (MLND), quality-of-service multicast tree (QoSMT) [4], quality-of-service Steiner tree [10, 18], and Priority Steiner Tree [6]. Motivated by multi-level graph visualization, we refer to this problem as the multi-level Steiner tree problem.

▶ **Definition 1** (Multi-level Steiner tree (MLST)). *Let $G = (V, E)$ be a connected graph, and $T \subseteq V$ be a subset of terminals. Each terminal $t \in T$ has a priority $P(t) \in \{1, 2, \ldots, \ell\}$. A multi-level Steiner tree (MLST) is a tree G' with edge rates $y(e) \in \{1, 2, \ldots, \ell\}$ such that for any two terminals u, $v \in T$, the u–v path in G' uses edges of rate greater than or equal to* $\min\{P(u), P(v)\}$.

We use 1 for the lowest priority and ℓ for the highest, and assume without loss of generality that there exists $v \in V$ such that $P(v) = \ell$. If $\ell = 1$, then Definition 1 reduces to the definition of Steiner tree.

The cost of an MLST G' is defined as the sum of the edge costs in G' at their respective rates. Specifically, for $1 \leq i \leq \ell$, we denote by $c_i(e)$ the cost of including edge e with rate i, in which the cost of an MLST is $\sum_{e \in E(G')} c_{y(e)}(e)$. Naturally, an edge with a higher rate should be more costly, so we assume that $c_1(e) \leq c_2(e) \leq \ldots \leq c_\ell(e)$ for all $e \in E$. The MLST problem is to compute an MLST with minimum cost.

We note that equivalent formulations [4, 6] include a root (or source) vertex $r \in V$ in which the problem is to compute a tree rooted at r such that the path from r to every terminal $t \in T$ uses edges of rate at least as good as $P(t)$. One can observe that Definition 1 is equivalent to this formulation as we can fix the root to be any terminal $r \in T$ such that $P(r) = \ell$. In an optimized MLST, the path from the root to any terminal uses non-increasing edge rates. Note that this becomes relevant for the discussion of the exact value of the approximation given by our algorithm and the state-of-the-art algorithm [4]. We use the phrase "multi-level" since a tree G' with a root having top priority and edge rates $y(\cdot)$ induces a sequence of ℓ nested Steiner trees, where the tree induced by $\{e \in E : y(e) \geq i\}$ is a Steiner tree over terminals $T_i = \{t \in T : P(t) \geq i\}$ for $1 \leq i \leq \ell$.

We distinguish the special case with proportional costs, where the cost of an edge is equal to its rate multiplied by some "base cost" (e.g., $c_1(e)$). This is similar to the rate model in [4] as well as the setup in [10].

▶ **Definition 2.** *An instance of the MLST problem has proportional costs if $c_i(e) = ic_1(e)$ for all $e \in E$ and for all $i \in \{1, 2, \ldots, \ell\}$. Otherwise, the instance has non-proportional costs.*

For $u, v \in T$, we define $\sigma(u, v)$ to equal the cost of a minimum cost u–v path in G using edges of rate $\min\{P(u), P(v)\}$. In other words, $\sigma(u, v)$ represents the minimum possible cost of connecting u and v using edges of the appropriate rate. Note that σ is symmetric, but does not satisfy the triangle inequality, and is not a metric. Lastly, we denote by H_k the k^{th} harmonic number given by $H_k = 1 + \frac{1}{2} + \ldots + \frac{1}{k}$.

1.1 Related work

The Steiner tree (ST) problem admits a simple $2\left(1 - \frac{1}{|T|}\right)$-approximation (see Section 2.1). Currently, the best known approximation ratio is $\rho = \ln 4 + \varepsilon \approx 1.39$ by Byrka et al. [3]. It is NP-hard to approximate the ST problem with ratio better than $\frac{96}{95} \approx 1.01$ [5].

In [1], simple top-down and bottom-up approaches are considered for the MLST problem with proportional costs. In the top-down approach, a Steiner tree is computed over terminals $\{v \in T : P(v) = \ell\}$. For $i = \ell-1, \ldots, 1$, the Steiner tree over terminals $\{v \in T : P(v) = i+1\}$ is contracted into a single vertex, and a Steiner tree is computed over terminals with $P(v) = i$. In the bottom-up approach, a Steiner tree is computed over all terminals, which induces a feasible solution by setting the rate of all edges to ℓ. These approaches are $(\frac{\ell+1}{2})\rho$- and $\ell\rho$-approximations, respectively [1] (moreover, these bounds are tight). It is worth noting that the bottom-up approach can perform arbitrarily poorly in the non-proportional setting.

If edge costs are proportional, Charikar et al. [4] give a simple 4ρ-approximation algorithm (which we later denote by C_1) by rounding the vertex priorities up to the nearest power of 2, then computing a ρ–approximate Steiner tree for the terminals at each rounded-up priority. They then give an $e\rho \approx 4.213$-approximation for the same problem (using $\rho \approx 1.55$ [12]). Karpinski et al. [10] tighten the analysis from [4] to show that this problem admits a 3.802-approximation with an unbounded number of priorities. Ahmed et al. [1] generalize the above techniques by considering a composite heuristic which computes Steiner trees over a subset of the priorities, and show that this achieves a $2.351\rho \approx 3.268$-approximation for $\ell \leq 100$. They provide experimental comparisons of the simple top-down, bottom-up, 4ρ-approximation of Charikar et al. [4], and a generalized composite algorithm. The experiments in [1] show that the bottom-up approach typically provides the worst performance while the composite algorithm typically performs the best, and these results match the theoretical guarantees.

For non-proportional costs, which is the more general setting, Charikar et al. [4] give a $\min\{2(\ln|T|+1), \ell\rho\}$-approximation for QoSMT, consisting of taking the better solution returned by two sub-algorithms (which we denote by C_{2a} and C_{2b}, Section 2.2). On the other hand, Chuzhoy et al. [6] show that PST cannot be approximated with ratio better than $\Omega(\log\log n)$ in polynomial time unless $\text{NP} \subseteq \text{DTIME}(n^{O(\log\log\log n)})$. However, the problem setup for PST [6] is slightly more specific; each edge has a single cost c_e and a Quality of Service (priority) given as input, and a solution consists of a tree such that the path from the root to each terminal t uses edges of QoS at least as good as $P(t)$.

1.2 Our contributions

In this paper, we propose approximation algorithms for the MLST problem based on Kruskal's and Prim's algorithms for computing a minimum spanning tree (MST). We show that the Kruskal-based algorithm is a $2\ln|T|$-approximation even for non-proportional costs, matching the state-of-the-art algorithms. An interesting feature of this algorithm is that for the single level case, it reduces to the standard Kruskal approximation to the Steiner tree problem, which is not the case of other state-of-the-art algorithms for MLST. We also show that, somewhat surprisingly, a natural approach based on Prim's algorithm can perform rather poorly. We then describe an integer linear program (ILP) to compute exact solutions to the MLST problem given non-proportional edge costs and evaluate the approximation ratios of the proposed approximation algorithms experimentally. Specifically, we provide an experimental comparison between the algorithm of Charikar et al. [4] and our Kruskal-based algorithm, in which the latter performs better with respect to the optimum a majority of the time in both proportional and non-proportional settings. Experiments are performed on random graphs from various generators as well as instances of the MLST problem derived from the SteinLib library [11] of hard ST instances. Finally, we describe a class of graphs for which the Kruskal-based algorithm always performs significantly better than that by Charikar et al. [4].

2 Preliminaries

In this section, we review some existing approximation algorithms that are pivotal for the subsequent developments in this paper.

2.1 Kruskal- and Prim-based approximations for the ST problem

A well-known $2\left(1-\frac{1}{|T|}\right)$-approximation algorithm for the ST problem first constructs the metric closure graph $\tilde{G}$ over T: the complete graph $K_{|T|}$ where each vertex corresponds to a terminal in T, and each edge has weight equal to the length of the shortest path between corresponding terminals. An MST over $\tilde{G}$ induces $|T|-1$ shortest paths in G; combining all induced paths and removing cycles yields a feasible Steiner tree whose cost is at most $2\left(1-\frac{1}{|T|}\right)$ times the optimum.

For computing an MST over $\tilde{G}$, one can use any known MST algorithm (e.g., Kruskal's, Prim's, or Borůvka's algorithm). However, one can directly construct a Steiner tree from scratch based on these MST algorithms without the need to construct $\tilde{G}$; Poggi de Aragão and Werneck provide details for such implementations [7] (see also [13, 17]).

Specifically, the Prim-based approximation algorithm for the ST problem due to Takahashi and Matsuyama [13] grows a tree rooted at a fixed terminal. In each iteration, the closest terminal not yet connected to the tree is connected through its shortest path. The process continues for $|T|-1$ iterations until all terminals are spanned. The resulting Steiner tree achieves the $2\left(1-\frac{1}{|T|}\right)$ approximation guarantee [13]. The Kruskal-based algorithm for the ST problem due to Wang [14] maintains a forest initially containing $|T|$ singleton trees. In each iteration, the closest pair of trees is connected via a shortest path between them. The process continues for $|T|-1$ iterations until the resulting forest is a tree. Widmayer showed that this algorithm achieves the $2\left(1-\frac{1}{|T|}\right)$ bound [16].

2.2 Review of the QoSMT algorithm of Charikar et al.

Charikar et al. [4] give a $\min\{2(\ln|T|+1), \ell\rho\}$-approximation for QoSMT which we denote by C_2, consisting of taking the better of the solutions returned by two sub-algorithms (denoted $\mathrm{C}_{2\mathrm{a}}$ and $\mathrm{C}_{2\mathrm{b}}$). For this section, we focus primarily on the $2(\ln|T|+1)$-approximation, Algorithm $\mathrm{C}_{2\mathrm{a}}$. The $\ell\rho$-approximation, Algorithm $\mathrm{C}_{2\mathrm{b}}$, simply computes a ρ-approximate Steiner tree over the terminals of each priority separately, then merges the ℓ computed trees and prunes cycles to output a tree; this leads to a better approximation ratio if $\ell \ll |T|$.

The first sub-algorithm ($\mathrm{C}_{2\mathrm{a}}$) sorts the terminals T by decreasing priority $P(\cdot)$, starting with a root node r (here, we may treat the root as any terminal with priority ℓ). Then, for $i=1,\ldots,|T|$, the i^{th} terminal t_i is connected to the existing tree spanning the previous $i-1$ terminals using the minimum cost path with edges of rate at least $P(t_i)$, where the cost of this path is defined as the connection cost of t_i.

The authors show that for $1 \le m \le |T|$, the m^{th} most expensive connection cost is at most $\frac{2\mathrm{OPT}}{m}$, which implies that the total cost is at most $2\mathrm{OPT}\left(1+\frac{1}{2}+\frac{1}{3}+\ldots+\frac{1}{|T|}\right) \le 2(\ln|T|+1)\mathrm{OPT}$. While not explicitly mentioned in [4], this approximation ratio is roughly tight (see Figure 1). Algorithm $\mathrm{C}_{2\mathrm{a}}$ can be implemented by running Dijkstra's algorithm from t_i until a vertex already in the tree is encountered. The running time of $\mathrm{C}_{2\mathrm{a}}$ is roughly $|T|$ times the running time of Dijkstra's algorithm, or $O(nm+n^2\log n)$ [4].

3 Kruskal-based MLST algorithms

We propose Algorithm KruskalMLST for the MLST problem. The main distinction compared to Algorithm C_{2a} is that the subsequent algorithm connects the "closest" pairs of terminals first, rather than connecting terminals in order of priority. Algorithm KruskalMLST proceeds as follows: initializing $S = T$, while $|S| \geq 1$, find terminals $u, v \in S$ with $P(u) \geq P(v)$ which minimize the cost of connecting them. If $\mathcal{P}$ is the u–v path chosen, then the rate of each edge in $\mathcal{P}$ is upgraded to $P(v)$ (if its rate is less). Remove v from S. We will say that v is connected at the current iteration. At this point, we do not need to worry about v anymore, and u (the node it is connected to) essentially becomes responsible for v for the rest of the algorithm. When $|S| = 1$, if there are no cycles, then the resulting tree is a feasible MLST rooted at some vertex r with $P(r) = \ell$. Otherwise, we can prune one edge from each cycle with the lowest rate to produce a tree. We note that KruskalMLST takes $|T| - 1$ iterations while C_{2a} takes $|T|$ iterations; this follows as the setting for MLST does not specify a root vertex while QoSMT does. As such, there is a small constant difference in the approximation ratios, which is not significant.

When finding $u, v \in S$ which minimize $\sigma(u, v)$, Algorithm KruskalMLST takes into account edges which have already been included at lower rates. In other words, line 6 seeks a pair of vertices (u, v) which minimizes the cost of "upgrading" the rates of some edges so that u and v are connected via a path of rate $\min\{P(u), P(v)\}$. We denote this cost by $\sigma'(u, v)$, and observe that $\sigma'(u, v) \leq \sigma(u, v)$.

Algorithm KruskalMLST(graph G, priorities P, costs c).

1: Initialize $y(e) = 0$ for $e \in E$
2: $c'_i(e) = c_i(e)$ for $i \in [\ell], e \in E$
3: $S = T$
4: **while** $|S| > 1$ **do**
5: Compute $\sigma'(\cdot, \cdot)$ for all $(\cdot, \cdot) \in S \times S$
6: Find $u, v \in S$ with $P(u) \geq P(v)$ which minimizes $\sigma'(u, v)$
7: $\mathcal{P}$ = path chosen of cost $\sigma'(u, v)$
8: $y(e) = \max\{y(e), P(v)\}$ for $e \in \mathcal{P}$
9: $c'_i(e) = \max\{0, c_i(e) - c_{y(e)}(e)\}$ for $e \in \mathcal{P}$ and $i \in \{1, \ldots, \ell\}$
10: $S = S \setminus \{v\}$
11: **end while**
12: **return** y

▶ **Theorem 3.** *Algorithm* KruskalMLST *is a* $2 \ln |T|$*-approximation to the MLST problem.*

Proof. Define the connection cost of v to be $\sigma'(u, v)$ (line 6), and note that the cost of the returned solution is the sum of the connection costs over all terminals $T \setminus \{r\}$. Now let t_1, t_2, …, $t_{|T|-1}$ be the terminals in sorted order by which they were connected, and let OPT denote the cost of a minimum cost MLST for the instance. We have the following lemma.

▶ **Lemma 4.** *For* $2 \leq m \leq |T|$*, consider the iteration of Algorithm* KruskalMLST *when* $|S| = m$*. Let* t_i *be the terminal connected during this iteration (where* $i = |T| + 1 - m$*). Then the connection cost of* t_i *is at most* $\frac{2\text{OPT}}{m}$*.*

Proof. Note that immediately before t_i is connected, we have $S = \{t_i, t_{i+1}, \ldots, t_{|T|-1}, r\}$ of size m. Consider the optimum solution $\mathcal{T}^*$ for the instance, and let $\mathcal{T}'$ be the minimal subtree of $\mathcal{T}^*$ containing all terminals in S. The total cost of the edges in $\mathcal{T}'$ is at most OPT. Perform a depth-first traversal starting from any terminal in $\mathcal{T}'$ and returning to that terminal. Since every edge in $\mathcal{T}'$ is traversed twice, the cost of the traversal is at most 2OPT.

Consider pairs of consecutive terminals t_j, t_k visited for the first time along the traversal. The path connecting t_j and t_k in $\mathcal{T}'$ necessarily uses edges of rate at least $\min\{P(t_j), P(t_k)\}$. Then, the cost of the edges along this path is at least $\sigma(t_j, t_k)$. There are m pairs of consecutive terminals along the traversal (including the pair containing the first and last terminals visited), and the sum of the costs of these m paths is at most 2OPT. Hence, some pair t_j, t_k of terminals is connected by a path of cost $\leq \frac{2\text{OPT}}{m}$ in the optimum solution, implying that for this pair t_j, t_k, we have $\sigma'(t_j, t_k) \leq \sigma(t_j, t_k) \leq \frac{2\text{OPT}}{m}$. Since KruskalMLST selects the pair which minimizes $\sigma'(\cdot, \cdot)$, the connection cost of t_i is at most $\frac{2\text{OPT}}{m}$. ◀

Lemma 4 immediately implies Theorem 3. Indeed, summing from $m = 2$ to $m = |T|$, the total cost is at most $2\text{OPT}\left(\frac{1}{2} + \frac{1}{3} + \ldots + \frac{1}{|T|}\right) = 2\text{OPT}(H_{|T|} - 1) \leq 2\ln|T|\text{OPT}$. ◀

An interesting note is that Algorithm KruskalMLST reduces to the Kruskal-based algorithm [14] for computing a Steiner tree, when there are no priorities on the terminals (i.e., the single level case when $\ell = 1$). As mentioned earlier, this is a $2(1 - \frac{1}{|T|})$-approximation, whereas algorithm $\text{C}_{2\text{a}}$ is still a $2\ln|T|$ one, and this is an advantage of the proposed algorithm.

A simple variant of our algorithm, GreedyMLST, yields the same theoretical approximation ratios and is easier to implement. The difference is that GreedyMLST does not update the costs σ at each iteration of the while loop.

Algorithm GreedyMLST(graph G, priorities P, costs c).

```
Initialize y(e) = 0 for e ∈ E
S = T
while |S| > 1 do
    Find u, v ∈ S with P(u) ≥ P(v) which minimizes σ(u, v)
    P = path chosen of cost σ(u, v)
    y(e) = max(y(e), P(v)) for e ∈ P
    S = S \ {v}
end while
return y
```

▶ **Theorem 5.** *Algorithm* GreedyMLST *is a* $2\ln|T|$*-approximation to the MLST problem.*

The proof follows the same argument as that for Theorem 3; indeed the use of σ' implies that KruskalMLST should perform better than GreedyMLST, but is more costly to run.

3.1 Tightness

The approximation ratio for Algorithms $\text{C}_{2\text{a}}$ [4] and GreedyMLST is tight up to a constant, even if $\ell = 1$ or if $|E| = O(|V|)$. As a tightness example, we use a graph construction $(G_i)_{i\geq 0}$ given by Imase and Waxman [9] for the inapproximability of the dynamic Steiner tree problem. Let G_0 contain two vertices v_0, v_1 with an edge of cost 1 connecting them. We say that v_0 and v_1 are depth zero vertices. For $i \geq 1$, graph G_i is obtained by replacing each edge uv in G_{i-1} with two depth i vertices w_1, w_2, and adding edges uw_1, w_1v, uw_2, and w_2v.

Let $G = G_k$ for sufficiently large k, let $\ell = 1$ (i.e., the Steiner tree problem), and let each edge of G_i have a cost of $\frac{1}{2^i}$, so that the cost of any shortest v_0-v_1 path is 1. Let the terminals T be the vertices of some v_0-v_1 path (Figure 1, left), so that OPT $= 1$. Note that any u-v path contains 2^k edges, so $|T| = 2^k + 1$. Algorithm $\mathrm{C}_{2\mathrm{a}}$ first sorts the terminals by priority; since all terminals in G_k have the same priority, we consider a worst possible ordering where T is ordered in increasing depth, with v_0 the root. In this case, it is possible that Algorithm $\mathrm{C}_{2\mathrm{a}}$ connects v_1 to v_0 via a shortest path which does not include other terminals, then connects subsequent terminals via shortest paths which include no other terminal, as shown in Figure 1. Conversely in the worst case, Algorithm GreedyMLST may connect depth k, $k-1$, $k-2$, ... terminals in order while avoiding previously-used paths, as Algorithm GreedyMLST does not consider existing edges. In both cases, the cost of the returned solution is

$$\text{Cost} = \frac{1}{2}k + 1 = \frac{1}{2}\log_2(|T| - 1) + 1 \geq \frac{1}{2}\left(\log_2 |T| + 1\right) \text{OPT} \approx \left(0.72 \ln |T| + \frac{1}{2}\right) \text{OPT}.$$

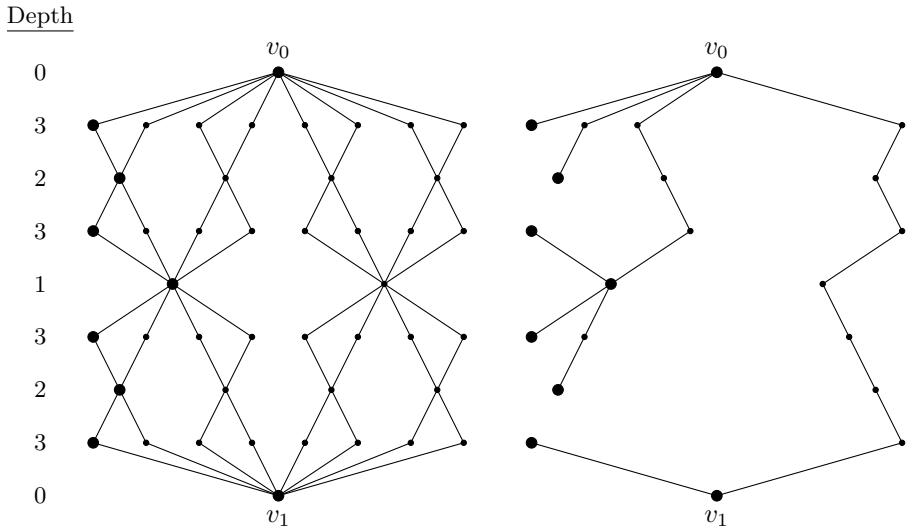

Figure 1 Left: Example instance where $G = G_3$ using the construction by Imase and Waxman [9], $\ell = 1$, with terminals bolded. All edges have cost $\frac{1}{8}$ so that OPT $= 1$. Right: Example solution $\mathcal{T}$ which could be returned by Algorithms $\mathrm{C}_{2\mathrm{a}}$ and GreedyMLST, with cost $\frac{20}{8}$. Note that in hindsight, G may be sparsified so that $|E| = O(|V|)$, by letting $E = E(\mathcal{T}) \cup E(\mathcal{T}^*)$, then contracting each simple path between two terminals to a single edge with cost equal to the length of the path.

3.2 Running Time

The running time of Algorithm GreedyMLST is similar to that of Algorithm $\mathrm{C}_{2\mathrm{a}}$, namely $|T|$ times the running time of Dijkstra's algorithm. This can be implemented as follows: before line 4, for each terminal $t \in T$, run Dijkstra's algorithm from t using edge weights $c_{P(t)}(\cdot)$, and only keep track of distances from t to terminals with priority $\geq P(t)$. Thus, each terminal $t \in T$ keeps a dictionary of distances from t to a subset of T. Then at each iteration (line 6), find the minimum distance among at most $|T|$ distances. The running time of KruskalMLST is $|T|^2$ times that of Dijkstra's algorithm due to the update step (line 9 of Algorithm KruskalMLST).

4 Prim-based MLST algorithm

A natural approach based on Prim's algorithm is as follows. Choose a root terminal r with $P(r) = \ell$ and remove r from T. Then, find a terminal $v \in T$ whose connection cost is minimum, where the connection cost is defined to be the cost of installing or upgrading edges from r to v using rate $P(v)$ (namely, using edge costs $c_{P(v)}(\cdot)$). Remove v from T, and decrement costs. Repeat this process of connecting the existing MLST to the closest terminal until T is empty. Interestingly, unlike Algorithm GreedyMLST, this approach can return a solution $|T|$ times the optimum, which is rather poor. We remark that Algorithm $\mathrm{C}_{2\mathrm{a}}$ [4] is similar to the Prim-based algorithm, where terminals are connected in order of priority rather than connecting the closest terminals first.

As an example, suppose G is a cycle containing $|V| = \ell + 1$ vertices v_1, v_2, v_3, …, v_ℓ, r in that order (Figure 2, left). Let $P(v_i) = i$, and let $P(r) = \ell$. Let $c_i(rv_\ell) = 1$ (edge rv_ℓ has cost 1 regardless of rate), and let $c_i(rv_1) = i(1-\varepsilon)$. Let all other edges have cost zero (or perhaps a small $\varepsilon' \ll \varepsilon$), regardless of rate. Then the Prim-based algorithm greedily connects v_1, v_2, …, v_ℓ in that order, incurring a cost of $1-\varepsilon$ at each iteration. Hence the cost returned is $\ell(1-\varepsilon) \approx |T|$, while $\mathrm{OPT} = 1$.

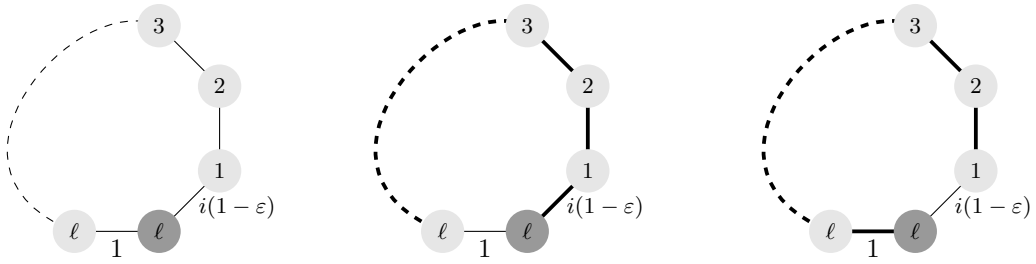

Figure 2 Left: Simple example demonstrating that a Prim-based algorithm can perform poorly. The priorities $P(\cdot)$ and edge costs $c_i(\cdot)$ are shown, and the root r is bolded. Center: Solution found by the Prim-based algorithm with cost $\ell(1-\varepsilon)$. Right: Optimum solution with cost $\mathrm{OPT} = 1$.

5 Integer linear programming (ILP) formulation

In [1], ILP formulations were given for the MLST problem with proportional costs. We extend these and give an ILP formulation for non-proportional costs. First, direct the graph G by replacing each edge $e = uv$ with two directed edges (u, v) and (v, u). Let $x^i_{uv} = 1$ if (u, v) appears in the solution with rate greater than or equal to i, and 0 otherwise. Let $c'_i(u, v)$ denote the incremental cost of edge (u, v) with rate i, defined as $c_i(e) - c_{i-1}(e)$ where $e = uv$ and $c_0(e) = 0$. Fix a root $r \in T$ with $P(r) = \ell$. For $i = 1, \ldots, \ell$, let $T_i = \{t \in T : P(t) \geq i\}$ denote the set of terminals requiring priority at least i. For every edge $e = (u, v)$ we define two flow variables f^i_{uv} and f^i_{vu}.

$$\text{Minimize} \quad \sum_{i=1}^{\ell} \sum_{(u,v)\in E} c'_i(u,v) x^i_{uv} \text{ subject to} \tag{1}$$

$$\sum_{(v,w)\in E} f^i_{vw} - \sum_{(u,v)\in E} f^i_{uv} = \begin{cases} |T_i| - 1 & \text{if } v = r \\ -1 & \text{if } v \in T_i \setminus \{r\} \\ 0 & \text{else} \end{cases} \qquad \forall\, v \in V; 1 \leq i \leq \ell \tag{2}$$

$$x_{uv}^i \leq x_{uv}^{i-1} \qquad \forall\,(u,v) \in E; 2 \leq i \leq \ell \tag{3}$$

$$0 \leq f_{uv}^i \leq (|T_i| - 1) \cdot x_{uv}^i \qquad \forall\,(u,v) \in E; 1 \leq i \leq \ell \tag{4}$$

$$x_{uv}^i \in \{0,1\} \qquad \forall\,(u,v) \in E; 1 \leq i \leq \ell \tag{5}$$

In the optimal solution, the edges of rate greater than or equal to i form a Steiner tree over T_i, so the flow constraint ensures that this property holds. The second constraint ensures that if an edge is selected at rate i or greater, then it must be selected at lower rates. The third constraint ensures that the indicator variable is set equal to one if and only if the corresponding edge is in a tree. The last constraint ensures that the x_{uv}^i variables are 0–1.

▶ **Theorem 6.** *The optimal solution for the ILP induces an MLST with cost* OPT.

The proof is deferred to Appendix A. Additionally, it can be seen from the formulation that the number of variables is $O(\ell|E|)$ and the number of constraints is $O(\ell(|E| + |V|))$.

6 Experiments

We run two primary kinds of experiments: first, we compare the various MLST approximation algorithms discussed here on random graphs from different generators; second, to provide comparison with the Steiner tree literature, we perform experiments on instances generated using the SteinLib library [11]. In both cases, we consider natural questions about how the number of priorities, number of vertices, and decay rate of terminals with respect to priorities affect the running times and (experimental) approximation ratios (cost of returned solution divided by OPT) of the algorithms explored here. We also record how often the algorithms proposed here provide better approximation ratios than pre-existing algorithms. Moreover, we illustrate a class of graphs for which Algorithm KruskalMLST always performs better than Algorithm $\mathrm{C}_{2\mathrm{a}}$.

6.1 Experiment Parameters

We run experiments first to test runtime vs. parameters discussed above, and then to test the experimental approximation ratio vs. the parameters. Each set of experiments has several parameters: the graph generator (random generators or SteinLib instances), the maximum number of priorities ℓ, $|V|$, how the size of the terminal sets T_i (terminals requiring priority at least i) decrease as i decreases, and proportional vs. non-proportional edge costs.

In what follows, we use the Erdős–Rényi (ER) [8], Watts–Strogatz (WS) [15], and Barabási–Albert (BA) [2] models or SteinLib instances [11] to generate the input graph (more on how SteinLib instances are given priorities later). The number of vertices of the graphs generated by different models varies from 10 to 100. We consider number of priorities $\ell \in \{2, \ldots, 7\}$, and adopt two methods for selecting terminal sets (equivalently priorities): linear and exponential. A terminal set T_ℓ with lowest priority of size $n(1 - \frac{1}{\ell+1})$ in the linear case and $\frac{n}{2}$ in the exponential case is chosen uniformly at random. For each subsequent priority, $\frac{1}{\ell+1}$ terminals are deleted at random in the linear case, whereas half the remaining terminals are deleted in the exponential case. Priorities and terminal sets are related via $T_i = \{t \in T : P(t) \geq i\}$. For the proportional edge weight case, we choose $c_1(e)$ uniformly at random from $\{1, \ldots, 10\}$ for each edge independently and set $c_i(e) = ic_1(e)$ for $i = 1, \ldots, \ell$.

For the non-proportional setting, we select the incremental edge costs $c_1(e)$, $c_2(e) - c_1(e)$, $c_3(e) - c_2(e)$, ..., $c_\ell(e) - c_{\ell-1}(e)$ uniformly at random from $\{1, 2, 3, \ldots, 10\}$ for each edge independently.

In the case that the input graph comes from SteinLib, it has a prescribed terminal set (since SteinLib graphs are instances of ST problem for a single priority). For these inputs, priorities are generated in two ways: filtered terminals and augmented terminals. To generate filtered terminals we divide the set of original terminals from the SteinLib into ℓ sets (with $\ell \in \{2, \ldots, 6\}$). We assign the first set as the topmost priority terminals. We assign the second set to the next priority and so on. For the augmented case, we start with the initial terminals from the SteinLib instance and add additional terminals uniformly at random from the remaining vertices. We assign 5 vertices as top priority terminals, double the number of terminals in the next priority, and so on until the maximum number of terminals is reached (we assign $\ell \in \{2, 3, 4\}$ priorities). Augmentation makes sense given that some of the original SteinLib instances have very few terminals. We have generated our datasets from two subsets of SteinLib: I080 and I160; we generate both types of terminals (filtered and augmented) for each of these datasets. The reason we run our experiment on the two SteinLib datasets is that the sizes of the graphs are relatively smaller. Our exact algorithm based on the ILP formulation has an exponential running time, and will not be able to terminate in a reasonable time for the datasets that contain large instances.

An experimental instance of the MLST problem here is thus characterized by five parameters: graph generator, number of vertices $|V|$, number of priorities ℓ, terminal selection method TSM $\in$ {Linear,Exponential}, and proportionality of the edge weights TE $\in$ {Prop,Non-prop}. As there is randomness involved, we generated five instances for every choice of parameters (e.g., ER, $|V| = 70$, $\ell = 4$, Linear, Non-prop).

For the following experiments, we implement the KruskalMLST and C_1 algorithms in the proportional case, and the KruskalMLST and C_{2a} algorithms in the non-proportional case. We note here that Algorithm GreedyMLST achieves much poorer results with respect to OPT than KruskalMLST in practice despite having similar theoretical guarantees. The reason for the poor performance is that the algorithm over–counts the edge costs when it is considered multiple times. On the other hand, KruskalMLST updates the cost of the edges so that for a particular edge and rate, it pays only once. Hence, in our experiment we only use KruskalMLST. To compute the approximation ratios, we use the ILP described in Section 5 using CPLEX 12.6.2 as an ILP solver.

6.2 Results

As one would expect, runtime for both the ILP and all approximation algorithms increased as $|V|$ or ℓ increased. Runtime was typically higher for linear terminal selection than for exponential. See Figures 12–14 in the Appendix for detailed plots. We do note that the running times of the approximation algorithms are significantly faster than the running time of the ILP; the latter takes a couple of minutes for whereas the approximation algorithms take only a couple of seconds for the same instances generated in our experiments.

There was no discernible trend in plots of Ratio (defined as cost/OPT) vs. $|V|$, ℓ, or the terminal selection method (linear or exponential). In all cases, for all graph generators, both the KruskalMLST and C_1 (or C_{2a} in the non-proportional case) exhibited similar statistical behavior independent of the given parameter (see Figures 5–9 in the Appendix for detailed plots). For a brief illustration, we show the behavior for Erdős–Rényi graphs with $p = (1 + \varepsilon)\frac{\ln n}{n}$ in Figure 3, and include the performance of the Composite Algorithm of [1] (CMP) as it gives the best *a priori* approximation ratio guarantee. In the non-proportional

case, Charikar et al. [4] have used another algorithm C_{2b} beside C_{2a} and returned the best solution. In the experiment, we only compare with C_{2a} since C_{2b} runs an iteration for each priority to get the final solution and in this paper, we are primarily interested in techniques that run in a single iteration similar to the spanning tree algorithms.

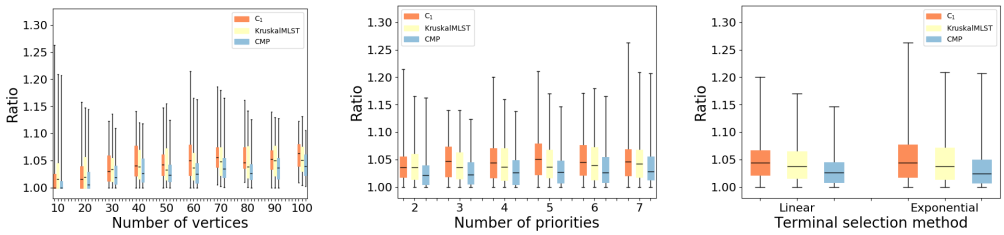

Figure 3 Performance of C_1 [4], KruskalMLST, and CMP [1] on Erdős–Rényi graphs w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights.

From Figure 3, we see that on average KruskalMLST outperforms C_{2a}. However, it is instructive to compare the instance-wise performance of the different algorithms. Tables 1 and 2 show comparisons of the statistical performance of the the two approximation algorithms for various graph generators in the proportional and non-proportional case, respectively. For each graph generator, there are a total of 1140 instances consisting of 5 graphs for each set of parameters ($|V|$, ℓ, etc.).

Table 1 Statistics of Algorithms C_1 [4] and KruskalMLST (abbreviated K) with proportional edge cost. Best Approx. reports the percentage of instances (out of 1140) that each algorithm achieved strictly better experimental approximation ratio. Best performance in each category is bolded. The statistics correspond to the experimental approximation ratio.

Min	**1.0**	**1.0**	**1.0**	**1.0**	**1.0**	**1.0**
Max	1.667	**1.54**	1.863	**1.601**	1.941	**1.667**
Best Approx.	37.20%	**61.22%**	34.83%	**63.85%**	30.62%	**68.24%**

We see from these tables that KruskalMLST consistently outperforms the algorithms of [4] in each of the statistical categories, and also achieves better instance-wise results a majority of the time, although this behavior depends somewhat on the graph generator. A full suite of figures is given in the Appendix to further illustrate the performance of each algorithm for the various generators. The trends are essentially the same and are as follows. KruskalMLST outperforms C_{2a} on a majority of instances, but has marginally longer runtime (though the difference is not appreciable); the number of priorities has little effect on runtime or experimental approximation ratio; the number of vertices increases the runtime for some generators, but has little effect on the experimental approximation ratio; experimental approximation ratios are typically better on average for exponentially decreasing terminal sets (which makes sense given that $|T|$ is smaller and the approximation guarantees are $O(\ln |T|)$). Finally, we note that the Composite algorithm of [1] can achieve better approximation in the proportional edge cost setting, but is not known to work for the non-proportional setting; additionally Composite suffers from exponential growth in runtime with respect to ℓ, which is a feature not exhibited by KruskalMLST.

6.3 Graphs for which KruskalMLST always outperforms C_{2a}

Here we generate a special class of graphs for which the Kruskal-based algorithm always provides near-optimal solutions, but Algorithm C_{2a} performs poorly. This class of graphs consists of cycles with randomly added edges. Begin with a cycle $v_1, v_2, \cdots, v_n, v_1$ and set the weight of edge v_1v_n be $w - \epsilon$ where length of the path $v_1, v_2, \cdots, v_n$ is w. We select v_1 and v_n as higher-priority terminals, and the remaining vertices as lower-priority terminals. An algorithm that works in a top-down manner will take the edge v_1v_n for higher priority and pay significantly more than the optimal solution [1]. Doing this to every edge (v_i, v_{i+1}) results an MLST instance where a top-down approach performs arbitrarily poorly. On these graphs, the algorithm provided in Charikar et al. [4] for proportional instances of MLST performs noticeably worse than our Kruskal-based approach (see Figure 4). We generated 500 graphs of this type (augmented with some additional edges at random). The script to generate these graphs are available on Github at `https://github.com/abureyanahmed/Kruskal_based_approximation`.

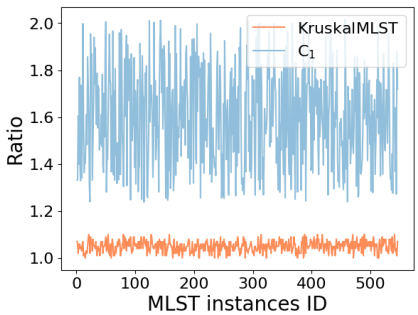

Figure 4 A class of graphs for which the Algorithm KruskalMLST significantly outperforms Algorithm C_{2a} [4]. The x–axis is the instance number and carries no meaning of time; the y–axis is the approximation ratio.

7 Conclusion

We proposed two algorithms for the MLST problem based on Kruskal's and Prim's algorithms. We showed that the Kruskal-based algorithm is a logarithmic approximation, matching the best approximation guarantee of Charikar et al. [4], while the Prim-based algorithm can perform arbitrarily poorly. We formulated an ILP for the general MLST problem and provided an experimental comparison between the algorithm provided by Charikar et al. [4], Ahmed et al. [1], and the Kruskal-based algorithm, KruskalMLST. We demonstrated that KruskalMLST compares favorably to other algorithms in terms of experimental approximation ratio for both the proportional and non-proportional edge costs while incurring a minor cost in run time. Finally, we generated a special class of graphs for which KruskalMLST always performs significantly better than that by Charikar et al. [4]. A natural question is whether the analysis of any of these algorithms GreedyMLST, KruskalMLST, or C_{2a} can be tightened, improving the approximability gap between $O(\log \log n)$ and $O(\log n)$ for the MLST problem with non-proportional edge costs.

A Proof of Theorem 6

Proof. We first show that the flow variables take only integer values from zero to $|T_i| - 1$ although it is not specifically mentioned in the formulation. Note that for every priority the ILP generates a connected component in order to fulfill the conditions of the second equation. The algorithm will compute a tree for every priority, otherwise, there is a cycle at a tree of a particular priority and removing an edge from the cycle minimizes the objective. According to the second equation, the flow variable corresponding to an incoming edge connected to a terminal that is not root is equal to one if the edge is in the tree. Since the difference between the incoming and outgoing flow is $|T_i| - 1$ for the root and zero for any intermediate node, every flow variable must be equal to an integer. Also if we do not have integer flows (for example the incoming flow is one and there are two outgoing flows with values 1/2), then because of the conditions in second equation cycles will be generated. Because of this property, the fourth equation ensures that x^i_{uv} is equal to one iff the corresponding flow variable has a value greater than or equal to one. In other words, an indicator variable is equal to one iff the corresponding edge is in the tree. Note that, the formulation has only one assumption on the edge weights: the cost of an edge for a particular rate is greater than or equal to the weight of the edge having lower rates. Hence, the formulation computes the optimal solution for (non-)proportional instances. ◀

B Additional Experimental Results

In this section, we provide some details of the experiments discussed in Section 6.

B.1 Graph Generator Parameters

Given a number of vertices, n, and probability p, the model $\mathrm{ER}(n, p)$ assigns an edge to any given pair of vertices with probability p. An instance of $\mathrm{ER}(n, p)$ with $p = (1 + \varepsilon)\frac{\ln n}{n}$ is connected with high probability for $\varepsilon > 0$ [8]. For our experiments we use $n \in \{10, 15, 20, \cdots, 100\}$, and $\varepsilon = 1$.

The Watts–Strogatz model [15] is used to generate graphs that have the small-world property and high clustering coefficient. The model, denoted by $\mathrm{WS}(n, K, \beta)$, initially creates a ring lattice of constant degree K, and then rewires each edge with probability $0 \leq \beta \leq 1$ while avoiding self-loops or duplicate edges. In our experiments, the values of K and β are set to 6 and 0.2 respectively.

The Barabási–Albert model generates networks with power-law degree distribution, i.e., few vertices become hubs with extremely large degree [2]. The model is denoted by $\mathrm{BA}(m_0, m)$, and uses a preferential attachment mechanism to generate a growing scale-free network. The model starts with a graph on m_0 vertices. Then, each new vertex connects to $m \leq m_0$ existing nodes with probability proportional to its instantaneous degree. This model is a network growth model. In our experiments, we let the network grow until the desired network size n is attained. We vary m_0 from 10 to 100 in our experiments, and set $m = 5$.

B.2 Computing Environment

For computing the optimum solution, we implemented the ILP described in Section 5 using CPLEX 12.6.2 as an ILP solver. The model of the HPC system we used for our experiment is Lenovo NeXtScale nx360 M5. It is a distributed system; the models of the processors in this HPC are Xeon Haswell E5-2695 Dual 14-core and Xeon Broadwell E5-2695 Dual 14-core. The speed of a processor is 2.3 GHz. There are 400 nodes each having 28 cores. Each node has 192 GB memory. The operating system is CentOS 6.10.

B.3 Experimental Setup

We have considered proportional and non-proportional instances separately. The Kruskal-based algorithm is the same in both settings, but the algorithms of [4] admit 2 variants: C_1 for proportional edge costs which is a 4ρ–approximation, and C_{2a} for non-proportional edge costs which is a $2(\ln|T|+1)$–approximation. In figures below, Ratio stands for the approximation ratio given by the cost of the solution returned by the approximation algorithm divided by the optimum cost OPT returned by the ILP.

All box plots shown below show the minimum, interquartile range (IQR) and maximum, aggregated over all instances using the parameter being compared.

B.4 Approximation Ratio vs. Parameters – Proportional edge costs

First, we take a look at how the approximation ratio of the approximation algorithms is affected by the parameters chosen. Figures 3, 5, and 6 illustrate the change in approximation for different parameters ($|V|$, ℓ, and the terminal selection method) in the case of proportional edge costs. For comparison to [1], we include the performance of the Composite algorithm (CMP) described therein.

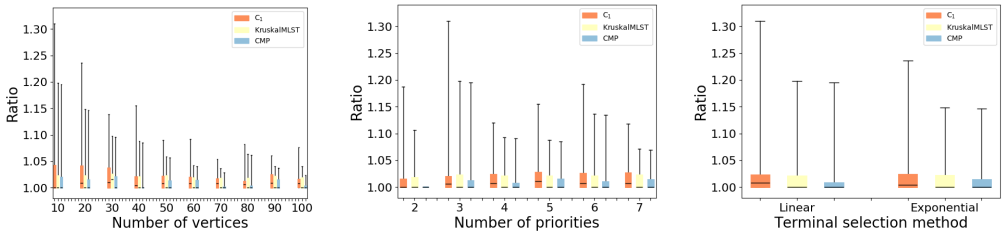

Figure 5 Performance of C_1 [4], KruskalMLST, CMP [1] on Watts–Strogatz graphs w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights.

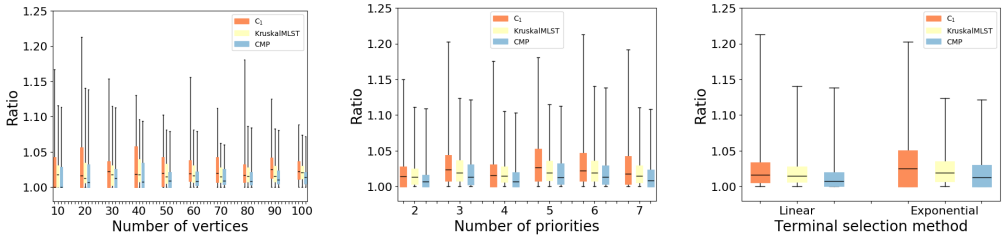

Figure 6 Performance of C_1 [4], KruskalMLST, and CMP [1] on Barabási–Albert graphs w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights.

We see that for Erdős–Rényi graphs, the number of vertices marginally increases the approximation ratio over time, while for the other generators this does not appear to be the case. Overall, no discernible trend occurs for the number of priorities regardless of the generator. Interestingly, for randomly generated graphs, there appears to be no relation to the rate of decrease of terminal sets (i.e., linear vs. exponential) with the statistics of the approximation ratios.

B.5 Approximation Ratio vs. Parameters – Non-Proportional Edge Costs

Here we consider the case non-proportional edge cost, in which we compare Algorithms C_{2a} and KruskalMLST. The Composite algorithm of [1] was not designed for non-proportional edge costs and so is not included here. Figures 7–9 show the approximation ratios vs. parameters for each of the random graph generators discussed above.

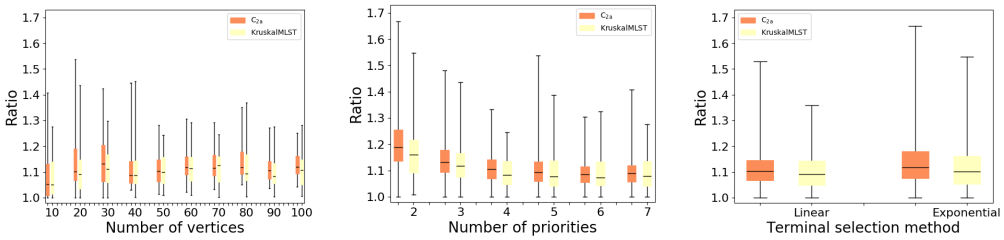

Figure 7 Performance of C_{2a} [4] and KruskalMLST w.r.t. $|V|$, ℓ, and terminal selection method with non-proportional edge weights on Erdős–Rényi graphs.

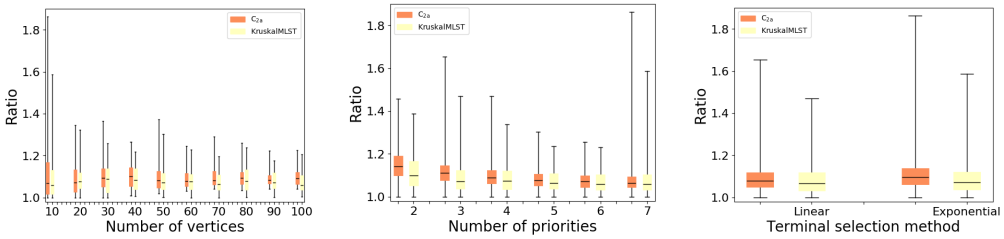

Figure 8 Performance of C_{2a} [4] and KruskalMLST w.r.t. $|V|$, ℓ, and terminal selection method with non-proportional edge weights on Watts–Strogatz graphs.

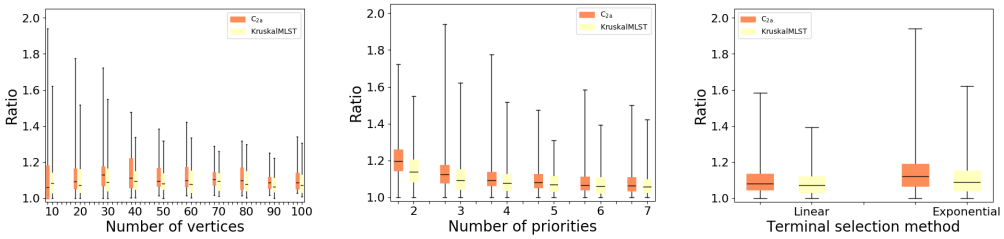

Figure 9 Performance of C_{2a} [4] and KruskalMLST w.r.t. $|V|$, ℓ and terminal selection method with non-proportional edge weights on Barabási–Albert graphs.

In the non-proportional case, it is interesting that the approximation ratio appears to be little affected by any of the parameters, and even appears to decrease with respect to the number of priorities. It is unclear if this trend would continue for large number of priorities, but it is an interesting one nonetheless. Of additional note is that KruskalMLST typically has less variance in its approximation ratio than the algorithms of Charikar et al. [4] in both the proportional and non-proportional case.

B.6 Approximation Ratio vs. Parameters – SteinLib Instances

For the experiments on the SteinLib graphs [11], we first extended two datasets (I080 and I160) to have priorities via filtering or augmenting as described in Section 6. We provide the plots showing the Performance of C_1 [4], KruskalMLST, and CMP [1] on I080 and I160 graphs w.r.t. ℓ with filtered priorities in Figure 10, and for augmented priorities in Figure 11.

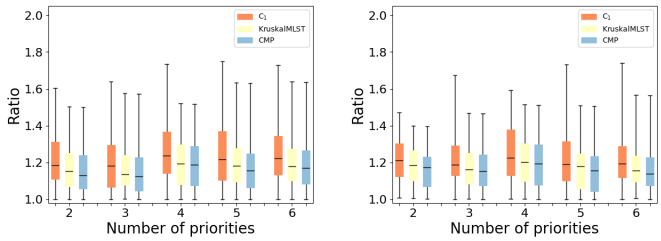

Figure 10 Performance of C_1 [4], KruskalMLST, and CMP [1] on I080 and I160 graphs w.r.t. ℓ with filtered priorities.

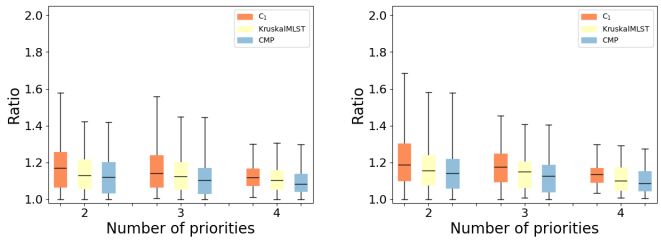

Figure 11 Performance of C_1 [4], KruskalMLST, and CMP [1] on I080 and I160 graphs w.r.t. ℓ with augmented priorities.

B.7 Runtime vs. Parameters – Proportional Edge Costs

Now we take a look at the affect of the parameters mentioned above on the average runtimes of the approximation algorithms in the case of proportional edge costs. Figures 12–14 show the runtime of the algorithms C_{2a}, KruskalMLST, and GreedyMLST versus $|V|$, ℓ, and the terminal selection method.

As is to be expected, on all generators, the average runtime increases as $|V|$ increases, as does the variance in the runtime. Interestingly, average runtime does not appear to be much affected by the number of priorities, although the variance in runtime does substantially increase with ℓ. Runtime is lower for exponentially decreasing terminals, which makes sense given that in this case, the overall size of the terminal sets is smaller than in the linearly decreasing case.

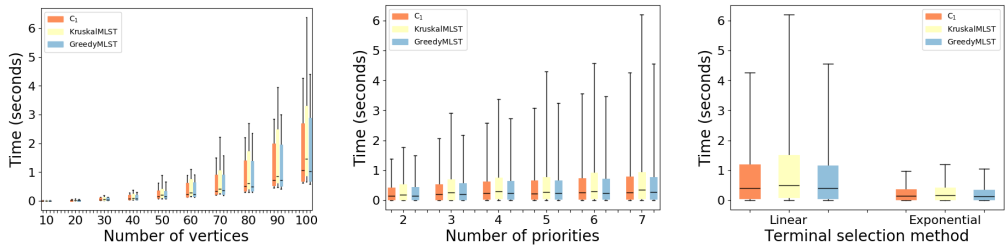

Figure 12 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Erdős–Rényi graphs.

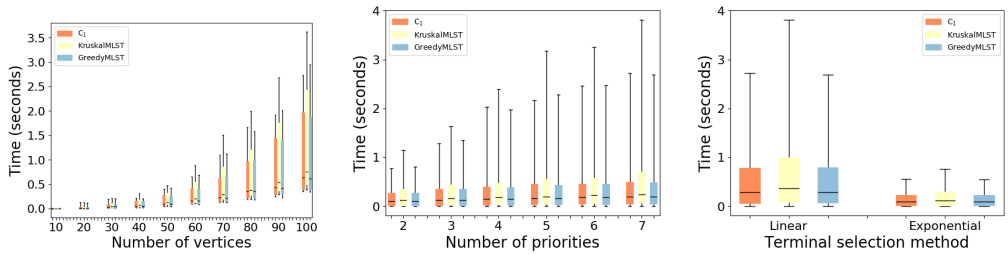

Figure 13 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Watts–Strogatz graphs.

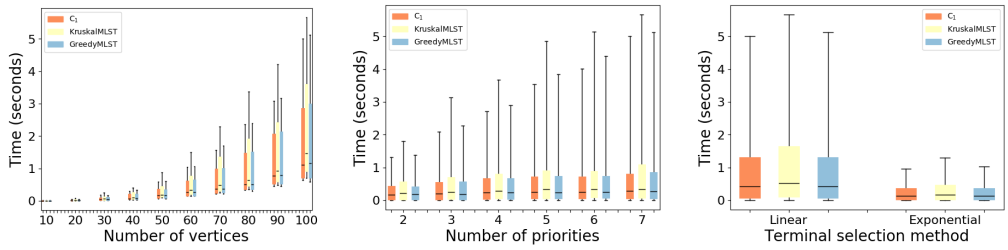

Figure 14 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Barabási–Albert graphs.

B.8 Runtime vs. Parameters – Non-Proportional Edge Costs

Now we take a look at the affect of the parameters mentioned above on the average runtimes of the approximation algorithm in the non-proportional case. Figures 15–17 show the runtime of the algorithms C_{2a}, KruskalMLST, and GreedyMLST versus $|V|$, ℓ, and the terminal selection method.

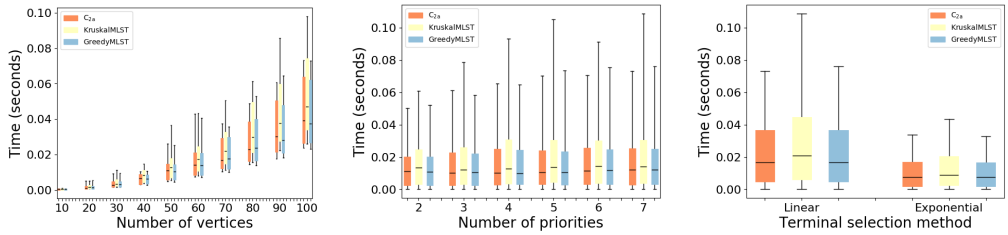

Figure 15 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with non-proportional edge weights on Erdős–Rényi graphs.

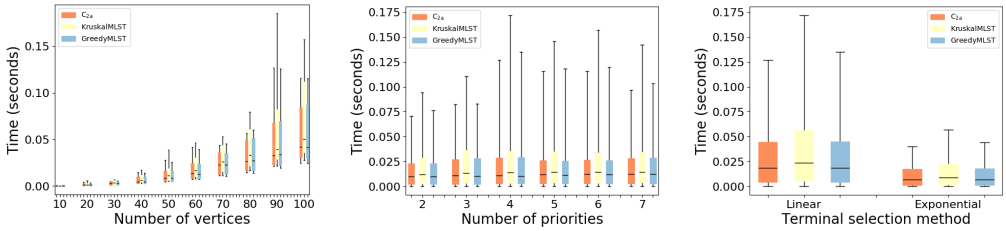

Figure 16 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with non-proportional edge weights on Watts–Strogatz graphs.

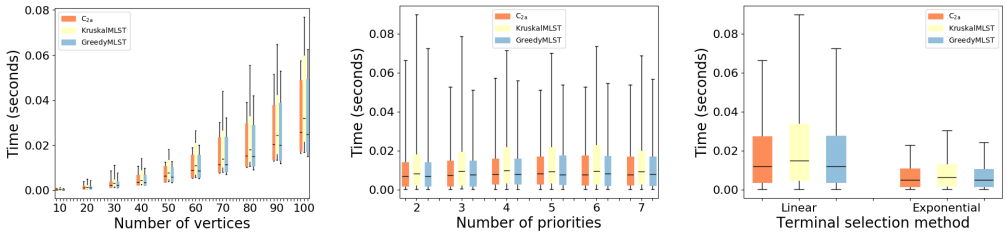

Figure 17 Experimental running times for computing approximation algorithm solutions w.r.t. $|V|$, ℓ, and terminal selection method with non-proportional edge weights on Barabási–Albert graphs.

The trends are essentially the same as in the case of proportional edge costs; however, we note that the overall runtimes are almost two orders of magnitude smaller on average in the non-proportional trials run here.

C ILP Solver

Without doubt, the most time consuming part of the experiments above was calculating the exact solutions of all MLST instances. For illustration, we show the runtime trends for the ILP solver with respect to $|V|$, ℓ, and the terminal selection method for proportional edge costs in Figures 18–20 and for non-proportional edge costs in Figures 21–23 for all of the random graph generators.

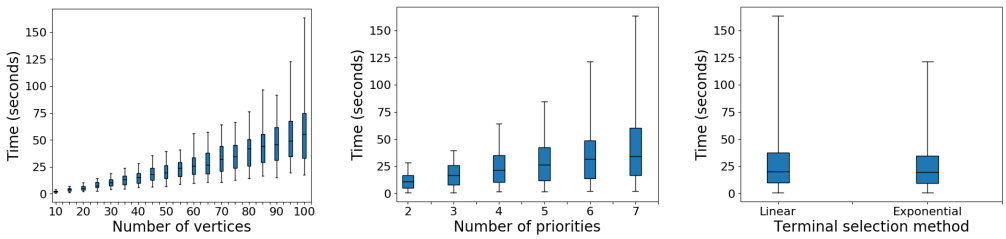

Figure 18 Experimental running times for computing exact solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Erdős–Rényi graphs.

As expected, the running time of the ILP gets worse as $|V|$ and ℓ increase. The running time of the ILP is worse for the linear terminal selection method, again likely because of the overall larger terminal set T. Note that the running time of the approximation algorithms are significantly faster than the running time of the exact algorithm. The exact algorithm takes a couple of minutes whereas the approximation algorithms take only a couple of seconds.

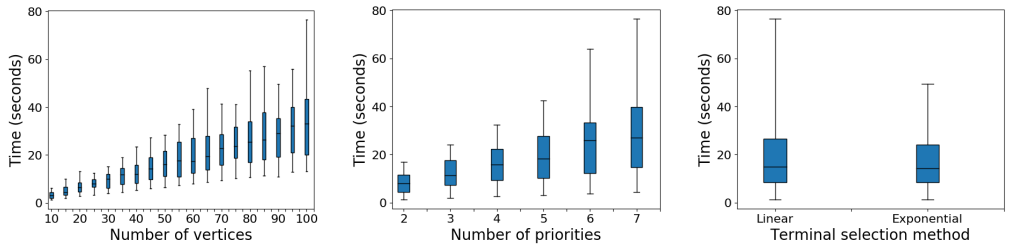

Figure 19 Experimental running times for computing exact solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Watts–Strogatz graphs.

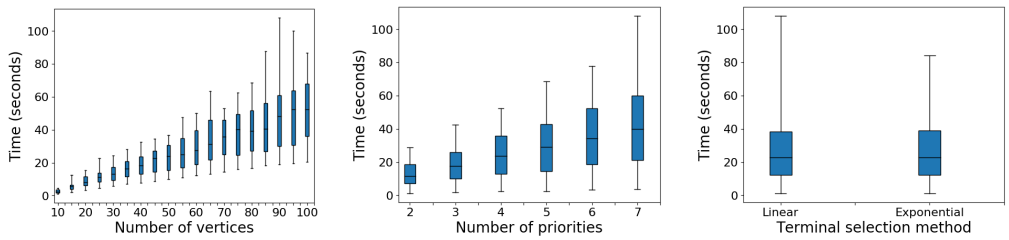

Figure 20 Experimental running times for computing exact solutions w.r.t. $|V|$, ℓ, and terminal selection method with proportional edge weights on Barabási–Albert graphs.

Abstract

The *recovery problem* is the problem whose input is a *corrupted* text T that was originally *periodic*, and where one wishes to recover its original period. The algorithm's *input* is T without any information about either the period's length or the period itself. An algorithm that solves this problem is called a *recovery algorithm*. In order to make recovery possible, there must be some assumption that not "too many" errors corrupted the initial periodic string. This is called the *error bound*. In previous recovery algorithms, it was shown that a given error bound of $\frac{n}{(2+\epsilon)p}$ can lead to $O(\log_{1+\epsilon} n)$ period candidates, that are *guaranteed* to include the original period, where p is the length of the original period (unknown by the algorithm) and $\epsilon > 0$ is an arbitrary constant.

This paper provides the first analysis of the relationship between the error bound and the number of candidates, as well as identification of the error parameters that still guarantee recovery. We improve the previously known upper error bound on the number of corruptions, $\frac{n}{(2+\epsilon)p}$, that outputs $O(\log_{1+\epsilon} n)$ period candidates. We show how to (1) remove ϵ from the bound, (2) relax the error bound to allow more errors while keeping the candidates set of size $O(\log n)$. It turns out that this relaxation on the previously known upper bound is quite challenging.

To achieve this result we provide what, to our knowledge, is the first known non-trivial lower bound on the *Hamming* distance between two periodic strings. This proof leads to an error bound, that produces a family of period candidates of size $2\log_3 n$. We show that this result is tight and further provide a compact representation of the period candidates. We call this representation the *canonic period seed*.

In addition to providing less restrictive error bounds that guarantee a smaller candidate set, we also provide a *hierarchy* of more restrictive upper error bounds that asymptotically reduces the size of the potential period candidate set.

1 Introduction

Deterministic algorithms live in a "sterile" world: The problem is combinatorially clean, the environment is exact and unchanging, and thus the result is well defined. Reality is seldom so accommodating. Therefore, when applying algorithms to real world problems, one is generally required to approximate a solution.

Such approximations are derived from two sources: (1) Problems that can't be solved efficiently, due to their inherent complexity, and (2) input that has been corrupted by various error-inducing sources. Theoretical Computer Science, in the field of Algorithms Development and Analysis, solves the above first problem by optimization algorithms (see e.g. [11–13, 22]). These are algorithms that come provably close to the optimal solution. The second problem is generally solved using the assumption that the input incurred the *smallest* number of possible corruptions (see e.g. [1, 15–17]). Two examples are the following:

The first solution to the Human Genome Sequencing project [21] used "shotgun sequencing". Since the genome can not be read in its entirety, we are really presented with a "soup" of small subsequences of the genome. These subsequences need to be combined to produce the full sequence. The assumption was that the *shortest common superstring* [20] is the solution, i.e. the shortest string that can be cut into the input subsequences. Of course, there is no absolute guarantee that the original input was, indeed, the shortest. But this is the assumption that was made. Whenever there is statistical support for an assumption on the nature of the output, this support strengthens the result, but one can never be 100% sure that the produced output is indeed the "real" one.

The second example deals with Evolutionary Biology. By 1987, 145 races of humans were identified. The question was, how did the different races evolved? Cann, Stoneking, and Wilson [7] wrote their paper on human evolution, based on mitochondrial DNA. The idea is to fix a gene, and by its differences in the different races, construct a tree depicting the evolution, with races having smaller differences in the gene being closer to each other in the tree than races with greater differences. These evolutionary trees are constructed with the idea of parsimony in mind [8]. Clearly, though, the resulting tree is not the initial one, since different genes cause different trees, which then need to be reconciled [4, 9, 18, 19].

The above two are just examples of our shortcoming in approximating scientific phenomena. The scientific paradigm for reconstructing a phenomenon, at best can produce a measure of confidence, but never guarantee that the result of the algorithm indeed recovers the initial object.

The reconstruction task is the problem in which one has sampled a corrupted text T that was originally periodic, and wishes to recover its original period phenomenon. The input is T without any information about either the period's length nor the period itself. This problem seems doomed since in most cases, even one error can lead to an ambiguity. However, in 2012, Amir et. al [3] introduced the *recovery model*. They have achieved some surprising results. They identified a phenomenon - *periodicity* - where one can get a corrupted input and produce a very small set of solutions (logarithmic in the input size), one of which is **guaranteed** to be the initial uncorrupted source, provided that the number of errors is reasonably bounded. This result was succeeded by additional papers, dealing with various types of error measures [2, 14], and recovering different phenomena [5].

In the *recovery model* for periodic strings, the output is a set of period candidates that must include the original period. Algorithms in such a model assume that the number of errors introduced into the text is limited. The error bound ensures that the recovery algorithm outputs a set of at most $o(n)$ candidates. However, there has not been a systematic study of what types of errors are to be bound, or whether the bound is tight. Nor has the relation between the error bound and the number of potential candidates ever been studied.

One of the topics that this work investigates is different types of error bounds. An error bound *type* is defined by the variables that it limits. We may consider a *universal error bound*, i.e. that in the entire string T there do not appear more than a constant number of errors. We may say that the number of errors is a function of the length of T. Another possibility is that the number of errors is a function of cycles of the period. In other words, how many copies of the period have to pass by without corruption. This last is the type of error considered historically. Some of those variables allow a degree of freedom, some are known while others might be unknown, and even without the ability to be estimated. For example, the historic error bound of [3] has a known value n, which is the length of input T, an unknown value p, the length of the original period (which is not part of the input), a set degree of freedom ϵ, and a parameter c determined by the metric. We can say in an abbreviated manner that previously known error bounds are of (n, p, ϵ, c)-type.

In this paper, we make the first attempt at a systematic analysis of the required error bound for recovery of a periodic string under mismatch errors. The only currently known relations between error bounds and number of candidates are: (1) the trivial bound of $|\Sigma|^{n/2}$ candidates for n possible errors, where Σ is the alphabet, since all possible periodic strings are candidates, and (2) The bound shown in Amir et al. [3]: Let T be an n-length periodic string with period P of length p. For $\epsilon > 0$, if we are guaranteed that there are no more than $\frac{n}{(2+\epsilon)p}$ mismatch errors, then a set of $\log_{1+\epsilon} n$ candidates can be constructed in $O(n \log n)$ time, that is guaranteed to include the original period P.

Amir et al. [3] proved their error bound result for pseudo-local metrics. For simplicity, we consider the *Hamming distance* as the distance metric, i.e. errors counted as the number of replacements. All our results can be easily extended to c-pseudo local metrics.

We desire answers to the following questions:
Past upper bounds depended on p. The first question to ask is whether this dependency is essential. In this paper, we study the case where the upper bound on errors is the number k. We are departing from the historical (n, p, ϵ, c)-type upper bounds, and instead consider k-type bounds, where k is either known or could be estimated. In this case, when one wants to reproduce the original periodic phenomena, the period length is unknown. On the other hand, the estimation of the number of corrupt copies of the period, as high as k, is assumed to be known.

In previous results, there is a "degree of freedom" variable ϵ. it seems that ϵ is not a natural variable to have in the upper bound formula. Its only use was to support the analysis. Indeed, one might want ϵ to be as close to zero as possible to relax upper bound on errors. However, this aim increases the number of candidates. This observation leads to our second question, whether it is possible to improve such analysis and get rid of ϵ without having too many candidates.

The second question leads to a greater task of how significant the upper bound of (n, p, c)-type can be relaxed while ensuring $o(n)$ candidates. This paper uses algebraic techniques to improve the upper bound on errors while preserving the property of $o(n)$ candidates. We give a partial answer, but believe that the question of how can be upper bound be further relaxed, and yet offer $o(n)$ periodic candidates is difficult and open to future research.

This paper successfully answers the above two questions.

However, on the path toward that goal, our first non-trivial insight is that even a single error (when $k = 1$) in text T might result in $\Theta(n)$ indistinguishable candidates. That is, without any additional knowledge on the problem, having a universal upper bound with $o(n)$ candidates is impossible. We further show that if the original period is repeated in the text $k + 1$ times, i.e. there exists a *single* complete uncorrupted occurrence of the original period, then it is still possible to construct an example with $\Theta(\frac{n}{k(k+1)}) = \Theta(n)$ candidates.

The novel combinatorial results are that (1) if the number of original period repetitions is $2k+1$ or higher then there is at most one candidate, i.e. *the original period can be recovered*, and (2) if the period originally repeated $2k$ times or higher ($k \geq 2$) then there are at most 2 indistinguishable candidates. We conclude that when k is known, the only required additional knowledge to find a constant number of period candidates is whether $p \leq \frac{n}{2k+1}$ or $p \leq \frac{n}{2k}$, respectively. Analysing the candidate set size when the number of repetitions is in the range between $k+1$ and $2k$ requires future research.

We highlight a connection between (n,p)-type and k-type upper bounds. Assume the case when k is unknown, but the above assumption about the repetitions holds. Then we should look at all possible k values and add their number of candidates. This leads us to the bounds $\lfloor \frac{n-p}{2p} \rfloor$ and $\lfloor \frac{n}{2p} \rfloor$, respectively. However, there are $\Theta(n)$ different values for k, and we require that the number of candidates must be $o(n)$, therefore we provide a new proof methodology.

In this paper, we analyze the $\lfloor \frac{n}{2p} \rfloor$ upper bound on errors, and prove that the number of candidates is $2\log_3 n$ and that this bound is tight by providing a family of examples. Moreover, we show that these candidates can be represented by a single *canonic period seed*.

Finally, we show a hierarchy of more restricted upper bounds of (n,p,ϵ,c)-type that yield $\Theta(\log^{(i)} n)$ candidates, where $\log^{(i)} n$ is $\log\log\cdots\log n$ i times.

In Fig. 1 we show the known bounds and the results of this paper. The formulae on the horizontal axis are error bounds, we show a hierarchy of candidate set size upper bounds. In various cases we show examples where this upper bound is indeed tight.

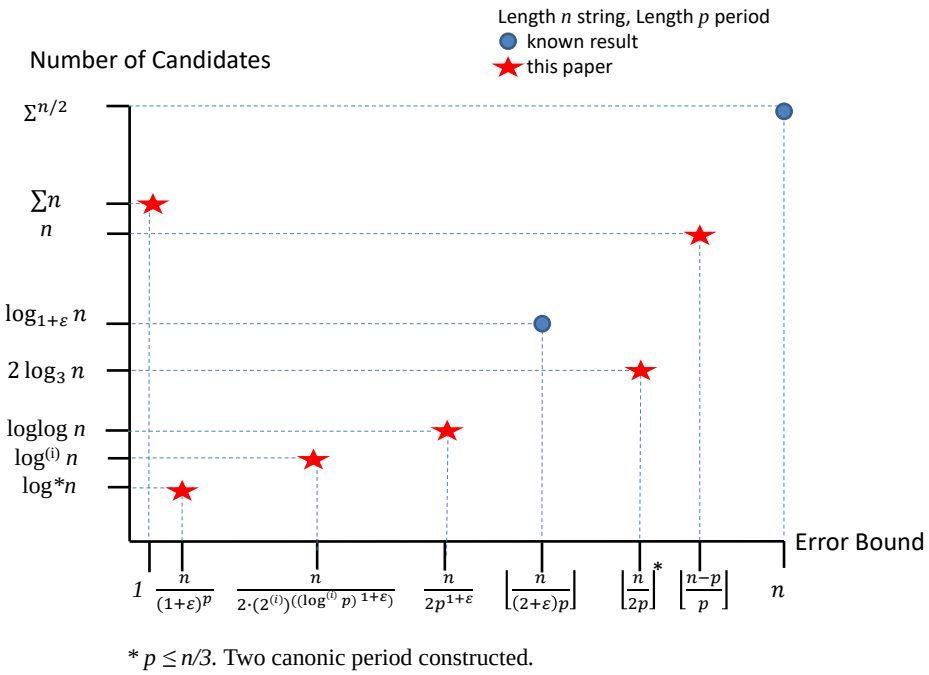

Figure 1 The results of this paper.

This paper is organized as follows: In Section 5, we discuss the k-type upper bounds. In Section 6, we tighten the logarithmic bound on the number of candidates. While in [3] the log base was dependent on ϵ of the allowed error bound, we show that for all ϵ the bound

is $2\log_3 n$. In this section, we introduce a new algebraic method to analyze the distance between periodic strings derived by different seeds. This enables us to further tighten the upper error bounds to $\lfloor \frac{n}{2p} \rfloor$, and construct a **single** *canonic period seed*, where no more than $2\log_3 n$ candidates derived from it, among which the initial period is guaranteed to exist. Finally, in Section 7, we give a hierarchy of upper bounds that produce decreasing number of candidates that include the original period. The hierarchy decreases from $\log n$ via $\log\log n$, $\log^{(i)} n$, to $\log^* n$.

2 Preliminaries

Let Σ be an alphabet. A *string* T over Σ is a finite sequence of letters from Σ. By $T[i]$, for $0 \leq i \leq t-1$, we denote the i^{th} letter of T. The *empty string* is denoted by λ. By $T[i..j]$ we denote the string $T[i]\dots T[j]$ called a *substring* of T (if $i > j$, then the substring is the empty string). A substring is called a *prefix* if $i = 0$ and a *suffix* if $j = t-1$. The prefix of length $j+1$ is denoted by $T[..j]$. While by $T[i..]$ we denote the suffix which starts from index i in T. We will follow the convention of using capital letters for string names, and the same small letter for the length of the string. For example: the length of string T is t. Other notations we use is $T[-i] = T[t-i]$.

An n-length string T is periodic if $T = P^k P'$, where $k \in \mathbb{N}$, $k \geq 2$, and P' is a prefix of P (the prefix might be empty). P^k is the concatenation of P to itself k times. It is clear that P is a substring of T and $p \leq t/2$.

If T is periodic, the shortest P, such that $T = P^k P'$ is called *the period of* T. There is a unique such period by the *periodicity lemma* [10]. The periodicity lemma states that for two different periods of lengths p and q, where $n \geq p + q - gcd(p, q)$, there exists a period of length $gcd(p, q)$, where $gcd(a, b)$ is the greatest common divisor of a and b. A string P is *primitive* if there is no string S such that $P = S^k$ and $k > 1$.

The recovery problem seeks the original period of a corrupted text T. The corruption may have caused T to be non periodic. Thus there may be a number of indistinguishable periods that generate strings of length t. We are seeking an error bound on the distance between these strings and T that forces only a small set of such periods.

▶ **Example 1.** $T = abaabaab$, then $P = aba$ is the period. In our exposition, for the sake of brevity, we may denote this string by $T = P^{2\frac{2}{3}}$. We allow ourselves to use fractions $\frac{x}{y}$ where $\frac{x}{y} \times t$ is an integer. In this example, we could not use $\frac{1}{4}$ because $\frac{1}{4} \times 3$ is not an integer.

Let T and S be two n-length strings, their *Hamming distance*, denoted by $Ham(T, S)$, is the number of mismatches between these strings. The Hamming distance represents the number of substitutions required to convert one string to the other.

Let P be a primitive string of length p. Let T be a n-length string, P^∞ denotes the periodic string of length ℓ, where the value of ℓ is clear from the context. For example, in the expression $Ham(T, P^\infty)$, both operands T and P^∞ should be of equal lengths, $\ell = n$. P is called a *period candidate* with bound e if $Ham(T, P^\infty) \leq e$. If $\ell = n$, we denote $T_P = P^\infty$. This notation simplifies the expressions when dealing with two different periodic candidates of T. For example, when observing $Ham(T_P, T_Q)$, where P and Q are two different periods.

Let P be a periodic candidate of T. The substring ranges of the form $[i, i+p-1]$, where $i = 1, p+1, 2p+1, \dots, (\lfloor \frac{n}{p} \rfloor - 1)p + 1$ denote *full occurrences* of P in T. A *full occurrence* $[i, i+p-1]$ is called an *exact occurrence* of P if $P = T[i..i+p-1]$, otherwise it is a *corrupted occurrence*.

3 A universal Error Bound Does not Allow Recovery

We begin by proving that a universal error bound, even if it is a single error in the string, does not suffice for $o(n)$ candidates. We describe an example of $\Omega(n)$ indistinguishable candidates when there is only a single corruption in some periodic text. Then we generalize it to any number of corruptions $k \in \mathbb{N}$.

▶ **Example 2.** Let $T = a^{2\ell}ba^{4\ell+1}$, where $n = 6\ell + 2$. We show that there are $\frac{n}{6}$ indistinguishable period candidates.

The original periodic source of the text T is one of the following.
$C = \{a^{2\ell}b\ a^{2\ell}b\ a^{2\ell}, a^{2\ell}ba\ a^{2\ell}ba\ a^{2\ell-2}, a^{2\ell}ba^2\ a^{2\ell}ba^2\ a^{2\ell-4}, \ldots, a^{2\ell}ba^{\ell}\ a^{2\ell}ba^{\ell}\}$
$= \{(a^{2\ell}b)^{2+\frac{2\ell}{2\ell+1}}, (a^{2\ell}ba)^{2+\frac{2\ell-2}{2\ell+2}}, (a^{2\ell}ba^2)^{2+\frac{2\ell-4}{2\ell+3}}, \ldots, (a^{2\ell}ba^{\ell})^2\}$

Each such possible source text has a different period. And for each such source, the number of the introduced corruptions is exactly 1. The second b is replaced by an a.

It is clear that $|C| = O(n)$, because of the following reason. Observe that the third occurrence of the period is not complete, only a suffix of it occurs. It begins with $a^{2\ell}$ and for each successive item, the length of the suffix of the third period occurrence decreases by 2, until it becomes the empty string. Thus, $|C| = \ell + 1 \approx \frac{n}{6}$.

It is easy to generalize the example to the case where k corruptions are allowed and there are $k + 1$ full occurrences of the period, in other words, we still have one uncorrupted periodic occurrence. In this case, the constructed example would has $\Omega(\frac{n}{k(k+1)}) = \Omega(n)$ indistinguishable period candidates.

▶ **Example 3.** $T = a^{\ell k}ba^{\ell k^2+k-\ell-1}$, where $n = \ell k^2 + \ell k + k$, $k \geq 2$, and $\ell \geq k$. We show that there are $\Omega(\frac{n}{k(k+1)})$ indistinguishable period candidates.

The original periodic source of the text T is one of the following.
$C = \{(a^{\ell k}b)^k\ a^{\ell k}, (a^{\ell k}ba)^k\ a^{\ell k-k}, (a^{\ell k}ba^2)^k\ a^{\ell k-2k}, \ldots, (a^{\ell k}ba^{\ell})^k\}$
$= \{(a^{\ell k}b)^{k+\frac{\ell k}{\ell k+1}}, (a^{\ell k}ba)^{k+\frac{\ell k-k}{\ell k+2}}, (a^{\ell k}ba^2)^{k+\frac{\ell k-2k}{\ell k+3}}, \ldots, (a^{\ell k}ba^{\ell})^k\}$

Thus, $|C| = \ell + 1 = \Theta(\frac{n}{k(k+1)})$.

4 Results

Our main contributions are the following.

▶ **Theorem 4.** *Let k be a fixed integer value. Let P be a period for which $Ham(T, T_P) \leq k$, and P has at least $2k + 1$ full occurrences in T. Then the number of possible candidates for P is at most 1.*

▶ **Theorem 5.** *Let $k \geq 2$ be a fixed integer value. Let P be a period for which $Ham(T, T_P) \leq k$, and P has at least $2k$ full occurrences in T. Then the number of possible candidates for P is at most 2.*

▶ **Theorem 6.** *Let P be a period for which $Ham(T, T_P) \leq \lfloor \frac{n}{2p} \rfloor$, and $p \leq \frac{t}{3}$. Then the number of possible candidates for P is at most $2\log_3(n) = O(\log n)$.*

5 k-Type Upper Error Bounds

In this section, we prove Theorems 4 and 5. Doing so requires a few new lemmas. We begin by examining the case where $k = 1$. Then we generalize our results to any $k \in \mathbb{N}$.

Let P, Q be two period candidates of T, with lengths p, q, respectively. Without loss of generality, assume $p > q$. We recall a useful lemma that was proven when P fully occurs at least twice.

▶ **Lemma 7** ([3]). *For any two periods P and Q, if they both fully occur at least twice, then $Ham(T_P, T_Q) \geq 2$.*

In [3], it is claimed that for the general case $Ham(T_P, T_Q) \geq \frac{n}{p}$. Our Corollary 10 is exactly this result. However, the previous proof fails to handle properly the case where $\left\lfloor \frac{n}{p} \right\rfloor$ is odd. We take care of this missed case.

▶ **Lemma 8.** *Let T be a text and assume there is at most one corruption error in T. Further assume that T is a corruption of an original periodic string T_P where the period P fully occurs at least 3 times in T (neither the period nor its length is part of the input) . Then there is a single period candidate for the original text.*

Proof. Let us assume in contradiction that there are P and Q two possible period candidates for T, $P \neq Q$. We begin by showing that $p \neq q$. If $p = q$, there are three occurrences of P and Q which are of the same length, but $Ham(T_P, T_Q) \leq 2$. It means that one full occurrence of P is equal to the corresponding full occurrence of Q, namely, $P = Q$. As a consequence, $p \neq q$. The proof is divided into three cases.

Case 1. When $q \mid p$. Let $k = \frac{p}{q}$.

P is primitive, against each full occurrence of P there are Q^k. That is, each full occurrence of P in T_P should cause at least 1 mismatch with T_Q, otherwise P is not primitive, thus $Ham(T_P, T_Q) \geq 3$. However, one error is assumed thus, $Ham(T_P, T_Q) \leq Ham(T, T_P) + Ham(T, T_Q) = 2$. Thus, we got a contradiction.

Case 2. When $q \mid 2p$ and $q \nmid p$.

First, we observe that q must be even. Let $Q = Q_P Q_S$, where Q_P and Q_S are exactly the first and last half of Q of lengths $q/2$. We observe the prefix of length $\frac{3q}{2}$ of the three first full occurrences of P. It is easy to see that against the first and third occurrence of P in T_P, there are $Q_P Q_S Q_P$ in T_Q. On the other hand, against the second full occurrence of P there are $Q_S Q_P Q_S$. It is clear that $Q_P \neq Q_S$, otherwise Q is not primitive. Thus, we must have at least 3 mismatches between T_P and T_Q, in contradiction.

Case 3. Otherwise, when $q \nmid 2p$ and $q \nmid p$.

From the alignment lemma, the number of mismatches between T_P and T_Q is at least 4, in contradiction. ◀

▶ **Corollary 9.** *For any two periods P and Q that fully occur at least three times, then $Ham(T_P, T_Q) \geq 3$.*

▶ **Corollary 10.** *Let $k \geq 2$. For any two periods P and Q that fully occur at least k times, then $Ham(T_P, T_Q) \geq k$.*

Proof. If k is even then use Lemma 7 on all disjoint consecutive pairs of full occurrences of P against the rotations of Q. If k is odd, use Lemma 7 for all full occurrences of P except its last three full occurrences. Handle these occurrences by Corollary 9. ◀

We now have the tools to prove the main theorems. The proofs can be found in the full version of this paper.

▶ **Theorem 4.** *Let k be a fixed integer value. Let P be a period for which $Ham(T, T_P) \leq k$, and P has at least $2k + 1$ full occurrences in T. Then the number of possible candidates for P is at most 1.*

▶ **Theorem 5.** *Let $k \geq 2$ be a fixed integer value. Let P be a period for which $Ham(T, T_P) \leq k$, and P has at least $2k$ full occurrences in T. Then the number of possible candidates for P is at most 2.*

6 Tighter Bounds for $2\log_3 n$ Candidates

In this section we relax the constraints of Amir et al. [3] regarding the number of allowed mismatches, and yet provide a much smaller candidate set. The main tool in achieving this is a string combinatorics theorem that improves the best known lower bound on the Hamming distance between two periodic strings.

6.1 Lower bound on the Hamming distance between strings

We start by improving the best known lower bound on the number of errors between two periodic strings. We provide a new nontrivial expression that tightens the lower bound and give tight examples. Our formula results from a careful analysis of the *Turning Points*, *Windows*, and *Adjacency Strings* of the two strings.

▶ **Definition 11.** *A string P is called* Non-trivial if it contains at least two distinct characters.

▶ **Theorem 12.** *Let P, Q be non-periodic, non-trivial strings of lengths p, q, respectively, s.t. $q < p, q \nmid p$, and let $p = aq + b, \quad 0 < b < q$, then*

1. $\forall m, 4 \leq m < \frac{q}{\gcd(p,q)}, \quad Ham(P^m, Q^\infty) \geq m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor$
2. $\forall m, 2 \leq m < \frac{q}{\gcd(p,q)}, \quad Ham(P^m, Q^\infty) \geq m(a+1) - 2$

In the next subsections, we provide the proof of Theorem 12 in-depth.
For pedagogical reasons and for simplicity and comprehensibility, we will prove the theorem for strings of co-prime lengths and binary alphabet, $\Sigma = \{\alpha, \beta\}$, and then show a reduction from the general case to the simplified cases.

Troughout the proof, we will assume w.l.o.g that $p > q$ and that α appears in Q at least as many times as β. We will also let a, b satisfy $p = aq + b, \quad a, b > 0$.

We begin with definitions that will help in understanding the motive and correctness of the proof and methods.

6.1.1 Groundwork

▶ **Definition 13** (Index mapping function)**.** *The* index mapping function *is defined as follows:*

$$\delta_m : [0, p-1] \to [0, q-1], \quad \textit{where} \quad \delta_m(i) = i + (m-1)p \mod q$$

The index mapping function maps the index of the m_{th} occurrence of $P[i]$ in P^m to the corresponding index in Q^∞. Note, that the mapping function is also dependent on the lengths of P, Q. We refrain from indexing the function with these symbols for simplicity's sake.

▶ **Definition 14** (Adjacency string)**.** *Let P, Q be strings of co-prime lengths, and $p > q$. The adjacency string $\tilde{Q}_p$ is a string of length q that satisfies $\forall i, 0 \leq i < q, \tilde{Q}_p[i] = Q[i \cdot p \mod q]$. The adjacency subset-string $\tilde{P}_q$ is a multi-string of length q that satisfies*

$$\forall i, 0 \leq i < q, \tilde{P}_q[i] = \{P[j] | j \equiv_q i \cdot p\}$$

A *subset string* is a string where each string-position might contain several characters. The term was originally defined at [6]. Note that in our case, the same character can recur multiple times at a single position.

The motivation behind this representation is to encapsulate the index-mapping function. It holds that $\forall m, i, j$ where $j \equiv_q i \cdot p$ implies $\tilde{Q}_p[(j+m) \mod q] = Q[\delta_{m+1}(i)]$. In words, it means that a character in $\tilde{P}$ that aligns against $\tilde{Q}_p[i]$, will align against $\tilde{Q}_p[i+1]$ in its next recurrence. $\tilde{P}$ was defined for mere convenience; $Q[i] = \tilde{Q}_p[j] \rightarrow P[i + n \cdot q] \in \tilde{P}_q[j]$, for all $i + n \cdot q < p$ [1].

We will often omit the subscript and simply write $\tilde{Q}, \tilde{P}$. Fig. 2 shows an example of an adjacency string. In this example, one can see that if a character σ in P is aligned with $\tilde{Q}[i]$, the next occurrence of σ will align with $\tilde{Q}[(i+1) \mod q]$.

P=0123456 $\quad \widetilde{P}_4$ ={0,4}3{2,6}{1,5}
Q=abcd $\quad \widetilde{Q}_7$ =adcb

P^4 =0123456012345601234560123456
Q^7 =abcdabcdabcdabcdabcdabcdabcd

Figure 2 Example for adjacency string, Definition 14.

During the proof, we refer to the symbol "β" as *Black node*, and to "α" as *White node*.

▶ **Definition 15.** *The* m-forward window $W_m^f(i)$ *is the multi-set of characters in* Q *that align against* $\tilde{P}[i]$ *in the next* m *repetitions of* P*, which is* $\{\tilde{Q}[i], ..., \tilde{Q}[i+m-1]\}$
The m-backward window $W_m^b(i)$ *is the multi-set of characters in* P *that align against* $\tilde{Q}[i]$ *in the next* m *repetitions of* P*, which is* $\{\tilde{P}[i], ..., \tilde{P}[i-m+1]\}$

In Fig. 3 we see an example for backwards and forwards windows. One can see that $W_3^b(2)$ contains all the characters that touch $\tilde{Q}[2]$ in the next 3 repetitions of P, and that $W^f(0)$ contains all the characters that touch $\tilde{P}[0]$ in the next 3 repetitions. It is also apparent that W_3^b contains the character '0' twice.

P =01234067 $\quad \widetilde{P}_5$ ={0,0}3{1,6}4{2,7}
Q =abcde $\quad \widetilde{Q}_7$ =adbec

Q^∞=abcdeabc|deabcdea|bcdeabcd
$W_3^b(2) = \{\widetilde{P}[2], \widetilde{P}[1], \widetilde{P}[0]\} = \{1, 6, 3, 0, 0\}$

P^3 =01234067|01234067|01234067
Q^∞=abcdeabc|deabcdea|bcdeabcd
$W_3^f(0) = \{\widetilde{Q}[0], \widetilde{Q}[1], \widetilde{Q}[2]\} = \{a, d, b\}$

Figure 3 Example for backward and forward windows, Definition 15.

[1] The converse is not true for, as the mapping function maps to characters in Q.

▶ **Definition 16** (Heavy index). *We say that i is a* heavy index *if it satisfies* $|\tilde{P}[i]| = \left\lceil \frac{p}{q} \right\rceil = a+1$.

We will call the last b characters of P *heavy characters*.

▶ **Corollary 17.** *$\forall m, i$, the number of characters in $W_m^b(i)$ are at least $am + \left\lfloor \frac{mb}{q} \right\rfloor$.*

Proof. Considering $\tilde{P}$ has at least a characters at every index, and the number of heavy indices in any m repetitive recurrences is at least $\left\lfloor \frac{mb}{q} \right\rfloor$, giving the required result. The heavy indices are distributed equally in $\tilde{P}$ because in P, the if the heavy indices are $0, 1, ..., j-1$, then on the next recurrence they will align with $j, j+2, ..., 2(j-1)$, and so on, and by abstract algebra the distribution of heavy indices in $\tilde{P}$ is equal, though not probabilistic. ◀

▶ **Definition 18 (Turning points).** *Let $t_1, t_2, ..., t_\ell$ be the indices such that $\tilde{Q}_p[t_i] \neq \tilde{Q}_p[t_i + 1 \mod q]$. We call these indices* Turning points.

This definition will help in counting mismatches; Turning points create mismatches, as a character that matches a turning point will create a mismatch in the next recurrence of P.

See Fig. 4 for an example of Turning points.

```
P  =0101010101010101
Q  =0100010011011
Q̃7 =0001101111000
```

Figure 4 Example for Turning points, Definition 18.

▶ **Corollary 19.** *ℓ is even.*

Proof. Given that turning points are the only indices that satisfy $q[t_i] \neq q[t_{i+1}]$, and therefore if ℓ is odd, then it can be expressed as $2\ell' + 1$, and

$q[t_1] \neq q[t_2] ... \neq q[t_{2\ell'+1}] \neq q[t_1] \rightarrow$
$q[t_1] = q[t_3] = ... = q[t_{2\ell'+1}] \neq q[t_1] \rightarrow$
$q[t_1] \neq q[t_1]$ ◀

▶ **Corollary 20.** $\ell \geq 2$

Proof. Let us assume that $\ell = 0$. Since there are no turning points, there is no index s.t. $\tilde{Q}_p[i] \neq \tilde{Q}_p[i+1]$, and consequently the string Q is trivial, a contradiction.
This means $\ell \geq 1$, and by using Corollary 19, $\ell \geq 2$. ◀

▶ **Corollary 21.** $Ham(P^2, Q^\infty) \geq \sum_{i=1}^{\ell} |\tilde{P}[i]| \geq a\ell$.

Proof. Let i be a turning point. By the definition of adjacency string, all the characters in $\tilde{P}[i]$ will align in the next two repetitions against $\tilde{Q}[i], \tilde{Q}[(i+1) \mod q]$. By the definition of turning point, $\tilde{Q}[i] \neq \tilde{Q}[(i+1) \mod q]$ and accordingly each character in $\tilde{P}[i]$ will cause exactly one mismatch. Hence, the minimal number of mismatches is $\sum_{i=1}^{\ell} |\tilde{P}[i]|$. Considering that $\forall i, \tilde{P}[i]$ contains at least a characters, the expression is at least $a\ell$. ◀

Given the above facts, we can now proceed to the proof of Theorem 12.

6.1.2 Co-prime proof

In this subsection, we constrain p, q to be co-prime, namely, $\gcd(p, q) = 1$.

Proof. We will divide the proof to 3 cases, and treat each of them separately.

▶ **Case 1** ($\ell \geq 4$.). When $m = 2$, it holds that

$$Ham(P^2, Q^\infty) \geq 4a = 2(a+1) - 2 + 2a > 2(a+1) - 2 + \left\lfloor \frac{2b}{q} \right\rfloor.$$

We can,accordingly, assume that $m \geq 3$.

Using Corollary 17, at least $4\left\lfloor \frac{mb}{q} \right\rfloor$ indices in the m-backward windows of the turning points are heavy; So using Corollary 21, every $m+1$ repetitions we get at least that many mismatches in addition to the already-calculated number. Set $e_m = \left\lfloor \frac{mb}{q} \right\rfloor$. Given that $m \geq 3$, it holds that either $e_m \geq 1$, or $e_{m+2} \leq 1$ [2], and thus $e_{m+2} \leq 4e_m + 1$.

Using the above results, we show that $Ham(P^{2m}, Q^\infty)$ causes more mismatches than allowed for $Ham(P^{2m+1}, Q^\infty)$.

$$\begin{aligned} Ham(P^{2m}, Q^\infty) &\geq 4am + 4e_{2m-1} \\ &\geq 4am + e_{2m+1} - 1 \geq 4am - 1 + e_{2m+1} \\ &\geq (2m+1)(a+1) + 2am - a - 2m - 2 + e_{2m+1} \\ &\geq (2m+1)(a+1) + 2(m-1)(a-1) - 3 + a + e_{2m+1} \\ &\geq (2m+1)(a+1) - 2 + e_{2m+1} \end{aligned}$$

⌟

In the rest of the cases, there are only two turning points. We denote, for simplicity, t_w, t_b as the turning points from white to black and from black to white, respectively.

▶ **Case 2.** $[\ell = 2, \quad (t_b - t_w) \mod q = 1]$ In words, it means that there is only one occurrence of the character β in Q. Let i_b be an index such that $\tilde{Q}[i_b] = \beta$. By the assumptions, this index is unique.

Let $W = W_m^b(i_b)$. Let $c = |W|$, and set c_w to be the number of white characters in W. The number of black characters in the window, denoted by c_b satisfies $c_b = c - c_w$. Using Corollary 17, we can claim $c \geq ma + \left\lfloor \frac{mb}{q} \right\rfloor$.

If $c_b = 0$, then the black character that must exist in P (since it is not trivial), did not align against the only black character of Q, and thus created m mismatches, so we can assume w.l.o.g that at least one black character appears in the window, as it reduces the number of errors by at least 1.

Putting it all together and maximizing c_w to be $c - 1$, leads to

$$\begin{aligned} Ham(P^m, Q^\infty) &\leq c_w \cdot 1 + (c - c_w) \cdot (m-1) \\ &\leq_1 (c-1) \cdot 1 + m(c - (c-1))(m-1) \\ &= m + c - 2 \\ &= m + am + \left\lfloor \frac{mb}{q} \right\rfloor - 2 \\ &= m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor \end{aligned} \tag{1}$$

⌟

[2] If $\frac{3b}{q} < 1$, then $\frac{5b}{q} < 2$

▶ **Case 3** ($\ell = 2, \quad (t_b - t_w) \mod q \neq 1$)**.** First, define $d = (t_b - t_w) \mod q$.

▶ **Corollary 22.** *The number of mismatches caused by each character on index i in the adjacency string $\tilde{P}$ after m repetitions is the minimum between the number of white nodes and black nodes in the m-forward windows of i.*

Proof. Each character creates a mismatch by either aligning with a white index or a black index, so the smallest number of mismatches a character can cause is the minimum between the black and white indices in its next occurrences. ◀

We consider three cases here; the first is where $m \geq d+1$. The second is where $m \leq d$, and also $m \geq 4$. The last is $m \leq d, m \in \{2,3\}$.

▶ **Case 3.1** ($m \geq d+1$)**.** Recall that there are at least as many white characters as black. Mark $W_w = W^b_{m-1}(t_w)$, and $W_b = W^b_2(t_w+2)$. Since $d \geq 2$ and $q \geq m+1$, there are no overlaps between the windows, and all the indices in W_b are black.

In W_w, all of the characters will align against both t_w, t_w+1, and hence create a mismatch. Note that each of the indices $\{t_w - 1, ..., t_w - m + 3\}$ will also align against $t_w - 1$ and $t_w + 2$, hence creating two mismatches. Thus, the total sum of mismatches is at least $a(2+2((t_w-1)-(t_w-m+3)+1)) = 2a(m-2)$, as each index of $\tilde{P}$ has at least a characters.

Considering that $m > d$, $t_w + 1$ will align against $t_b + 1$ and $t_w + 2$ will align against $t_b + 2$, and as a consequence we get at least 2 mismatches for each index, regardless of m. Therefore the total number of mismatches is at least $2a$, which leads to a total sum of $2a(m-1)$ mismatches in both windows. Evaluating this value:

$$\begin{aligned}
&2a(m-1) = 2am - 2a \\
&= am + am - 2a \\
&= m(a+1) + a(m-2) - m \\
&\geq m(a+1) - 2 \text{ (by minimizing } m \text{ to 2)}
\end{aligned}$$

We now show $\left\lfloor \frac{mb}{q} \right\rfloor$ additional mismatches. The number of heavy indices in the m-backwards window of $t_w + 1$ is at least $\left\lfloor \frac{mb}{q} \right\rfloor$, and all of the characters in the window create at least one mismatch, leading to $\left\lfloor \frac{mb}{q} \right\rfloor$ additional mismatches. ⌟

▶ **Case 3.2** ($4 \leq m, \quad m \leq d$)**.** First, it is trivial (yet crucial) to see that $d \geq 4$. Using the previous method, we consider $W^b_{m-1}(t_w)$. Given that $m \leq d$, and using Corollary 22, any character at position $t_w - i$ will cause $\min(i+1, m-i-1)$ mismatches, so we have $1 + 2 + ... + \lfloor \frac{m}{2} \rfloor + ... + 2 + 1 \geq a(1 + 2(m-3) + 1) = 2a(m-2)$ mismatches. The same claim can be made for $W^b_{m-1}(t_b)$, summing up to at least $4a(m-2)$ mismatches after m repetitions.

$$\begin{aligned}
&Ham(P^m, Q^\infty) \geq 4a(m-2) \\
&\geq m(a+1) - m + 3am - 8a \geq m(a+1) + m(3a-1) - 8a \\
&\geq m(a+1) + 4(3a-1) - 8a \geq m(a+1) + 12a - 8a - 4 \\
&\geq m(a+1) + 4(a-1) \geq m(a+1)
\end{aligned}$$

We now need to find $\left\lfloor \frac{mb}{q} \right\rfloor - 2$ additional mismatches. The inequality $\left\lfloor \frac{(m-1)b}{q} \right\rfloor \geq \left\lfloor \frac{mb}{q} \right\rfloor - 1$ holds, and accordingly we have an additional $2\left\lfloor \frac{(m-1)b}{q} \right\rfloor \geq 2(\left\lfloor \frac{mb}{q} \right\rfloor - 1) \geq \left\lfloor \frac{mb}{q} \right\rfloor - 2$ mismatches. ⌟

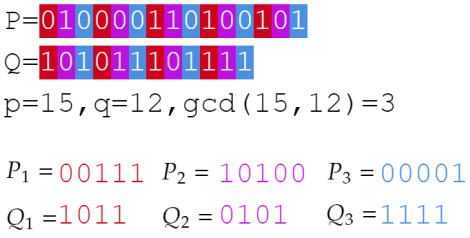

Figure 5 Example for strings decomposition (Definition 25).

▶ **Case 3.3** ($m \leq d, \quad 2 \leq m \leq 3$). In this case, we only have to show that $Ham(P^m, Q^\infty) \geq m(a+1) - 2$.
If $m = 2$, then we have $2a = m(a+1) - 2$ mismatches directly from Corollary 21.
If $m = 3$, then $t_w, t_w - 1, t_b, t_b - 1$ will all create at least one mismatch, which results in $4a$ mismatches, and

$$4a = 3a + a = 3(a+1) - 2 + a - 1 \geq 3(a+1) - 2 = m(a+1) - 2$$ ⌟

◀

6.1.3 Non-divisible proof

The case of $gcd(p, q) = 1$ was proven in Subsection 6.1.2. We now prove that the theorem is true for the more general version, where $q \nmid p$. Let $gcd(p, q) = g > 1$, and let $q' = \frac{q}{g}, p' = \frac{p}{g}$, and $p' = a'q' + b'$.

▶ **Corollary 23.** $\left\lfloor \frac{mb}{q} \right\rfloor = \left\lfloor \frac{mb'}{q'} \right\rfloor$

Proof.

$$\left\lfloor \frac{mb}{q} \right\rfloor = \left\lfloor \frac{m(p \mod q)}{q} \right\rfloor = \left\lfloor \frac{m(g(a'q' + b') \mod gq')}{gq'} \right\rfloor = \left\lfloor \frac{m(gb' \mod gq')}{gq'} \right\rfloor = \left\lfloor \frac{mgb'}{gq'} \right\rfloor = \left\lfloor \frac{mb'}{q'} \right\rfloor$$

◀

▶ **Corollary 24.** $a' = a$

We will now decompose P and Q to smaller strings of co-prime lengths.

▶ **Definition 25** (Decomposed strings). *Given strings P, Q, $\gcd(p, q) = g$, the decomposed string of P at index i is $P_i = P[i]P[i+g]...P[i+(p'-1)g]$. The decomposed strings of Q are defined respectively.*

▶ **Corollary 26.** *$\exists i$ s.t. P_i is non-trivial.*

Proof. If such an index does not exist, for each index i, P_i is trivial, hence $\forall i, P_i = c^{p'}$, and accordingly $P = (P[0]...P[g-1])^{p'}$, and P is periodic, a contradiction to our assumptions. The same claim can be made about Q. ◀

▶ **Definition 27.** *Let P, Q be strings, and let i, j be the minimal indices such that P_i and P_j are not trivial. We will say P, Q are* aliens *if $i \neq j$, and we will say P, Q are* similar *if $i = j$. If $\gcd(p, q) = 1$, then P, Q are aliens regardless.*

The latter definition is rather synthetic, since we only consider the minimal indices.

▶ **Case 1** (P, Q are aliens). Let i, j be the minimal indices s.t. P_i, Q_j are non-trivial.
In this case, $Ham(P^m, Q^\infty) \geq Ham(P_i^m, c_i^\infty) + Ham(c_j^{p'm}, Q_j^\infty)$, where $P_i = c_i^{p'}, Q_j = c_j^{q'}$.
Now,

$$Ham(P_i^m, c_i^\infty) = m \cdot Ham(P_i, c_i^{p'}) \geq m \tag{1}$$

$$\begin{aligned} Ham(c_j^{p'm}, Q_j^\infty) &\geq m \cdot Ham(c_j^{p'}, Q_j^{\left\lfloor \frac{p'm}{q'} \right\rfloor}) \\ &\geq \left\lfloor \frac{p'm}{q'} \right\rfloor = \left\lfloor \frac{m(a'q'+b')}{q'} \right\rfloor \\ &= ma' + \left\lfloor \frac{mb'}{q'} \right\rfloor = ma + \left\lfloor \frac{mb}{q} \right\rfloor \end{aligned} \tag{2}$$

So,

$$Ham(P^m, Q^\infty) \geq Ham(P_i^m, c_i^\infty) + Ham(c_j^{p'm}, Q_j^\infty) \geq m + am + \left\lfloor \frac{mb}{q} \right\rfloor = m(a+1) + \left\lfloor \frac{mb}{q} \right\rfloor \quad ⌟$$

▶ **Corollary 28.** *If P, Q are alien strings of non co-prime lengths, then $Ham(P^m, Q^\infty) \geq m(a+1) + \left\lfloor \frac{mb}{q} \right\rfloor$, for all $m > 0$.*

▶ **Case 2** (P, Q are similar). Let i, j be the minimal indices s.t. P_i, Q_j are not trivial. It holds that

$$Ham(P^m, Q^\infty) \geq Ham(P_i^m, Q_i^\infty) \geq m(a'+1) - 2 + \left\lfloor \frac{mb'}{q'} \right\rfloor = m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor$$

Which is exactly the required expression, with the LCM occurring more often. ⌟

6.2 Candidates for periods

▶ **Definition 29.** *Let T be a text, and P a string. We say that P is a* periodic seed *(or* seed*) of T, if $Ham(T, P^\infty) = k \to t \geq 2kp$ and P is non-periodic.*

▶ **Lemma 30.** *Let P, Q be non-trivial strings of co-prime lengths (i.e., $\gcd(p, q) = 1$), then $Ham(P^q, Q^p) \geq d(p-2) + q$, where d is the number of occurrences of the less frequent character in either P or Q.*

Proof. Let P, Q be non-trivial strings of co-prime lengths p, q. Let σ_S be the number of occurrences of a character σ in a string S.
In the LCM, i.e., when the strings P, Q appear enough times to perfectly align with each other, each characters of P aligns with each character of Q exactly once (using basic abstract algebra properties). It means that $Ham(P^q, Q^p) = \alpha_P\beta_Q + \beta_P\alpha_Q$.
Seeing that P, Q are both binary strings implies $\beta_P = p - \alpha_P$, and $\beta_Q = q - \alpha_Q$.
Assume $\alpha_Q \geq \beta_Q$, and that $\beta_Q \geq d \geq 1$.

$$\begin{aligned} Ham(P^q, Q^p) &= \alpha_P\beta_Q + \beta_P\alpha_Q \\ &= \alpha_P(q - \alpha_Q) + (p - \alpha_P)\alpha_Q \\ &\geq_1 (p-1)(q - \alpha_Q) + 1\alpha_Q \\ &= (p-1)d + (q-d) \\ &= d(p-2) + q \end{aligned}$$

(1) is true since $a_Q \geq b_Q$, so be minimizing b_P we minimize the expression. ◀

▶ **Lemma 31.** *For alien strings Q, P s.t. $q \leq \frac{p}{4}$, $\gcd(p,q) = 1$ and $p = aq + b, 2 \leq m < q$,*

$$Ham(P^{nq+m}, Q^{\infty}) \geq n(p+q-2) + m\left\lceil \frac{p}{q} \right\rceil - 2 + \left\lfloor \frac{mb}{q} \right\rfloor$$

Proof. Using Theorem 12, we only need to show this is true when $d \geq 2, m \leq d$, where d is $(t_b - t_w) \mod q$, as defined. Because the case where $d = 1 \vee m \geq 4 \vee m > d$ is proved regardless of m, d and when $m \leq 1$ the expression can simply evaluate to 0. If $q \leq \frac{p}{4}$, then either $m \geq 4$ or $n \geq 1$. One case is already proven, so we can presume $n \geq 1$. Naturally, $m \leq 3$, as otherwise the lemma is trivially proven.
By Lemma 30, the distance at the LCM is $d(p-2)+q$. Consider the distance at the LCM in the original expression: $p+q-2$. The difference between these values is $(d-1)(p-2) \geq p-2$. This means the number of mismatches is increased by at least $p-2$ every LCM.

By Theorem 12, $Ham(P^m,Q^{\infty}) \geq m(a+1)$–2, and we attempt to show that $Ham(P^m,Q^{\infty}) \geq m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor$, leaving us to show that the additional $p-2$ mismatches are greater than $\left\lfloor \frac{mb}{q} \right\rfloor$. Evaluate:

$$p - 2 = aq + b - 2 \geq b > \left\lfloor \frac{mb}{q} \right\rfloor$$ ◀

▶ **Theorem 32.** *Let T be a text, and let P be a seed of T such that $p \leq \frac{t}{4}$, then for all strings Q s.t. $q < p, q \nmid p$, then Q can not be a seed of T.*

Proof. Let P be a seed of T of length $p \leq \frac{t}{4}$, and assume Q is a seed of T, and $q < p, q \nmid p$. In this proof, we use the same notations as in Theorem 31.
Set $occ_p = \left\lfloor \frac{t}{p} \right\rfloor = nq + m, 0 \leq m < q$, and set $p = aq + b, 1 \leq b < q$. $nq + m \geq 4$.
Obviously, $t < (nq + m + 1)p$. Therefore the maximum number of mismatches between T and P^{∞}, marked as k_p is at most $\left\lfloor \frac{nq+m}{2} \right\rfloor$. The number of occurrences of Q in T is $occ_q = \left\lfloor \frac{t}{q} \right\rfloor = \left\lfloor \frac{(nq+m+1)p-1}{q} \right\rfloor$, and thus the number of mismatches between T and Q^{∞}, marked as k_q accordingly is at most $\left\lfloor \frac{occ_q}{2} \right\rfloor$.

By the triangle inequality, $Ham(P^{nq+m}, Q^{\infty}) \leq Ham(T, P^{\infty}) + Ham(T, Q^{\infty}) \leq k_p + k_q$. We will show that $Ham(P^{nq+m}, Q^{\infty}) > k_p + k_q$, which will lead to a contradiction.

We split the proof into two cases - in the first case P, Q are aliens, and in the second, P, Q are similar (See Definition 27).

6.2.1 Proof for alien strings

Begin by evaluating the minimal number of errors:

$$Ham(P^{nq+m}, Q^{\infty}) \geq n(p+q-2) + m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor$$

Since we required $p \leq \frac{t}{4}$, then $n \geq 1$ or $m \geq 4$. We consider both cases.

▶ **Case 1** ($n = 0, m \geq 4$)**.** Begin by re-evaluating the previous expressions by setting $n = 0$, which will lead to significantly shorter expressions.

$$Ham(P^{nq+m}, Q^{\infty}) = n(p+q-2) + m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor = m(a+1) - 2 + \left\lfloor \frac{mb}{q} \right\rfloor \quad (1)$$

$$occ_p = m \quad (2)$$

$$occ_q = \frac{\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor}{2} \quad (3)$$

Again split into two cases:

1. $b \geq \frac{q}{2}$
2. $b < \frac{q}{2}$

▶ **Case 1.1** ($b \geq \frac{q}{2}$)**.** In this case, $\left\lfloor \frac{mb}{q} \right\rfloor \geq \left\lfloor \frac{mq}{2q} \right\rfloor = \lfloor \frac{m}{2} \rfloor$. Seeing that the latter is exactly the value of k_p, let's us subtract $\lfloor \frac{m}{2} \rfloor$ from both sides of the equation, which leads to the following inequality:

$$m(a+1) - 2 > k_q = \left\lfloor \frac{\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor}{2} \right\rfloor$$

Given that we required $b \geq \frac{q}{2}$, we will evaluate $\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor$ in worst-case settings in terms of mismatches, i.e. $b = q - 1$.

$$\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor \leq \left\lfloor \frac{(m+1)((a+1)q-1)-1}{q} \right\rfloor = \left\lfloor \frac{q(m+1)(a+1)-m-2}{q} \right\rfloor \leq (a+1)(m+1)-1$$

What left to prove is $m(a+1) - 2 > \left\lfloor \frac{(a+1)(m+1)-1}{2} \right\rfloor$.

$$\begin{aligned} m(a+1) - 2 > \left\lfloor \frac{(a+1)(m+1)-1}{2} \right\rfloor &\rightarrow 2m(a+1) - 4 > (a+1)(m+1) - 1 \\ &\rightarrow 2am + 2m - 4 > am + a + m + 1 - 1 \\ &\rightarrow am + m - a - 4 > 0 \\ &\rightarrow a(m-1) + m - 4 > 0 \\ &\rightarrow 2m - 5 > 0 \rightarrow m \geq 3 \end{aligned}$$

⌟

▶ **Case 1.2** ($b < \frac{q}{2}$)**.** In this case, we suppose that $\left\lfloor \frac{mb}{q} \right\rfloor = 0$, and again evaluate $\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor$ in worst-case settings ($b = \frac{q}{2}$).

$$(m+1)p - 1 \leq (m+1)((a+0.5)q - 1) - 1 \leq (m+1)(a+0.5)q - 1$$

Using the above result, the inequality $\left\lfloor \frac{(m+1)p-1}{q} \right\rfloor \leq (m+1)(a+0.5) - 1$ holds, and thereby the resulting inequality is

$$m(a+1) - 2 > \left\lfloor \frac{(m+1)(a+0.5)-1}{2} \right\rfloor + \left\lfloor \frac{m}{2} \right\rfloor$$

Further evaluation leads to

$$\begin{aligned} m(a+1) - 2 > \left\lfloor \frac{(m+1)(a+0.5)-1}{2} \right\rfloor + \left\lfloor \frac{m}{2} \right\rfloor \\ \rightarrow 4m(a+1) - 8 > (m+1)(2a+1) - 2 + 2m \\ \rightarrow 4am + 4m > 2am + m + 2a + 2m + 1 + 8 - 2 \\ \rightarrow 2am + m - 2a \geq 8 \\ \rightarrow 2a(m-1) + m \geq 8 \\ \rightarrow 2 \cdot 3 + 4 \geq 8 \qquad \text{(Setting } a = 1, m = 4\text{)} \end{aligned}$$

⌟

▶ **Case 2** ($n \geq 1, m \in \{0,1\}$)**.** This case is rather complicated. Begin by examining the case $m = 0$ which is the easier one.

▶ **Case 2.1** ($m = 0$)**.** Recall that $nq + m \geq 4 \rightarrow nq \geq 3 \rightarrow q \geq 3 \vee n \geq 2$. We require $nq \geq 3$ and not $nq \geq 4$, so we will also be able to use the expression when $m = 1$.
In this case, the number of occurrences of Q in T is $occ_q \leq np + a$, so we need to show that $n(p + q - 2) > \lfloor \frac{np+a}{2} \rfloor + \lfloor \frac{nq}{2} \rfloor$. We will multiply it by 2 to obtain

$$\begin{aligned} &2n(p+q-2) > np + a + nq \\ &\rightarrow n(p+q-4) \geq a+1 \\ &\rightarrow n((a+1)q-3) \geq a+1 \\ &\rightarrow_1 n(2q-3) \geq 2 \rightarrow q \geq 3 \vee n \geq 2 \end{aligned}$$

(1) - Because we are incrementing a increments the left hand-side by qn, and the right hand-side by only 1 ($qn > 1$).

▶ **Corollary 33.** $Ham(Q^{a+m+1}, P^2) \geq 2m, \quad m < a$

Proof. First, define $P_{\rightarrow i}$ as the string cyclic shift of P i positions to the right.
Consider the hamming distance $Ham(Q^{m+1}, Q^{m+1}_{\rightarrow(q-b)})$. The first string is aligned with the first repetition of P, the other is aligned with the second repetition of P.
Since there are m full repetitions of Q in both strings, there are at least $2m$ mismatches. Using the triangle inequality:

$$2m \leq Ham(Q^{m+1}, Q^{m+1}_{\rightarrow(q-b)}) \leq Ham(Q^{m+1}, P) + Ham(P, Q^{m+1}_{\rightarrow(q-b)}) \leq Ham(Q^{a+m+1}, P^2)$$

◀

▶ **Corollary 34.** *If Q is a seed of a text with tail size $t = t - (nq+1)p$ s.t. $t \geq 2q - b$, then Q is also the seed of a text with tail size $2q - b - 1$.*

The proof is trivial: any additional occurrence of Q in T will cause at-least 2 more verified mismatches. We allow one mismatch for 2 occurrences so it is always possible to reduce the number of mismatches by 2 and the number of occurrences by 1.

▶ **Lemma 35.** *If $Ham(Q^{a+1}, P^2) = 0$, then $b \geq 2$*

Proof. By definition, $q(a+1) > p$. If $Ham(Q^{a+1}, P^2) = 0$, then $P = Q^a Q[..b]$, and that $P[..q-b] = Q[b..] \rightarrow Q[..q-b] = Q[b..]$.
Assume $b = 1$. This means $Q[..q-1] = Q[1..]$, or

$$Q[0] = Q[1], Q[1] = Q[2], ...Q[-2] = Q[-1]$$

Which implies that Q is a trivial periodic string, contradiction. ◀

▶ **Case 2.2** ($m = b = 1$)**.** In this case, Q can occur at most a times in the tail without creating an extra mismatch. Thus, we will suppose it occurs exactly a times in the tail.
$n(p + q - 2) > \lfloor \frac{np+a}{2} \rfloor + \lfloor \frac{nq+1}{2} \rfloor$

This is almost exactly the same as the case where $m = 0$, with the difference of k_p, which changed from $\lfloor \frac{nq}{2} \rfloor$ to $\lfloor \frac{nq+1}{2} \rfloor$. If either n or q are even, it is exactly the same expression as before, and accordingly we presume $q \neq 2 \rightarrow q \geq 3 \rightarrow p \geq 4$.

Evaluating the expression in a similar manner to case 2.1 will lead to the inequality $n(2q-3) \geq 3$, and by setting $q = 3, n = 1$, we get $1 \cdot (2 \cdot 3 - 3) = 3 \geq 3$.

▶ **Case 2.3** ($m = 1, b > 1$)**.** This case is trivial. Requiring $b \geq 2$ results in $p \geq q + 2$, which in turn causes an additional mismatch on the LCM expression $p + q - 2$, but creates only one additional occurrence for Q, and the problem can be reduced to previous case. ⌟

▶ **Case 3** ($n \geq 1, m \geq 2$)**.** This is the simplest case of the three. We have $p > q \geq 3$, as $m < q < p$, and $m \geq 2$.

Proof. The length of T is at most $(nq + m + 1)p - 1$. The string Q occurs in nqp characters exactly np times. And $(m + 1)p - 1 = (m + 1)(aq + b) - 1 = maq + mb + aq + b - 1$, which contains $a(m + 1) + \left\lfloor \frac{b(m+1)-1}{q} \right\rfloor$ instances of Q.
The inequality $\left\lfloor \frac{b(m+1)-1}{q} \right\rfloor \leq \left\lfloor \frac{bm}{q} \right\rfloor + 1$ holds, and as a result we claim that the number of occurrences of Q in T is $\left\lfloor \frac{b(m+1)-1}{q} \right\rfloor + 1$.

The expression $\left\lfloor \frac{bm}{q} \right\rfloor$ also appears in $Ham(P^m, Q^\infty)$, so we can subtract it from both sides, which will simplify the expression to $n(p+q-2)+m(a+1)-2 > \left\lfloor \frac{np+a(m+1)+1}{2} \right\rfloor + \left\lfloor \frac{nq+m}{2} \right\rfloor$. Multiply it by 2, and get the following:

$$
\begin{aligned}

6.2.2 Proof for similar strings

We now present the proof of the theorem when $\gcd(p, q) > 1$, and $i = j$.

We use the definition of P_i, Q_i, p', q' as usual, and also define T_i as $T[i]T[i + g][T + 2g]$....
Because t is not necessarily divisible by g some T_i might be shorter than the others.
Let i be the index such that both P_i, Q_i are non-trivial. The inequality $\forall j, T_j \geq 4p'$ holds as $t \geq 4pg$.
As k_p is the maximal number of full occurrences of P in T, the number of occurrences of P_i in T_i is at least k_p. Proof for k_q is the same.

We now have Q_i, P_i, T_i, where $P_i \leq \frac{|T_i|}{4}$ and $gcd(P_i, Q_i) = 1$, and therefore P_i and Q_i cannot both be seeds of T_i, or in other words, $Ham(p_i^{nq+m}, q_i^\infty) > k_q + k_p$. In contrast, we know that $Ham(p^{nm+q}, q^\infty) \geq Ham(p_i^{nq+m}, q_i^\infty) > k_q + k_p$, and P, Q cannot both be seeds. ◀

▶ **Definition 36** (Binary Renaming Function)**.** *A binary renaming function is a function from general alphabet to binary alphabet, $\delta : \Sigma \to \{a, b\}$. The generalized renaming function $\delta^* : \Sigma^* \to \{a, b\}^*$ is defined in the standard way:*

1. $\delta^*(\epsilon) = \epsilon$
2. $\delta^*(P) = \delta(P[0])\delta^*(P[1..])$

▶ **Lemma 37.** *Let P, Q be non-trivial strings over Σ. W.l.o.g $p \geq q$. $\forall \delta^*, m$, $Ham(P^m, Q^\infty) \geq Ham(\delta^*(P)^m, \delta^*(Q)^\infty)$*

Proof. Let e_i be an indicator on mismatch on index i between P^m and Q^∞, and e'_i be defined respectively for $\delta^*(P^m)$, $\delta^*(Q^\infty)$. Since $e_i = 0$ indicates a match, then $e'_i = 0$ as well, which implies $e'_i \leq e_i$. The contrary is not true. The direct implication is our lemma. ◀

▶ **Corollary 38.** *Theorem 12 is true for general alphabet.*

▶ **Corollary 39.** *Theorem 43 is true for general alphabet.*

Proof. Assume there are $P, Q \in \Sigma^*$ that contradict 43. This means that $Ham(T, P^\infty) + Ham(T, Q^\infty) \leq k_p + k_q$, but using Lemma 37,

$$\exists \delta^*, Ham(T, P^\infty) + Ham(T, Q^\infty) \geq Ham(\delta^*(T), \delta^*(P)^\infty) + Ham(\delta^*(T), \delta^*(Q)^\infty) >_1 k_q + k_p$$

And (1) is true directly from Theorem 43. ◀

6.3 The Number of Candidates

▶ **Lemma 40.** *Let T be text, and let P, Q be periodic seeds of T, such that $p > q, q \nmid p, p \leq \frac{t}{3}$. Then, $\exists g$ s.t. $p = 3g, q = 2g$.*

The proof appears in the full version of the paper,

▶ **Corollary 41.** *Given a text T, there is at most one periodic seed P of length $\frac{t}{4} < p \leq \frac{t}{3}$.*

▶ **Corollary 42.** *If P, Q are seeds of a text T and $p = q$ then $Ham(P, Q) \leq 1$*

Proof. Assume $Ham(P, Q) \geq 2$, and that $\ell = \left\lfloor \frac{t}{p} \right\rfloor$. Using the definition of a seed, $Ham(P^\ell, Q^\ell) \leq Ham(T, P^\infty) + Ham(T, Q^\infty) \leq \ell$, at the same time $Ham(P^\ell, Q^\ell) = 2\ell$, contradiction. ◀

▶ **Theorem 43.** *There are at most $2\log_3 n$ candidates of length $\ell \leq \frac{t}{3}$*

Proof. We begin by proving a useful lemma regarding the number of candidates of divisible length.

▶ **Lemma 44.** *If there are two candidates of length g, there is at most one candidate of length $2g$.*

The proof appears in the full version of the paper.

▶ **Corollary 45.** *If all of the periods of length $\ell \leq n$ divide n, then there are at most $2\log_3 n$ periods of length $\leq n$.*

The proof appears in the full version of the paper. ◀

▶ **Corollary 46.** *There are at most 2 periods that are canonical.*

Proof. As we have proved, if there are 3 different periods, then the length of the shortest period, divides the length of the longer periods, and by simple induction the minimal period's length divides the lengths of the rest of the periods, and is canonical to them.
If there are no 3 different periods then we can call all of the periods canonical. ◀

▶ **Corollary 47** (Generalized gcd-theorem)**.** *Let T be a text, and let P, Q be seeds of T that occur at least 3 full times in T, then T has a seed of length* $\gcd(p, q)$.

7 The Error Upper Bounds Hierarchy

The previously known [3] upper error bound was $\lfloor \frac{n}{(2+\epsilon)p} \rfloor$ and led to $O(\log_{1+\epsilon} n)$ period candidates. To achieve a hierarchy of upper bounds, we follow similar techniques to those of [3]. The innovation is the new *Hamming distance* error bounds that we define. All the upper bounds in this section are of (n, p, ϵ)-type. We do not get rid of ϵ at the moment. However, we feel that by methods similar to those of Section 6, the ϵ can be eliminated from the error bounds.

▶ **Lemma 48.** *Let T be the input text. For any period P, assume that $Ham(T, T_P) \leq \frac{n}{(2+\epsilon)\cdot(2^{(i)})((\log^{(i)} p)^{1+\epsilon})}$. Then there are $O(\log^{(i+1)} n)$ candidates for P, for any $i \geq 0$. Note that, for $i = 0$, the upper bound is $Ham(T, T_P) \leq \frac{n}{(2+\epsilon)\cdot p^{1+\epsilon}}$*

▶ **Lemma 49.** *Let T be the input text. For any period P, assume that $Ham(T, T_P) \leq \frac{n}{(2+\epsilon)^{p+1}}$. Then there are $O(\log^* n)$ candidates for P*

▶ **Lemma 50.** *Lemmas 48 and 49 have tight examples.*

8 Conclusions and Open Problems

We showed that $\lfloor \frac{n}{2p} \rfloor$ is a tight upper error bound and it results in $2\log_3 n$ candidates if P fully occurs at least 3 times in T. Otherwise, if P fully occurs twice (maybe with a tail) then we provide an example with $\Omega(n)$ candidates.

It is easy to show that our result can be generalized to *c-pseudo local metrics* [3]. Such a metric Δ behaves like *Hamming distance* in the manner that for every pair of equal length strings T and S, $\Delta(T, S) \leq c \cdot Ham(T, S)$. An example of such a metric is *swap distance*, where the distance counted by the number of swaps of two consecutive letters (each letter can only participate in a single swap). It is easy to verify that $\lfloor \frac{n}{2cp} \rfloor$ is a tight upper bound, and the result of *canonic period seed* can also be applied to such metrics. By a similar fashion, replacing $(2+\epsilon)$ by $(2c+\epsilon)$ in the hierarchy upper bounds allows the hierarchy generalization to *c-pseudo local metrics*.

In this paper, corruptions are of the replacement type. That is, the error count is the number of changed letters. It is of interest to analyze different types of error distance metrics besides the *Hamming Distance*. One example of such a metric, that has been considered in the recovery algorithms literature, is the *Edit Distance* [2, 14].

It is of interest to apply the ideas of section 6 to the $\log^{(i)}$ hierarchy and eliminate the dependence on ϵ.

Finally, can the hierarchy be extended to the other side? Come up with tight error bounds that lead to a set of n^ϵ period candidates, where $\epsilon < 1$.

Abstract

The ubiquity of massive graph data sets in numerous applications requires fast algorithms for extracting knowledge from these data. We are motivated here by three electrical measures for the analysis of large small-world graphs $G = (V, E)$ – i. e., graphs with diameter in $\mathcal{O}(\log |V|)$, which are abundant in complex network analysis. From a computational point of view, the three measures have in common that their crucial component is the diagonal of the graph Laplacian's pseudoinverse, $\mathbf{L}^\dagger$. Computing $\mathrm{diag}(\mathbf{L}^\dagger)$ exactly by pseudoinversion, however, is as expensive as dense matrix multiplication – and the standard tools in practice even require cubic time. Moreover, the pseudoinverse requires quadratic space – hardly feasible for large graphs. Resorting to approximation by, e. g., using the Johnson-Lindenstrauss transform, requires the solution of $\mathcal{O}(\log |V|/\epsilon^2)$ Laplacian linear systems to guarantee a relative error, which is still very expensive for large inputs.

In this paper, we present a novel approximation algorithm that requires the solution of only one Laplacian linear system. The remaining parts are purely combinatorial – mainly sampling uniform spanning trees, which we relate to $\mathrm{diag}(\mathbf{L}^\dagger)$ via effective resistances. For small-world networks, our algorithm obtains a $\pm\epsilon$-approximation with high probability, in a time that is nearly-linear in $|E|$ and quadratic in $1/\epsilon$. Another positive aspect of our algorithm is its parallel nature due to independent sampling. We thus provide two parallel implementations of our algorithm: one using OpenMP, one MPI + OpenMP. In our experiments against the state of the art, our algorithm (i) yields more accurate approximation results for $\mathrm{diag}(\mathbf{L}^\dagger)$, (ii) is much faster and more memory-efficient, and (iii) obtains good parallel speedups, in particular in the distributed setting.

1 Introduction

Massive graph data sets are abundant these days in numerous applications. Extracting knowledge from these data thus requires fast algorithms. One common matrix to represent a graph $G = (V, E)$ with n vertices and m edges in algebraic algorithms is its Laplacian $\mathbf{L} = \mathbf{D} - \mathbf{A}$. Here, $\mathbf{D}$ is the diagonal degree matrix with $\mathbf{D}[u, u]$ being the (possibly weighted) degree of vertex $u \in V$. The matrix $\mathbf{A}$ is the (possibly weighted) adjacency matrix of G. It is well-known that $\mathbf{L}$ does not have full rank and is thus not invertible. Its Moore-Penrose pseudoinverse [25] $\mathbf{L}^\dagger$, in turn, has numerous applications in physics and engineering [60] as well as applied mathematics [25] and graph (resp. matrix) algorithms [38].

We are motivated by one particular class of applications: *electrical centrality measures* for the analysis of small-world networks – i. e., graphs whose diameter is bounded by $\mathcal{O}(\log n)$. Many important real-world networks (social, epidemiological, information, biological, etc.) have the small-world feature [48]. Centrality measures, in turn, belong to the most widely used network analysis concepts and indicate the importance of a vertex (or edge) in the network [13]. Numerous measures exist, some based on shortest paths, others consider paths of arbitrary lengths. Electrical centrality measures fall into the latter category. They exploit the perspective of graphs as electrical networks (see e. g., [41]). One well-known of such measures is *electrical closeness centrality*, a. k. a. *current-flow closeness* or *information centrality* [16], $c^{el}(\cdot)$. It is the reciprocal of the average effective resistance $\mathbf{r}(u, \cdot)$ between u and all other vertices:

$$c^{el}(u) := \frac{n-1}{\sum_{v \in V \setminus \{u\}} \mathbf{r}(u, v)}. \tag{1}$$

In an electrical network corresponding to G, $\mathbf{r}(u, v)$ is the potential (voltage) difference across terminals u and v when a unit current is applied between them [23]. It can be computed by solving $\mathbf{L}\mathbf{x} = \mathbf{e}_u - \mathbf{e}_v$ for $\mathbf{x}$, where $\mathbf{e}_z$ is the canonical unit vector for vertex z. Then, $\mathbf{r}(u, v) = \mathbf{x}[u] - \mathbf{x}[v]$, also see Section 2.1.

Effective resistance also plays a major role in two other electrical measures we consider here, *normalized random-walk betweenness* [47] and *Kirchhoff index centrality* [39]. Also note that effective resistance is a graph metric with numerous other applications, well beyond its usage in electrical centralities (cf. Refs. [2, 23]). A straightforward way to compute electrical closeness (or the other two measures) would be to compute $\mathbf{L}^\dagger$. Without exploiting structure, this takes $\mathcal{O}(n^\omega)$ time, where $\omega < 2.38$ is the exponent for fast matrix multiplication. The standard tools in practice even require cubic time, cf. [52]. $\mathbf{L}^\dagger$ is also in general a dense matrix (also for sparse $\mathbf{L}$). Thus, full (pseudo)inversion is clearly limited to small inputs.

Conceptually similar to inversion would be to solve $\Theta(n)$ Laplacian linear systems. In situations with lower accuracy demands, fewer linear systems suffice: using the Johnson-Lindenstrauss transform (JLT) in connection with a fast Laplacian solver such as Ref. [19], one gets a relative approximation guarantee by solving $\mathcal{O}(\log n/\epsilon^2)$ systems [57] in $\tilde{\mathcal{O}}(m \log^{1/2} n \log(1/\epsilon))$ time each, where $\tilde{\mathcal{O}}(\cdot)$ hides a $\mathcal{O}((\log\log n)^{3+\delta})$ factor for $\delta > 0$.

As pointed out previously [15], the (only) relevant part of $\mathbf{L}^\dagger$ for computing electrical closeness is its diagonal (we will see that this is true for other measures as well). Numerical methods for sampling-based approximation of the diagonal of implicitly given matrices do exist [9]. Yet, for our purpose, they solve $\mathcal{O}(\log n/\epsilon^2)$ Laplacian linear systems as well to obtain an ϵ-approximation with high probability, see Section 2.2 for more details.

While this number of Laplacian linear systems can be solved in parallel, their solution can still be time-consuming in practice, in part due to high constants hidden in the $\mathcal{O}$-notation.

Contribution and Outline. We propose a new algorithm for approximating $\text{diag}(\mathbf{L}^\dagger)$ of a Laplacian matrix $\mathbf{L}$ that corresponds to weighted undirected graphs (Section 3). Our main technique is the approximation of effective resistances between a pivot vertex $u \in V$ and all other vertices of G. It is based on sampling uniform (= random) spanning trees (USTs). The resulting algorithm is highly parallel and (almost) purely combinatorial – it relies on the connection between Laplacian linear systems, effective resistances, and USTs.

For small-world graphs, our algorithm obtains an absolute $\pm\epsilon$-approximation guarantee with high probability in (sequential) time $\mathcal{O}(m \log^4 n \cdot \epsilon^{-2})$. In particular, compared to using the fastest theoretical Laplacian solvers in connection with JLT, our approach is off by only a polylogarithmic factor. Probably more importantly, after some algorithm engineering (Section 4), our algorithm performs much better than the state of the art, already in our sequential experiments (Section 5): (i) it is much faster and more memory-efficient, (ii) it yields a maximum absolute error that is one order of magnitude lower, and (iii) results in a more accurate complete centrality ranking of elements of $\text{diag}(\mathbf{L}^\dagger)$. Due to good parallel speedups, we can even compute a reasonably accurate diagonal of $\mathbf{L}^\dagger$ on a small-scale cluster with 16 compute nodes in less than 8 minutes for a graph with $\approx$ 13.6M vertices and $\approx$ 334.6M edges. **Material omitted due to space constraints can be found in the appendix of the full version of this paper [4].**

2 Preliminaries

2.1 Problem Description and Notation

We type vectors and matrices in bold font. As input we consider simple, finite, connected undirected graphs $G = (V, E)$ with n vertices, m edges, and non-negative edge weights $\mathbf{w} \in \mathbb{R}^m_{\geq 0}$. For the complexity analysis, we usually assume that the diameter of G is $\mathcal{O}(\log n)$, but our algorithm would also work correctly without this assumption.

Graphs as electrical networks. We interpret G as an electrical network in which every edge $e \in E$ represents a resistor with resistance $1/\mathbf{w}[e]$. In this context, it is customary to fix an arbitrary orientation $E^\pm$ of the edges in E and to define a unit s-t-current flow (also called electrical flow) in this network as a function of the edges (written as vector) $\mathbf{f} \in \mathbb{R}^{|E^\pm|}_{\geq 0}$. Whenever possible, we use $\mathbf{f}[u, v]$ as shorthand notation for $\mathbf{f}[\{u, v\}]$ or $\mathbf{f}[(u, v)]$. Note that $\mathbf{f}[e] = -\mathbf{f}[-e]$ for $e \notin E^\pm$. This sign change in the s-t current when the flow direction is changed, is required to adhere to Kirchhoff's current law on flow conservation:

$$\sum_{w \in \delta^+(v)} \mathbf{f}[v, w] - \sum_{u \in \delta^-(v)} \mathbf{f}[u, v] = \begin{cases} 1 & \text{if } v = s \\ -1 & \text{if } v = t \\ 0 & \text{otherwise,} \end{cases} \tag{2}$$

where $\delta^+(v)$ [$\delta^-(v)$] is the set of edges having v as head [tail] in the orientation we choose in $E^\pm$. Such a flow also adheres to Kirchhoff's voltage law (sum in cycle is zero when considering flow directions) and Ohm's law (potential difference = resistance $\cdot$ current), cf. [14, 43]. The effective resistance between two vertices u and v, $\mathbf{r}(u, v)$, is defined as the potential difference between u and v when a unit current is injected into G at u and extracted at v, comp. [14, Ch. IX]. To compute $\mathbf{r}(u, v)$, let $\mathbf{e}_z$ be the canonical unit vector for vertex z, i. e., $\mathbf{e}_z(z) = 1$ and $\mathbf{e}_v = 0$ for all vertices $v \neq z$. Then,

$$\mathbf{r}(u, v) = (\mathbf{e}_u - \mathbf{e}_v)^T \mathbf{L}^\dagger (\mathbf{e}_u - \mathbf{e}_v) = \mathbf{L}^\dagger[u, u] - 2\mathbf{L}^\dagger[u, v] + \mathbf{L}^\dagger[v, v] \tag{3}$$

or, equivalently, $\mathbf{r}(u,v) = \mathbf{x}[u] - \mathbf{x}[v]$, where $\mathbf{x}$ is the solution vector of the Laplacian linear system $\mathbf{L}\mathbf{x} = \mathbf{e}_u - \mathbf{e}_v$. The Laplacian pseudoinverse, $\mathbf{L}^\dagger$, can be expressed as $\mathbf{L}^\dagger = (\mathbf{L} + \frac{1}{n}\mathbf{J})^{-1} - \frac{1}{n}\mathbf{J}$ [60], where $\mathbf{J}$ is the $n \times n$-matrix with all entries being 1.

Also note that the effective resistance between the endpoints of an edge $e \in E$ equals the probability that e is an edge in a uniform spanning tree (UST), i. e., a spanning tree selected uniformly at random among all spanning trees of G, cf. [14, Ch. II].

Electrical Closeness. The combinatorial counterpart of electrical closeness is based on shortest-path distances $\mathrm{dist}(u,v)$ for vertices u and v in G: $c^c(u) := (n-1)\,/\,f^c(u)$, where the denominator is the *combinatorial farness* of u:

$$f^c(u) := \sum_{v \in V \setminus \{u\}} \mathrm{dist}(u,v). \tag{4}$$

Electrical farness $f^{el}(\cdot)$ is defined analogously to combinatorial farness – shortest-path distances in Eq. (4) are replaced by effective resistances $\mathbf{r}(u,v)$. Closeness centrality (both combinatorial and electrical) are not defined for disconnected graphs due to infinite distances. We can get around this, however: a combinatorial generalization for closeness called Lin's index (cf. [10]) can be adapted to the electrical case, too. Thus, our assumption of G being connected is no limitation.

Normalized Random-Walk Betweenness. Classical betweenness, based on shortest paths, is one of the most popular centrality measures. The betweenness of vertices using random-walk routing instead of shortest paths is given by the normalized random-walk betweenness (NRWB) [47]. This measure counts each random walk passing through a vertex only once. By mapping the random walk problem to current flowing in a network, Ref. [47] obtains a closed-form expression of NRWB and provides an analysis of its scaling bahavior as a function of n. Then, the NRWB $c_b(\cdot)$ of a vertex v is:

$$c_b(v) = \frac{1}{n} + \frac{1}{n-1} \sum_{t \neq v} \frac{\mathbf{M^{-1}}[t,t] - \mathbf{M^{-1}}[t,v]}{\mathbf{M^{-1}}[t,t] + \mathbf{M^{-1}}[v,v] - 2\mathbf{M^{-1}}[t,v]}, \tag{5}$$

where $\mathbf{M} := \mathbf{L} + \mathbf{P}$, with $\mathbf{P}$ the projection operator onto the zero eigenvector of the Laplacian $\mathbf{L}$ such that $\mathbf{P}[i,j] = 1/n$. We show in Section 3.4 how to simplify this expression.

We also consider the Kirchhoff index and related centrality measures. Their description can be found in Appendix B.1.

2.2 Related Work

Solving Laplacian Systems. A straightforward approach to compute electrical closeness and related centralities is to compute $\mathbf{L}^\dagger$, by solving a number of Laplacian systems. Brandes and Fleischer [16] computed electrical closeness from the solution of n linear systems using conjugate gradient (CG) in $\mathcal{O}(mn\sqrt{\kappa})$ time, where κ is the condition number of the appropriately preconditioned Laplacian matrix.[1] Later, Spielman and Srivastava proposed an approximation algorithm for computing effective resistance distances [57]. The main ingredients of the algorithm are a dimension reduction with Johnson-Lindenstrauss [29] and the use of a fast Laplacian solver for $\mathcal{O}(\log n/\epsilon^2)$ Laplacian systems. The algorithm approximates

[1] Brandes and Fleischer provide a rough estimate of κ as $\Theta(n)$, leading to a total time of $\mathcal{O}(mn^{1.5})$.

effective resistance values for all edges within a factor of $(1 \pm \epsilon)$ in $\mathcal{O}(I(n,m) \log n/\epsilon^2)$ time, where $I(n,m)$ is the running time of the Laplacian solver, assuming that the solution of the Laplacian systems is exact. With an approximate Laplacian solution, the algorithm yields a $(1+\epsilon)^2$-approximation. Significant progress in the development of fast Laplacian solvers with theoretical guarantees [19, 30, 32, 33, 37] has resulted in the currently best one running in $\mathcal{O}(m \log^{1/2} n \log(1/\epsilon))$ time (up to polylogarithmic factors) [19]. Parallel algorithms for solving linear systems on the more general SDD matrices also exist in the literature [12, 51]. To date, the fastest algorithms for electrical closeness and spanning edge centrality extend the idea of Spielman and Srivastava [11, 27, 45]. (Similar ideas are used for centrality measures based on the Kirchhoff index, see Appendix B.2). Since theoretical Laplacian solvers rely on heavy graph-theoretic machinery such as low-stretch spanning trees, one rather uses multigrid solvers [11, 34, 40] in practice instead.

Diagonal Estimation. Recall from the introduction that the diagonal (or in case of the Kirchhoff index even only its sum, the trace – see Appendix B.1) of $\mathbf{L}^\dagger$ is enough to compute electrical closeness and related measures, also see Eq. (6) below. Algorithms that approximate the diagonal (or the trace) of matrices that are only implicitly available often use iterative methods [56], sparse direct methods [3, 28], Monte Carlo [22] or deterministic probing techniques [9, 59]. A popular approach is the standard Monte-Carlo method for the trace of $\mathbf{A}$, due to Hutchinson [22]. The idea is to estimate the trace of $\mathbf{A}$ by observing the action of $\mathbf{A}$ (in terms of matrix-vector products) on a sufficiently large sample of random vectors r_k. In our case, this would require to solve a large number of Laplacian linear systems with vectors r_k as right-hand sides. Avron and Toledo [6] proved that the method takes $\mathcal{O}(\log n/\epsilon^2)$ samples to achieve a maximum error ϵ with probability at least $1-\delta$. The approach from Hutchinson [22] has been extended by Bekas et al. [9] for estimating the diagonal of $\mathbf{A}$. Finally, Barthelmé et al. [8] have recently proposed a combinatorial algorithm to approximate the trace (not the diagonal) of the inverse of a matrix closely related to the Laplacian. Their algorithm can be seen as a special case of our algorithm in the situation where a universal vertex exists.

Normalized Random Walk Betweenness. Along with the introduction of the measure, Ref. [47] provided numerical evaluations of Eq. (5) on various graph models. However, no algorithm to compute the measure without (pseudo)inverting $\mathbf{L}$ has been proposed yet.

3 Approximation Algorithm

3.1 Overview

In order to compute the electrical closeness for all vertices in $V(G)$, the main challenge is obviously to compute their electrical farness, $f^{el}(\cdot)$. Recall from the introduction that the diagonal of $\mathbf{L}^\dagger$ is sufficient to compute $f^{el}(\cdot)$ for all vertices simultaneously (comp. Ref. [15, Eq. (15)] with a slightly different definition of electrical closeness). This follows from Eq. (3) and the fact that each row/column in $\mathbf{L}^\dagger$ sums to 0:

$$f^{el}(u) := \sum_{v \in V \setminus \{u\}} \mathbf{r}(u,v) = n \cdot \mathbf{L}^\dagger[u,u] + \mathrm{tr}(\mathbf{L}^\dagger) - 2 \sum_{v \in V} \mathbf{L}^\dagger[u,v] = n \cdot \mathbf{L}^\dagger[u,u] + \mathrm{tr}(\mathbf{L}^\dagger), \tag{6}$$

since the trace $\mathrm{tr}(\cdot)$ is the sum over the diagonal entries.

We are interested in an approximation of $\mathrm{diag}(\mathbf{L}^\dagger)$, since we do not necessarily need exact values for our particular applications. To this end, we propose an approximation algorithm for which we give a rough overview first. Our algorithm works best for small-world networks – thus, we focus on this important input class. Let G be unweighted for now; we discuss the extension to weighted graphs in Section 3.4.

1. Select[2] a pivot vertex $u \in V$ and solve the linear system $\mathbf{Lx} = \mathbf{e}_u - \frac{1}{n} \cdot \mathbf{1}$, where $\mathbf{1} = (1, \ldots, 1)^T$. The solution $\mathbf{x}$ is $\mathbf{L}^\dagger[:, u]$, the column of $\mathbf{L}^\dagger$ corresponding to u [60].
2. Throughout the rest of this paper we denote $V' := V \setminus \{u\}$. As a direct consequence from Eq. (3), the diagonal entries $\mathbf{L}^\dagger[v, v]$ for all $v \in V'$ can be computed as:

$$\mathbf{L}^\dagger[v, v] = \mathbf{r}(u, v) - \mathbf{L}^\dagger[u, u] + 2\mathbf{L}^\dagger[v, u]. \tag{7}$$

3. It remains to approximate these $n - 1$ effective resistance values $\mathbf{r}(\cdot, \cdot)$. In order to do so, we employ Kirchhoff's theorem, which connects electrical flows with spanning trees [14, Ch. II]. To this end, let N be the total number of spanning trees of G; moreover, let $N_{s,t}(a, b)$ be the number of spanning trees in which the unique path from s to t traverses the edge $\{a, b\}$ *in the direction from a to b.*

   ▶ **Theorem 1** (Kirchhoff, comp. [14]). *Let $\mathbf{f}[a, b] := (N_{s,t}(a, b) - N_{s,t}(b, a))/N$. Distribute current flows on the edges of G by sending a current of size $\mathbf{f}[a, b]$ from a to b for every edge $\{a, b\}$. Then there is a total current of size 1 from s to t satisfying Kirchhoff's laws.*

   As a result of Theorem 1, the effective resistance between s and t is the potential difference between s and t induced by the current-flow given by $\mathbf{f}$. Vice versa, since the current flow is induced by potential differences (Ohm's law), one simply has to add the currents on a path from s to t to compute $\mathbf{r}(s, t)$ (see Eq. (8) in Section 3.2). Actually, as a proxy for the current flows, we use the (approximate) $N(\cdot)$-values mentioned in Theorem 1.
4. It is impractical to compute exact values for N (e. g., by Kirchhoff's matrix-tree theorem [24], which would require the determinant or all eigenvalues of $\mathbf{L}^\dagger$) or $N(\cdot)$ for large graphs. Instead, we obtain approximations of the desired values via sampling: we sample a set of uniform spanning trees and determine the $N(\cdot)$-values by aggregation over all sampled trees. This approach provides a probabilistic absolute approximation guarantee.

The pseudocode of the algorithm, in adjusted order, is shown and discussed as Algorithm 1 in Appendix A.1. Components and properties of Algorithm 1 are explained in the remainder of Section 3; reading Section 3.2 while/before studying the pseudocode is recommended.

Note that Steps 2-4 of the algorithm are entirely combinatorial. Step 1 may or may not be combinatorial, depending on the Laplacian solver used. Corresponding implementation choices are discussed in Section 4.

3.2 Effective Resistance Approximation by UST Sampling

Extending and generalizing work by Hayashi et al. [27] on spanning edge centrality, our main idea is to compute a sufficiently large sample of USTs and to aggregate the $N(\cdot)$-values of the edges in these USTs. Given G and an electrical flow with source u and sink v, recall that the effective resistance between them is the potential difference $\mathbf{x}[u] - \mathbf{x}[v]$, where $\mathbf{x}$ is the solution vector in $\mathbf{Lx} = \mathbf{e}_u - \mathbf{e}_v$. Since $\mathbf{x}$ is a potential and the electrical flow $\mathbf{f}$ results from its difference, $\mathbf{r}(u, v)$ can be computed given *any* path $\langle u = v_0, v_1, \ldots, v_{k-1}, v_k = v \rangle$ as:

[2] As we will see later on, one can improve the empirical running time when u is not arbitrary, but chosen so as to have low eccentricity, i. e., the length of its longest shortest path. The correctness and the asymptotic time complexity of the algorithm are not affected by the selection, though.

$$\begin{aligned}\mathbf{r}(u,v) &= \sum_{i=0}^{k-1} \mathbf{f}[v_i, v_{i+1}] \\ &= 1/N \sum_{i=0}^{k-1} \left(N_{u,v}(v_i, v_{i+1}) - N_{u,v}(v_{i+1}, v_i)\right). \end{aligned} \tag{8}$$

Recall that the sign of the current flow changes if we traverse an edge against the flow direction. This is reflected by the second summand in the sum of Eq. (8). Since we can choose any path from u to v, for efficiency reasons we use *one shortest* path $P(v)$ per vertex $v \in V'$. We compute these paths with one breadth-first search (BFS) with root u, resulting in a tree B_u whose edges are considered as implicitly directed from the root to the leaves. For each vertex $v \in V'$, we maintain an estimate $R[v]$ of $\mathbf{r}(u,v)$, which is initially set to 0 for all v. After all USTs have been processed, we divide all entries of R by τ, the number of sampled trees, i. e., τ takes the role of N in Eq. (8).

Sampling USTs. In total, we sample τ USTs, where τ depends on the desired approximation guarantee and is determined later. The choice of the UST algorithm depends on the input: for general graphs, the algorithm by Schild [53] with time complexity $\mathcal{O}(m^{1+o(1)})$ is the fastest. Among others, it uses a sophisticated shortcutting technique using fast Laplacian solvers to speed up the classical Aldous-Broder [1,17] algorithm. For unweighted small-world graphs, however, Wilson's simple algorithm using loop-erased random walks is in $\mathcal{O}(m \log n)$, as outlined in Appendix A.2. Thus, for our class of inputs, Wilson's algorithm is preferred.

Data structures. When computing the contribution of a UST T to $N(\cdot)$, we need to update for each edge $e = (a,b) \in E(T)$ its contribution to $N_{u,v}(a,b)$ and $N_{u,v}(b,a)$, respectively – for exactly every vertex v for which (a,b) [or (b,a)] lies on $P(v)$. Hence, the algorithm that aggregates the contribution of UST T to R will need to traverse $P(v)$ for each vertex $v \in V$. To this end, we represent the BFS tree B_u as an array of parent pointers for each vertex $v \in V$. On the other hand, the tree T can conveniently be represented by storing a child and a sibling for each vertex $v \in V$. Compared to other representations (such as adjacency lists), this data structure can be constructed and traversed with low constant overhead.

Tree Aggregation. After constructing a UST T, we process it to update the intermediate effective resistance values $R[\cdot]$. Note that we can discard T afterwards and do not have to store the full sample, which has a positive effect on the memory footprint of our algorithm. The aggregation algorithm is shown as Algorithm 2 in Appendix A.1. Recall that we need to determine for each vertex v and each edge $(a,b) \in P(v)$, whether (a,b) or (b,a) occurs on the unique u-v path in T. To simplify this test, we root T at u; hence, it is enough to check if (a,b) [or (b,a)] appears above v in T. For general graphs, the test still incurs quadratic overhead in running time (in particular, the number of vertex-edge pairs that need to be considered is $f^c(u) = \sum_{v \in V'} |P(v)| = \mathcal{O}(n^2)$). We remark that, perhaps surprisingly, a bottom-up traversal of T does not improve on this, either; it is similarly difficult to determine all $R[v]$ that a given $(a,b) \in E(T)$ contributes to (those v form an arbitrary subset of descendants of b in T). However, we can exploit the fact that on small-world networks, the depth of B_u can be controlled, i. e., $f^c(u)$ is sub-quadratic. To accelerate the test, we first compute a DFS data structure for T, i. e., we determine discovery and finish timestamps for all vertices in V, respectively. For an arbitrary $v \in V$ and $(a,b) \in V \times V$, this data structure allows us

to answer in constant time (i) whether either (a, b) or (b, a) is in T and (ii) if $(a, b) \in E(T)$, whether v appears below (a, b) in T. Finally, we loop over all $v \in V$ and all $e = (a, b) \in P(v)$ and aggregate the contribution of T to $N_{u,v}(a, b)$. To do so, we add [subtract] 1 to [from] $R[v]$ if e has the same [opposite] direction in B_u. If e is not in B_u, $R[v]$ does not change.

3.3 Algorithm Analysis

The choice of the pivot u has an effect on the time complexity of our algorithm. The intuitive reason is that the BFS tree B_u should be shallow in order to have short paths to the root u, which is achieved by a u with small eccentricity. The proofs of this subsection can be found in Appendices A.3 and A.4. Regarding aggregation, we obtain:

▶ **Lemma 2.** *Tree aggregation (Algorithm 2 in Appendix A.1) has time complexity $\mathcal{O}(f^c(u))$, which can be bounded by $\mathcal{O}(n \cdot \mathrm{ecc}(u)) = \mathcal{O}(n \cdot \mathrm{diam}(G))$.*

In high-diameter networks, the farness of u can become quadratic (consider a path graph) and thus problematic for large inputs. In small-world graphs, however, we obtain $\mathcal{O}(n \log n)$ per aggregation. We continue the analysis with the main algorithmic result.

▶ **Theorem 3.** *Let G be an undirected and unweighted graph with n vertices, m edges, diameter $\mathrm{diam}(G)$ and Laplacian $\mathbf{L} = \mathbf{L}(G)$. Then, our diagonal approximation algorithm (Algorithm 1 in Appendix A.1) computes an approximation of $\mathrm{diag}(\mathbf{L}^\dagger)$ with absolute error $\pm\epsilon$ with probability $1 - \delta$ in time $\mathcal{O}(m \cdot \mathrm{ecc}^3(u) \cdot \epsilon^{-2} \cdot \log(m/\delta))$. For small-world graphs and with $\delta := 1/n$ to get high probability, this yields a time complexity of $\mathcal{O}(m \log^4 n \cdot \epsilon^{-2})$.*

Thus, for small-world networks, we have an approximation algorithm whose running time is nearly-linear in m (i. e., linear up to a polylogarithmic factor), quadratic in $1/\epsilon$, and logarithmic in $1/\delta$. By choosing a "good" pivot u, it is often possible to improve the running time of Algorithm 1 by a constant factor (i. e., without affecting the $\mathcal{O}$-notation). In particular, there are vertices u with $\mathrm{ecc}(u)$ as low as $\frac{1}{2}\mathrm{diam}(G)$. A discussion on the algorithm's parallelization in the work-depth model can be found in Appendix A.1.2.

▶ Remark 4. If G has constant diameter, Algorithm 1 has time complexity $\mathcal{O}(m \log n \cdot \epsilon^{-2})$ to obtain an absolute ϵ-approximation guarantee. This is faster than the best JLT-based approximation (which provides a relative guarantee instead).

3.4 Generalizations

In this section we show how our algorithm can be adapted to work for weighted graphs and for normalized random-walk betweenness as well. The extensions to Kirchhoff-related indices are presented in Appendix B.3.

Extension to Weighted graphs. For an extension to weighted graphs, we need a weighted version of Kirchhoff's theorem. To this end, the weight of a spanning tree T is defined as the product of the weights (= conductances) of its edges. Then, let N^* be the sum of the weights of all spanning trees of G; also, let $N^*_{s,t}(a, b)$ be the sum of the weights of all spanning trees in which the unique path from s to t traverses the edge $\{a, b\}$ in the direction from a to b.

▶ **Theorem 5** (comp. [14], p. 46)**.** *There is a distribution of currents satisfying Ohm's law and Kirchhoff's laws in which a current of size 1 enters at s and leaves at t. The value of the current on edge $\{a, b\}$ is given by $(N^*_{s,t}(a, b) - N^*_{s,t}(b, a))/N^*$.*

Consequently, our sampling approach needs to estimate N^* as well as the $N^*(\cdot)$-values. It turns out that no major changes are necessary. Wilson's algorithm also yields a UST for weighted graphs (if its random walk takes edge weights for transition probabilities into account) [62]. Yet, the running time bound for Wilson needs to mention the graph volume, $\mathrm{vol}(G)$, explicitly now: $\mathcal{O}(\mathrm{ecc}(u) \cdot \mathrm{vol}(G))$. The weight of each sampled spanning tree can be accumulated during each run of Wilson. It has to be integrated into Algorithm 2 by adding [subtracting] the tree weight in Line 9 [Line 12] instead of 1. For the division at the end, one has to replace τ by the total weight of the sampled trees. Finally, the tree B_u remains a BFS tree. The eccentricity and farness of u then still refer in the analysis to their unweighted versions, respectively, as far as B_u is concerned.

To conclude, the only important change regarding bounds happens in Theorem 3. In the time complexity, m is replaced by $\mathrm{vol}(G)$.

Normalized Random-Walk Betweenness. Ref. [47] proposes normalized random-walk betweenness as a measure for the influence of a vertex in the network, but the paper does not provide an algorithm (beyond implicit (pseudo)inversion). We propose to compute normalized random-walk betweenness with Algorithm 1 and derive (proof in Appendix A.5):

▶ **Lemma 6.** *Normalized random-walk betweenness $c_b(v)$ (Eq. (5)) can be rewritten as:*

$$c_b(v) = \frac{1}{n} + \frac{\mathrm{tr}(\mathbf{L}^\dagger)}{(n-1)f^{el}(v)}. \tag{9}$$

Hence, since Algorithm 1 approximates the diagonal of $\mathbf{L}^\dagger$ and both trace and electrical farness depend only on the diagonal, the following proposition holds:

▶ **Proposition 7.** *Let $G = (V, E)$ be a small-world graph as in Theorem 3. Then, Algorithm 1 approximates with high probability $c_b(v)$ for all $v \in V$ with absolute error $\pm\epsilon$ in $\mathcal{O}(m \log^4 n \cdot \epsilon^{-2})$ time.*

4 Engineering Aspects and Parallelization

Important engineering decisions concern the choice of the UST sampling algorithm, decomposition of the input graph into biconnected components, selection of the pivot u, and the linear solver used for the initial linear system. For these aspects, we refer the reader to Appendix C.1.

Our implementation uses OpenMP for shared memory and MPI+OpenMP for distributed memory. We assume that the entire graph fits into main memory (even in the distributed case). Hence, we can parallelize Algorithm 1 to a large extent by sampling and aggregating multiple USTs in parallel. In particular, we turn the main sampling loop into a **parallel for** loop. We also solve the initial Laplacian system using a shared-memory parallel Conjugate Gradient (CG) solver (see Appendix C.1). Note that we do not employ parallelism in the other steps of the algorithm. In particular, the BFS to compute B_u is executed sequentially. We also do not parallelize over the loops in Algorithm 2 to avoid nested parallelism with multiple invocations of Algorithm 2. We note that, in contrast to the theoretical work-depth model, solving the initial Laplacian system and performing the BFS are not the main bottlenecks in practice. Instead, sampling and aggregating USTs together consume the majority of CPU time (see Figure 5 in Appendix E.1 of the full version [4]). More details regarding shared and distributed memory, in particular load balancing for the distributed case, are discussed in Appendix C.2.

5 Experiments

5.1 Settings

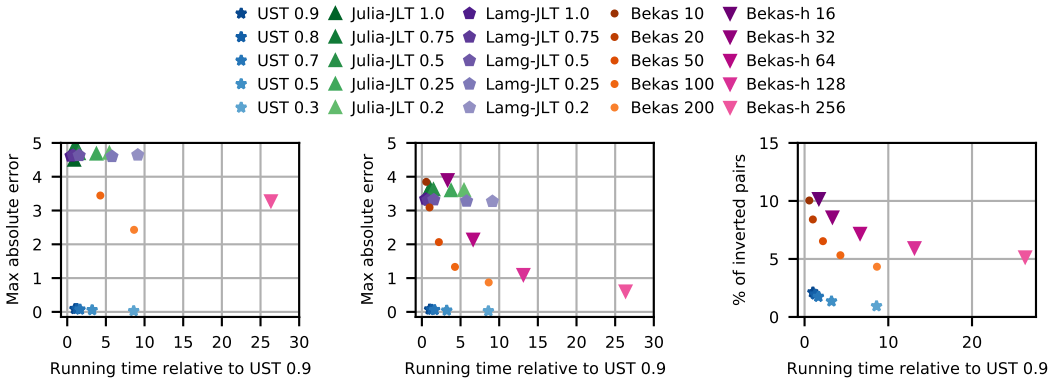
We conduct experiments to demonstrate the performance of our approach compared to the state-of-the-art competitors. Unless stated otherwise, we implemented all algorithms in C++, using the NetworKit [58] graph APIs. Our own algorithm is labelled UST in the sections below. All experiments were conducted on a cluster with 16 Linux machines, each equipped with an Intel Xeon X7460 CPU (2 sockets, 12 cores each), and 192 GB of RAM. To ensure reproducibility, all experiments were managed by the SimexPal [5] software. We executed our experiments on the graphs in Tables 2, 3, 4, and 5 (see Appendix D.2 of the full version of this paper [4] for further details on input graphs). All of them are unweighted and undirected. They have been downloaded from the public KONECT [35] repository and reduced to their largest connected component.

Quality Measures and Baseline. To evaluate the diagonal approximation quality, we measure the maximum absolute error ($\max_i \mathbf{L}^\dagger_{ii} - \widetilde{\mathbf{L}^\dagger_{ii}}$) on each instance, and we take both the maximum and the arithmetic mean over all the instances. Since for some applications [48, 49] a correct ranking of the entries is more relevant than their scores, in our experimental analysis we compare complete rankings of the elements of $\widetilde{\mathbf{L}^\dagger}$. Note that the lowest entries of $\mathbf{L}^\dagger$ (corresponding to the vertices with highest electrical closeness) are distributed on a significantly narrow interval. Hence, to achieve an accurate electrical closeness ranking of the top k vertices, one would need to solve the problem with very high accuracy. For this reason, all approximation algorithms we consider do not yield a precise top-k ranking, so that we (mostly) consider the complete ranking.

Using `pinv` in NumPy or Matlab as a baseline would be too expensive in terms of time (cubic) and space (quadratic) on large graphs (see Appendix D.2 of the full version [4]). Thus, as quality baseline we employ the LAMG solver [40] (see also next paragraph) as implemented within NetworKit [11] in our experiments (with 10^{-9} tolerance). The results in Table 6 in Appendix E.4 indicate that the diagonal obtained this way is sufficiently accurate.

Competitors in Practice. In practice, the fastest way to compute electrical closeness so far is to combine a dimension reduction via the Johnson-Lindenstrauss lemma [29] (JLT) with a numerical solver. In this context, Algebraic MultiGrid (AMG) solvers exhibit better empirical running time than fast Laplacian solvers with a worst-case guarantee [45]. For our experiments we use JLT combined with LAMG [40] (named Lamg-jlt); the latter is an AMG-type solver for complex networks. We also compare against a Julia implementation of JLT together with the fast Laplacian solver proposed by Kyng et al. [36], for which a Julia implementation is already available in the package Laplacians.jl.[3] This solver generates a sparse approximate Cholesky decomposition for Laplacian matrices with provable approximation guarantees in $\mathcal{O}(m \log^3 n \log(1/\epsilon))$ time; it is based purely on random sampling (and does not make use of graph-theoretic concepts such as low-stretch spanning trees or sparsifiers). We refer to the above implementation as Julia-jlt throughout the experiments. For both Lamg-jlt and Julia-jlt, we try different input error bounds (they correspond to the respective numbers next to the method names in Figure 1). This is a relative error, since these algorithms use numerical approaches with a relative error guarantee, instead of an absolute one (see Appendix E of the full version [4] for results in terms of different quality measures).

[3] `https://github.com/danspielman/Laplacians.jl`



(a) Maximum of the maximum absolute errors.

(b) Arithmetic mean of the maximum absolute error.

(c) Geometric mean of the percentage of inverted pairs in the full ranking of $\mathrm{diag}(\mathbf{L}^{\dagger})$.

Figure 1 Quality results over the instances of Table 2 (full version [4]). All runs are sequential.

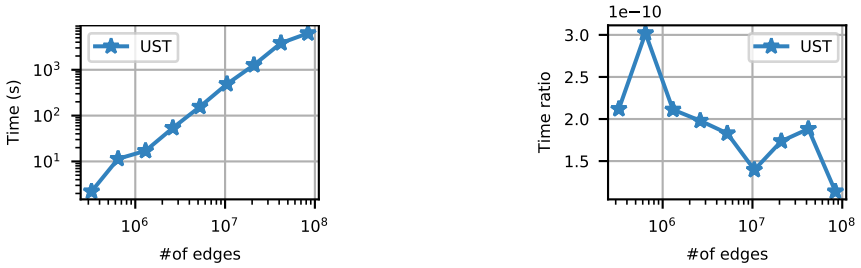
Finally, we compare against the diagonal estimators due to Bekas et al. [9], one based on random vectors and one based on Hadamard rows. To solve the resulting Laplacian systems, we use LAMG in both cases. In our experiments, the algorithms are referred to as Bekas and Bekas-h, respectively. Excluded competitors are discussed in Appendix D.1 (full version [4]).

5.2 Running Time and Quality

Figure 1a shows that, in terms of maximum absolute error, every configuration of UST achieves results with higher quality than the competitors. Even when setting $\epsilon = 0.9$, UST yields a maximum absolute error of 0.09, and it is 8.3× faster than Bekas with 200 random vectors, which instead achieves a maximum absolute error of 2.43. Furthermore, the running time of UST does not increase substantially for lower values of ϵ, and its quality does not deteriorate quickly for higher values of ϵ. Regarding the average of the maximum absolute error, Figure 1b shows that, among the competitors, Bekas-h with 256 Hadamard rows achieves the best precision. However, UST yields an average error of 0.07 while also being 25.4× faster than Bekas-h, which yields an average error of 0.62. Note also that the number next to each method in Figure 1 corresponds to different values of absolute (for UST) or relative (for Lamg-jlt, Julia-jlt) error bounds, and different numbers of samples (for Bekas, Bekas-h). For Bekas-h the number of samples needs to be a multiple of four due to the dimension of Hadamard matrices.

In Figure 1c we report the percentage of inverted pairs in the full ranking of $\widetilde{\mathbf{L}^{\dagger}}$. Note that JLT-based approaches are not depicted in this plot, because they yield $> 15\%$ of rank inversions. Among the competitors, Bekas achieves the best time-accuracy trade-off. However, when using 200 random vectors, it yields 4.3% inversions while also being 8.3× slower than UST with $\epsilon = 0.9$, which yields 2.1% inversions only.

For validation purposes, we also measure how well the considered algorithms compute the *set* (not the ranking) of top-k vertices, i. e., those with highest electrical closeness centrality, with $k \in \{10, 100\}$. For each algorithm we only consider the parameter settings that yields the highest accuracy. JLT-based approaches appear to be very accurate for this purpose, as their top-k sets achieve a Jaccard index of 1.0. As expected (due to its absolute error guarantee), UST performs slightly worse: on average, it obtains 0.95 for $k = 10$ and 0.98 for $k = 100$, which still shows a high overlap with the ground truth.



(a) Running time of UST w. r. t. #of edges.

(b) Ratio of running time of UST w. r. t. its theoretical running time (see Theorem 3).

Figure 2 Scalability of UST on random hyperbolic graphs ($\epsilon = 0.3$, 1×24 cores).

The memory consumption is shown and discussed in more detail in Appendix E.3 (full version [4]). In summary, as our algorithm can discard each UST after its aggregation, it is rather space-efficient and requires less memory than the competitors.

5.3 Parallel Scalability

The log-log plot in Figure 4a (Appendix E.1, full version [4]) shows that on shared-memory UST achieves a moderate parallel scalability w. r. t. the number of cores; on 24 cores in particular it is 11.9× faster than on a single core. Even though the number of USTs to be sampled can be evenly divided among the available cores, we do not see a nearly-linear scalability: on multiple cores the memory performance of our NUMA system becomes a bottleneck. Therefore, the time to sample a UST increases and using more cores yields diminishing returns. Limited memory bandwidth is a known issue affecting algorithms based on graph traversals in general [7, 42]. Finally, we compare the parallel performance of UST indirectly with the parallel performance of our competitors. More precisely, assuming a perfect parallel scalability for our competitors Bekas and Bekas-h on 24 cores, UST would yield results 4.1 and 12.6 times faster, respectively, even with this strong assumption for the competition's benefit.

UST scales better in a distributed setting. In this case, the scalability is affected mainly by its non-parallel parts and by synchronization latencies. The log-log plot in Figure 4b shows that on up to 4 compute nodes the scalability is almost linear, while on 16 compute nodes UST achieves a 15.1× speedup w. r. t. a single compute node.

Figure 5 (Appendix E.1, full version [4]) shows the fraction of time that UST spends on different tasks depending on the number of cores. We aggregated over "Sequential Init." the time spent on memory allocation, pivot selection, solving the linear system, the computation of the biconnected components, and on computing the tree B_u. In all configurations, UST spends the majority of the time in sampling, computing the DFS data structures and aggregating USTs. The total time spent on aggregation corresponds to "UST aggregation" and "DFS" in Figure 5, indicating that computing the DFS data structures is the most expensive part of the aggregation. Together, sampling time and total aggregation time account for 99.4% and 95.3% of the total running time on 1 core and 24 cores, respectively. On average, sampling takes 66.8% of this time, while total aggregation takes 31.2%. Since sampling a UST is on average 2.2× more expensive than computing the DFS timestamps and aggregation, faster sampling techniques would significantly improve the performance of our algorithm.

Table 1 Running time of UST on large real-world networks (16×24 cores).

5.4 Scalability to Large Networks

Results on Synthetic Networks. The log-log plots in Figure 2a show the average running time of UST (1×24 cores) on networks generated with the random hyperbolic generator from von Looz et al. [61].[4] For each network size, we take the arithmetic mean of the running times measured for five different randomly generated networks. Our algorithm requires 184 minutes for the largest inputs (with up to 83.9 million edges). Interestingly, Figure 2b shows that the algorithm scales slightly better than our theoretical bound predicts. In Figure 6 (Appendix E.2, full version [4]) we present results on an additional graph class, namely R-MAT graphs. On these instances, the algorithm exhibits a similar running time behavior; however, the comparison to the theoretical bound is less conclusive.

Results on Large Real-World Networks. In Table 1 we report the performance of UST in a distributed setting (16×24 cores) on large *real-world* networks. With $\epsilon = 0.3$ and $\epsilon = 0.9$, UST always runs in less than 8 minutes and 1.5 minutes, respectively.

6 Conclusions

We have proposed a new parallel algorithm for approximating $\mathrm{diag}(\mathbf{L}^\dagger)$ of Laplacian matrices $\mathbf{L}$ corresponding to small-world networks. Compared to the main competitors, our algorithm is about one order of magnitude faster, it yields results with higher quality in terms of absolute error and ranking of $\mathrm{diag}(\mathbf{L}^\dagger)$, and it requires less memory. The gap between the theoretical bounds and the much better empirical error yielded by our algorithm suggests that tighter bounds on the number of samples are a promising direction for future work. So is an improvement of the running time for high-diameter graphs, both in theory and practice.

A Algorithmic Details and Omitted Proofs

A.1 Our Approximation Algorithm in More Detail

Overall algorithm. Algorithm 1 already receives the pivot vertex u as input. Lines 4 to 10 approximate the effective resistances. To do so, Lines 4 to 7 perform initializations: first, the estimate of the effective resistance is set to 0 for all vertices. Then the accuracy η of the linear solver is computed so as to ensure an absolute ϵ-approximation for the whole algorithm. The BFS tree B_u with root u realizes shortest paths between u and all other vertices. The sample size τ depends on the parameters ϵ and δ, among others.

The first `for`-loop does the actual sampling and aggregation (the latter with Algorithm 2). Afterwards, Lines 11 to 14 fill the u-th column and the diagonal of $\mathbf{L}^\dagger$ – to the desired accuracy. Apart from that, the algorithm's high-level ideas have been provided already in Section 3.1.

Algorithm 1 Approximation algorithm for $\mathrm{diag}(\mathbf{L}^\dagger)$.

1: **function** ApproxDiagLpinv(G, u, ϵ, δ)
2: **Input:** Undirected small-world graph $G = (V, E)$, pivot $u \in V$, error bound $\epsilon > 0$, probability $0 < \delta < 1$
3: **Output:** $\mathrm{diag}(\widetilde{\mathbf{L}^\dagger})$, i. e., an (ϵ, δ)-approximation of $\mathrm{diag}(\mathbf{L}^\dagger)$
4: $R[v] \leftarrow 0 \ \forall v \in V$ ▷ $\mathcal{O}(n)$
5: Pick constant $\kappa \in (0, 1)$ arbitrarily; $\eta \leftarrow \frac{\kappa\epsilon}{3\sqrt{mn \log n \operatorname{diam}(G)}}$
6: Compute BFS tree B_u of G with root u ▷ $\mathcal{O}(n + m)$
7: $\tau \leftarrow \mathrm{ecc}(u)^2 \cdot \lceil \log(2m/\delta)/(2(1-\kappa)^2\epsilon^2) \rceil$ ▷ $\mathcal{O}(1)$
8: **for** $i \leftarrow 1$ to τ **do** ▷ τ times
9: Sample UST T_i of G with root u ▷ $\mathcal{O}(m \log n)$
10: $R \leftarrow$ Aggregate(T_i, R, B_u) ▷ $\mathcal{O}(n \log n)$
11: Solve $\mathbf{L}\mathbf{x} = \mathbf{e}_u - \frac{1}{n} \cdot \mathbf{1}$ for $\mathbf{x}$ (accuracy: η) ▷ $\tilde{\mathcal{O}}(m \log^{1/2} n \log(1/\eta))$
12: $\widetilde{\mathbf{L}^\dagger}[u, u] \leftarrow \mathbf{x}[u]$ ▷ $\mathcal{O}(1)$
13: **for** $v \in V'$ **do** ▷ All iterations: $\mathcal{O}(n)$
14: $\widetilde{\mathbf{L}^\dagger}[v, v] \leftarrow R[v]/\tau - \mathbf{x}[u] + 2\mathbf{x}[v]$
15: **return** $\mathrm{diag}(\widetilde{\mathbf{L}^\dagger})$

▶ Remark 8. Due to the fact that Laplacian linear solvers provide a relative error guarantee (and not an absolute $\pm\epsilon$ guarantee), the (relative) accuracy η for the initial Laplacian linear system (Lines 5 and 11) depends in a non-trivial way on our guaranteed absolute error ϵ. For details, see the proofs in Appendix A.4.

We also remark that the value of the constant κ does not affect the asymptotic running time (nor the correctness) of the algorithm. However, it does affect the empirical running time by controlling which fraction of the error budget is invested into solving the initial linear system vs. UST sampling.

A.1.1 Aggregation algorithm

Algorithm 2 Aggregation of T's contribution to $R[\cdot]$.

```
1:  function AGGREGATE(T, R, B_u)
2:      Input: spanning tree T, array of effective resistance estimates R, shortest-path tree B_u
3:      Output: R updated with T's contribution
4:      {α, Ω} ← DFS(T)                          ▷ α(v), Ω(v): discovery/finish times of v
5:      for v ∈ V' do
6:          for (a, b) ∈ P(v) obtained from B_u do
7:              if parent(b) = a then
8:                  if α(b) < α(v) and Ω(v) < Ω(b) then
9:                      R[v] ← R[v] + 1
10:             else if parent(a) = b then
11:                 if α(a) < α(v) and Ω(v) < Ω(a) then
12:                     R[v] ← R[v] − 1
13:     return R
```

Algorithm 2 depicts the pseudocode of the tree aggregation algorithm that is discussed in Section 3.2. Here, $\alpha(\cdot)$ and $\Omega(\cdot)$ denote our DFS discovery and finish timestamps, respectively. The test whether (a, b) [or (b, a)] is in T is carried out in Line 7 [or Line 10, respectively]. If that is indeed the case, Line 8 [or Line 11] checks whether v is below (a, b) [or (b, a), respectively]. If that is the case, the effective resistance estimate is adapted in Line 9 [Line 12].

A.1.2 Parallelism

Algorithm 1 can be parallelized by sampling and aggregating USTs in parallel. This yields a work-efficient parallelization in the work-depth model. The depth of the algorithm is dominated by (i) computing the BFS tree B_u, (ii) sampling each UST (Line 9) and (iii) solving the Laplacian linear system (Line 11). With current algorithms, the latter two procedures have depth $\mathcal{O}(m \log n)$ and $\tilde{\mathcal{O}}(m \log^{\frac{1}{2}} n \log(1/\eta))$, respectively (simply by executing them sequentially). We note that parallelizing the loops of Algorithm 2 results in a depth of $\mathcal{O}(n)$ for Algorithm 2; however, this does not impact the depth of Algorithm 1. We also note that by using a parallel Laplacian solver, the depth of solving the initial linear system becomes polylogarithmic [51]. Nevertheless, real-world implementations show a good parallelization behavior by parallelizing only Algorithm 1 (see Sections 4 and 5); consequently, we do not focus on parallelizing the sampling itself.

A.2 Wilson's UST Algorithm

Given a path P, its loop erasure is a simple path created by removing all cycles of P in chronological order. Wilson's algorithm grows a sequence of sub-trees of G, in our case starting with u as root of T. Let $M = \{v_1, \ldots, v_{n-1}\}$ be an enumeration of $V \setminus \{u\}$. Following the order in M, a random walk starts from every unvisited v_i until it reaches (some vertex in) T and its loop erasure is added to T.

▶ **Proposition 9** ([62], comp. [27]). *For a connected and unweighted undirected graph $G = (V, E)$ and a vertex $u \in V$, Wilson's algorithm samples a uniform spanning tree of G with root u. The expected running time is the mean hitting time of G, $\sum_{v \in V'} \pi_G(v)\kappa_G(v, u)$, where $\pi_G(v)$ is the probability that a random walk stays at v in its stationary distribution and where $\kappa_G(v, u)$ is the commute time between v and u.*

▶ **Lemma 10.** *Let G be as in Proposition 9. Its mean hitting time can be rewritten as $\sum_{v \in V'} \deg(v) \cdot \mathbf{r}(u, v)$, which is $\mathcal{O}(\mathrm{ecc}(u) \cdot m)$. In small-world graphs, this is $\mathcal{O}(m \log n)$.*

Proof of Lemma 10. First, we replace $\pi_G(v)$ by $\frac{\deg(v)}{\mathrm{vol}(G)}$ in the sum [41]. By using the well-known relation $\kappa_G(v, u) = \mathrm{vol}(G) \cdot \mathbf{r}(v, u)$ [18], the volumes cancel and we obtain $\sum_{v \in V'} \deg(v) \cdot \mathbf{r}(u, v)$. We can bound this from above by $\sum_{v \in V'} \deg(v) \cdot \mathrm{dist}(u, v) \leq \mathrm{vol}(G) \cdot \mathrm{ecc}(u)$, because effective resistance is never larger than the graph distance [21]. In unweighted graphs, $\mathrm{vol}(G) = 2m$ and in undirected graphs $\mathrm{ecc}(u) \leq \mathrm{diam}(G)$ for all $u \in V$, which proves the claim. ◀

A.3 Proof of Lemma 2

Proof of Lemma 2. DFS in T takes $\mathcal{O}(n)$ time since T is a spanning tree. Furthermore, Algorithm 2 loops over $\mathcal{O}(f^c(u))$ vertex-edge pairs (as $|P(v)| = \mathrm{dist}(u, v)$), with $\mathcal{O}(1)$ query time spent per pair. Since no path to the root in B_u is longer than $\mathrm{ecc}(u)$, we obtain $\mathcal{O}(n \cdot \mathrm{ecc}(u))$, which is by definition $\mathcal{O}(n \cdot \mathrm{diam}(G))$. ◀

A.4 Proof of Theorem 3

The proof of our main theorem makes use of Hoeffding's inequality. In the inequality's presentation, we follow Hayashi et al. [27].

▶ **Lemma 11.** *Let $X_1, \ldots, X_\tau$ be independent random variables in $[0, 1]$ and $X = \sum_{i \in [\tau]} X_i$. Then for any $0 < \epsilon < 1$, we have*

$$Pr[|X - \mathbb{E}[X]| > \epsilon\tau] \leq 2\exp(-2\epsilon^2\tau). \tag{10}$$

Before we can prove Theorem 3, we need auxiliary results on the equivalence of norms. For this purpose, let $\|\mathbf{x}\|_{\mathbf{L}} := \sqrt{\mathbf{x}^T\mathbf{L}\mathbf{x}}$ for any $\mathbf{x} \in \mathbb{R}^n$. Note that $\|\cdot\|_{\mathbf{L}}$ is a norm on the subspace of $\mathbb{R}^n$ with $\mathbf{x} \perp \mathbf{1}$. We show that:

▶ **Lemma 12.** *Let $G = (V, E)$ be a connected undirected graph with n vertices and m edges. Moreover, let $\mathbf{L}$ be its Laplacian matrix and λ_2 the second smallest eigenvalue of $\mathbf{L}$. The volume of G, $\mathrm{vol}(G)$, is the sum of all (possibly weighted) vertex degrees.*

For any $\mathbf{x} \in \mathbb{R}^n$ with $\mathbf{x} \perp \mathbf{1}$ we have:

$$\sqrt{\lambda_2} \cdot \|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_{\mathbf{L}} \leq \sqrt{2\,\mathrm{vol}(G)} \cdot \|\mathbf{x}\|_\infty. \tag{11}$$

Proof. Since $\mathbf{L}$ is positive semidefinite, it can be seen as a Gram matrix and written as $\mathbf{K}^T\mathbf{K}$ for some real matrix $\mathbf{K}$. The second smallest eigenvalue of $\mathbf{K}$ is then $\sqrt{\lambda_2}$ and we can write:

$$\sqrt{\lambda_2} \cdot \|\mathbf{x}\|_\infty \leq \sqrt{\lambda}_2 \cdot \|\mathbf{x}\|_2 = \|\sqrt{\lambda}_2 \cdot \mathbf{x}\|_2 \leq \|\mathbf{K}\mathbf{x}\|_2 = \|\mathbf{x}\|_{\mathbf{L}}. \tag{12}$$

The first, second, and last (in)equality in Eq. (12) follow from basic linear algebra facts, respectively. The third inequality follows from the Courant-Fischer theorem, since the eigenvector corresponding to the smallest eigenvalue 0, $\mathbf{1}$, is excluded from the subspace of $\mathbf{x}$ (comp. for example Ch. 3.1 of Ref. [54].)

Using the quadratic form of the Laplacian matrix, we get:

$$\|\mathbf{x}\|_{\mathbf{L}} = \left(\sum_{\{i,j\}\in E} \mathbf{w}(u,v)(\mathbf{x}[i]-\mathbf{x}[j])^2 \right)^{1/2} \tag{13}$$

$$\leq \left(\frac{1}{2}\operatorname{vol}(G)\cdot(2\|\mathbf{x}\|_\infty)^2 \right)^{1/2} = \sqrt{2\operatorname{vol}(G)}\cdot\|\mathbf{x}\|_\infty \tag{14}$$

◀

We are now in the position to prove our main result:

Proof of Theorem 3. Solving the initial linear system with the solver by Cohen et al. [19] takes $\tilde{\mathcal{O}}(m\log^{1/2} n\cdot\log(1/\eta))$ time to achieve a relative error bound of $\|\tilde{\mathbf{x}}-\mathbf{x}\|_{\mathbf{L}} \leq \eta\|\mathbf{x}\|_{\mathbf{L}}$. Here, $\mathbf{x}$ is the true solution, $\tilde{\mathbf{x}}$ the estimate, and $\|\mathbf{x}\|_{\mathbf{L}} = \sqrt{\mathbf{x}^T\mathbf{L}\mathbf{x}}$. To make this error bound compatible with the absolute error we pursue, we first note that $\sqrt{\lambda_2}\cdot\|\tilde{\mathbf{x}}\|_\infty \leq \|\tilde{\mathbf{x}}\|_{\mathbf{L}} \leq \sqrt{2\operatorname{vol}(G)}\cdot\|\tilde{\mathbf{x}}\|_\infty$ (Lemma 12), where λ_2 is the second smallest eigenvalue of $\mathbf{L}$. We may use Lemma 12, as $\tilde{\mathbf{x}}$ and $\mathbf{x}$ are both perpendicular to $\mathbf{1}$ (since the image of $\mathbf{L}$ is perpendicular to its kernel, which is $\mathbf{1}$). It is known that $\lambda_2 \geq 4/(n\cdot\operatorname{diam}(G))$ [46]. Hence, if we set $\eta := \frac{\kappa\epsilon}{3\cdot\sqrt{mn\log n}\operatorname{diam}(G)}$, we get for small-world graphs:

$$\begin{aligned}
\|\tilde{\mathbf{x}}-\mathbf{x}\|_\infty &\leq \frac{1}{\sqrt{\lambda_2}}\cdot\|\tilde{\mathbf{x}}-\mathbf{x}\|_{\mathbf{L}} \leq \frac{\eta}{\sqrt{\lambda_2}}\cdot\|\mathbf{x}\|_{\mathbf{L}} \\
&\leq \frac{\eta}{\sqrt{4/(n\cdot\operatorname{diam}(G))}}\cdot\|\mathbf{x}\|_{\mathbf{L}} \leq \frac{\eta\sqrt{n\log n}}{2}\cdot 2\sqrt{m}\cdot\|\mathbf{x}\|_\infty \\
&= \frac{\kappa\epsilon}{3\sqrt{mn\log n}\operatorname{diam}(G)}\cdot\sqrt{mn\log n}\cdot\|\mathbf{x}\|_\infty \\
&\leq \frac{\kappa\epsilon}{3\operatorname{diam}(G)}\|\mathbf{x}\|_\infty \leq \frac{\kappa\epsilon}{3\operatorname{diam}(G)}\operatorname{diam}(G) \leq \frac{\kappa}{3}\epsilon.
\end{aligned}$$

The second last inequality follows from the fact that $\mathbf{x}$ expresses potentials scaled by $1/n$, arising from $n-1$ (scaled) effective resistance problems fused together. The maximum norm of $\mathbf{x}$ can thus be bounded by $(n-1)\frac{1}{n}\mathbf{r}(u,v) \leq \operatorname{diam}(G)$, because $\mathbf{r}(\cdot,\cdot)$ is bounded by the graph distance.

Taking Eq. (7) into account, this means that the maximum error of a diagonal value in $\widetilde{\mathbf{L}^\dagger}$ as a consequence from the linear system can be bounded by $\kappa\epsilon$. The resulting running time for the solver is then $\tilde{\mathcal{O}}(m\log^{1/2} n\log(\frac{3\sqrt{mn\log n}\operatorname{diam}(G)}{\kappa\epsilon})) = \tilde{\mathcal{O}}(m\log^{1/2} n\log(n/\epsilon))$.

The main bottleneck is the loop that samples τ USTs and aggregates their contribution in each iteration. According to Lemma 10, sampling takes $\mathcal{O}(m\log n)$ time per tree in small-world graphs. Aggregating a tree's contribution is less expensive (Lemma 2).

Let us determine next the sample size τ that allows the desired guarantee. To this end, let $\epsilon' := (1-\kappa)\epsilon$ denote the possible absolute error for the effective resistance estimates. Plugging $\tau := \operatorname{ecc}(u)^2\cdot\lceil\log(2m/\delta)/(2(\epsilon')^2)\rceil$ into Hoeffding's inequality (Lemma 11), yields for each single edge $e\in E$ and its estimated electrical flow $\tilde{\mathbf{f}}(e)$: $Pr[\tilde{\mathbf{f}}(e) = \mathbf{f}(e)\pm\epsilon'/\operatorname{ecc}(u)] \geq 1-\delta/m$. Using the union bound, we get that $Pr[\tilde{\mathbf{f}}(e) = \mathbf{f}(e)\pm\epsilon'/\operatorname{ecc}(u)]$ for all $e\in E$ at the same time holds with probability $\geq 1-\delta$. Since for all v the path length $|P(v)|$ is bounded by $\operatorname{ecc}(u)$, another application of the union bound yields that $Pr[R[v] = \mathbf{r}(u,v)\pm\epsilon'] \geq 1-\delta$. ◀

A.5 Proof of Lemma 6

Proof. Recall that the normalized random-walk betweenness is expressed as follows (Eq. (5)):

$$c_b(v) = \frac{1}{n} + \frac{1}{n-1} \sum_{t \neq v} \frac{\mathbf{M^{-1}}[t,t] - \mathbf{M^{-1}}[t,v]}{\mathbf{M^{-1}}[t,t] + \mathbf{M^{-1}}[v,v] - 2\mathbf{M^{-1}}[t,v]}$$

where $\mathbf{M} := \mathbf{L} + \mathbf{P}$ with $\mathbf{L}$ the Laplacian matrix and $\mathbf{P}$ the projection operator onto the zero eigenvector of the Laplacian such that $\mathbf{P}[i,j] = 1/n$. We also have $\mathbf{L}^\dagger := (\mathbf{L} + \mathbf{P})^{-1} - \mathbf{P}$ and thus we can replace $\mathbf{M}^{-1}$ with $\mathbf{L}^\dagger + \mathbf{P}$. Then, for the numerator of Eq. (5) we have:

$$\begin{aligned}
&\sum_{t \neq v} (\mathbf{M^{-1}}[t,t] - \mathbf{M^{-1}}[t,v]) = \\
&\sum_{t \neq v} (\mathbf{L}^\dagger[t,t] - \mathbf{P}[t,t] - \mathbf{L}^\dagger[t,v] + \mathbf{P}[t,v]) = \\
&\sum_{t \neq v} (\mathbf{L}^\dagger[t,t] - \mathbf{L}^\dagger[t,v]) = \operatorname{tr}(\mathbf{L}^\dagger) - \mathbf{L}^\dagger[v,v] - \sum_{t \neq v} \mathbf{L}^\dagger[t,v] = \\
&\operatorname{tr}(\mathbf{L}^\dagger). \qquad (15)
\end{aligned}$$

The second equality holds because $\sum_{l \neq v} (\mathbf{P}[t,v] - \mathbf{P}[t,t]) = 0$ for all $t, v \in V$. The final equality holds since $\sum_{t \neq v}^{n} \mathbf{L}^\dagger[t,v] = -\mathbf{L}^\dagger[v,v]$ for all $v \in V$.

Then, for the denominator we have:

$$\begin{aligned}
&(n-1) \sum_{t \neq v} (\mathbf{M^{-1}}[t,t] + \mathbf{M^{-1}}[v,v] - 2\mathbf{M^{-1}}[t,v]) = \\
&(n-1) \sum_{t \neq v} (\mathbf{L}^\dagger[t,t] + \mathbf{P}[t,t] + \mathbf{L}^\dagger[v,v] + \mathbf{P}[v,v] - 2\mathbf{L}^\dagger[t,v] - 2\mathbf{P}[t,v]) = \\
&(n-1) \sum_{t \neq v} (\mathbf{L}^\dagger[t,t] + \mathbf{L}^\dagger[v,v] - 2\mathbf{L}^\dagger[t,v]) = \\
&(n-1) f^{el}(v). \qquad (16)
\end{aligned}$$

The second equality holds since $\sum_{t \neq v} \mathbf{P}[t,t] + \mathbf{P}[v,v] - 2\mathbf{P}[t,v] = 0$ for all $t, v \in V$ and the last equality due to Eq. (3) and the definition of electrical farness. The claim follows from combining Eqs. (15) and (16). ◀

B Kirchhoff Index and Related Centralities

B.1 Description

The sum of the effective resistance distances over all pairs of vertices is an important measure for network robustness known as the Kirchhoff index $\mathcal{K}(G)$ or (effective) graph resistance [20, 31]. The Kirchhoff index is often computed via the closed-form expression $\mathcal{K}(G) = n \operatorname{tr}(\mathbf{L}^\dagger)$ [31], where the trace is the sum of the diagonal elements. Li and Zhang [39] recently adapted the Kirchhoff index to obtain two edge centrality measures for $e \in E$: (i) $\mathcal{C}_\theta(e) := n \operatorname{tr}(\mathbf{L}^\dagger \setminus_\theta e)$, where $\mathbf{L} \setminus_\theta e$ corresponds to a graph in which edge e has been down-weighted according to a parameter θ and (ii) $\mathcal{C}^\Delta_\theta(e) := \mathcal{C}_\theta(e) - \mathcal{K}(G)$, which quantifies the difference of the Kirchhoff indices between the new and the original graph.

B.2 Related Work

To calculate the Kirchhoff edge centralities, Ref. [39] uses techniques such as partial Cholesky factorization [36], fast Laplacian solvers and the Hutchinson estimator. For $\mathcal{C}_\theta^\Delta(e)$, which is the more interesting measure in our context, they propose an ϵ-approximation algorithm that approximates $\mathcal{C}_\theta^\Delta(e)$ for all edges in $\mathcal{O}(m\epsilon^{-2}\theta^{-2}\log^{2.5} n \log(1/\epsilon))$ time (up to polylogarithmic factors). The algorithm uses the Sherman-Morrison formula [55], which gives a fractional expression of $(\mathbf{L}^\dagger \setminus_\theta e - \mathbf{L}^\dagger)$. The numerator is approximated by the Johnson-Lindenstrauss lemma, and the denominator by effective resistance estimates for all edges.

B.3 Kirchhoff Index and Edge Centralities

It is easy to see that Algorithm 1 can approximate Kirchhoff Index, exploiting the expression $\mathcal{K}(G) = n\,\mathrm{tr}(\mathbf{L}^\dagger)$ [31]. As a direct consequence, we have:

▶ **Proposition 13.** *Let G be a small-world graph as in Theorem 3. Then, Algorithm 1 approximates with high probability $\mathcal{K}(G)$ with absolute error $\pm\epsilon$ in $\mathcal{O}(m\log^4 n \cdot \epsilon^{-2})$ time.*

We also observe that we can use a component of Algorithm 1 to approximate $\mathcal{C}_\theta^\Delta(e)$. Recall that $\mathcal{C}_\theta^\Delta(e) = \mathcal{C}_\theta(e) - \mathcal{K}(G) = n(\mathrm{tr}(\mathbf{L}^\dagger \setminus_\theta e) - \mathrm{tr}(\mathbf{L}^\dagger))$. Using the Sherman-Morrison formula, as done in Ref. [39], we have:

$$\mathcal{C}_\theta^\Delta(e) = n(1-\theta)\frac{\mathbf{w}(e)\,\mathrm{tr}(\mathbf{L}^\dagger \mathbf{b}_e \mathbf{b}_e^\top \mathbf{L}^\dagger)}{1-(1-\theta)\mathbf{w}(e)\mathbf{b}_e^\top \mathbf{L}^\dagger \mathbf{b}_e}, \tag{17}$$

where $\mathbf{b}_e$ for $e = (u, v)$ is the vector $\mathbf{e}_u - \mathbf{e}_v$.

Ref. [39] approximates $\mathcal{C}_\theta^\Delta(e)$ with an algorithm that runs in $\mathcal{O}(m\theta^{-2}\log^{2.5} n \log(1/\epsilon)\,\mathrm{poly}(\log\log n)\cdot\epsilon^{-2})$ time. The algorithm is dominated by the denominator of Eq. (17), which runs in $\mathcal{O}(m\theta^{-2}\log^{2.5} n\,\mathrm{poly}(\log\log n)\cdot\epsilon^{-2})$. For the numerator of Eq. (17), they use the following Lemma:

▶ **Lemma 14** (paraphrasing from Ref. [39])**.** *Let $\mathbf{L}$ be a Laplacian matrix and ϵ a scalar such that $0 < \epsilon \leq 1/2$. There is an algorithm that achieves an ϵ-approximation of the numerator of Eq. (17) with high probability in $\mathcal{O}(m\log^{1.5} n \log(1/\epsilon)\cdot\epsilon^{-2})$ time.*

The algorithm in Lemma 14 uses the Monte-Carlo estimator with $\mathcal{O}(\epsilon^{-2}\log n)$ random vectors $\mathbf{z}_i$ to calculate the trace of the implicit matrix $\mathbf{y}_i^\top \mathbf{b}_e \mathbf{b}_e^\top \mathbf{y}_i$, where $\mathbf{y}_i$ is the approximate solution of $\mathbf{y}_i := \mathbf{L}^\dagger \mathbf{z}_i$ – derived from solving the corresponding linear system involving $\mathbf{L}$. For each system, the Laplacian solver runs in $\mathcal{O}(m\log^{1/2} n \log(1/\epsilon))$ time.

We notice that a UST-based sampling approach works again for the denominator: The denominator is just $1-(1-\theta)\mathbf{w}(e)\mathbf{r}(e)$, where $e \in E$ ($\mathbf{r}(e) = \mathbf{b}_e^\top \mathbf{L}^\dagger \mathbf{b}_e$). Approximating $\mathbf{r}(e)$ for every $e \in E$ then requires sampling USTs and counting for each edge e the number of USTs it appears in. Moreover, we only need to sample $q = \lceil 2\epsilon^{-2}\log(2m/\delta)\rceil$ to get an ϵ-approximation of the effective resistances for all edges (using Theorem 8 in Ref. [27]). Since $\mathbf{r}(e)$ are approximate, we need to bound their approximation when subtracted from 1. Following Ref. [39], we use the fact that $0 < \theta < 1$ and that for each edge $\mathbf{w}(e)\mathbf{r}(e)$ is between 0 and 1, bounding the denominator. The above algorithm can be used to approximate the denominator of Eq. (17) with absolute error $\pm\epsilon$ in $\mathcal{O}(m\log^2 n \cdot \epsilon^{-2})$ time. Combining the above algorithm and Lemma 14, it holds that:

▶ **Proposition 15.** *Let $G = (V, E)$ be a small-world graph as in Theorem 3. Then, there is an algorithm (using Lemma 14 and our Wilson-based sampling algorithm) that approximates with high probability $\mathcal{C}_\theta^\Delta(e)$ for all $e \in E$ with absolute error $\pm\epsilon$ in $\mathcal{O}(m\log^2 n \log(1/\epsilon)\cdot\epsilon^{-2})$ time.*

C Detailed Engineering Aspects

C.1 UST Generation, Pivot Selection, and the Linear System

Wilson's algorithm [62] using loop-erased random walks is the best choice in practice for UST generation and also the fastest asymptotically for unweighted small-world graphs. A fast random number generator is required for this algorithm; our code uses PCG32 [50] for this purpose. For our implementation we use a variant of Wilson's algorithm to sample each tree, proposed by Hayashi et al. [27]: first, one computes the biconnected components of G, then applies Wilson to each biconnected component, and finally combines the component trees to a UST of G. In each component, we use a vertex with maximal degree as root for Wilson's algorithm. Using this approach, Hayashi et al. [27] experienced an average performance improvement of around 40% on sparse graphs compared to running Wilson directly.

As a consequence of Theorem 3, the pivot vertex u should be chosen to have low eccentricity. As finding the vertex with lowest eccentricity with a naive APSP approach would be too expensive, we compute a lower bound on the eccentricity for all vertices of the graph and choose u as the vertex with the lowest bound. These bounds are computed using a strategy analogous to the double sweep lower bound by Magnien et al. [44]: we run a BFS from a random vertex v, then another BFS from the farthest vertex from v, and so on. At each BFS we update the bounds of all the visited vertices; an empirical evaluation has shown that 10 iterations yield a reasonably accurate approximation of the vertex with lowest eccentricity.

As a result from preliminary experiments, we use a general-purpose Conjugate Gradient (CG) solver for the single (sparse) Laplacian linear systems, together with a diagonal preconditioner. We choose the implementation of the C++ library Eigen [26] for this purpose and found that the accuracy parameter $\kappa = 0.3$ yields a good trade-off between the CG and UST sampling steps.

C.2 Parallel Implementation

Shared memory. Our implementation uses OpenMP for shared-memory parallelism. We aggregate $R[\cdot]$ in thread-local vectors and perform a final parallel reduction over all $R[\cdot]$. We found that on the graphs that we can handle in shared memory, no sophisticated load balancing strategies are required to achieve reasonable scalability.

Distributed memory. We provide an implementation of our algorithm for replicated graphs in distributed memory that exploits hybrid parallelism based on MPI + OpenMP. On each compute node, we take samples and aggregate $R[\cdot]$ as in shared memory. Compared to the shared-memory implementation, however, our distributed-memory implementation exhibits two main peculiarities: (i) we still solve the initial Laplacian system on a single compute node only; we interleave, however, this step with UST sampling on other compute nodes, and (ii) we employ explicit load balancing. The choice to solve the initial system on a single compute node only is done to avoid additional communication among nodes. In fact, we only expect distributed CG solvers to outperform this strategy for inputs that are considerably larger than the largest graphs that we consider. Furthermore, since we interleave this step of the algorithm with UST sampling on other compute nodes, our strategy only results in a bottleneck on input graphs where solving a single Laplacian system is slower than taking *all* UST samples – but these inputs are already "easy".

For load balancing, the naive approach would consist of statically taking $\lceil \tau/p \rceil$ UST samples on each of the p compute nodes. However, in contrast to the shared-memory case, this does not yield satisfactory scalability. In particular, for large graphs, the running

time of the UST sampling step has a high variance. To alleviate this issue, we use a simple *dynamic* load balancing strategy: periodically, we perform an asynchronous reduction (`MPI_Iallreduce`) to calculate the total number of UST samples taken so far (over all compute nodes). Afterwards, each compute node calculates the number of samples that it takes before the next asynchronous reduction (unless more than τ samples were taken already, in which case the algorithm stops). We compute this number as $\lceil \tau/(b \cdot p^\xi) \rceil$ for fixed constants b and ξ. We also overlap the asynchronous reduction with additional sampling to avoid idle times. Finally, we perform a synchronous reduction (`MPI_Reduce`) to aggregate $R[\cdot]$ on a single compute node before outputting the resulting diagonal values. By parameter tuning [5], we found that choosing $b = 25$ and $\xi = 0.75$ yields the best parallel scalability.

Cutting Polygons into Small Pieces with Chords: Laser-Based Localization

Abstract

Motivated by indoor localization by tripwire lasers, we study the problem of cutting a polygon into small-size pieces, using the chords of the polygon. Several versions are considered, depending on the definition of the "size" of a piece. In particular, we consider the area, the diameter, and the radius of the largest inscribed circle as a measure of the size of a piece. We also consider different objectives, either minimizing the maximum size of a piece for a given number of chords, or minimizing the number of chords that achieve a given size threshold for the pieces. We give hardness results for polygons with holes and approximation algorithms for multiple variants of the problem.

1 Introduction

Indoor localization is a challenging and important problem. While GPS technology is very effective outdoors, it generally performs poorly inside buildings, since GPS depends on line-of-sight to satellites. Thus, other techniques are being considered for indoor settings. One of the options being investigated for localization and tracking is to use one-dimensional

tripwire sensors [16] such as laser beams, video cameras with a narrow field of view [31], and pyroelectric or infrared sensors [12, 14]. In these approaches, multiple sensors emitting directional signal beams are deployed in an environment, with the beams inducing an arrangement that cuts the domain into cells, allowing one to track the movement of a mobile target from one cell to another when it crosses the signal beam. Since the accuracy of the localization depends on the sizes of the cells, it is desirable to cut the polygon into *small* pieces. With such beam deployment, one can also ensure that no "large" object can be "hidden" in the domain, since any such object will necessarily intersect one of the beams.

In the literature there have been studies of target localization and tracking using such "tripwire" sensors. Zheng, Brady, and Agarwal [32] consider general models of "boundary sensors" that are triggered when an object crosses them. They assume that the position of the sensors is already given and consider the signal processing problem of determining the location and trace of a target by the spatial and temporal sequence of the laser beams crossed by the target. In this paper, we focus on the problem of optimizing the placement of signal beam sensors to minimize the ambiguity of target location within each cell.

Problem Formulation and Notation. We study various versions of the laser cutting problem. The input polygon, denoted by P, is a closed polygonal domain (i.e., a connected compact set in $\mathbb{R}^2$ with piecewise linear boundary) having a total of n vertices, r of which are reflex (having internal angle greater than π). The terms "cut" and "laser" will be used interchangeably to denote a chord of P, i.e., a maximal line segment in P whose relative interior lies in the interior of P. The *measure* (or *size*) of a cell in the arrangement will be (a) the cell's area, (b) its diameter (defined as the maximum Euclidean distance between two points of the cell), or (c) the radius of the largest inscribed disk within the cell.

For each measure, we consider two formulations of the optimization problem:

- MinMeasure: Given a positive integer k, determine how to place k laser beams in P to minimize the maximum measure, δ, of a cell in the arrangement of the lasers.
- Min-LaserMeasure: Given $\delta > 0$, determine the smallest number of laser beams to cut P into cells each of measure at most δ.

In Min-LaserMeasure, no generality is lost by taking the cell size bound, δ, to be 1. We assume that the optimal solution is greater than a constant c; otherwise, the problem can be solved optimally in $O(n^{\text{poly}(c)})$ time (in the real RAM model of computation, standard for geometric algorithms) by reducing it to a mathematical program whose variables are the locations of the lasers endpoints on the boundary of P (the space of the variables would be split into regions of fixed combinatorial types for all the lasers, and in each region, the measures for the cells of the partition of P will be explicitly written and optimized – since each cell has $\text{poly}(c) = O(1)$ complexity, the optimization problem will be of constant size). It may be interesting to investigate also the opposite scenario and obtain efficient algorithms for minimizing the measures using a small given number of lasers. Further variants of the problem may be defined. One possible requirement is to use only axis-aligned lasers – in fact, with this restriction (of primarily theoretical interest) we obtain better approximations than for the more general case of unrestricted-orientation lasers.

Results. We give hardness results and approximation algorithms for several variants of the problems, using a variety of techniques. Specifically,

- Section 2 proves hardness of our problems in polygons *with holes*: we show that it is NP-hard to decide whether one can split the domain into pieces of measure at most δ, using a given number k of lasers (this holds for any of the measures, which implies that

both MinMeasure and Min-LaserMeasure are hard for polygons with holes). Our hardness reductions hold using axis-parallel lasers, as well, which implies that the problem is hard with or without the restriction to axis-aligned lasers.

- Section 3.1 gives an $O(\log r)$-approximation for Min-LaserArea in *simple* polygons. The algorithm "unrefines" the ray shooting subdivision by Hershberger and Suri [17], merging the triangles bottom-up along the decomposition tree; the merging stops whenever the next merge would create a cell of area greater than δ, implying that the boundaries between the merged cells can be charged to disjoint parts of P of area more than δ. The lasers are then put along the cell boundaries of the coarsened subdivision; since the subdivision is obtained by cutting out $O(1)$ children from parents in a tree on the original subdivision (where the children were separated from parents by polygonal chains of $O(1)$ complexity), we can charge these $O(1)$ lasers to the intersection of OPT with a region of area more than δ. The remaining large pieces in the coarsened subdivision (e.g., triangles of area more than δ in the initial triangulation) are cut with a suitable grid of lasers, which is within a constant factor of optimal subdivision for each piece. The $O(\log n)$ approximation factor then follows from the fact that each laser could pass through $O(\log n)$ cells of the original subdivision (the subdivision's core property). To bring the approximation factor down to $O(\log r)$ we decompose P into convex pieces with a decomposition whose stabbing number is $O(\log r)$ (a result, which may be of independent interest) and use the same scheme as with the Hershberger–Suri decomposition.
- In Section 3.2 we present a bi-criteria approximation to the diameter version for *simple* polygons: if k lasers can cut P into pieces of diameter at most δ, we find a cutting with at most $2k$ lasers into $O(\delta)$-diameter pieces. In Section 3.3 we use the bi-criteria algorithm to give a constant-factor approximation to MinDiameter. Both algorithms use only axis-aligned lasers, yielding the same approximation guarantees for the versions with general-direction lasers and with axis-aligned lasers.
- Section 4 gives a constant-factor approximation to Min-LaserDiameter and Min-LaserArea in *simple* polygons under the restriction that the lasers are axis-aligned. The algorithms are based on "histogram decomposition" with constant stabbing number and solving the problems in each histogram separately.
- In Section 5 we give a bi-criteria approximation to the diameter version in polygons *with holes* under the restriction that lasers are axis-parallel. The algorithm is similar to the one for simple polygons in that they both use a grid; however, everything else is different: in simple polygons we place lasers along grid lines, while in polygons with holes the grid lines just subdivide the problem (in fact, we consider the vertical and the horizontal strips separately). More importantly, even though we place axis-aligned lasers in both simple and nonsimple polygons, for the former we approximate cutting with arbitrary-direction lasers, while for the latter only cuttings with axis-aligned lasers (approximating cuttings with general-direction lasers in polygons with holes is open). We use the bi-criteria algorithm to give a constant-factor approximation to MinDiameter in polygons with holes – this part is the same as for simple polygons.
- Section 6 gives an $O(\log \mathrm{OPT})$-approximation for Min-LaserCircle in polygons *with holes*. The algorithm is based on a reduction to the SetCover problem.

Table 1 summarizes our results. The running times of our algorithms depend on the output complexity, which may depend on the size (area, perimeter, etc.) of P. Some of our algorithms can be straightforwardly made to run in strongly-polynomial time, producing a strongly-polynomial-size representation of the output; for others, such conversion – which in general is outside our scope – is not easily seen. Many versions of the problem still remain

open. For simple polygons, despite considerable attempts, we have neither hardness results nor polynomial-time algorithms to compute an optimal solution; all of our positive results are approximation algorithms.

Table 1 Approximations for simple polygons. The results marked with asterisks apply also to polygons with holes (either directly or with a similar/extended algorithm).

Related Previous Work. Previous results on polygon decomposition [21] use models that do not support laser cuts or are restricted to convex bodies. For example, *Borsuk's conjecture* [5, 18, 19] seeks to partition a convex body of unit diameter in $\mathbb{R}^d$ into the minimum number of pieces of diameter less than one. Conway's *fried potato problem* [3, 9] seeks to minimize the maximum in-radius of a piece after a given number of *successive* cuts by hyperplanes for a convex input polyhedron in $\mathbb{R}^d$. Croft et al. [9, Problem C1] raised a variant of the problem in which a convex body is partitioned by an *arrangement* of hyperplanes (i.e., our problem in $\mathbb{R}^d$), but no results have been presented.

Equipartition problems ask to partition convex polygons into convex pieces all having the same area or the same perimeter (or other measures) [2, 4, 20, 22, 27, 29]. In these problems, the partition is not restricted to chords (or hyperplanes). Topological methods are used for existential results in this area, and very few algorithmic results are known [1]. Another related problem is the family of so-called *cake cutting problems* [13, 28], in which an infinite straight line "knife" is used to cut a convex "cake" into (convex) pieces that represent a "fair" division into portions. In contrast, we are interested in cutting *nonconvex* polygons into connected pieces.

In [6] several variants of Chazelle's result from [8] were explored, including cutting the polygon along a chord to get approximately equal areas of the two resulting parts. Yet another related problem is that of "shattering" with arrangements [11], in which one seeks to isolate objects in cells of an arrangement of a small number of lines, but without consideration of the size of the cells (as is important in our problem).

2 Hardness in Polygons with Holes

We show that for all three measures (area, diameter, the radius of the largest inscribed circle) it is NP-hard to decide whether a given polygon P *with holes* can be divided into pieces of small measure using a given number of lasers, both for unrestricted-orientation and axis-aligned lasers. However, it is currently open whether these problems remain NP-hard for simple polygons.

We prove hardness by reduction from the 3SAT problem. Our polynomial-time reduction is similar to previous reductions for line cover problems, which are geometric variants of set cover [23]. In particular, Megiddo and Tamir [25] proved that the LineCover problem is NP-complete: Given n points in the plane and an integer k, decide whether the points can be covered by k lines. Hassin and Megiddo [15] proved hardness for MinimumHittingHorizontalUnitSegments problem: Given n horizontal line segments in the plane, each of

unit length, and an integer k, decide whether there exists a set of k axis-parallel lines that intersects all n segments. Our reduction is based on the idea of Hassin and Megiddo, but requires some adjustments to generate a subdivision of a polygon.

▶ **Theorem 1.** *In a polygon with holes, both MinArea and Min-LaserArea are NP-hard (with or without the axis-aligned lasers restriction).*

Proof. We reduce from 3-SAT. Let Φ be a boolean formula in 3CNF with m clauses $c_1, \ldots, c_m$, and n variables $x_1, \ldots, x_n$. We construct an orthogonal polygon P with holes and an integer k such that Φ is satisfiable if and only if P can be subdivided into regions of area at most 2 using k lasers. (The reduction goes through with or without the restriction that all lasers are axis-parallel).

We construct a polygon P from the rectangle $B = [0, 7m + 2] \times [0, 3n + 4]$ by carving rectangular "rooms" connected by narrow corridors. The rooms are pairwise disjoint and they each have area of 2. The corridors are axis-parallel, run between opposite sides of the bounding box B, and their width is $1/(100 \max\{m, n\})$. See Fig. 1 for an illustration.

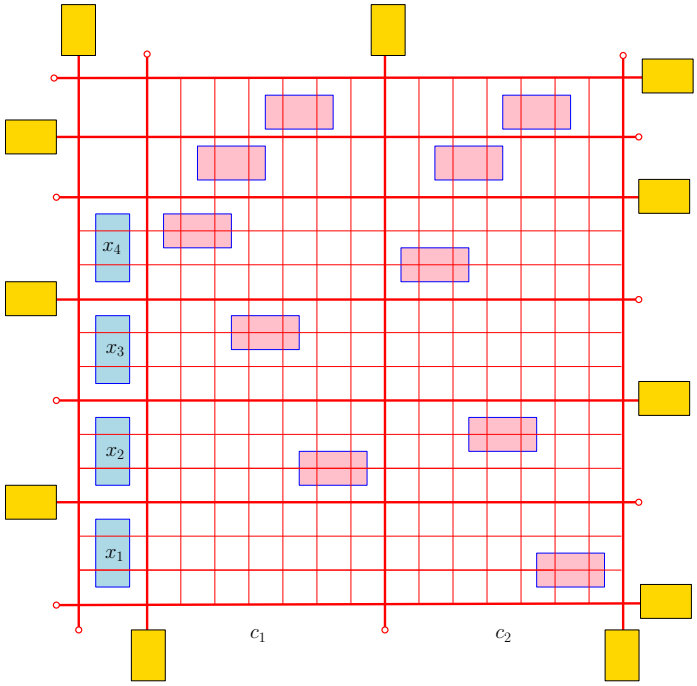

Figure 1 An example for the rooms and corridors for $\Phi = (x_2 \vee \overline{x}_3 \vee \overline{x}_4) \wedge (x_1 \vee \overline{x}_2 \vee x_4)$. The rooms corresponding to variables are in blue. The rooms corresponding to clauses (five rooms per clause) are in pink. The corridors are shown in red, some of which are connected to additional rooms (shown in yellow). The polygon is composed of the union of all the rooms and corridors.

Variable rooms. For each variable x_i, $i = 1, \ldots, n$, create one room: $[\frac{1}{2}, \frac{3}{2}] \times [3(i-1) + \frac{1}{2}, 3i - \frac{1}{2}]$. Note that all rooms are to the left of the line $x = 2$.

Clause rooms. For each clause c_j, $j = 1, \ldots, m$, create five rooms. All five rooms have size 2×1 and lie between the lines $x = 7(j-1)+2$ and $x = 7j+2$. Three out of five rooms are aligned with the variable rooms. Suppose c_j contains the variables x_i, $x_{i'}$, and $x_{i''}$, where $i < i' < i''$. If x_i is nonnegated, then create the room $[7(j-1) + \frac{1}{2}, 7(j-1) + \frac{5}{2}] \times [3(i-1) + \frac{1}{2}, 3i - \frac{3}{2}]$;

otherwise create the room $[7(j-1)+\frac{1}{2}, 7(j-1)+\frac{5}{2}]\times[3(i-1)+\frac{3}{2}, 3i-\frac{1}{2}]$. We create a room for $x_{i'}$ (resp., $x_{i''}$) analogously, shifted by a horizontal vector $(0,2)$ (resp;., $(0,4)$). Note that the x-projections of these rectangles do not overlap. Two additional rooms lie above the variable rooms: $[7(j-1)+\frac{3}{2}, 7(j-1)+\frac{7}{2}]\times[2n+\frac{1}{2}, 2n+\frac{3}{2}]$ and $[7(j-1)+\frac{7}{2}, 7(j-1)+\frac{11}{2}]\times[2n+\frac{5}{2}, 2n+\frac{7}{2}]$.

Corridors and separator gadgets. Create narrow corridors along the vertical lines $x = 0, 2, 3, \ldots, 7m$ and horizontal lines $y = 0, 1, 2, \ldots, 3n$, $y = 3n+2$, and $y = 3n+4$. Add rectangular rooms of area 2 at one end of some of the corridors. Specifically, we add rooms to the corridors at $x = 0$ and $x = 7j+2$ for $j = 0, 1, \ldots, m$ alternately at the top and bottom endpoints; and similarly for the corridors at $y = 3i$ for $i = 0, 1, \ldots, n$, $y = 3n+2$, and $y = 3n+4$, alternately at the left and right endpoints. Altogether, $m+n+5$ corridors have rooms at their endpoints.

Finally, we set the parameter $k = 3m+2n+5$. This completes the description of an instance corresponding to the Boolean formula Φ.

Equivalence. Let $\tau : x_i \to \{\texttt{true}, \texttt{false}\}$ be a satisfying truth assignment for Φ. We show that P can be subdivided by k lasers into regions of area at most 2. Place lasers at all horizontal and vertical lines that have additional rooms at their endpoints; this requires $m+n+5$ lasers. These lasers subdivide P into subpolygons that each intersect at most one room. For $i = 1, \ldots, n$, if $\tau(x_i) = \texttt{true}$, then place a horizontal laser at $y = 3(i-1)+1$ (along the bottom corridor touching room for x_i), otherwise at $y = 3(i-1)+2$ (along the top corridor touching room for x_i). These lasers split each variable room into two rectangles of area $\frac{1}{2}$ and $\frac{3}{2}$. For $j = 1, \ldots, m$, we place two vertical lasers that subdivide the rooms associated with clause c_j. Since τ is a satisfying truth assignment, the rooms corresponding to true literals are already split by horizontal lasers. As can easily be checked, the remaining (at most 4) rooms can be split using two vertical lasers. Now P is subdivided into pieces that each intersect at most one room, and contains at most 1.5 area of each room. Since the corridors are narrow, the area of each piece is less than 2, as required. We have used n horizontal lasers for the variables, and $2m$ vertical lasers for clauses. Overall, we have used $(m+n+5)+n+2m = 3m+2n+5$ lasers.

Suppose now that $k = 3m+2n+5$ lasers can subdivide P into polygons of area at most 2. We show that Φ is satisfiable. The area of each room is about 2, so they each intersect at least one laser. Each variable room requires at least one laser; and the n variable rooms jointly require n lasers (as no laser can intersects two variable rooms). Each clause is associated with two rooms above the line $y = 3n$; which jointly require two lasers. Overall these rooms require $2m$ lasers.

Note that a laser that intersects a clause rooms above $y = 3n$ or a variable room cannot intersect any room at the end of corridors. We are left with at most $k-(n+2m) = m+n+5$ lasers to split these rooms. Since we have precisely $m+n+5$ rooms at the end of the corridors, and no laser can intersect two such rooms, there is a unique laser intersecting each of these rooms. As argued above, for $i = 1, \ldots, n$, the room associated with x_i intersects only one laser. If this laser intersects the corridor at $y = 3(i-1)+1$, then let $\tau(x_i) = \texttt{true}$, otherwise $\tau(x_i) = \texttt{false}$. For $j = 1, \ldots, m$, there are two lasers that intersect the two rooms associated with c_j above $y = 3n$. These two lasers cannot intersect all three rooms associated with c_j below $y = 3n$. Consequently, at least one of these rooms intersects a laser coming from a variable room. Hence each clause contains a true literal, and Φ is satisfiable. ◀

The proofs of the following two theorems are presented in the full version of the paper.

▶ **Theorem 2.** *In polygons with holes, both MinDiameter and Min-LaserDiameter are NP-hard (with or without the axis-aligned lasers restriction).*

▶ **Theorem 3.** *In polygons with holes, both MinCircle and Min-LaserCircle are NP-hard (with or without the axis-aligned lasers restriction).*

3 Decomposition Algorithms for Simple Polygons

In this section, we present approximation results for decomposing a simple polygon P by lasers of arbitrary orientations (recall that n denotes the total number of vertices of P and r is the number of reflex vertices). We describe an $O(\log r)$-approximation for Min-LaserArea (Section 3.1), a bi-criteria algorithm for diameter (Section 3.2), and a $O(1)$-approximation for MinDiameter (Section 3.3).

3.1 Min-LaserArea

Given a simple polygon P and a threshold δ, we wish to find the minimum number of lasers that subdivide P into pieces, each of area at most 1. We start with the easy $O(1)$-approximation in the special case when P is a convex polygon (Proof in the full version).

▶ **Lemma 4.** *For every convex polygon P, we can find a set of $k = O(\sqrt{\text{area}(P)})$ lasers that subdivide P into pieces, each of area at most 1, in $O(k+n)$ time. Every decomposition into pieces of area at most 1 requires $\Omega(\sqrt{\text{area}(P)})$ lasers.*

Overview. We give a brief overview of our approximation algorithm for a simple polygon P. The basic idea is to decompose P into convex pieces, and use Lemma 4 to further decompose each convex piece. There are two problems with this naïve approach: (1) a laser in an optimal solution may intersect several convex pieces (i.e., the sum of lower bounds for the convex pieces is not a global lower bound); and (2) the lasers used for a convex decomposition are not accounted for. We modify the basic approach to address both of these problems.

We use the Hershberger–Suri triangulation (as a convex subdivision). For a simple polygon P with n vertices, Hershberger and Suri [17] construct a Steiner triangulation into $O(n)$ triangles such that every chord of P intersects $O(\log n)$ triangles. We can modify their construction to produce a Steiner decomposition into a set $\mathcal{C}$ of convex cells (rather than triangles) such that each laser intersects $O(\log r)$ convex cells, where r is the number of reflex vertices of P. Thus, each laser of OPT can help partition $O(\log r)$ convex cells; this factor dominates the approximation ratio of our algorithm.

A convex cell $C \in \mathcal{C}$ is *large* if $\text{area}(C) > 1$, otherwise it is *small*. We decompose each large convex cell using Lemma 4. We can afford to place $O(1)$ lasers along the boundary of a large cell. We cannot afford to place lasers on the boundaries of all small cells. If we do not separate the small cells, however, they could merge into a large (nonconvex) region, so we need *some* separation between them. In the algorithm below, we construct such separators recursively by carefully unrefining the Hershberger–Suri triangulation. The unrefined subdivision is no longer a triangulation, but we maintain the properties that (i) each cell is bounded by $O(1)$ lasers within each pseudotriangle (and an arbitrary number of consecutive edges of P), and (ii) every chord of P intersects $O(\log n)$ cells.

Basic properties of the Hershberger–Suri triangulation. Given a simple polygon P with n vertices, Hershberger and Suri [17] construct a Steiner-triangulation in two phases (see Fig. 2 for an example): First, they subdivide P into $O(n)$ pseudotriangles (i.e., simple

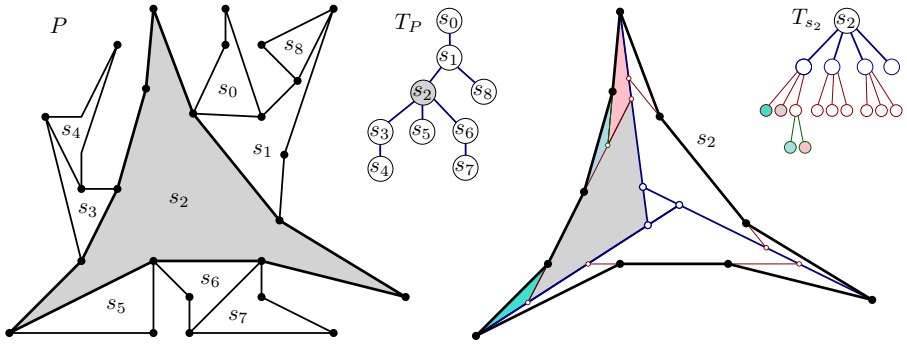

Figure 2 Left: A simple polygon P, decomposed into pseudotriangles, and the dual graph T_P. Right: A pseudotriangle s_2 is recursively subdivided into Steiner triangles, with recursion tree T_{s_2}.

polygons with precisely three convex vertices) using $O(n)$ noncrossing diagonals of P; and then subdivide each pseudotriangle into Steiner triangles. The runtime of their algorithm, as well as the number of Steiner triangles, is $O(n)$. Let $\mathcal{S}$ denote the set of pseudotriangles produced in the first phase; and let T_P be the *dual tree* of the pseudotriangles, in which each node corresponds to a pseudotriangle, and two nodes are adjacent if and only if the corresponding pseudotriangles share an edge (a diagonal of P). Note that the degree of T_P is not bounded by a constant (it is bounded by n), as a pseudotriangle may be adjacent to arbitrarily many other pseudotriangles. We consider T_P to be a rooted tree, rooted at an arbitrary pseudotriangle. Then every nonroot pseudotriangle s in $\mathcal{S}$ has a unique edge incident to the parent of s; we call this edge the *parent edge of* s.

Hershberger and Suri subdivide each pseudotriangle $s \in S$ recursively: In each step, they use $O(1)$ line segments to subdivide a pseudotriangle into $O(1)$ pseudotriangles, which are further subdivided recursively until they obtain triangles. Let us denote by T_s the recursion tree for s. Each vertex $v \in T_s$ represents a region $R_v \subset s$: The root of T_s represents s, and the leaves represent the Steiner triangles in s. The recursive subdivision maintains the following two properties: (a) Every edge of s is incident to a unique region in each level of T_s, (b) For each node $v \in T_s$, the boundary between R_v and $s \setminus R_v$ is a polyline with $O(1)$ edges (that is, R_v is bounded by $O(1)$ line segments inside s, and some sequence of consecutive edges of s).

Algorithm. We are ready to present an approximation algorithm for Min-LaserArea. Given a simple polygon Q, we begin by computing the Hershberger–Suri triangulation, the pseudotriangles $\mathcal{S}$, the dual tree T_P, and a recursion tree T_s for each pseudotriangle $s \in \mathcal{S}$. We then process the pseudotriangles in a bottom-up traversal of T_P.

Within each pseudotriangle $s \in \mathcal{S}$, we unrefine the Steiner triangulation of s by merging some of the cells into one cell (the resulting larger cells need not be triangular or convex). Initially, each node $v \in T_s$ corresponds to a region $R_v \subseteq s$. However, if we do not place lasers along the edges of s, then R_v may be adjacent to (and merged with) other cells that are outside the pseudotriangle s, along the boundary of s. Since we have an upper bound on the total area of each cell in the final decomposition, we need to keep track of the area of the region on both sides of an edge of the pseudo-triangulation. In the course of unrefinement algorithm for all $s \in \mathcal{S}$, we compute nonnegative *weights* $w(\cdot)$ for all edges of the pseudotriangulation. The weights are used for bookkeeping purposes. Specifically, the edges of P have zero weight. In a bottom-up traversal of T_P, when we start processing a pseudotriangle s, the *weights* $w(e)$

have already been computed for all edges of the pseudo-triangle s except the parent edge of s. The weight $w(e)$ for the parent edge e of s is determined when we have computed the unrefined subdivision of s; and $w(e)$ will be the area of the unrefined cell in s adjacent to the parent edge. A node $v \in T_s$ initially corresponds to a region R_v within the pseudotriangle s, but in the final decomposition of P, the node is part of some larger cell $\widehat{R}_v \subseteq P$, with $\text{area}(\widehat{R}_v) = \text{area}(R_v) + \sum_e w(e)$, where the summation is over all edges of s on the boundary of R_v, and $w(e)$ denotes the area of the cell on the opposite side of e.

As the weight of the parent edge is not available yet when we unrefine s, we modify the recursion tree T_s as follows: We choose the root to be the leaf $v_0 \in T_s$ adjacent to the parent edge of s, and reverse the parent-child relation on all edges of T_s along the s-v_0 path. We denote the modified recursion tree T'_s (Fig. 3 (left)). For all nodes v along the s-v_0 path (including s and v_0), we redefine the corresponding regions of the nodes in T'_s as follows. We denote by $R_v(T_s)$ and $R_v(T'_s)$ the regions corresponding to node v in trees T_s and T'_s, respectively. We set $R_{v_0}(T'_s) := s$ and for all other nodes v along the s-v_0 path (including s), we set $R_v(T'_s) := s \setminus R_u(T_s)$, where u is the parent of v in T'_s. With a slight abuse of notation, we set $R_v = R_v(T'_s)$ for all $v \in T'_s$ for the remainder of the algorithm. Note that $\text{area}(R_v)$ monotonically decreases with the depth in T'_S.

In a bottom-up traversal of T_P, consider every $s \in \mathcal{S}$. We proceed with two phases (see Fig. 3 for an example).

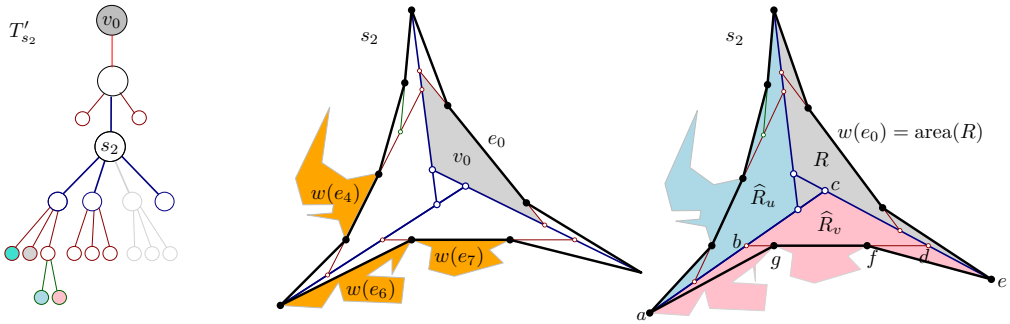

Figure 3 Left: The modified recursion tree T'_{s_2}. Middle: pseudotriangle s_2 with the initial Steiner triangulation, edge weights representing the areas of adjacent regions in the descendants of s_2, and the parent edge e_0 of s_2. Right: The unrefined subdivision of s_2 into R_u, R_v, and R; larger cells $\widehat{R}_u$ and $\widehat{R}_v$ (blue and pink), and the weight $w(e_0) = \text{area}(R)$ of the parent edge of s_2 (gray).

Phase 1 of the algorithm is an unrefinement process, that successively merges small cells of the Hershberger–Suri triangulation (no lasers are involved). We initialize three variables:

$$R := s, \qquad T := T'_s, \qquad U_s := \emptyset,$$

where $R \subseteq s$ is the region yet to be handled, T is a subtree of T'_s corresponding to the region R, and U_s is the set of interior-disjoint faces in s produced by the unrefinement process. While $\text{area}(R) > 1$, do the following:

- Find a lowest node $v \in T$ for which $\text{area}(\widehat{R}_v) > 1$,
- Set $U_s := U_s \cup \{\widehat{R}_v\}$,
- Set $R := R \setminus R_v$,
- Delete the subtree rooted at v from T, and
- For all ancestors u of v, set $\widehat{R}_u := \widehat{R}_u \setminus \widehat{R}_v$.

When the while loop ends, define the weight of the parent edge of s to be $\text{area}(R)$.
Phase 2 of the algorithm positions lasers in a pseudotriangle s as follows.
For every region $\widehat{R}_v \in U_s$, do:

- Step 1. Place lasers along all edges of the boundary between $\widehat{R}_v$ and $s \setminus \widehat{R}_v$, and the boundaries between R_v and $R_{v'}$ for all children v' of v. For example in Fig. 3 (right), two lasers are placed along the edges (a, c) and (c, e) that disconnect $\widehat{R}_v$ from s_2. Also, a laser that is placed along edge (b, d) that separates the children of R_v.
- Step 2. If $\text{area}(R_v) \geq 1$ (which means R_v has not merged with any other region in Phase 1, i.e., $\widehat{R}_v = R_v$ hence $\widehat{R}_v$ is convex), subdivide $\widehat{R}_v$ by $\Theta(\sqrt{\text{area}(R_v)})$ lasers according to Lemma 4.

This completes the description of our algorithm.

▶ **Theorem 5.** *Let P be a simple polygon with n vertices, and let k^* be the minimum number of lasers that subdivide P into pieces of area at most 1. We can find an integer k with $k^* \leq k \leq O(k^* \log n)$ in $O(n)$ time, and a set of k lasers that subdivide P into pieces of area at most 1 in output-sensitive $O(k + n)$ time.*

Proof. Phase 1 of our algorithm (unrefinement) subdivides each pseudotriangle $s \in \mathcal{S}$ into regions such that each region corresponds to a subtree rooted at some node v of the recursion tree T'_s. Node v corresponds to a region $R_v \subset s$, and a possibly larger region $\widehat{R}_v \subset P$ which is the union of R_v and adjacent regions in the descendant pseudotriangles of s adjacent to R_v. Phase 1 of the algorithm ensures that $\text{area}(\widehat{R}_v) > 1$ (therefore, $\widehat{R}_v$ must intersect at least one laser in OPT), but for all children v' of v in T'_s, we have $\text{area}(\widehat{R}_{v'}) \leq 1$.

In Step 1, the algorithm uses $O(1)$ lasers for each $v \in U_s$ to separate $\widehat{R}_v$ from $s \setminus \widehat{R}_v$. Recall that the recursion tree T_s has bounded degree. Consequently, we use $O(1)$ lasers to separate $\widehat{R}_{v'}$ from $\widehat{R}_v \setminus \widehat{R}_{v'}$ for all children v' of v. These polylines subdivide $\widehat{R}_{v'}$ into smaller regions of area at most 1. Overall, we have used $O(1)$ lasers for each of these nodes $v \in T'_s$, $s \in \mathcal{S}$. Note that each region $\widehat{R}_v$ is the union of triangles from the Hershberger–Suri Steiner triangulation, and so each laser in OPT intersects $O(\log n)$ such regions. Consequently, we use $O(k^* \log n)$ lasers in Step 1.

Finally, consider the lasers used in Step 2 for subdividing the triangles $t \in T$ with $\text{area}(t) > 1$. By Lemma 4, each such triangle intersects at least $\Omega(\sqrt{\text{area}(t)})$ lasers in any valid solution; and conversely each laser of an optimal solution intersects $O(\log n)$ regions in T. Consequently, the number of lasers uses in Step 2 is $\sum_{t \in T} O(\sqrt{\text{area}(t)}) \leq O(k^* \log n)$.

It remains to show that the algorithm runs in $O(n + k)$ time. The Hershberger-Suri Steiner triangulation can be computed in $O(n)$ time [17]. It consists of $O(n)$ triangles, hence the combined size of the dual tree T_p, and the recursion trees T_s, $s \in \mathcal{S}$, is also $O(n)$. The unrefinement algorithm is done in a single traversal of these trees, spending $O(1)$ time at each node. For each large cell (triangle) of the Hershberger-Suri triangulation, by Lemma 4, we can compute a minimum bounding box and the *number* of lasers used by the algorithm in $O(1)$ time. Computing all k lasers requires $O(k)$ additional time. ◀

An $O(\log r)$ Approximation for Min-LaserArea in Simple Polygons. We can improve the approximation ratio in Theorem 5 from $O(\log n)$ to $O(\log r)$, where r is the number of reflex vertices of P, if we replace the Hershberger–Suri triangulation with a convex decomposition. (Hershberger and Suri decompose P into *triangles* to support ray shooting queries, but for our purposes a decomposition into convex cells suffices.)

Let $(v_1, \ldots, v_n)$ be the n vertices of P; assume they are in general position. Let R be the set of reflex vertices of P. For every reflex vertex $v \in R$, the angle bisector of the interior angle at v hits some edge $a_v b_v$ of P. Let $L = \{v, a_v, b_v : v \in R\}$, that is, L is the set of all reflex vertices of P, and both endpoints of the edges hit by the angle bisectors of reflex angles. Clearly, $|L| \leq 3r$.

▶ **Lemma 6.** *There is a simple polygon $Q \subset P$ whose vertex set is L, and every connected component of $P \setminus Q$ is a convex polygon. The polygon Q can be computed in $O(n \log n)$ time.*

Proof. We describe an algorithm that decomposes P along noncrossing diagonals into a collection $\mathcal{P}$ of convex polygons and their complement $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ will be polygon Q. Initially $\mathcal{P} = \{P\}$ and $Q = \emptyset$.

The algorithm has two steps. In the first step, a collection $\mathcal{P}$ of convex polygons is created such that the vertex set of the complement $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ is L. However, $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ is not necessarily connected. In the second step, the connected components of $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ are merged into a simple polygon Q (a single connected component) with the same vertex set L.

First step. While there is a nonconvex polygon $P' \in \mathcal{P}$, we replace P' with one or more smaller polygons in $\mathcal{P}$ as follows. Let v be a reflex vertex of P'. Since $P' \subset P$, vertex v is also a reflex vertex of P. Denote by $\vec{r}_v$ the angle bisector of P at v. Note that $\vec{r}_v$ enters the interior of P' at v; denote by ab the edge of P' where $\vec{r}_v$ first exits P'. Let $P(v)$ be the geodesic triangle formed by the edge ab and the shortest paths from v to a and to b, respectively. Update $\mathcal{P}$ by replacing P' with the polygons in $P' \setminus P(v)$. See Figure 4 for an example. In the course of the algorithm, every polygon in $\mathcal{P}$ is formed by a sequence of consecutive vertices of the input polygon P.

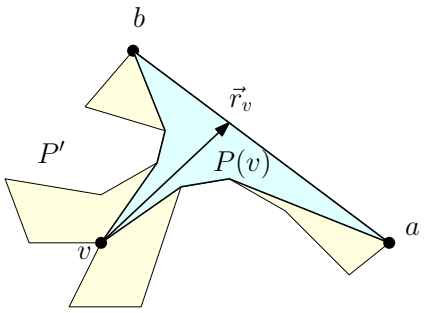

Figure 4 Replace P' by four polygons (in yellow), after taking out the geodesic triangle $P(v)$ where v is a reflex vertex.

We claim that in each iteration of the algorithm, all vertices of $P(v)$ are in L. Clearly, v is a reflex vertex in P', hence a reflex vertex of P, as well. Similarly, the interior vertices of the shortest paths from v to a and to b are reflex vertices in P', hence in P. It remains to show that $a, b \in L$. If ab is an edge of P, then $a, b \in L$ by the definition of L. Otherwise, ab is a diagonal of P, and so it is an edge of a geodesic triangle $P(v')$ of some previous iteration of the algorithm – by induction, they are in L, as well. At the end of the while loop, all polygons in $\mathcal{P}$ are convex, however, the complement $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ is not necessarily connected. See Figure 5 for an illustration.

Second step. While there is a (convex) polygon $P' \in \mathcal{P}$ incident to three or more vertices in L, we replace P' with smaller polygons: In particular, let $V(P')$ be the vertex set of P'. If $|V(P') \cap L| \geq 3$, then replace P' with the polygons in $P' \setminus \text{conv}(V(P') \cap L)$, where conv(.) stands for the convex hull. In each iteration, all polygons in $\mathcal{P}$ remain convex. At the end of the while loop, every polygon in $\mathcal{P}$ is incident to exactly two vertices in L, and $P \setminus (\bigcup_{A \in \mathcal{P}} A)$ is a simple polygon with vertex set L. ◀

▶ **Lemma 7.** *Every simple polygon P on n vertices, r of which are reflex, can be decomposed into convex faces such that every chord of P intersects $O(\log r)$ faces. Such a decomposition can be computed in $O(n \log n)$ time.*

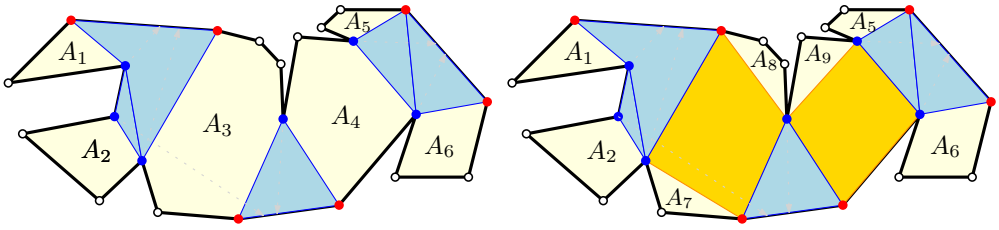

Figure 5 A simple polygon P, the vertices in L are blue (reflex) or red (hit by angle bisector). Left: The first step produces convex polygons $\mathcal{P} = \{A_1, \ldots, A_6\}$, but $P \setminus \bigcup_{i=1}^{6} A_i$ is disconnected. Right: The second step merges $P \setminus \bigcup_{i=1}^{6} A_i$ into a simple polygon Q. As $|A_3 \cap L| \geq 3$ and $|A_4 \cap L| \geq 3$, the second step creates $\text{conv}(V(A_3) \cap L)$ and $\text{conv}(V(A_4) \cap L)$ (shown in deep yellow) which merges $P \setminus \bigcup_{i=1}^{6} A_i$ into a single connected component Q.

Proof. We can compute the set L of up to $3r$ vertices and a simple polygon $Q \subset P$ described in Lemma 6 in $O(n \log n)$ time. We then compute the Hershberger–Suri triangulation for Q, which is a Steiner triangulation of $O(r)$ triangles such that every chord of Q intersects $O(\log r)$ triangles [17]. This triangulation of Q, together with the convex polygons in $P \setminus Q$, form a subdivision of P into convex faces.

We claim that every chord of P intersects at most $O(\log r)$ faces: at most $O(\log r)$ triangles in Q and at most two convex sets in $P \setminus Q$. If a chord ℓ of P intersects three components of $P \setminus Q$, say C_1, C_2, C_3 in this order, then ℓ crosses the boundary of C_2 twice, so C_2 must have at least two edges on the boundary between C_2 and Q. However, by Lemma 6, every edge of Q is either an edge or a diagonal of P. Therefore the boundary between Q and a component of $P \setminus Q$ is a single diagonal of P. Thus ℓ intersects at most two components of $P \setminus Q$; moreover $\ell \cap Q$ is a chord of Q, so it intersects $O(\log r)$ triangles inside Q. ◀

By performing the algorithm on the convex subdivision in Corollary 7, the approximation ratio improves to $O(\log r)$.

▶ **Theorem 8.** *Let P be a simple polygon with n vertices, r of which are reflex, and let k^* be the minimum number of lasers needed to subdivide P into pieces of area at most 1. We can find an integer k with $k^* \leq k \leq O(k^* \log r)$ in $O(n \log n)$ time, and a set of k lasers that subdivide P into pieces of area at most 1 in output-sensitive $O(k + n \log n)$ time.*

3.2 Bi-Criteria Approximation for Diameter

For the diameter version in a simple polygon, we describe a bi-criteria approximation algorithm (Theorem 11). We start from deriving a lower bound for the minimum number of lasers in a decomposition into pieces of diameter at most δ (for bi-criteria approximation algorithm we use general δ, instead of δ =1, because we will scroll over δ when using the algorithm to get an approximation for MinDiameter).

Consider the infinite set of vertical lines, $\mathcal{L}_V$, evenly spaced with separation δ; that is, $\mathcal{L}_V = \{x = i\delta : i \in \mathbb{Z}\}$. The lines in $\mathcal{L}_V$ decompose P into a set $\mathcal{P}_V$ of simple polygons, that we call *cells*. By construction, the orthogonal projection of each cell to the x-axis is an interval of length at most δ. (More precisely, we consider the polygon P to be a closed set in the plane. Subtracting the union of vertical lines $\mathcal{L}_V$ from P results in a set of connected components; the closures of these components are the simple polygons in $\mathcal{P}_V$). The polygons in $\mathcal{P}_V$ are faces in the arrangement of the lines in $\mathcal{L}_V$ and the edges of P; the planar dual of this decomposition is a tree, whose nodes are the faces $\mathcal{P}_V$ and whose edges are dual to the vertical lines.

If the projection of polygon $Q \in \mathcal{P}_V$ onto the x-axis is an interval of length δ (which means it extends from $x = i\delta$ to $x = (i+1)\delta$, for some integer i), we say that Q is a *full-width* cell; otherwise the projection of Q onto the x-axis is of length less than δ, and we say that Q is a *narrow* cell. (It may be that P itself is a narrow cell if, e.g., P does not intersect any of the vertical lines L_V.)

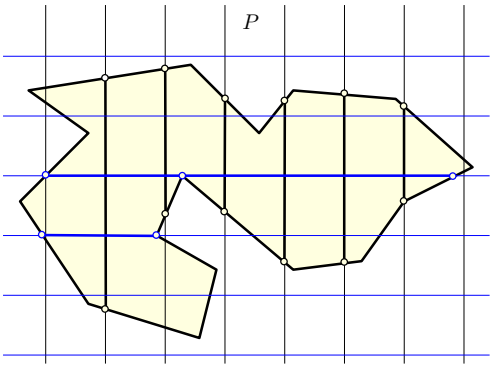

Figure 6 P is subdivided by a grid; the lasers are thick.

The intersection of the lines in $\mathcal{L}_V$ with P is a set of vertical chords of P. Let C_V be the set of these chords. While there is a chord $\ell \in C_V$ that lies on the boundary of some narrow cell, remove ℓ from C_V (thereby merging the cells on the two sides of ℓ into one cell). As a result, all remaining chords lie on the boundary between full-width cells. Let C'_V be the resulting set of chords, and let $k_V = |C'_V|$ denote their cardinality. Since any two full-width cells of $\mathcal{P}_V$ that are in adjacent vertical strips remain separated by a chord in C'_V, the x-extent of each face in the new decomposition of P is at most 3δ. We summarize this below.

▶ **Proposition 9.** *The remaining k_V chords C'_V, $k_V \geq 0$, subdivide P into a set $\mathcal{Q}$ of $k_V + 1$ polygons, each of which intersects at most two lines in $\mathcal{L}_V$, consequently its projection to the x-axis is an interval of length less than 3δ. Further, the dual graph of this decomposition is a tree (with k_V edges and $k_V + 1$ nodes).*

If $k_V = 0$, then there is just one cell, $\mathcal{Q} = \{P\}$. If $k_V \geq 1$, then each $Q \in \mathcal{Q}$ includes at least one full-width cell, since the only lasers remaining are those separating one full-width cell from an adjacent full-width cell sharing the laser.

Thus, the boundary of each $Q \in \mathcal{Q}$ includes at least two distinct (simple) paths connecting a point on one line of $\mathcal{L}_V$ to a point on an adjacent line of $\mathcal{L}_V$. Each of these paths has length at least δ. The endpoints of such a path are at distance at least δ away from each other. In any laser cutting of P into pieces of diameter at most δ, each such path contains a laser endpoint in its interior or at both endpoints (if the path is a horizontal line segment). In any case, each of these paths contains a laser endpoint in its interior or at its left endpoint. Thus overall, there must be at least $2|\mathcal{Q}| = 2(k_V + 1)$ endpoints of lasers. This implies that $k^* \geq k_V + 1$, where k^* is the minimum number of lasers in order to achieve pieces of diameter at most δ. Therefore we conclude,

▶ **Lemma 10.** *If $k_V \geq 1$, then $k^* \geq k_V + 1$.*

Now, we consider the set of horizontal lines, $\mathcal{L}_H = \{y = j\delta : j \in \mathbb{Z}\}$, and apply the above process to polygon P, yielding horizontal chords C_H, and then a subset $C'_H \subseteq C_H$ of chords after merging cells (removing lasers that separate a *full-height* cell from an adjacent *short*

cell). The result is a decomposition of P into $k_H+1 = |C'_H|+1$ pieces, each having projection onto the y-axis of length less than 3δ. Analogously to Lemma 10, we get $k^* \geq k_H + 1$ if $k_H \geq 1$.

If we now overlay the vertical chords C'_V and the horizontal chords C'_H, the resulting arrangement decomposes P into pieces each of which is a simple polygon having projections onto both the x- and the y-axis of lengths less than 3δ; thus, the resulting pieces each have diameter less than $3\delta\sqrt{2}$. The total number of lasers is $k_V + k_H \leq 2(k^* - 1)$.

▶ **Theorem 11.** *Let P be a simple polygon with n vertices, and let k^* be the minimum number of lasers that decompose P into pieces each of diameter at most δ for a fixed $\delta > 0$. One can compute a set of at most $2(k^* - 1)$ axis-aligned lasers that decompose P into pieces each of diameter at most $3\sqrt{2}\delta$ in time polynomial in n and $\mathrm{diam}(P)/\delta$.*

3.3 $O(1)$-Approximation for MinDiameter in Simple Polygons

In this section we consider the problem of minimizing the maximum diameter of a cell in the arrangement of k lasers, for a given number k. Our $O(1)$-approximation algorithm repeatedly decreases the x- and y- separation in the bi-criteria solution from Theorem 11 until the number of placed lasers is about to jump over $2k$; then, the number of lasers is halved while increasing the diameter by a constant factor.

Specifically, let $\ell(\delta)$ denote the number of lasers used in the end of the bi-criteria algorithm with the x- and y-separation between consecutive vertical and horizontal lines being δ. Our algorithm to approximate the diameter achievable with k lasers is as follows:

- Initialize $\delta = \mathrm{diam}(P)$, and $\varepsilon > 0$.
- While $\ell(\delta) \leq 2k$, set $\delta = \delta/(1+\varepsilon)$ and recompute $\ell(\delta)$.
- Let δ_0 be such that $\ell(\delta_0) \leq 2k$ but $\ell(\delta_0/(1+\varepsilon)) > 2k$.
- Let C_V and C_H be the $\ell(\delta_0) \leq 2k$ vertical and horizontal lasers, resp., found by the bi-criteria algorithm.
- Partition C_V into lasers along $x = i\delta_0$ for even i and the rest (odd i); let C'_V be a smallest part. Similarly, let C_H be a smaller part when we partition C_H into two subsets of lines where $y = i\delta_0$ is an even or odd multiple of δ_0.
- Return the lasers in $C'_V \cup C'_H$.

▶ **Theorem 12.** *Let P be a simple polygon with n vertices, and let δ^* be the optimal diameter achievable with k lasers. For every $\varepsilon > 0$, one can compute a set of at most k lasers that partition P into pieces each of diameter at most $4\sqrt{2}(1+\varepsilon)\delta^*$ in time polynomial in n, $\mathrm{diam}(P)/\delta^*$, and ε.*

The proof of Theorem 12 is presented in the full version of this paper.

4 Axis-Parallel Lasers

In this section we study Min-LaserDiameter and Min-LaserArea under the constraint that all lasers must be axis-parallel (the edges of P may have arbitrary orientations). The algorithms for both problems start with a "window partitioning" P into "(pseudo-)histograms" of stabbing number at most three, and are then tuned to the specific measures to partition the histograms. We use a simple sweepline algorithm for the diameter, and a dynamic program for the area. The main result is:

▶ **Theorem 13.** *Let P be a simple polygon with n vertices and let k^* be the minimum number of axis-parallel lasers needed to subdivide P into pieces of area (diameter) at most 1. There is an algorithm that finds $O(k^*)$ axis-parallel lasers that subdivide P into pieces of area (diameter) at most 1 in time polynomial in n and $\mathrm{area}(P)$ ($\mathrm{diam}(P)$).*

4.1 Reduction to Histograms

A *histogram* is a simple polygon bounded by an axis-parallel line segment, the *base*, and an x- or y-monotone polygonal chain between the endpoints of the base.

The *window partition* of a simple polygon was originally used for the design of data structures that support link distance queries [24, 30]. In this section, we use the axis-parallel version, which partitions a simple polygon P into histograms such that every axis-parallel chord of P intersects at most 3 histograms. Window partitions for orthogonal polygons can be computed by a standard recursion [24, 30]; we use a modified version where we recurse until the remaining subpolygons are below the size threshold 1. This modification guarantees termination on all simple polygons (not only orthogonal polygons).

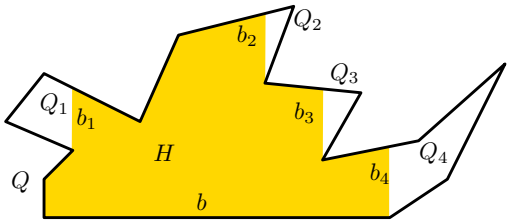

Figure 7 Window partition of a polygon Q with a horizontal base b into a maximal histogram H (colored gold) and four polygons Q_1, Q_2, Q_3, and Q_4 (in white). If the sizes (areas/diameters) of Q_1, Q_2, Q_3, and Q_4 are each at most 1, then Q is a pseudo-histogram.

Window Partition Algorithm. Given a simple polygon P, let b be an axis-parallel chord of P that subdivides P into two simple polygons P_1 and P_2 with a common base b. Let $\mathcal{S} = \{(P_1, b), (P_2, b)\}$ be a set of tuples where each tuple has a polygon and its axis-parallel base, and let $\mathcal{H} = \emptyset$ be the set of histograms. While $\mathcal{S}$ contains a pair (Q, b), where the size (e.g., the diameter) of Q is more than 1, do the following:

1. compute the maximal histogram[1] H of base b in Q, and add (H, b) to $\mathcal{H}$; see Figure 7;
2. update $\mathcal{S}$ by replacing (Q, b) with the pairs (Q_i, b_i), where the polygons Q_i are the connected components of $Q \setminus H$, and b_i is the boundary between Q_i and H.

Return $\mathcal{H}$ and $\mathcal{S}$.

Pseudo-histograms. Let T_1 and T_2 be the recursion trees of the algorithm, rooted at P_1 and P_2, respectively. Let $T = T_1 \cup T_2$. Each node $v \in T$ corresponds to a polygon $Q_v \subset P$. Every nonleaf node $v \in T$ also corresponds to a histogram $H_v \subset Q_v$; it is possible that $\text{size}(H_v) \leq 1$ but $\text{size}(Q_v) > 1$ (the size is area or diam based on the problem). For a leaf $v \in T$, we have either $\text{size}(Q_v) \leq 1$, or $H_v = Q_v$ and $\text{size}(H_v) > 1$. The polygons Q_v at leaf nodes and the histograms H_v at nonleaf nodes jointly form a subdivision of P.

Every node $v \in T$ in the recursion tree corresponds to a polygon-base pair (Q_v, b_v). For any subset $U \subset V(T)$, where $V(T)$ is the set of vertices of T, the bases $\{b_u : u \in U\}$ decompose P into simply connected cells. For every $u \in U$, there is a cell P_u in the decomposition such that $H_u \subset P_u \subset Q_u$. Since every axis-parallel chord of P crosses at most 2 bases, it can intersect at most 3 polygons in such a decomposition.

[1] Without loss of generality, assume b is horizontal. H can be obtained by taking all points of Q reachable through a vertical line from points on b.

In a bottom-up traversal of T, we can find a subset $U \subset V(T)$ such that $\{b_u : u \in U\}$ decomposes P into polygons P_u, $u \in U$, such that $\text{size}(P_u) > 1$ but the size of every component of $P_u \setminus H_u$ is at most 1. Each polygon P_u consists of a histogram H_u with base b_u, and subpolygons (*pockets*) of size at most 1 attached to some edges of H_u orthogonal to b_u. We call each such polygon P_u a *pseudo-histogram*. See Figure 7.

4.2 $O(1)$-Approximation for Min-LaserDiameter in Histograms

We start with an $O(1)$-approximation for histograms, and then extend our algorithm to pseudo-histograms and simple polygons. Without loss of generality, we assume that the base is horizontal.

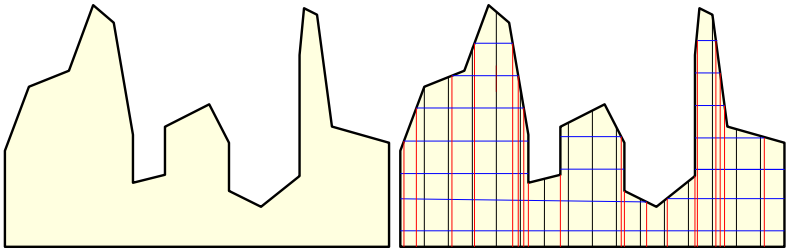

Figure 8 Left: A histogram polygon with a horizontal base. Right: lasers introduced in Phase 1 are shown in black. Horizontal (vertical) lasers introduced in Phase 2 are shown in blue (red).

▶ **Theorem 14.** *There is an algorithm that, given a histogram P with n vertices, computes an $O(1)$-approximation for the axis-parallel Min-LaserDiameter problem in time polynomial in n and $\text{diam}(P)$.*

Proof. We first describe the algorithm.

Algorithm. We are given a histogram P with a horizontal base ab. If $\text{diam}(P) \leq 1$, halt. Otherwise, do the following:

1. Subdivide ab into $\lceil 2|ab| \rceil$ intervals which all, except possibly one, have length $1/2$ and place vertical lasers on the boundary between consecutive intervals.
2. Sweep P with a horizontal line L top down, and maintain the set of cells formed by all lasers in step one and the line L. When the diameter of a cell C above L is precisely 1, place a horizontal laser pq along the bottom side of C, where $p, q \in \partial P$, and place two vertical lasers at p and q, respectively.

Analysis. Let OPT denote the set of lasers in an optimal solution, and let $k^* = |\text{OPT}|$. Denote by ALG the set of lasers computed by the algorithm; let ALG^1 be the number of vertical lasers computed in Phase 1, and let ALG^2_h and ALG^2_v be the set of horizontal and vertical lasers computed in Phase 2. Clearly, $|\text{ALG}^2_v| \leq 2|\text{ALG}^2_h|$. Therefore it is enough to prove that $|\text{ALG}^1| = O(k^*)$ and $|\text{ALG}^2_h| = O(k^*)$.

First we show that $|\text{ALG}^1| = O(k^*)$. The vertical lasers in OPT subdivide the base ab into segments of length at most 1. Therefore, $k^* \geq \lfloor |ab| \rfloor$. Combined with $k^* \geq 1$, this readily implies that $|\text{ALG}^1| = \lceil 2|ab| \rceil - 1 = O(k^*)$.

Next we prove that $|\text{ALG}^2_h| \leq 2k^*$ using a charging scheme. Specifically, we charge every laser in ALG^2_h to a laser in OPT such that each laser in OPT is charged at most twice. Recall for each laser $pq \in \text{ALG}^2_h$ placed by the algorithm, there is a cell $C = C_{pq}$ such that $\text{diam}(C_{pq}) = 1$ and pq contains the bottom edge of C_{pq}. Since $\text{diam}(C_{pq}) = 1$, the cell C_{pq}

intersects some laser in OPT; we charge pq to one of these lasers. Denote by $\mathrm{OPT}_h(C_{pq})$ and $\mathrm{OPT}_v(C_{pq})$, resp., the horizontal and vertical lasers in OPT that intersect C_{pq}. The charging scheme is described by the following rules:

(a) If $\mathrm{OPT}_h(C_{pq}) \neq \emptyset$, then charge pq to the lowest laser in $\mathrm{OPT}_h(C_{pq})$;
(b) else, if C_{pq} intersects ∂P, then charge pq to a laser in $\mathrm{OPT}_v(C_{pq})$ that is closest to $C_{pq} \cap \partial P$;
(c) else, if there is no horizontal laser in OPT that lies above pq, then charge pq to an arbitrary laser in $\mathrm{OPT}_v(C_{pq})$;
(d) else, charge pq to the lowest horizontal laser in OPT that lies above pq.

It remains to prove that each laser in OPT is charged at most once for each the four rules. Since (a) and (d) charge to horizontal lasers, and (b) and (c) charge to vertical lasers in OPT, then each laser in OPT is charged by at most two of the rules. In each case, we argue by contradiction. Assume that a laser $\ell \in \mathrm{OPT}$ is charged twice by one of the rules, that is, there are two lasers $pq, rs \in \mathrm{ALG}_h^2$, that are charged to ℓ by the same rule. The width of cells C_{pq} and C_{rs} is at most $1/2$, because of the spacing of the vertical lasers in ALG^1. Since $\mathrm{diam}(C_{pq}) = \mathrm{diam}(C_{rs}) = 1$, they each have height at least $\sqrt{3}/2$. Without loss of generality, we may assume that the algorithm chooses pq before rs.

(a) In this case, ℓ is the lowest horizontal laser in OPT that intersect C_{pq} and C_{rs}, respectively. Since pq is above rs, laser pq intersects the interior of C_{rs}, contradicting the assumption that C_{rs} is a cell formed by the arrangement of all lasers in ALG.
(b) In this case, ℓ is a vertical laser that intersects both C_{pq} and C_{rs}, and also intersect ∂P. When the algorithm places a horizontal laser at pq, it also places vertical lasers from p and q to the base of P. These three lasers separate ∂P from the portion of ℓ below pq. This contradict the assumption that C_{rs} is a cell formed by the arrangement of all lasers in ALG.
(c) In this case, both C_{pq} and C_{rs} intersects a vertical laser $\ell \in \mathrm{OPT}$, and they both lie above the highest horizontal laser that crosses ℓ. Consequently, they both intersect the two highest cells, say C_{left} and C_{right}, on the two sides of ℓ in the arrangement formed by OPT. The combined height of C_{pq} and C_{rs} is at least $\sqrt{3}$. Therefore, the height of C_{left} and C_{right} is at least $\sqrt{3} > 1$, contradicting the assumption that $\mathrm{diam}(C_{\mathrm{left}}) \leq 1$ and $\mathrm{diam}(C_{\mathrm{right}}) \leq 1$.
(d) In this case, ℓ is the lowest horizontal laser in OPT that lies above C_{pq} and C_{rs}, respectively. Let C_{below} be the cell of the arrangement of OPT that lies below ℓ. The combined height of C_{pq} and C_{rs} is at least $\sqrt{3}$. Therefore, the height of C_{below} is at least $\sqrt{3} > 1$, contradicting the assumption that $\mathrm{diam}(C_{\mathrm{below}}) \leq 1$. ◀

Adaptation to Pseudo-Histograms. In a laser cutting of P into pieces of diameter at most 1, each pseudo-histogram P_u intersects a laser, since $\mathrm{diam}(P_u) > 1$. An adaptation of the algorithm in Section 4.2 can find an $O(1)$-approximation for Min-LaserDiameter in each P_u. As noted above, each laser intersect at most 3 pseudo-histograms, hence the union of lasers in the solutions for pseudo-histograms is an $O(1)$-approximations for P.

The sweepline algorithm in Section 4.2 can easily be adapted to subdivide a pseudo-histogram P_u. Recall that P_u consists of a histogram H_u and pockets of diameter at most 1. We run steps 1 and 2 of the algorithm for the histogram H_u with two minor changes in step 2: (1) we compute the *critical* diameters with respect to P_u (rather than H_u), and (2) when the diameter of a cell C above a chord pq of P_u is precisely 1, we place up to *four* vertical lasers: at intersection points of L with ∂P_u the ∂H_u (the vertical lasers through $pq \cap \partial H_u$ cut possible pockets that intersect pq). The analysis of the sweepline algorithm is analogous to Section 4.2, and yields the following result.

▶ **Theorem 15.** *There is an algorithm that, given a simple polygon P with n vertices,computes an $O(1)$-approximation for the axis-parallel* Min-LaserDiameter *problem in time polynomial in n and* $\mathrm{diam}(P)$.

4.3 Discretization of the Solution Space in a Histogram Polygon

Consider a histogram polygon P having n vertices. We assume that the vertices are in general position, in the sense that no three vertices are collinear. We show that there is a discrete set of candidate orthogonal chords such that lasers chosen from this set yield an $O(1)$ approximation for minimizing the number of lasers, subject to a target measure bound 1 on the obtained pieces. This is useful for finding an $O(1)$ approximation for Min-LaserArea by dynamic programming.

We prove the following lemma in the full version, which extends to pseudo-histograms.

▶ **Lemma 16.** *For a histogram P, let k^* be the minimum number of axis-parallel lasers that subdivide P into pieces of area (diameter) at most 1. We can find a set C of $O(n + \mathrm{area}(P))$ ($O(n + per(P))$) chords of P, such that $O(k^*)$ lasers from C can subdivide P into pieces of area (diameter) at most 1.*

4.4 $O(1)$-Approximation for Min-LaserArea

We now consider the Min-LaserArea with axis-parallel lasers chosen from a discrete set to achieve pieces of area at most 1. An $O(1)$-approximation algorithm is based on the window partition method described earlier, allowing us to reduce to the case of subdividing a pseudo-histogram, for which we give a dynamic program to choose lasers from the discrete candidate set. In the full version, we describe the algorithm using area as the measure. With slight modifications, the algorithm also applies to the measure of diameter, allowing us to solve Min-LaserDiameter in pseudo-histograms (albeit in a higher polynomial time bound than stated in Theorem 14).

5 Diameter Measure in Polygons with Holes and Axis-Parallel Lasers

5.1 Bi-Criteria Approximation for Diameter

In this section we give a bi-criteria approximation for the diameter version in a polygon with holes when lasers are constrained to be axis-parallel. The approach is similar to the algorithm for simple polygons and lasers of arbitrary orientations (cf. Section 3.2) in that both use grid lines, but they differ significantly to handle holes in a polygon when the lasers are axis-parallel. Particularly, in simple polygons we place lasers along grid lines, while in polygons with holes the grid lines just divide the problem into sub-problems.

Lasers in Vertical Strips. Consider the infinite set of equally spaced vertical lines $\mathcal{L}_V = \{x = i\delta : i \in \mathbb{Z}\}$, for some $\delta > 0$. The lines subdivide P into a set $\mathcal{P}_V$ of polygons (possibly with holes), that we call *strips*. (Unlike Section 3.2, we do not place lasers along the lines in $\mathcal{L}_V$; we use the strips for a divide-and-conquer strategy.) The projection of any strip on the x-axis has length at most δ; we say that a strip is *full-width* if its projection has length exactly δ. Let $\mathcal{F}_V \subset \mathcal{P}_V$ denote the set of full-width strips, and let $F \in \mathcal{F}_V$ be a full-width strip.

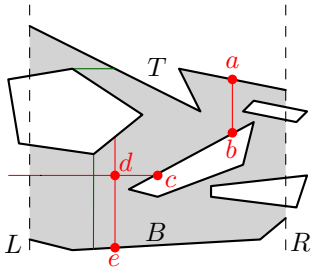

Figure 9 F is shaded, the holes are white. The L-R separating path $\gamma = abcde$ (vertices marked with red disks) alternates between holes and lasers (red) in the interior of P; $a_F(\gamma) = 2$ as there are two links ab and de in path γ whose extensions are fully contained in F. ab and cde are the maximal rectilinear subpaths of γ through the free space. The minimum-link path $\gamma(F)$ (darkgreen) also alternates between holes and free space.

The leftmost (resp., rightmost) points of F lie on a line $L = \{x = i\delta\}$ (resp., a line $R = \{x = (i+1)\delta\}$) for some $i \in \mathbb{Z}$ (see Fig. 9). Consequently, the outer boundary of F contains two simple paths between L and R; we denote them by T (top) and B (bottom).

Since the distance between L and R is δ, in any laser cutting of P into cells of diameter at most δ, there exists a T-B path $\gamma \subset F$ along the boundaries of cells that separates L and R. Since γ is disjoint from the interior of the cells, it must follow lasers in the interior of P. We may assume, w.l.o.g., that γ follows any laser at most once; otherwise we could shortcut γ along the laser. Since the lasers are axis-aligned, γ is an alternating sequence of subpaths that are either in ∂P or rectilinear paths through the interior of F; we call any such T-B path an *alternating* path.

An axis-aligned segment s, fully contained in F, is *associated* with F if it remains fully contained in F after it is maximally extended within P (i.e., if both endpoints of the supporting chord of P are on the boundary of F). For example, any *vertical* segment $s \subset F$ is associated with F (because T and B belong to the boundary of F). Let $a_F(\gamma)$ be the number of associated links of γ (i.e., the number of edges whose supporting chords are fully contained in F). Let $|\gamma|$ denote the total number of the (axis-aligned) edges in γ. A key observation is the following.

▶ **Lemma 17.** $|\gamma| \leq 3\, a_F(\gamma)$.

Proof. Let π be a (maximal) rectilinear subpath of γ through the free space, i.e., a part of γ whose endpoints lie on the boundary of P. If π is a single horizontal link, then the link is associated with F (because if any of its two ednpoints is outside F, then γ protrudes through L or R, not separating them). Otherwise (i.e., if π contains vertical links), the number of the vertical links is at least $1/3$ of the total number of links in π. The lemma follows by summation over all subpaths of γ. ◀

Our algorithm computes an alternating path $\gamma(F)$ with the minimum number of links and places one laser along every link of $\gamma(F)$ (the horizontal lasers may extend beyond F). To find $\gamma(F)$, we can build the *critical graph* of F, whose vertices are T, B, and components of ∂P within the strip F (including holes in the strip), and in which the weight of the edge between two vertices is the axis-parallel link distance between them. The weight of an edge between vertices i and j can be found by in polynomial time by standard wave propagation techniques [10, 26], i.e., by successively labeling the areas reachable with k links from i for increasing k, until j is hit by the wave. After the critical graph is built, $\gamma(F)$ is found as the shortest T-B path in the graph.

By minimality of $\gamma(F)$, the number links $|\gamma(F)|$ in it (and hence the number of lasers we place) is at most $|\gamma(F)|$. Let $k_V = \sum_{F \in \mathcal{F}_V} |\gamma(F)|$ be the total number of lasers placed in all full-width strips in $\mathcal{F}_V$, and let k^* be the minimum number of axis-parallel lasers in a laser cutting of P into cells of diameter at most δ. An immediate consequence of Lemma 17 is the following.

▶ **Corollary 18.** $k_V \leq 3k^*$.

Proof. As the links of $\gamma(F)$ follow lasers, at least $a_F(\gamma)$ lasers are fully contained in F. ◀

The k_V lasers placed in full-width strips subdivide P into polygonal pieces; let Q be one such piece.

▶ **Lemma 19.** *The length of the x-projection of Q on the x-axis is at most 2δ.*

Proof. We prove that Q intersects at most one line in $\mathcal{L}_V$. Suppose, to the contrary, that Q intersects two consecutive lines $\ell_1 : x = i\delta$ and $\ell_2 = x = (i+1)\delta$. Let λ be a shortest path in Q between points in $Q \cap \ell_1$ and $Q \cap \ell_2$, respectively. By minimality, λ lies in the strip between ℓ_1 and ℓ_2. Consequently, λ is contained in some full-width strip $F \subset \mathcal{F}_V$. However, the path $\gamma(F)$ intersects every path in F between $F \cap \ell_1$ and $F \cap \ell_2$; in particular, it intersects λ. Since we have placed a laser along every segment of $\gamma(F)$ in the interior of P, λ intersects a laser, contradicting the assumption that $\lambda \subset Q$. ◀

Lasers in Horizontal Strips. Similarly, we consider the set of horizontal lines $\mathcal{L}_H = \{y = j\delta : j \in \mathbb{Z}\}$ and apply the above process to P, yielding horizontal chords C_H that subdivide the polygon into horizontal strips (polygons, possibly with holes). We again work only with *full-height* strips, whose boundary intersect two consecutive lines in $\mathcal{L}_H$. In each full-height strip, we find a minimum-interior-link rectilinear path that separates the boundary points along the two lines in $\mathcal{L}_H$, and place lasers along the links of the path. Let k_H be the number of lasers over all full-height strips.

Putting Everything Together. We overlay the k_V lasers in full-width strips with the k_H lasers in full-height strips. The resulting arrangement partitions P into polygonal pieces (possibly with holes). The x- and y-projection of each piece has length at most 2δ by Lemma 19; thus, each piece has diameter less than $2\delta\sqrt{2}$. By Corollary 18, the total number of lasers used in the arrangement is $k_V + k_H \leq 6k^*$. We obtain the following theorem.

▶ **Theorem 20.** *Let P be a polygon with holes of diameter* $\operatorname{diam}(P)$ *having n vertices, and let k^* be the minimum number of laser cuts that partition P into pieces each of diameter at most δ for a fixed $\delta > 0$. In time polynomial in n and* $\operatorname{diam}(P)/\delta$*, one can compute a set of at most $6k^*$ lasers that subdivide P into pieces each of diameter at most $2^{3/2}\delta$.*

5.2 $O(1)$-Approximation to MinDiameter

Similarly to Section 3.3, we can use the bi-criteria algorithm to derive a constant-factor approximation for minimizing the maximum diameter of a cell in the arrangement of a given number k of axis-parallel lasers. Our $O(1)$-approximation algorithm (Theorem 21, proof in the full version) repeatedly decreases the x- and y- separation in the bi-criteria solution from Theorem 20 until the number of placed lasers is about to jump over $6k$; then, the number of lasers is decreased by a factor of 6 while increasing the diameter by a constant factor.

▶ **Theorem 21.** *Let δ^* be the minimum diameter achievable with k axis-parallel lasers. For every $\varepsilon > 0$, one can compute a set of at most k axis-parallel lasers that partition P into pieces each of diameter at most $12\sqrt{2}(1+\varepsilon)\delta^*$ in time polynomial in n,* $\operatorname{diam}(P)/\delta^*$*, and ε.*

6 $O(\log \mathrm{OPT})$-approximation for Min-LaserCircle

This section considers the radius of the largest inscribed circle as the measure of cell size; in particular, in Min-LaserCircle the goal is to split the polygon P (which may have holes) into pieces so that no piece contains a disk of radius 1. We give an $O(\log \mathrm{OPT})$-approximation algorithm for Min-LaserCircle based on reducing the problem to SetCover. The following reformulation is crucial for the approximation algorithm:

▶ **Observation 22.** *A set of lasers splits P into pieces of in-circle radius at most 1 if and only if every unit disk that lies inside P is hit by a laser.*

▶ **Theorem 23.** *For a polygon P with n vertices (possibly with holes), Min-LaserCircle admits an $O(\log \mathrm{OPT})$-approximation in time polynomial in n and $\mathrm{area}(P)$.*

Proof. We lay out a regular square grid of points at spacing of $\sqrt{2}$. The set of grid points within P is denoted by G. We may assume $|G| = O(\mathrm{area}(P))$ by a suitable (e.g., uniformly random) shift. Due to the spacing, every unit-radius disk in P contains a point of G (possibly on its boundary).

Consider an optimal set L^* of lasers that hit all unit disks that are contained within P. Replace each laser (chord) $c \in L^*$ with up to four anchored chords of the same homotopy type as c with respect to the vertices of P and the points G, obtained as follows: Shift the chord c vertically down (up), while keeping its endpoints on the same pair of edges of P, until it becomes incident to a point in G or a vertex of P, then rotate the chord clockwise (counterclockwise) around this point until it becomes incident to another point in G or a vertex of P. Since every unit disk within P contains a point of G, any unit disk within P that is intersected by c is also intersected by one of the shifted and rotated copies of c. This means that we can construct a candidate set, C, of $O((n + \mathrm{area}(P))^2)$ chords that can serve as lasers in an approximate solution, giving up at most a factor 4 of optimal. Further, in the arrangement of the segments C within P, any unit disk is intersected by some set of chords of C, thereby defining a combinatorial type for each unit disk in P. (Two disks are of the same type if they are intersected by the same subset of chords in C; one way to define the type is to associate it with a cell in the arrangement of lines drawn parallel to each chord $c \in C$ at distance 2 from c on each side of c. While the center of the disk is in one cell of the arrangement, the disk intersects the same chords.) Let D be the polynomial-size ($O(|C|^2)$) set of disks, one "pinned" (by two segments, from the set C and the set of edges of P) disk per combinatorial type. By construction, any set of chords from C that meets all disks of D must meet all unit disks within P.

We thus formulate a discrete set cover instance in which the "sets" correspond to the candidate set C of chords, and the "elements" being covered are the disks D. Since there are constant-size sets of disks that cannot be shattered, the VC dimension of the set system is constant, and an $O(\log \mathrm{OPT})$-approximate solution for the set cover can be found in time polynomial in the size of the instance [7]. ◀

The same algorithm works for the version in which the lasers are restricted to be axis-aligned (the only change is that the candidate set C consists of axis-aligned chords through points of the grid G and vertices of P).

Abstract

In most online problems with delay, clairvoyance (i.e. knowing the future delay of a request upon its arrival) is required for polylogarithmic competitiveness. In this paper, we show that this is not the case for set cover with delay (SCD) – specifically, we present the first non-clairvoyant algorithm, which is $O(\log n \log m)$-competitive, where n is the number of elements and m is the number of sets. This matches the best known result for the classic online set cover (a special case of non-clairvoyant SCD). Moreover, clairvoyance does not allow for significant improvement – we present lower bounds of $\Omega(\sqrt{\log n})$ and $\Omega(\sqrt{\log m})$ for SCD which apply for the clairvoyant case.

In addition, the competitiveness of our algorithm does not depend on the number of requests. Such a guarantee on the size of the universe alone was not previously known even for the clairvoyant case – the only previously-known algorithm (due to Carrasco et al.) is clairvoyant, with competitiveness that grows with the number of requests.

For the special case of vertex cover with delay, we show a simpler, deterministic algorithm which is 3-competitive (and also non-clairvoyant).

1 Introduction

In problems with delay, requests are released over a timeline. The algorithm must serve these requests by performing some action, which incurs a cost. While a request is pending (i.e. has been released but not yet served), the request accumulates delay cost. The goal of the algorithm is to minimize the sum of costs incurred in serving requests and the delay costs of requests.

There are two variants of such problems. In the clairvoyant variant, the delay function of a request (which determines the delay accumulation of that request over time) is revealed to the algorithm upon the release of the request. In the non-clairvoyant variant, at any point in time the algorithm is only aware of delay accumulated up to that point.

Most online problems with delay do not admit competitive non-clairvoyant algorithms – namely, there exist lower bounds for competitiveness which are polynomial in the size of the input space (e.g. the number of points in the metric space upon which requests are released). This is the case, for example, in the multilevel aggregation problem [10, 14], the facility location problem [7] and the service with delay problem [6]. However, these problems do admit *clairvoyant* algorithms which are polylog-competitive. An additional such problem is that of matching with delay (presented in [20]), for which the only known algorithms are for when all requests have an identical, linear delay function (and are in particular clairvoyant). Rather surprisingly, we show in this paper that the online set cover with delay problem *does* admit a competitive non-clairvoyant algorithm.

In the online set cover with delay problem (SCD), a universe of elements and a family of sets are known in advance. Requests then arrive over time on the elements, and accumulate delay cost until served by the algorithm. The algorithm may choose to buy a set at any time, at a cost specific to that set (and known in advance to the algorithm). Buying a set serves all pending requests (requests released but not yet served) on elements of that set; future requests on those elements, that have yet to arrive when the set is bought, must be served separately at a future point in time. For that reason, a set may be bought an unbounded number of times over the course of the algorithm. The goal of an algorithm is to minimize the sum of the total buying cost and the total delay cost. We note that one could also consider the problem in which sets are bought permanently, and cover future requests; however, it is easy to see that this problem is equivalent to the classic online set cover, and is thus of no additional interest. In the full version of this paper, we show that this problem is a special case of our problem.

As a variant of set cover, the SCD problem is very general, capturing many problems. Nevertheless, we give two possible motivations for the problem.

Summoning experts. consider a company which occasionally requires the help of experts. At any time, a problem may arise which requires external assistance in some field, and negatively impacts the performance of the company while unresolved. At any time, the company may hire any one of a set of experts to come to the company, solve all standing problems in that expert's fields of expertise, and then leave. The company aims to minimize the total cost of hiring experts, as well as the negative impact of unresolved problems.

Cluster-covering with delay. suppose antennas generate data requests over time, which must be satisfied by an external server, with a cost to leaving a request pending. To satisfy an update request by an antenna, the server sends the data to a center antenna which transmits it at a certain radius, at a certain cost (which depends on the center antenna and the radius). All requests on antennas inside that radius are served by that transmission. This problem is a covering problem with delay costs, which can be described in terms of SCD. As an SCD instance, the elements are the antennas, and the sets are pairs of a center antenna and a (reasonable) transmission radius (the number of sets is quadratic in the number of antennas).

Carrasco et al. [15] provided a clairvoyant algorithm for the SCD problem, which is $O(\log N)$ competitive (where N is the number of the requests). However, as the number of requests becomes large, the competitive ratio of this algorithm tends to infinity – even for a

very small universe of elements and sets. Thus, this algorithm does not provide a guarantee in terms of the underlying input space, as we would like. In addition, their algorithm has exponential running time (through making oracle calls which compute optimal solutions for NP-hard problems).

In this paper, we present the first algorithm for SCD which is polylog-competitive in the size of the universe, which is also the first algorithm for the problem which runs in polynomial time. Surprisingly, this algorithm is also non-clairvoyant, showing that the SCD problem admits non-clairvoyant competitive algorithms. Our randomized algorithm is $O(\log n \log m)$-competitive, where n is the number of elements and m is the number of sets. In this paper, we show a reduction from the classic online set cover to SCD, which implies (due to [27]) that our upper bound is tight for a polynomial-time, non-clairvoyant algorithm for SCD.

While our algorithm is optimal for the non-clairvoyant setting, one could wonder if there exists a *clairvoyant* algorithm which performs significantly better – especially considering the aforementioned problems, in which the gap between the clairvoyant and non-clairvoyant cases is huge. We answer this in the negative – namely, we show lower bounds of $\Omega(\sqrt{\log n})$ and $\Omega(\sqrt{\log m})$ on the competitiveness of any randomized clairvoyant algorithm, showing that there is no large gap which clairvoyant algorithms could bridge. Nevertheless, a quartic gap still exists, e.g. in the case that $m = \Theta(n)$. We conjecture that the gap is in fact quadratic, and leave this as an open problem.

In this paper, we also consider the problem of vertex cover with delay (denoted VCD). In the VCD problem, vertices of graph are given, with a buying cost associated with each vertex. Requests on the edges of the graph arrive over time, and accumulate delay until served by buying a vertex touching the edge (at the cost of that vertex's price). This problem corresponds to SCD where every element is in exactly two sets.

1.1 Our Results

We denote as before the number of elements in an SCD instance by n, and the number of sets by m. We also define $k \leq m$ to be the maximum number of sets to which a specific element may belong. We consider arbitrary (nondecreasing) continuous delay functions (not only linear functions).

In this paper, we present:

1. An $O(\log k \cdot \log n)$-competitive, randomized, non-clairvoyant algorithm for SCD, based on rounding of a newly-designed $O(\log k)$-competitive algorithm for the fractional version of SCD. The competitive ratio of this algorithm is tight – we show a reduction from (classic) online set cover to non-clairvoyant SCD.
2. Lower bounds of $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$ on competitiveness for **clairvoyant** SCD, showing that clairvoyance cannot improve competitiveness beyond a quadratic factor.
3. A simple, deterministic, non-clairvoyant algorithm for vertex cover with delay (VCD) which is 3-competitive.

Our randomized algorithm for SCD is the first (sub-polynomial competitive) non-clairvoyant algorithm for this problem. Moreover, this is the first algorithm which is polylog-competitive in the size of the universe (even among clairvoyant algorithms).

In the process of obtaining our $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$ lower bounds, we in fact obtain an $\Omega(\sqrt{\log m})$ lower bound (which immediately implies $\Omega(\sqrt{\log k})$ since $k \leq m$). The lower bounds also apply for the unweighted setting. These lower bounds improve over the lower bound of $\Omega(\log \log n)$ given in [15][1].

For VCD, while our algorithm is 3-competitive, note that there is a lower bound of 2. The lower bound uses a graph with a single edge which is requested multiple times; this graph corresponds to the TCP acknowledgment problem, analyzed in [19].

▶ Remark 1. While our $O(\log k \cdot \log n)$-competitive algorithm is presented for the case in which the sets and elements are known in advance, it can easily be modified for the case in which each element, as well as which of the sets contain it, becomes known to the algorithm only after the arrival of a request on that element. Moreover, the algorithm can in fact operate in the original setting of Carrasco et al. [15], as it does not need to know the family of sets itself, but rather the family of *restrictions* of the sets to the elements that have already arrived. This can be done through standard doubling techniques applied to $\log n$ and $\log k$ (i.e. squaring of n and k).

1.2 Our Techniques

In the course of designing a non-clairvoyant algorithm for the SCD problem, we also consider a fractional version of SCD. In this version, an algorithm may choose to buy a fraction of a set at any moment. Buying a fraction of a set partially serves requests present on an element of that set, which causes them to accumulate less future delay. As with the original version, a request is only served by fractions bought after its arrival. Hence, the sum of fractions bought for a single set over time is unbounded (i.e. a set may be bought many times).

In the **fractional $O(\log k)$-competitive algorithm**, each request that can be served by a set contributes some amount to the buying of that set. This amount depends exponentially on the delay accumulated by that request, as well as the delay of previous requests. Typically in algorithms with exponential contributions, these contributions are summed. Interestingly, our algorithm instead chooses the maximum of the contributions of the requests as the buying function of the set. The choice of maximum over sum is crucial to the proof (using sum instead of maximum would lead to a linear competitive ratio).

The analysis of this algorithm is based on dual fitting: we first present a linear programming representation of the fractional SCD problem, then use a feasible solution to the dual problem to charge the delay of the algorithm to the optimum. This is the reason for using the maximum in the buying function; each quantity satisfies a different constraint in the dual, and choosing the maximum satisfies all constraints. We then charge the buying cost of the algorithm to $O(\log k)$ times its delay, which concludes the analysis.

Next, we design a randomized competitive algorithm for the integer version of SCD using *2-level* randomized rounding of the fractional algorithm. At the *top level*, we construct a **randomized $O(\log k \cdot \log N)$-competitive algorithm for the integer version**, with N the number of requests. The top-level rounding consists of maintaining for each set a random threshold, and buying the set when the total buying of that set in the *fractional* algorithm exceeds the threshold. In addition, special service of a request is performed in the probabilistically unlikely event that the request is half-served in the fractional algorithm

[1] The lower bound of [15] shows $\Omega(\log N)$-competitiveness, but relies on a universe which is exponentially larger than the number of requests. As they mention in their paper, this therefore translates to an $\Omega(\log \log n)$ lower bound on competitiveness.

but is still pending in the rounding. Since in our problem we may buy a set an unbounded number of times, we require use of multiple subsequent thresholds. To analyze this, we make use of Wald's equation for stopping time.

We add the *bottom level* to improve the $O(\log k \cdot \log N)$-competitive algorithm to a **randomized $O(\log k \cdot \log n)$-competitive algorithm for the integer version**. The bottom level partitions time into phases for each element separately, and aggregates requests on that element that are released in the same phase. The competitive ratio of the resulting algorithm is asymptotically optimal for solving non-clairvoyant SCD in polynomial time, as shown by the reduction from the classic online set cover to non-clairvoyant SCD given in the full version of this paper.

Perhaps the most novel techniques in this paper are used for **the lower bounds of $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$** for the clairvoyant case. The lower bounds are obtained by a recursive construction. Given a recursive instance for which any algorithm has a lower bound on the competitive ratio, we amplify that bound by duplicating every set in the recursive instance into two sets, one slightly more expensive than the other. Both sets perform the same function with respect to the recursive instance, but the algorithm also has an incentive to choose the expensive family of sets, since they serve some additional requests. If the algorithm chooses to buy a lot of expensive sets, the optimum releases another copy of the recursive instance, serviceable only by expensive sets. This forces the algorithm to buy the expensive sets twice; the optimum only buys them once. If, on the other hand, the algorithm chooses the inexpensive sets, it misses the opportunity to serve the additional requests and the recursive instance simultaneously, and must serve them separately.

The recursive description of our construction for the lower bounds is significantly more natural than its iterative description. Few lower bounds in online algorithms have this property – another such lower bound is found in [8].

The 3-competitive deterministic algorithm for VCD is simple and based on counters. This algorithm is only $k + 1$ competitive for general SCD, and is thus significantly worse than the previous randomized algorithm that we have shown for general SCD.

1.3 Other Related Work

A different problem called online set cover is considered in [3], in which the algorithm accumulates value for every element that arrives on a bought set, and aims to maximize total value. This problem appears to be fundamentally different from the online set cover in which we minimize cost, in both techniques and results.

The problem of set cover in the online setting has seen much additional work, e.g. in [22, 9, 18, 29, 1]. The set cover problem has also been studied in the streaming model (e.g. [21, 16]), stochastic model (e.g. [24]), dynamic model (e.g. [23]), and in the context of universal algorithms (e.g. [25, 22]) and communication complexity (e.g. [28]).

There are known inapproximability results for the (offline) set cover and vertex cover problems. In [17] it is shown that the offline set cover problem is unlikely to be approximable in polynomial time to within a factor better than $\ln n$. For the offline vertex cover, it is shown in [26] that it is NP hard to approximate within a factor better than 2, assuming the *Unique Games Conjecture*. These results apply to our SCD and VCD problems, as an instance of offline set cover (or vertex cover) can be released at time 0. Of course, these inapproximability results do not constitute lower bounds for the online model, in which unbounded computation is allowed – unlike the information-theoretic lower bound of $\Omega(\sqrt{\log n})$ for SCD which is given in this paper.

The field of online problems with delay over time has been of interest recently. This includes the problems of min-cost perfect matching with delays [20, 5, 2, 12, 11, 4], online service with delay [6, 13, 7] and multilevel aggregation [10, 14, 7].

Paper Organization

In Section 3, we present and analyze a fractional non-clairvoyant algorithm for SCD. In Section 4, we show how to round the previous algorithm in a non-clairvoyant manner to obtain our algorithm for the original (integral) SCD. In Section 5, we show lower bounds for clairvoyant SCD. In the full version of this paper, we show that the algorithm obtained in Section 4 is optimal for the non-clairvoyant case. In Section 6, we give a simple, deterministic, non-clairvoyant algorithm for vertex cover with delay.

2 Preliminaries

We denote the sets by $\{S_i\}_{i=1}^m$, with m the number of sets. We denote by n the number of elements. We define k to be the minimal number for which every element belongs to at most k sets. Requests q_j arrive on the elements. We denote the arrival time of request q_j by r_j, and write (with a slight abuse of notation) $q_j \in S_i$ if the element on which q_j has been released belongs to the set S_i.

Each request q_j has an arbitrary momentary delay function $d_j(t)$, defined for $t \geq r_j$. The accumulated delay of the request at time $t \geq r_j$ is defined to be $\int_{r_j}^{t} d_j(t)\,\mathrm{d}t$. At any time in which a request is pending, its momentary delay is added to the cost of the algorithm; that is, the algorithm incurs a cost of $\int_{r_j}^{\tau_j} d_j(t)\,\mathrm{d}t$ (the accumulated delay of q_j at time τ_j) for every request q_j, where τ_j is the time in which q_j is served. Each set S_i has a price $c(S_i) \geq 1$ which the algorithm must pay when it decides to buy the set. Buying a set serves all pending requests which belong to the set (but does not affect future requests). The *buying cost* of an online algorithm ON is $\mathrm{Cost}^p_{\mathrm{ON}} = \sum_i n_i \cdot c(S_i)$, where n_i is the number of times S_i has been bought by the algorithm. The *delay cost* of ON is $\mathrm{Cost}^d_{\mathrm{ON}} = \sum_j \int_{r_j}^{\tau_j} d_j(t)\,\mathrm{d}t$, where τ_j is the time in which q_j is served by the algorithm (τ_j is ∞ if q_j is never served by the algorithm)[2].

Overall, the cost of ON for the problem is $\mathrm{Cost}_{\mathrm{ON}} = \mathrm{Cost}^p_{\mathrm{ON}} + \mathrm{Cost}^d_{\mathrm{ON}}$

3 The Non-Clairvoyant Algorithm for Fractional SCD

We first describe a fractional relaxation of the (integer) set cover with delay problem. In this fractional relaxation, a set can be bought in parts. A fractional algorithm determines for each set S_i a nonnegative momentary buying function $x_i(t)$. The total buying cost a fractional online algorithm F incurs is $\mathrm{Cost}^p_F = \sum_i c(S_i) \cdot \int_0^\infty x_i(t)\,\mathrm{d}t$.

In the fractional version, a request can be partially served. Under a fractional algorithm F, for any request q_j, and any set S_i such that $q_j \in S_i$, the set S_i covers q_j at a time $t \geq r_j$ by the amount $\int_{r_j}^{t} x_i(t')\,\mathrm{d}t'$ (which is obviously nondecreasing as a function of t). The total amount by which q_j is covered at time t is

$$\gamma_j(t) = \sum_{i|q_j \in S_i} \int_{r_j}^{t} x_i(t')\,\mathrm{d}t'.$$

[2] We solve the more general problem in which the algorithm doesn't have to serve all requests (observe that the adversary can still force the algorithm to serve all requests by adding infinite delay at time infinity). This allows the problem to capture additional problems (e.g. prize-collecting problems, in which a penalty could be paid to avoid serving a specific request)

If at time t we have $\gamma_j(t) \geq 1$, then q_j is considered served, and the algorithm does not incur delay. However, if $\gamma_j(t) < 1$, the algorithm F incurs delay proportional to the uncovered fraction of q_j. Formally, at time t the request q_j incurs $d_j^F(t)$ delay in F, where

$$d_j^F(t) = \begin{cases} d_j(t) \cdot (1 - \gamma_j(t)) & \text{if } \gamma_j(t) < 1 \\ 0 & \text{otherwise} \end{cases} \tag{3.1}$$

The delay cost of the algorithm is $\text{Cost}_F^d = \sum_j \int_{r_j}^{\infty} d_j^F(t)\,\mathrm{d}t$. The total cost of the fractional algorithm is thus $\text{Cost}_F = \text{Cost}_F^p + \text{Cost}_F^d$.

Description of the algorithm. We now describe an online algorithm called ONF for the fractional problem.

We define a total order $\preceq$ on requests, such that for any two requests q_{j_1}, q_{j_2} if $r_{j_1} < r_{j_2}$ we have $q_{j_1} \prec q_{j_2}$ (we break ties arbitrarily between requests with equal arrival time).

At any time t, the algorithm does the following.

1. For every request q_j, evaluate $d_j^{\text{ONF}}(t)$ by its definition in Equation 3.1.
2. For every set S_i and request $q_j \in S_i$, define
$$D_i^j(t) = \sum_{j' | q_{j'} \in S_i \wedge q_{j'} \preceq q_j} d_{j'}^{\text{ONF}}(t).$$
3. For every set S_i and request $q_j \in S_i$, define
$$x_i^j(t) = \frac{1}{k} \cdot \left(\frac{\ln(1+k)}{c(S_i)} \cdot D_i^j(t) \right) \cdot e^{\frac{\ln(1+k)}{c(S_i)} \int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'}.$$
4. Buy every set S_i according to $x_i(t)$, such that
$$x_i(t) = \max_j x_i^j(t).$$

This completes the description of the algorithm.

The intuition for the algorithm is that at any time t, the amount $\int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'$ is delay incurred by the algorithm until time t that the optimum possibly avoided by buying S_i at time r_j, and thus the algorithm wishes to minimize this amount. Thus, the request q_j places some "demand" on the algorithm to buy S_i. Since this is true for any $q_j \in S_i$, the algorithm chooses the maximum of the demands as the buying function of S_i.

This demand $x_i^j(t)$ placed on the algorithm by q_j to buy S_i is related to $\int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'$. If we wanted to make the total buying proportional to $\int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'$, it would sound reasonable to set $x_i^j(t)$ to be its derivative, namely $D_i^j(t)$. However, this would only be $\Omega(k)$-competitive, as demonstrated in Figure 3.1. We thus want the total buying to be proportional to an expression exponential in $\int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'$, which underlies the definition of $x_i^j(t)$ in our algorithm.

Denoting $X_i^j(t) = \int_{r_j}^{t} x_i^j(t')\,\mathrm{d}t'$, note that

$$X_i^j(t) = \frac{1}{k} \cdot \left[e^{\frac{\ln(1+k)}{c(S_i)} \int_{r_j}^{t} D_i^j(t')\,\mathrm{d}t'} - 1 \right]. \tag{3.2}$$

In the rest of this section, we prove the following theorem.

▶ **Theorem 2.** *The algorithm for fractional SCD described above is $O(\log k)$-competitive.*

We now analyze the algorithm for fractional SCD and prove Theorem 2.

In this figure, there are $k-1$ elements, where each element is contained in k sets of cost 1, one central set (which contains all elements) and $k-1$ peripheral sets (each contains exactly one element). Consider $k-1$ requests, one on each element, all arriving at time 0. Their delay functions are identical, and go to infinity as time progresses.
Consider an algorithm which buys sets linearly to the delay - that is, $x_i(t) = \max_j D_i^j(t) = \sum_{j|q_j \in S_i} d_j^{\text{ONF}}(t)$. The momentary delay of every request contributes equally to the buying functions of the k containing sets. Thus, the total fraction bought of peripheral sets is exactly $k-1$ times the total fraction bought of the central set. Consider the point in time in which all requests are half-covered (through symmetry, this happens for all requests at the same time, and must happen since the requests gather infinite delay). We have that the central set was bought for a fraction of exactly $\frac{1}{4}$ (which can again be seen through symmetry of the requests and their delay). Thus, the peripheral sets were bought for a fraction of $\frac{k-1}{4}$, for a total of $\frac{k}{4}$. Consider that the optimal solution costs 1, as the optimum buys the central set at time 0.

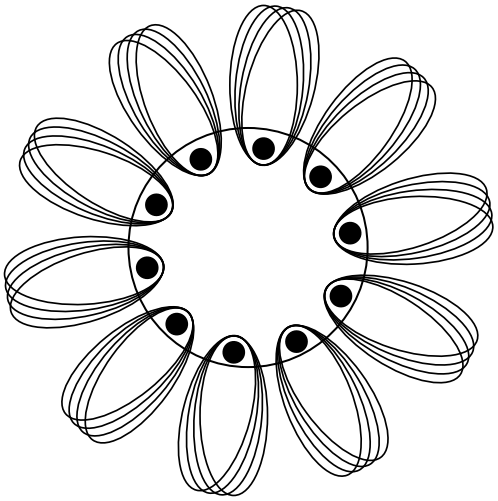

Figure 3.1 Linear Buying $\Omega(k)$ Example.

3.1 Charging Buying Cost to Delay

In this subsection we prove the following lemma.

▶ **Lemma 3.** $Cost^p_{\text{ONF}} \leq 2\ln(1+k) \cdot Cost^d_{\text{ONF}}$.

Proof. The proof is by charging the momentary buying cost at any time t to the $2\ln(1+k)$ times the momentary delay incurred by ONF at t. Let q_j be some request released by time t. For every i such that $q_j \in S_i$, we charge some amount $z_i^j(t)$ to $d_j^{\text{ONF}}(t)$. Denote by j_i the request in S_i such that

$$x_i(t) = x_i^{j_i}(t).$$

If $q_j \preceq q_{j_i}$, we choose

$$z_i^j(t) = \frac{\ln(1+k)}{k} \cdot d_j^{\text{ONF}}(t) \cdot e^{\frac{\ln(1+k)}{c(S_i)} \int_{r_{j_i}}^{t} D_i^{j_i}(t')\,\mathrm{d}t'}.$$

Otherwise, we choose $z_i^j(t) = 0$. Note that for every set S_i we have $\sum_{j|q_j \in S_i} z_i^j(t) = c(S_i) \cdot x_i(t)$, and thus the entire buying cost is charged.

The total buying cost charged to a request q_j at time t is $\sum_{i|q_j \in S_i} z_i^j(t)$. We show that for any j we have

$$\sum_{i|q_j \in S_i} z_i^j(t) \leq 2\ln(1+k) \cdot d_j^{\text{ONF}}(t).$$

Summing the previous equation over requests q_j and integrating over time yields the lemma.

If $d_j^{\text{ONF}}(t) = 0$ we have $z_i^j(t) = 0$ for every i, as required. From now on, we assume that $d_j^{\text{ONF}}(t) > 0$.

Denote by $T_j = \{i | q_j \in S_i \text{ and } z_i^j > 0\}$. We have

$$\begin{aligned}\sum_{i|q_j \in S_i} z_i^j(t) &= \sum_{i \in T_j} z_i^j(t) \\ &= \ln(1+k) \cdot d_j^{\text{ONF}}(t) \cdot \sum_{i \in T_j} \frac{1}{k} \cdot e^{\frac{\ln(1+k)}{c(S_i)} \int_{r_{j_i}}^t D_i^{j_i}(t')\,\mathrm{d}t'}.\end{aligned}$$

Now note that

$$\begin{aligned}\frac{1}{k} \cdot e^{\frac{\ln(1+k)}{c(S_i)} \int_{r_{j_i}}^t D_i^{j_i}(t')\,\mathrm{d}t'} &= \frac{1}{k} + X_i^{j_i}(t) \\ &\leq \frac{1}{k} + \int_{r_{j_i}}^t x_i(t')\,\mathrm{d}t' \\ &\leq \frac{1}{k} + \int_{r_j}^t x_i(t')\,\mathrm{d}t'\end{aligned}$$

where the equality is due to equation 3.2, the first inequality is due to the definition of $X_i^{j_i}(t)$ and since $x_i(t) \geq x_i^{j_i}(t)$, and the last inequality is due to $q_j \preceq q_{j_i}$.

Thus

$$\sum_{i|q_j \in S_i} z_i^j(t) \leq \ln(1+k) \cdot d_j^{\text{ONF}}(t) \cdot \sum_{i \in T_j} \left(\frac{1}{k} + \int_{r_j}^t x_i(t')\,\mathrm{d}t'\right) \leq 2\ln(1+k) \cdot d_j^{\text{ONF}}(t)$$

where the last inequality follows from $|T_j| \leq k$, and from $\sum_{i|q_j \in S_i} \int_{r_j}^t x_i(t')\,\mathrm{d}t' \leq 1$ (due to the assumption that $d_j^{\text{ONF}}(t) > 0$). ◀

3.2 Charging Delay to Optimum

In this subsection, we charge the delay of the algorithm to the optimum via dual fitting.

3.2.1 Linear Programming Formulation

We formulate a linear programming instance for the fractional problem, and observe its dual instance.

Primal. In the primal instance, the variables are:

- $x_i(t)$ for a set S_i and time t, which is the fraction by which the algorithm buys S_i at time t.
- $p_j(t)$ for a request q_j and time $t \geq r_j$, which is the fraction of q_j not covered by bought sets at time t.

The LP instance is therefore:

Minimize:

$$\sum_i \int_0^\infty c(S_i) \cdot x_i(t)\,\mathrm{d}t + \sum_j \int_{r_j}^\infty p_j(t) \cdot d_j(t)\,\mathrm{d}t$$

under the constraints:

$$\forall j, t \geq r_j : p_j(t) + \sum_{i|q_j \in S_i} \int_{r_j}^t x_i(t')\,\mathrm{d}t' \geq 1$$

$$p_j(t) \geq 0\,,\; x_i(t) \geq 0.$$

Dual. Maximize:

$$\sum_j \int_{r_j}^\infty y_j(t)\,\mathrm{d}t$$

under the constraints:

$$\forall i, t : \sum_{j|q_j \in S_i \wedge r_j \leq t} \int_t^\infty y_j(t')\,\mathrm{d}t' \leq c(S_i) \tag{C1}$$

$$\forall j, t \geq r_j : y_j(t) \leq d_j(t) \tag{C2}$$

$$y_j(t) \geq 0.$$

▶ Remark 4. As we chose to consider time as continuous, the linear program described here has an infinite number of variables and constraints. This is merely a choice of presentation, as discretizing time would yield a standard, finite LP. Nevertheless, weak duality for this infinite LP (the only duality property used in this paper) holds (see e.g. [30]).

3.2.2 Charging Delay to Optimum via Dual Fitting

We now charge the delay of the fractional algorithm to the cost of the optimum.

▶ **Lemma 5.** $Cost^d_{\mathrm{ONF}} \leq Cost_{OPT}$.

Proof. The proof is by finding a solution to the dual problem, such that the goal function value of the solution is equal to the delay of the algorithm.

For every request q_j and time t, we assign $y_j(t) = d_j^{\mathrm{ONF}}(t)$. This assignment satisfies that the goal function is the total delay incurred by the algorithm.

Note that the C2 constraints trivially hold, since $d_j^{\mathrm{ONF}}(t) \leq d_j(t)$ for any j, t. Now observe the C1 constraints. For any time t and a set S_i, the resulting C1 constraint is implied by the C1 constraint of time r_j and the set S_i, with q_j being the last request released by time t. We thus restrict ourselves to C1 constraints of time r_j for some j.

For a request q_j and a set S_i, we need to show:

$$\sum_{j'|q_{j'} \in S_i \wedge q_{j'} \preceq q_j} \int_{r_j}^\infty d_{j'}^{\mathrm{ONF}}(t')\,\mathrm{d}t' \leq c(S_i).$$

Using the definition of $D_i^j(t)$, we need to show:

$$\int_{r_j}^{\infty} D_i^j(t)\,\mathrm{d}t \le c(S_i).$$

Define t_0 to be the minimal time (possibly ∞) such that for all $t \ge t_0$ we have $D_i^j(t) = 0$. We must have that $\int_{r_j}^{t_0} x_i(t)\,\mathrm{d}t \le 1$; otherwise, all requests $q_{j'} \in S_i$ such that $q_{j'} \preceq q_j$ will be completed before t_0, in contradiction to t_0's minimality. Thus we have

$$\begin{aligned} 1 &\ge \int_{r_j}^{t_0} x_i(t)\,\mathrm{d}t \ge \int_{r_j}^{t_0} x_i^j(t)\,\mathrm{d}t \\ &= \frac{1}{k}\left[e^{\frac{\ln(1+k)}{c(S_i)}\int_{r_j}^{t_0} D_i^j(t)\,\mathrm{d}t} - 1\right] \end{aligned}$$

where the second inequality is due to the definition of $x_i(t)$, and the equality is due to equation 3.2. This yields

$$(1+k)^{\frac{1}{c(S_i)}\int_{r_j}^{t_0} D_i^j(t)\,\mathrm{d}t} \le 1+k$$

and thus

$$\int_{r_j}^{\infty} D_i^j(t)\,\mathrm{d}t = \int_{r_j}^{t_0} D_i^j(t)\,\mathrm{d}t \le c(S_i)$$

as required. ◀

We can now prove the main theorem.

Proof of Theorem 2. Using Lemmas 3 and 5, we have

$$\begin{aligned} \mathrm{Cost}_{\mathrm{ONF}} &= \mathrm{Cost}^p_{\mathrm{ONF}} + \mathrm{Cost}^d_{\mathrm{ONF}} \\ &\le (2\ln(1+k)+1)\cdot \mathrm{Cost}^d_{\mathrm{ONF}} \\ &\le (2\ln(1+k)+1)\cdot \mathrm{Cost}_{OPT} \end{aligned}$$

as required. ◀

▶ Remark 6. For the more difficult delay model in which a partially served request q_j incurs delay $d_j^{\mathrm{ONF}}(t) = d_j(t)$ instead of $d_j^{\mathrm{ONF}}(t) = d_j(t)\cdot(1-\gamma_j(t))$ in ONF, this algorithm is still $O(\log k)$ competitive against the fractional optimum in the easier delay model. The proof is identical.

4 Randomized Algorithm for SCD by Rounding

In this section, we describe a non-clairvoyant, polynomial-time randomized algorithm which is $O(\log k \cdot \log n)$-competitive for integral SCD. Our randomized algorithm uses randomized rounding of the fractional algorithm of Section 3. We describe the rounding in two steps. First, we show a somewhat simpler algorithm which is $O(\log k \cdot \log N)$-competitive. We then modify this algorithm to obtain a $O(\log k \cdot \log n)$-competitive algorithm.

The rounding of the fractional algorithm of section 3 costs the randomized integral algorithm of this section a multiplicative factor of $\log n$ over that fractional algorithm.

Denote by $x_i(t)$ the fractional buying function in the algorithm ONF of Section 3. For a request q_j, we denote by S_{i_j} the least expensive set containing q_j; that is, $i_j = \arg\min_{i|q_j \in S_i} c(S_i)$.

For every request q_j, we denote the total covering of q_j at time t in ONF by $\gamma_j(t)$, where

$$\gamma_j(t) = \sum_{i|q_j \in S_i} \int_{r_j}^{t} x_i(t')\,\mathrm{d}t'.$$

We denote by t_j the first time in which $\gamma_j(t) = \frac{1}{2}$.

$O(\log k \cdot \log N)$-Competitive Rounding

We now describe a randomized integral algorithm, called ONR, which is $O(\log k \cdot \log N)$ competitive with respect to the fractional optimum, with N the total number of requests. We assume a-priori knowledge of N for the algorithm.

The randomized integral algorithm runs the fractional algorithm of Section 3 in the background, and thus has knowledge of the function $x_i(t)$ for every i. The algorithm does the following.

1. At time 0:
  a. For every set S_i, choose Λ_i from the range $[0, \frac{1}{2\ln N}]$ uniformly and independently, and set $\tau_i = 0$.
2. At time t:
  a. For every i, if $\int_{\tau_i}^{t} x_i(t')\,\mathrm{d}t' \geq \Lambda_i$ then:
    i. Buy S_i.
    ii. Assign to Λ_i a new value drawn independently and uniformly from $[0, \frac{1}{2\ln N}]$.
    iii. Assign $\tau_i = t$.
  b. If there exists a pending request q_j such that $t \geq t_j$, buy S_{i_j}.

We refer to the buying of sets at Step 2a as "type a", and to the buying of sets at Step 2b as "type b".

The intuition for the randomized rounding scheme is that we would like the probability of buying a set in a certain interval of time to be proportional to the fraction of that set bought by the fractional algorithm in that interval, independently of the other sets. This is achieved by the "type a" buying. However, using "type a" alone is problematic. Consider, for example, a request on an element in k sets, such that the fractional algorithm buys $\frac{1}{k}$ of each of the sets to cover the request. Since the probability of buying a set is independent of other sets, there exists a probability that the randomized algorithm would not buy any of the k sets, leaving the request unserved. This bears possibly infinite delay cost for the rounding algorithm, which is not incurred by the underlying fractional algorithm.

The "type b" buying solves this problem, by serving a pending request *deterministically* when it is covered in the underlying fractional algorithm, through buying the cheapest set containing that request. This special service for the request might be expensive, but its probability is low, yielding low expected cost. This is ensured by the $2\log N$ "speedup" given to the "type a" buying, through choosing the thresholds Λ_i from $[0, \frac{1}{2\ln N}]$ (rather than $[0, 1]$).

▶ **Theorem 7.** *The randomized algorithm for SCD described above is $O(\log k \cdot \log N)$-competitive.*

The proof of Theorem 7 is given in the full version of this paper.

Improved $O(\log k \cdot \log n)$-Competitive Rounding

By modifying the $O(\log k \cdot \log N)$-competitive randomized rounding, we prove the following theorem.

▶ **Theorem 8.** *There exists a non-clairvoyant, randomized $O(\log k \cdot \log n)$-competitive algorithm for SCD.*

The modified rounding algorithm and its analysis appear in the full version of this paper.

5 Lower Bounds for Clairvoyant SCD

In this section, we show $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$ lower bounds on competitiveness for any randomized, clairvoyant algorithm for SCD or fractional SCD. While the lower bounds use instances in which different sets can have different costs, these instances can be modified to obtain instances with identical set costs. This implies that the lower bounds also apply to the unweighted setting. This modification is shown in Subsection 5.2.

This section shows the following theorem.

▶ **Theorem 9.** *Any randomized algorithm for SCD or fractional SCD is both $\Omega(\sqrt{\log k})$-competitive and $\Omega(\sqrt{\log n})$-competitive.*

In proving Theorem 9, we show a lower bound on competitiveness of a deterministic fractional algorithm against an integral optimum. Showing this is enough to prove the theorem, since any randomized online algorithm (fractional or integral) can be converted to a deterministic fractional online algorithm with identical (or lesser) cost. This follows from setting the momentary buying function of a set at a given time to be the expectation of that value in the randomized algorithm. Since the optimum is integral, the bound also holds for integral SCD, as the theorem states. Therefore, we only consider deterministic fractional online algorithms henceforth.

We show our lower bounds by constructing a set of SCD instances, $\{I_i\}_{i=0}^{\infty}$. For each $i \geq 0$, the SCD instance I_i contains 2^i sets and 3^i elements. We show that any algorithm must be $\Omega(\sqrt{i})$-competitive for I_i, which is both $\Omega(\sqrt{\log m})$ and $\Omega(\sqrt{\log n})$. Noting that $k \leq m$, we also have $\Omega(\sqrt{\log k})$ as required.

The instance I_i exists within the time interval $[0, 3^i)$. That is, no request of I_i is released before time 0, and at time 3^i the optimum has served all requests in I_i, and the algorithm has incurred a high enough cost.

We define the sequence $(c_i)_{i=0}^{\infty}$, which is used in the construction of I_i. The sequence is defined recursively, such that $c_0 = 1$ and for any $i \geq 1$, we have that

$$c_i = c_{i-1} + \frac{1}{12c_{i-1}}.$$

We now describe the recursive construction of the instance I_i. We first describe the universe of I_i, which consists of its sets and elements. We then describe the requests of I_i.

Universe of I_i

For the base instance I_0, the universe consists of a single element e and a single set $S = \{e\}$. We have that $c(S) = 1$.

For $i \geq 1$, the recursive construction of I_i using I_{i-1} is as follows. Denote by E_{i-1} the elements in the universe of I_{i-1}, and by H_{i-1} the family of sets in the universe of I_{i-1}. For the construction of I_i, consider three disjoint copies of E_{i-1} and H_{i-1}. For $l \in \{1, 2, 3\}$, we

This figure shows the universes of I_0, I_1 and I_2. In the figure, each element is a point and the sets are the bodies containing them, where each set has a distinct color. The costs of the sets are also shown in the figure. The figure shows how three copies of the set of elements E_{i-1} (of the instance I_{i-1}) appear in I_i – the copy E^1_{i-1} appears at the top of I_i's visualization, the copy E^2_{i-1} appears at the bottom-left, and the copy E^3_{i-1} appears at the bottom-right.

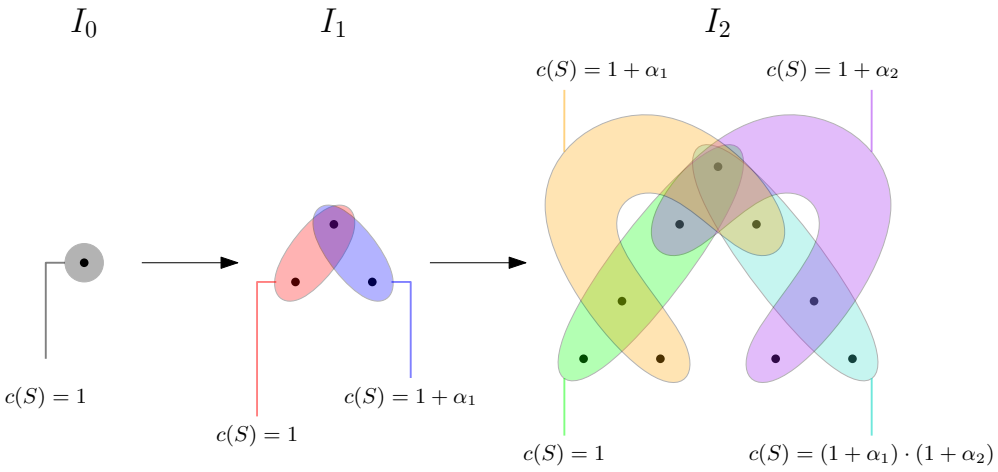

Figure 5.1 The Universes of I_0, I_1 and I_2.

denote by E^l_{i-1} and H^l_{i-1} the l'th copy of E_{i-1} and H_{i-1}, respectively. We denote by S^l the copy of the set $S \in H_{i-1}$ in H^l_{i-1}. Similarly, we denote by e^l the copy of an element $e \in E_{i-1}$ in E^l_{i-1}.

The universe of I_i consists of:

- The elements $E_i = E^1_{i-1} \cup E^2_{i-1} \cup E^3_{i-1}$.
- The family of sets $H_i = \mathcal{T}_1 \cup \mathcal{T}_2$, where $\mathcal{T}_1$ and $\mathcal{T}_2$ are defined below.

We define:

- The family of sets $\mathcal{T}_1 = \{S^1 \cup S^2 | S \in H_{i-1}\}$. A set $T \in \mathcal{T}_1$ formed from $S \in H_{i-1}$ has cost $c(T) = c(S)$.
- The family of sets $\mathcal{T}_2 = \{S^1 \cup S^3 | S \in H_{i-1}\}$. A set $T \in \mathcal{T}_2$ formed from $S \in H_{i-1}$ has cost $c(T) = (1 + \alpha_i) \cdot c(S)$, with $\alpha_i = \frac{1}{2c_{i-1}}$.

Requests of I_i

We first describe a type of request used in our construction. Let S be a set such that there exists an element $e \in S$ such that e is in no other set besides S (we call e unique to S). For times a, b such that $a < b$, we define a request $q^b_a(S)$ that can be released at any time $r \leq a$ on an element unique to S, and satisfies:

1. $\int_r^a d_j(t)\,\mathrm{d}t = 0$
2. $\int_r^b d_j(t)\,\mathrm{d}t \geq c(S)$.

▶ Remark 10. For the degenerate case of set cover with deadlines, when observing a request with deadline at time b, it can be said to accumulate 0 delay until any time before b, and infinite delay until time b. Therefore, deadline requests can function as $q^b_a(S)$ requests. Since all requests used in our construction are $q^b_a(S)$ requests for some a, b, S, our lower bound applies for set cover with deadlines as well.

To use those $q_a^b(S)$ requests, we require the following proposition, which states that a $q_a^b(S)$ request can be released on every S.

▶ **Proposition 11.** *For every set $T \in H_i$, there exists an element $e \in E_i$ unique to T.*

Proof. By induction on i. For the base case, this holds since there is only a single set with a single element. Assuming the proposition holds for I_{i-1}, we show that it holds for I_i by observing that there exists $S \in H_{i-1}$ such that $T = S^1 \cup S^l$ for $l \in \{2, 3\}$. Via induction, there exists an element $e \in E_{i-1}$ such that $e \in S$ and $e \notin S'$ for every $S' \in H_{i-1}$ such that $S' \neq S$. Choosing the element e^l yields the proposition. ◀

Base case of I_0 – at time 0, the request $q_0^1(S)$ is released on the single element e.

Recursive construction of I_i using I_{i-1} – we define $C(I_i)$ to be $\sum_{S \in H_i} c(S)$. We now define the instance I_i:

1. At time 0:
   a. Release $q_{2 \cdot 3^{i-1}}^{3^i}(T)$ for every $T \in \mathcal{T}_2$.
   b. Release I_{i-1} on the elements E_{i-1}^1 (see Remark (a)).
2. At time 3^{i-1}:
   a. If the algorithm has bought sets of $\mathcal{T}_2$ at a total cost of at least $\frac{1}{2} \cdot (1 + \alpha_i) \cdot C(I_{i-1})$, release $(1 + \alpha_i)I_{i-1}$ on the elements E_{i-1}^3 (see Remark (c)).
   b. Otherwise, release I_{i-1} on the elements of E_{i-1}^2 (see Remark (b)).

The construction of I_i includes releasing copies of I_{i-1} on the elements E_{i-1}^l, for $l \in \{1, 2, 3\}$. The following remarks make this well-defined.

▶ Remark (a). **The I_{i-1} on E_{i-1}^1**: every set $S \in H_{i-1}$ forms two sets in H_i, which are $T_1 = S^1 \cup S^2 \in \mathcal{T}_1$ and $T_2 = S^1 \cup S^3 \in \mathcal{T}_2$. The I_{i-1} construction on E_{i-1}^1 treats buying either of these sets as buying the set S. That is, it treats the sum of the momentary buying of T_1 and of T_2 as the momentary buying of S.

▶ Remark (b). **The I_{i-1} on E_{i-1}^2**: in this instance, for every set $S \in H_{i-1}$, the I_{i-1} construction treats buying $T_1 = S^1 \cup S^2 \in \mathcal{T}_1$ as buying S.

▶ Remark (c). **The scaled $(1 + \alpha_i)I_{i-1}$ on E_{i-1}^3**: similarly to Remark 5, in this instance, for every set $S \in H_{i-1}$, the I_{i-1} construction treats buying $T_2 = S^1 \cup S^3 \in \mathcal{T}_2$ as buying S. In addition, since the sets of $\mathcal{T}_2$ are $(1 + \alpha_i)$-times more expensive than the original sets of H_{i-1}, the delays of the jobs in I_{i-1} are also scaled by $1 + \alpha_i$ in order to maintain the I_{i-1} instance. We denote this scaled instance by $(1 + \alpha_i)I_{i-1}$.

5.1 Analysis of Lower Bounds

We show that any online fractional algorithm is at least c_i competitive on I_i with respect to the integral optimum.

▶ **Lemma 12.** *The optimal integral algorithm can serve I_i by time 3^i with no delay cost by buying every set in H_i exactly once, for a total cost of $C(I_i)$.*

Proof. Via induction on i. For the base case of $i = 0$, the optimal algorithm buys the single set S at time 0 and pays $c(S) = C(I_0)$. Now, for $i \geq 1$, suppose the optimum can serve the instance I_{i-1} according to the lemma. We observe the optimum in I_i according to the cases in the release of I_i:

Case 2a: In this case, the optimum could have served I_{i-1} on E^1_{i-1} by time 3^{i-1} by buying each set of $\mathcal{T}_1$ exactly once, with no delay cost. It could then serve $(1+\alpha_i)I_{i-1}$ on E^3_{i-1} by time $2 \cdot 3^{i-1}$ by buying each set of $\mathcal{T}_2$ exactly once, with no delay cost. Since the optimum has bought all of $\mathcal{T}_2$, the requests released on step 1a have also been served before incurring delay. The lemma thus holds for this case.

Case 2b: In this case, the optimum could have served I_{i-1} on E^1_{i-1} by time 3^{i-1} by buying each set of $\mathcal{T}_2$ exactly once, with no delay cost. It could then serve I_{i-1} on E^2_{i-1} by time $2 \cdot 3^{i-1}$ by buying each set of $\mathcal{T}_1$ exactly once, with no delay cost. Since the optimum has bought all of $\mathcal{T}_2$, the requests released on step 1a have again been served before incurring delay. The lemma thus holds for this case as well. ◀

We now analyze the cost of the algorithm.

▶ **Lemma 13.** *Any online algorithm has a cost of at least $c_i \cdot C(I_i)$ on I_i by time 3^i.*

Proof. By induction on i.

For $i = 0$, observe the algorithm at time 1. Denoting by Γ_S the total buying of the single set S by the algorithm by time 1, the algorithm has a cost of at least

$$c(S) \cdot \Gamma_S + (1 - \Gamma_S) \cdot \int_0^1 d_{q_0^1(S)}(t)\,\mathrm{d}t \geq c(S) = C(I_0)$$

where the inequality is due to the definition of $q_0^1(S)$. This finishes the base case of the induction.

For the case that $i \geq 1$, assume that the lemma holds for $i-1$. We show that it holds for i.

Fix any algorithm for I_i. We denote by Γ the total buying cost of the algorithm in the time interval $[0, 3^{i-1})$ for sets of $\mathcal{T}_2$. We again split into cases according to the chosen branch in the construction of I_i.

Case 2a: In this case we have $\Gamma \geq \frac{1}{2} \cdot (1+\alpha_i) \cdot C(I_{i-1})$. From the definition of the first I_{i-1} released, the adversary is oblivious to whether a copy of $S \in H_{i-1}$ came from $\mathcal{T}_1$ or $\mathcal{T}_2$. Using the induction hypothesis, any online algorithm for this instance incurs a cost of at least $c_{i-1} \cdot C(I_{i-1})$ by time 3^{i-1}, including the algorithm in which buying sets from $\mathcal{T}_2$ are replaced with buying the equivalent sets from $\mathcal{T}_1$. Such a modified online algorithm would cost $\frac{\alpha_i}{1+\alpha_i}\Gamma$ less than the current algorithm, which is at least $\frac{\alpha_i}{2} \cdot C(I_{i-1})$. Therefore, the algorithm pays at least $(c_{i-1} + \frac{\alpha_i}{2}) \cdot C(I_{i-1})$ in the interval $[0, 3^{i-1})$.

As for the second instance $(1+\alpha_i)I_{i-1}$, the algorithm must pay at least $(1+\alpha_i) \cdot c_{i-1} \cdot C(I_{i-1})$ by time $2 \cdot 3^{i-1}$ via induction.

Overall, the algorithm pays by time 3^i at least

$$\begin{aligned}
&\left(\left(c_{i-1} + \frac{\alpha_i}{2}\right) \cdot C(I_{i-1})\right) + ((1+\alpha_i) \cdot c_{i-1} \cdot C(I_{i-1})) \\
&\qquad = \left((2+\alpha_i)c_{i-1} + \frac{\alpha_i}{2}\right) \cdot C(I_{i-1}) \\
&\qquad = c_{i-1} \cdot C(I_i) + \frac{\alpha_i}{2} \cdot C(I_{i-1}) \\
&\qquad \geq \left(c_{i-1} + \frac{\alpha_i}{6}\right) \cdot C(I_i) \\
&\qquad = \left(c_{i-1} + \frac{1}{12c_{i-1}}\right) \cdot C(I_i)
\end{aligned}$$

where the inequality is due to $C(I_i) = (2+\alpha_i)C(I_{i-1}) \leq 3C(I_{i-1})$.

Case 2b: In this case we have $\Gamma < \frac{1}{2} \cdot (1+\alpha_i) \cdot C(I_{i-1})$. For the first I_{i-1} instance, the algorithm pays at least $c_{i-1} \cdot C(I_{i-1}) + \Gamma \cdot \frac{\alpha_i}{1+\alpha_i}$ by time 3^{i-1}, similar to the previous case. For the second I_{i-1} instance, released on E^2_{i-1}, the algorithm must pay via induction at least $c_{i-1} \cdot C(I_{i-1})$ by time $2 \cdot 3^{i-1}$. Since sets of $\mathcal{T}_2$ do not satisfy requests in this instance, this cost is either in buying sets of $\mathcal{T}_1$ or in delay of requests from that I_{i-1} instance.

In addition to the two I_{i-1} instances, due to the $q^{3^i}_{2 \cdot 3^{i-1}}(S)$ requests released in step 1a, the algorithm has a cost of at least $\left(\sum_{T \in \mathcal{T}_2} c(T)\right) - \Gamma = (1+\alpha_i)C(I_{i-1}) - \Gamma$ during the interval $[1,3)$ in either buying sets of $\mathcal{T}_2$ in order to finish these requests, or in delay by those requests (using a similar argument to that in the base case). Overall, the algorithm has a cost of at least

$$\begin{aligned}
&\left(c_{i-1} \cdot C(I_{i-1}) + \Gamma \cdot \frac{\alpha_i}{1+\alpha_i}\right) + (c_{i-1} \cdot C(I_{i-1})) + ((1+\alpha_i)C(I_{i-1}) - \Gamma) \\
&\qquad = (2c_{i-1} + 1 + \alpha_i) \cdot C(I_{i-1}) - \frac{1}{1+\alpha_i}\Gamma \\
&\qquad \geq (2c_{i-1} + 1 + \alpha_i) \cdot C(I_{i-1}) - \frac{1}{2}C(I_{i-1}) \\
&\qquad = \left(2c_{i-1} + \frac{1}{2} + \alpha_i\right) \cdot C(I_{i-1}) \\
&\qquad = \left((2+\alpha_i)c_{i-1} + \frac{1}{2} + (1-c_{i-1})\alpha_i\right) \cdot C(I_{i-1}) \\
&\qquad = c_{i-1} \cdot C(I_i) + \left(\frac{1}{2} + \frac{1}{2c_{i-1}} - \frac{1}{2}\right) \cdot C(I_{i-1}) \\
&\qquad \geq \left(c_{i-1} + \frac{1}{6c_{i-1}}\right) \cdot C(I_i) \geq c_i \cdot C(I_i)
\end{aligned}$$

where the fourth equality and the second inequality are due to $C(I_i) = (2+\alpha_i)C(I_{i-1}) \leq 3C(I_{i-1})$, and the fourth equality uses the definition of α_i. ◀

Proof of Theorem 9. Lemmas 12 and 13 immediately imply that any deterministic fractional algorithm is at least c_i-competitive on I_i with respect to the integral optimum. Solving the recurrence in the definition of c_i, we have that $c_i = \Omega(\sqrt{i})$. To observe this, note that for every i, the first index $i' \geq i$ such that $c_{i'} \geq c_i + 1$ is at most $O(c_i)$ larger than i. Since $k \leq m = 2^i$ and $n = 3^i$, this provides lower bounds of $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$ for deterministic algorithms for fractional SCD. As stated before, this implies the same lower bound for randomized algorithms for both SCD and fractional SCD. ◀

5.2 Reduction to Unweighted

The lower bound above uses weighted instances, in which sets may have different costs. In this subsection, we describe how to convert a weighted instance to an unweighted instance, in which all set costs are equal. This conversion maintains both the $\Omega(\sqrt{\log k})$ and $\Omega(\sqrt{\log n})$ lower bounds on competitiveness. The conversion consists of creating multiple copies of each element, and converting each original set to multiple sets of cost 1. The cost of the original set affects the cardinality of the new sets, such that a set with higher cost turns into smaller sets of cost 1.

We suppose that the costs of all sets are integer powers of 2. This can easily be achieved by rounding the costs to powers of 2 (losing a factor of 2 in the lower bound), and then scaling the instance (both delays and buying costs) by the inverse of the lowest cost.

Denote by $C = 2^M$ the largest cost in the instance. The universe of the unweighted instance is the following:

- For each element e in the original instance, we have C elements in the unweighted instance, denoted by $e_0, ..., e_{C-1}$.
- For each set S, we have $c(S)$ sets in the unweighted instance, labeled $S_0, ..., S_{c(S)-1}$.
- We have that $e_i \in S_j$ if and only if both $e \in S$ and $i \equiv j \mod c(S)$.

Whenever a request q_j arrives in the original instance on an element e with delay function $d_j(t)$, C requests $q_{j,0}, ..., q_{j,C-1}$ arrive in the unweighted instance on the elements $e_0, ..., e_{C-1}$ respectively. For each $0 \leq l \leq C-1$, the request $q_{j,l}$ has the delay function $d_{j,l}(t) = \frac{d_j(t)}{C}$.

For the instance I_i described above, we consider its unweighted conversion, denoted by I'_i. Any fractional online algorithm for I'_i can be converted to a fractional online algorithm for I_i with a cost which is at most that of the original algorithm. This is done by setting the buying function of a set S in I_i to the average of the buying functions of $S_0, ..., S_{c(S)-1}$.

In addition, the integral optimum described in the analysis of I_i can be modified to an integral optimum for I'_i with identical cost. This is by converting each buying of the set S in I_i to buying the sets $S_0, ..., S_{c(S)-1}$ in I'_i.

The aforementioned facts imply that any fractional algorithm is $\Omega(\sqrt{i})$ competitive on I'_i. Note that the parameter k is the same for I_i and I'_i, implying $\Omega(\sqrt{\log k})$-competitiveness on I'_i. In addition, denoting by n' the number of elements in I'_i, we have that $n' = C \cdot n$. Observing the construction of I_i, we have that $n = 3^i$ and $C \leq 2^i$ (Using the fact that $(1 + \alpha_j) \leq 2$ for any j). Therefore, $\log n' \leq \log(6^i)$, yielding that $i = \Omega(\log n')$, and a $\Omega(\sqrt{\log n'})$ lower bound on competitiveness for I'_i.

6 Vertex Cover with Delay

In this section, we show a 3-competitive deterministic algorithm for VCD. Recall that VCD is a special case of SCD with $k = 2$, where k is the maximum number of sets to which an element can belong. In fact, we show a $(k+1)$-competitive deterministic algorithm for SCD, which is therefore 3-competitive for VCD. Recall that since the TCP acknowledgment problem is a special case of VCD with a single edge, the lower bound of 2-competitiveness for any deterministic algorithm on the TCP acknowledgment problem (shown in [19]) applies to VCD as well.

The $(k+1)$-competitive algorithm for SCD, ON, is as follows.

1. For every set S, maintain a counter $z(S)$ of the total delay incurred by ON over requests on elements in S (all $z(S)$ are initialized to 0).
2. If for any S, we have that $z(S) = c(S)$:
   a. Buy S.
   b. Zero the counter $z(S)$.

We denote by $z(S, t)$ the value of $z(S)$ at time t. We prove the following theorem.

▶ **Theorem 14.** *The algorithm* ON *for SCD has a competitive ratio of* $k + 1$. *In particular,* ON *is* 3*-competitive for VCD.*

▶ **Lemma 15.** *The cost of the algorithm is at most* $k + 1$ *times its delay cost.*

Proof. It is sufficient to bound the buying cost in terms of the delay cost. For each purchase of a set S, $z(S)$ must increase from 0 to $c(S)$. A delay for a request contributes to the increase of at most k counters. Thus, the buying cost is at most k times the delay cost. ◀

We are left to bound the delay cost of the algorithm by the adversary's cost.

▶ **Lemma 16.** *For any set* S, *let* T *be a subset of the requests on elements of* S *such that all requests of* T *are unserved at time* t. *Then we have* $\sum_{j|q_j \in T} \int_t^\infty d_j^{\mathrm{ON}}(t')\,\mathrm{d}t' \leq c(S)$.

Proof. Denote by $\hat{t}$ the first time in which all requests in T are served. We have that

$$\sum_{j|q_j \in T} \int_t^{\infty} d_j^{\mathrm{ON}}(t')\,\mathrm{d}t' = \sum_{j|q_j \in T} \int_t^{\hat{t}} d_j^{\mathrm{ON}}(t')\,\mathrm{d}t'.$$

At time t, we have $z(S,t) \geq 0$. Observe that the algorithm never bought S in the time interval $[t, \hat{t})$. Thus, at any time $t'' \in [t, \hat{t})$ we have that

$$z(S,t'') = z(S) + \sum_{j|q_j \in T} \int_t^{t''} d_j^{\mathrm{ON}}(t')\,\mathrm{d}t'.$$

Observe that $z(S,t'') < c(S)$, otherwise the algorithm would have bought S at t', serving all requests in T, in contradiction to the definition of $\hat{t}$. Therefore $\sum_{j|q_j \in T} \int_t^{t''} d_j^{\mathrm{ON}}(t')\,\mathrm{d}t' < c(S)$. The claim follows as t'' approaches $\hat{t}$. ◀

▶ **Lemma 17.** *The delay cost of the algorithm is at most the adversary's cost.*

Proof. We construct a solution to the dual LP from section 3, with a goal function which is the delay cost of the algorithm. This charges the delay cost of the algorithm to the fractional optimum, and thus to the integer optimum as well.

Specifically, we set $y_j(t) = d_j^{\mathrm{ON}}(t)$ for every j, t. Obviously, the C2 constraints hold. In order to show that the C1 constraint for a set S_i and a time t holds, observe that any request $q_j \in S_i$ served in ON before time t has $d_j^{\mathrm{ON}}(t') = 0$ for all $t' \geq t$. Using Lemma 16 for the requests unserved at t concludes the proof. ◀

Proof of theorem 14. The proof of the theorem results directly from lemmas 16 and 17. ◀

Note that this algorithm's competitive ratio is indeed as bad as $k+1$. Consider, for example, a single request in k sets with unit costs, which the optimum solves with cost 1 and the algorithm has cost $k+1$.

Improved Bounds for Metric Capacitated Covering Problems

Sayan Bandyapadhyay
Department of Informatics, University of Bergen, Norway
sayan.bandyapadhyay@gmail.com

Abstract

In the Metric Capacitated Covering (MCC) problem, given a set of balls $\mathcal{B}$ in a metric space P with metric d and a capacity parameter U, the goal is to find a minimum sized subset $\mathcal{B}' \subseteq \mathcal{B}$ and an assignment of the points in P to the balls in $\mathcal{B}'$ such that each point is assigned to a ball that contains it and each ball is assigned with at most U points. MCC achieves an $O(\log |P|)$-approximation using a greedy algorithm. On the other hand, it is hard to approximate within a factor of $o(\log |P|)$ even with $\beta < 3$ factor expansion of the balls. Bandyapadhyay et al. [SoCG 2018, DCG 2019] showed that one can obtain an $O(1)$-approximation for the problem with 6.47 factor expansion of the balls. An open question left by their work is to reduce the gap between the lower bound 3 and the upper bound 6.47. In this current work, we show that it is possible to obtain an $O(1)$-approximation with only 4.24 factor expansion of the balls. We also show a similar upper bound of 5 for a more generalized version of MCC for which the best previously known bound was 9.

1 Introduction

In any metric space P with metric d, a ball $B(c, r)$ with center $c \in P$ and radius r is defined as the set of points at a distance at most r from c, i.e., $B(c, r) = \{p \in P \mid d(c, p) \leq r\}$. In the *Metric Capacitated Covering* (MCC) problem, we are given a set of balls $\mathcal{B}$ in the metric space P with metric d. We are also given a capacity parameter $U \in \mathbb{N}$ for the balls. The goal is to find a minimum sized subset $\mathcal{B}' \subseteq \mathcal{B}$ and an assignment $\phi : P \to \mathcal{B}'$ such that for any point $p \in P$, the ball $\phi(p)$ contains p and the number of points assigned to a ball $B \in \mathcal{B}'$ via ϕ is at most U, i.e., $|\phi^{-1}(B)| \leq U$. For $B_i \in \mathcal{B}$, we denote its center and radius by c_i and r_i, respectively.

The greedy algorithm of [28] yields an $O(\log |P|)$-approximation for MCC. Indeed, this approximation factor is tight, which can be proved using the following simple reduction from set cover. For each element, add a point. For each set, add a ball of radius 1. If an element is in a set, then the distance between the center of the corresponding ball and the corresponding point is set to 1. Consider the metric space induced by the centers and the points. The capacity of each ball is set to the total number of elements, say n. Now, if there is a set cover of size k, then all the points can be covered by k balls without violating the

capacities. The converse is also true. As set cover is hard to approximate within a factor of $o(\log n)$ under standard complexity theoretic assumptions [16], it is not possible to find an approximation for MCC which is asymptotically better than $O(\log n)$.

As it is not possible to obtain a $o(\log n)$-approximation for MCC, researchers have focused on obtaining bicriteria approximation. An (α, β) bicriteria approximation for MCC is a solution where the balls can be expanded by a factor of β (i.e., for a ball $B_i \in \mathcal{B}$ and a point p_j assigned to B_i, $d(c_i, p_j) \leq \beta \cdot r_i$) and the size of the solution is at most α times the optimum solution size (that does not expand the balls). From the above reduction, it follows that no $(o(\log n), \beta)$ bicriteria approximation is possible for MCC under standard complexity theoretic assumptions for any $\beta < 3$. This is true, as in the construction for a ball B_i that does not contain a point p_j, the distance between c_i and p_j is at least 3. Thus, with less than 3 factor expansion, B_i cannot contain any more points than before.

On the positive side, Bandyapadhyay et al. [4] obtained an $(O(1), 6.47)$ bicriteria approximation for the problem, i.e., with only a 6.47 factor expansion of the balls it is possible to obtain a constant approximation. Their algorithm is based on rounding of the natural LP relaxation of MCC. One problem that was left open by the work of [4] is to reduce the gap between the lower bound 3 and the upper bound 6.47. Thus, for what possible value of $3 \leq \beta < 6.47$ can one obtain an $(O(1), \beta)$ bicriteria approximation for MCC? They also consider a generalization of MCC – *Metric Monotonic Capacitated Covering* (MMCC). This problem is similar to MCC except each ball B_i has its individual capacity $U_i \in \mathbb{N}$ which must be satisfied if it is chosen in the solution and the capacities are *monotonic* – for any two balls B_i and B_j if the radius of B_i is at least the radius of B_j, then $U_i \geq U_j$. At first glance, this assumption might seem artificial. However, this model has applications in wireless network. In a wireless network, coverage areas of antennas can be modelled using balls. Moreover, it might be economical to invest in capacity of an antenna to serve more clients, if its coverage area is larger. Bandyapadhyay et al. [4] gave an $(O(1), 9)$ bicriteria approximation for MMCC using the same approach.

1.1 Our Results and Techniques

In this paper, we obtain improved results both for MCC and MMCC.

- For MCC, we obtain an $(O(1), 4.24)$ bicriteria approximation, i.e., it is possible to obtain an $O(1)$-approximation with only 4.24 factor expansion of the balls when the capacities are uniform.
- For MMCC, we obtain an $(O(1), 5)$ bicriteria approximation, i.e., it is possible to obtain an $O(1)$-approximation with only 5 factor expansion of the balls when the capacities are monotonic.

Similar to [4] our results are also based on LP rounding. Indeed, our starting point is their rounding algorithm. For the purpose of giving an overview of our technique, let us focus on MMCC. The algorithm in [4] consists of three steps – Preprocessing, Cluster Formation and Selection of Balls. Each of Preprocessing and Selection of Balls incurs an overhead of a factor 3 expansion of the balls, resulting in the 9 factor expansion. In our algorithm we judiciously avoid the preprocessing step to save the factor 3 expansion. At first glance, it is not entirely clear how to do the rounding without preprocessing, as the preprocessed solution has several "nice" properties. Nevertheless, we partition the set of points into two subsets and construct two auxilliary LPs. Using the initial fractional LP solution, we construct two feasible fractional solutions to these two LPs. We round these two solutions independently to obtain two integral solutions corresponding to the two subsets of points. For rounding the

first LP, we use an algorithm similar to the one in [4], but without preprocessing. We show that the constructed fractional LP solution has equally nice properties so that the algorithm in [4] can be extended in this case. For rounding the second LP, we use a rather simple algorithm.

The sets of balls involved in two LPs are not necessarily disjoint, and thus a ball can be selected in both of the solutions. But, taking multiple copies of a ball is not allowed. To resolve this issue, we first identify a subset of balls and allow only these balls to be involved in both solutions. Moreover, we scale down the capacities of these balls by a suitable factor. This ensures that even if a ball is selected in both solutions, the total capacity used by the copies does not exceed the original capacity. Note that the scaling of capacities leads to a new issue that the capacities no longer satisfy the monotonicity property in general. However, we show that it is possible to overcome this issue by considering two classes of balls separately – one whose capacities remain unchanged and the other whose capacities are scaled down.

1.2 Related Work

Considering the hardness of MCC, researchers have studied the Euclidean version of the problem with the goal of obtaining better approximation. The dimension d of the space is assumed to be a constant. One interesting case is when the set $\mathcal{B}$ contains all possible unit balls, which appeared in the Sloan Digital Sky Survey project [25]. Ghasemi and Razzazi [18] have obtained a PTAS for this case. In the general Euclidean case the best known approximation factor is still $O(\log n)$. Bandyapadhyay et al. [4] showed that in this special case of MCC only $1+\epsilon$ expansion of the balls is sufficient to obtain a constant approximation.

MCC is a special version of *Capacitated Set Cover* (CSC). CSC is similar to set cover except each set S_i has a capacity U_i. Moreover, we want to find an assignment of the points to the chosen subfamily of sets such that each element is assigned to a set it is in and at most U_i elements are assigned to each set S_i. CSC is a well-studied problem. Wolsey [28] designed a greedy algorithm for CSC that achieves a tight $O(\log n)$-approximation. Capacitated vertex cover is another special case of CSC, where each element is contained in exactly two sets. A 3-approximation for this problem was given by Chuzhoy and Naor [12]. The approximation factor was subsequently improved to 2 by Gandhi et al. [17]. The generalization where each element belongs to at most a bounded number of sets is also well-studied [20, 29].

The uncapacitated version of MCC (*Metric Uncapacitated Covering* (MUC)), where each set can be assigned with any number of points is another extensively studied problem. Note that the same bicriteria hardness of MCC mentioned above holds even for MUC. But, using a simple LP rounding scheme one can obtain a $(1, 3)$ bicriteria approximation for this problem. The MUC problem in the fixed-dimensional Euclidean space also has received huge attention from the researchers. Brönnimann and Goodrich [7] have designed an $O(1)$-approximation for this problem in the plane. In a celebrated work, Mustafa and Ray [26] improved this result by obtaining a PTAS for the problem. In dimension more than 2, the problem is notoriously hard and the best known approximation is $O(\log n)$. Considering this situation Har-Peled and Lee [19] gave a $(1+\epsilon, 1+\epsilon)$ bicriteria approximation.

Capacitated clustering and facility location problems are another set of interesting and well-studied problems. One such interesting problem is capacitated k-center. $O(1)$-approximations are known both for the uniform [6, 21] and non-uniform [2, 14] version of this problem. Another popular clustering problem is capacitated k-median for which no $O(1)$-approximation is known so far. Seemingly the existing techniques are not capable of handling the combination of the global constraint on the number of centers and the capacity constraint. Indeed, if either of these constraints is allowed to be violated by an

$O(1)$ factor, $O(1)$-approximations are known in those cases [9, 8, 10, 13, 15, 23, 24]. For capacitated facility location $O(1)$-approximations are known based on local search paradigm [1, 5, 11, 22, 27] and rounding of LP [3].

1.3 Paper Outline

In Section 2 we describe the natural LP for MMCC and have some definitions, which will be useful throughout the paper. In Section 3 we give an overview of the algorithm of [4]. Our LP rounding algorithm for MMCC and the analysis appear in Section 4. In Section 5 we show how to modify our algorithm for MMCC in the uniform case to obtain the improved bound. Finally, in Section 6 we conclude with some open problems.

2 Preliminaries

Recall that in MMCC we are given a set of points P and a set of balls $\mathcal{B}$. The capacity of each ball $B_i \in \mathcal{B}$ is U_i. Also, these capacities satisfy monotonicity, i.e., for any two balls B_i and B_j, if $r_i \geq r_j$, $U_i \geq U_j$.

The relaxation of the natural LP for MMCC is shown in the following. In the LP for MMCC, we have a variable y_i for each ball $B_i \in \mathcal{B}$ that indicates whether B_i is in the solution ($y_i = 1$) or not ($y_i = 0$). For each ball B_i and each point $p_j \in P$, there is a variable x_{ij} that indicates whether p_j is assigned to B_i ($x_{ij} = 1$) or not ($x_{ij} = 0$). Constraint 1 ensures that if a point is assigned to a ball, the ball must be selected in the solution. Constraint 2 ensures that the total number of points assigned to B_i is at most U_i. Constraint 3 ensures that each point is assigned to exactly one ball. Constraint 4 ensures that if a point p_j is assigned to a ball B_i, p_j must be contained in B_i. The remaining constraints are relaxed in MMCC-LP, which define the domains of the variables. We note that the LP relaxation for MCC is same as MMCC-LP except there all the U_i are equal.

$$\text{minimize} \quad \sum_{B_i \in \mathcal{B}} y_i \qquad \text{(MMCC-LP)}$$

$$\text{s.t.} \quad x_{ij} \leq y_i \qquad \forall p_j \in P,\ \forall B_i \in \mathcal{B} \qquad (1)$$

$$\sum_{p_j \in P} x_{ij} \leq y_i \cdot U_i \qquad \forall B_i \in \mathcal{B} \qquad (2)$$

$$\sum_{B_i \in \mathcal{B}} x_{ij} = 1 \qquad \forall p_j \in P \qquad (3)$$

$$x_{ij} = 0 \qquad \forall p_j \in P,\ \forall B_i \in \mathcal{B} \text{ such that } p_j \notin B_i \qquad (4)$$

$$x_{ij} \geq 0 \qquad \forall p_j \in P,\ \forall B_i \in \mathcal{B} \qquad (5)$$

$$0 \leq y_i \leq 1 \qquad \forall B_i \in \mathcal{B} \qquad (6)$$

We denote any solution to MMCC-LP by (x, y). To distinguish between two different solutions, we use different annotations with x and y. The cost of (x, y) is defined as, $\text{cost}(x, y) = \sum_{B_i \in \mathcal{B}} y_i$. For an integral solution, the cost is exactly the number of balls in the solution. Consider any solution (x, y) to MMCC-LP. For a ball B_i and a point p_j, if $x_{ij} > 0$, we say B_i *serves* p_j and p_j receives x_{ij} amount of *flow* from B_i. The *flow out* of B_i is the total amount of flow $\sum_{p_j \in P} x_{ij}$ that B_i gives to all the points. Next, we define an operation that we call "reroute". For a point p_j and two balls B_i and B_ℓ, rerouting of f amount of flow for p_j from B_i to B_ℓ means we increase $x_{\ell j}$ by f and decrease x_{ij} by f. For two balls B_i and B_ℓ, rerouting of flow from B_i to B_ℓ means for each point p_j served by B_i,

we reroute x_{ij} amount of flow for p_j from B_i to B_ℓ. Thus, the flow out of B_i becomes 0 after this operation. For a point p_j, a set of balls S and a ball $B_\ell \notin S$, rerouting of f amount of flow from the balls in S to B_ℓ means we increase $x_{\ell j}$ by f and decrease x_{ij} by $f_i \geq 0$ for each $B_i \in S$ such that $\sum_{B_i \in S} f_i = f$.

3 Overview of the Algorithm of [4]

Our algorithm is based on the algorithm of [4]. In this section we give an overview of the algorithm of [4]. Let (x, y) be a feasible solution to MMCC-LP. The LP rounding algorithm of [4] rounds the solution so that y values of all the balls become integral. We note that it is sufficient to obtain such a solution. Indeed, as all the capacities are integral, it is possible to find another solution with the same y values where all the x values are also integral [12]. The algorithm has three major steps. The first step is the preprocessing step. Fix a $0 < \alpha \leq 3/8$. A ball B_i is called *heavy* if $y_i = 1$ and *light* if $0 \leq y_i \leq \alpha$. Let $\mathcal{H}$ and $\mathcal{L}$ be the respective set of heavy and light balls. We note that the sets of heavy and light balls are always defined w.r.t. an LP solution. But, for simplicity we do not explicitly mention that in the notations $\mathcal{H}$ and $\mathcal{L}$. The implicit solution w.r.t. which $\mathcal{H}$ and $\mathcal{L}$ are defined can be easily derived from the context. Now, it might not be true that for all $p_j \in P$, the sum of the y values of the balls in $\mathcal{L}$ that serve p_j is at most α. In the preprocessing step, the algorithm of [4] modifies the computed LP solution to obtain another LP solution such that the above mentioned property is satisfied. In particular, they prove the following lemma.

▶ **Lemma 1** (Lemma 3.1 of [4]). *Given a feasible LP solution $\sigma = (x, y)$, and a parameter $0 < \alpha \leq \frac{3}{8}$, there exists a polynomial time algorithm to obtain another LP solution $\overline{\sigma} = (\overline{x}, \overline{y})$ that satisfies all the constraints of MMCC-LP (Constraints 1-6), except Constraint 4. Additionally, $\overline{\sigma}$ satisfies the following properties.*

1. *Any ball $B_i \in \mathcal{B}$ with non-zero $\overline{y_i}$ is either heavy ($\overline{y_i} = 1$) or light ($0 < \overline{y_i} \leq \alpha$).*
2. *For each point $p_j \in P$, we have that*

$$\sum_{B_i \in \mathcal{L}: \overline{x}_{ij} > 0} \overline{y_i} \leq \alpha, \tag{7}$$

   where $\mathcal{L}$ is the set of light balls with respect to $\overline{\sigma}$.
3. *For any heavy ball B_i, and any point $p_j \in P$ served by B_i, $d(c_i, p_j) \leq 3r_i$.*
4. *For any light ball B_i, and any point $p_j \in P$ served by B_i, $d(c_i, p_j) \leq r_i$.*
5. $\text{cost}(\overline{\sigma}) \leq \frac{1}{\alpha}\text{cost}(\sigma)$.

Note that a point p_j can be fractionally assigned by the algorithm in Lemma 1 to a heavy ball B_i even if $p_i \notin B_i$, but, in this case $d(c_i, p_j)$ must be at most $3r_i$. Hence, a factor 3 expansion of the ball is sufficient for it to serve the point. In summary, the preprocessing step implicitly incurs an expansion factor of 3 for the heavy balls with respect to the new LP solution $\overline{\sigma}$. We also note that the preprocessing algorithm uses the fact that the capacities are monotonic.

The second step of the algorithm is the key step and is called Cluster Formation. In the following, we give an overview of this step. The algorithm maintains an LP solution $\overline{\sigma} = (\overline{x}, \overline{y})$ which is initially the output of the preprocessing step. This solution is essentially altered throughout the step and when the step finishes $\overline{y}_i \in \{0, 1\}$ for all $B_i \in \mathcal{B}$. Each heavy ball B_i forms a cluster which initially consists of itself ($\{B_i\}$). For any light ball B_t, either B_t is opened fully in the solution or it joins a cluster of a heavy ball by rerouting its flow to the heavy ball. The algorithm runs for several iterations until the fate of all these light balls are decided.

In each iteration, every heavy ball uses its available capacity to reroute the flow of as many intersecting light balls as possible to itself. Each such light ball joins the cluster of the heavy ball. From the remaining light balls whose fate are not yet decided, a ball is selected greedily to be included in the solution. Also, for points inside the selected ball, an appropriate amount of flow is rerouted from other balls to this ball to utilize its capacity. We skip the details of this flow rerouting in this overview. This completes the overview of the step.

Note that the flow rerouting from heavy balls to a light ball when the light ball is opened fully, is an essential component of the analysis for obtaining the constant factor guarantee on the size of the solution. Consider a light ball B_t which is selected for opening fully and assume that it serves $k_t \leq U_t$ points. Then, we can set the $\overline{x}_{tj}$ value for each of these k_t points to 1, i.e., we fully assign p_j to B_t. Note that preprocessing ensures that $\sum_{B_i \in \mathcal{L}: \overline{x}_{ij} > 0} \overline{y_i} \leq \alpha$ or $\sum_{B_i \in \mathcal{H}: \overline{x}_{ij} > 0} \overline{y_i} \geq 1 - \alpha$. Thus, when these points are fully assigned to B_t, at least $(1-\alpha)k_t$ amount of flow is rerouted from the heavy balls to B_t which they can now use to reroute flow from other light balls. This argument is essential in the analysis. Now, we have an observation which follows due to the way light balls are added to a cluster.

▶ **Observation 2.** *Consider a cluster of a heavy ball B_h that contains the light balls $B_1, \ldots, B_\ell$. Then, when the Cluster Formation finishes,*

1. *For each $1 \leq i \leq \ell$, there is a point p_j such that $p_j \in B_h \cap B_i$.*
2. *$\sum_{i=1}^{\ell} \sum_{j \in P} \overline{x}_{ij} \leq U_h - \sum_{j \in P} \overline{x}_{hj}$, i.e., the total amount of flow out of the balls in the cluster of B_h is at most U_h.*

The third step is called Selection of Balls. In this step, from each cluster a ball is carefully selected and expanded so that it can serve all the points served by the balls in the cluster. For a cluster of a heavy ball B_h, if it is the largest ball in the cluster then B_h is selected and with three factor expansion it can serve all the points served by the cluster. As during preprocessing the heavy ball might have been expanded by a factor of 3, its total expansion factor is 9. If B_h is not the largest ball, the largest ball B_ℓ is a light ball of the cluster. Then, we select this light ball and expand by a factor of 5 so that it can serve all the points served by the cluster. The light ball can serve the total flow assigned to the cluster, as $U_\ell \geq U_h$ due to monotonicity. This is another place where the monotonicity assumption on the capacities is necessary.

The following lemma that states the guarantee achieved by the above algorithm follows due to the analysis of [4].

▶ **Lemma 3.** *There is a $(6 + 5\alpha)/\alpha$-approximation for MMCC that expands the balls by at most a factor of 9.*

4 The Modified Algorithm for MMCC

In this section, we describe our algorithm. Note that among the 9 factor expansion needed in the algorithm of [4] 3 factor is contributed by the preprocessing step. Our algorithm avoids this preprocessing step to save this factor 3 expansion.

Fix $0 < \alpha \leq 1/60$. We first compute a fractional LP solution $\sigma^* = (x^*, y^*)$ to MMCC-LP. Set $y_i = 1$ if $y_i^* > \alpha$, otherwise $y_i = y_i^*$. Also, set $x = x^*$. Note that $\sigma = (x, y)$ is a feasible solution to MMCC-LP such that $\text{cost}(\sigma) \leq \text{cost}(\sigma^*)/\alpha$. We define the sets $\mathcal{H}$ and $\mathcal{L}$ of heavy and light balls w.r.t. σ in the same way, i.e., $\mathcal{H} = \{B_i \mid y_i = 1\}$ and $\mathcal{L} = \{B_i \mid 0 < y_i \leq \alpha\}$. Note that in σ, any ball that gives some flow to a point is either a heavy or a light ball. We take one copy of the set of heavy balls and two copies of the set of light balls. Let these sets be $\mathcal{H}_1$, $\mathcal{L}_1$ and $\mathcal{L}_2$, respectively.

Next, we partition the point set into two subsets. Let P_1 be the subset of points such that $p_j \in P_1$ if $\sum_{B_i \in \mathcal{L}} x_{ij} \leq 4\alpha$, i.e., p_j gets a flow of at most 4α from the balls in $\mathcal{L}$. Let $P_2 = P \setminus P_1$. Based on these sets P_1, P_2, we are going to construct two LP solutions to two auxilliary LPs and round them independently. Finally, we combine these two solutions to find a solution to MMCC-LP where for each $B_i \in \mathcal{B}$, $y_i \in \{0, 1\}$. Intuitively, we satisfy the demands of these two sets of points independently. The light balls are involved in both of the solutions and they might get opened fully in both of the solutions. However, we are not allowed to open multiple copies of a ball. To avoid this situation we reduce the capacity of the light balls by appropriate factor in the auxilliary LP.

Let the new capacity $U_i' = U_i/10$ for each light ball B_i. The new capacity of each heavy ball B_i remains same as before, i.e., $U_i' = U_i$. At this point the reader might wonder about the value of the scaling factor. We note that it is carefully chosen through back calculation to ensure that the analysis goes through. The first auxilliary LP that we consider is as follows.

$$\text{minimize} \quad \sum_{B_i \in \mathcal{L}_1 \cup \mathcal{H}_1} y_i \tag{AUX-LP1}$$

$$\text{s.t.} \quad x_{ij} \leq y_i \qquad \forall p_j \in P_1,\ \forall B_i \in \mathcal{L}_1 \cup \mathcal{H}_1 \tag{8}$$

$$\sum_{p_j \in P_1} x_{ij} \leq y_i \cdot U_i' \qquad \forall B_i \in \mathcal{L}_1 \cup \mathcal{H}_1 \tag{9}$$

$$\sum_{B_i \in \mathcal{L}_1 \cup \mathcal{H}_1} x_{ij} = 1 \qquad \forall p_j \in P_1 \tag{10}$$

$$x_{ij} = 0 \qquad \forall p_j \in P_1,\ \forall B_i \in \mathcal{L}_1 \cup \mathcal{H}_1 \text{ such that } p_j \notin B_i \tag{11}$$

$$x_{ij} \geq 0 \qquad \forall p_j \in P_1,\ \forall B_i \in \mathcal{L}_1 \cup \mathcal{H}_1 \tag{12}$$

$$0 \leq y_i \leq 1 \qquad \forall B_i \in \mathcal{L}_1 \cup \mathcal{H}_1 \tag{13}$$

Note that the above LP has a variable y_i for each ball B_i in $\mathcal{L}_1 \cup \mathcal{H}_1$, and a variable x_{ij} for each ball B_i in $\mathcal{L}_1 \cup \mathcal{H}_1$ and each point $p_j \in P_1$. We are not going to solve this LP. Instead, we construct a solution to this LP using σ and round it using an algorithm similar to the one in [4]. This LP is used to compare the cost of the rounded solution and the cost of σ^* in the end.

We construct an LP solution $\overline{\sigma} = (\overline{x}, \overline{y})$ from σ in the following manner. For $B_i \in \mathcal{H}_1$, $\overline{y}_i = y_i$. For $B_i \in \mathcal{L}_1$, $\overline{y}_i = 10 \cdot y_i \leq 10\alpha < 1$ ($\alpha \leq 1/60$). For $p_j \in P_1$, $B_i \in \mathcal{L}_1 \cup \mathcal{H}_1$, $\overline{x}_{ij} = x_{ij}$.

▶ **Lemma 4.** *$\overline{\sigma} = (\overline{x}, \overline{y})$ is a feasible solution to AUX-LP1 with cost at most $\text{cost}(\sigma^*)/\alpha$.*

Proof. First note that,

$$\text{cost}(\overline{\sigma}) = \sum_{B_i \in \mathcal{H}_1} y_i + 10 \sum_{B_i \in \mathcal{L}_1} y_i \leq (1/\alpha) \sum_{B_i \in \mathcal{H}_1} y_i^* + 10 \sum_{B_i \in \mathcal{L}_1} y_i^* \leq \text{cost}(\sigma^*)/\alpha.$$

For $p_j \in P_1$, $B_i \in \mathcal{L}_1 \cup \mathcal{H}_1$, $\overline{x}_{ij} = x_{ij} \leq y_i \leq \overline{y}_i$. Thus, Constraint 8 is satisfied.

For $B_i \in \mathcal{H}_1$, $\sum_{p_j \in P_1} \overline{x}_{ij} = \sum_{p_j \in P_1} x_{ij} \leq y_i \cdot U_i = \overline{y}_i \cdot U_i'$. For $B_i \in \mathcal{L}_1$, $\sum_{p_j \in P_1} \overline{x}_{ij} = \sum_{p_j \in P_1} x_{ij} \leq y_i \cdot U_i = (10 \cdot y_i) \cdot (U_i/10) = \overline{y}_i \cdot U_i'$. Thus, Constraint 9 is satisfied.

For $p_j \in P_1$, $\sum_{B_i \in \mathcal{L}_1 \cup \mathcal{H}_1} \overline{x}_{ij} = \sum_{B_i \in \mathcal{L}_1 \cup \mathcal{H}_1} x_{ij} = 1$. Thus, Constraint 10 is satisfied. Also, it is trivial to verify that Constraints 11-13 are also satisfied. Hence, the lemma follows. ◀

Next, we describe our second auxilliary LP. Let us again consider the solution $\sigma = (x, y)$ to MMCC-LP and the set of light balls $\mathcal{L}$ w.r.t. σ. Also, consider the second copy $\mathcal{L}_2$ of the set of light balls. For each point p_j in P_2, define the demand $d_j = \sum_{B_i \in \mathcal{L}_2} x_{ij}$.

$$\text{minimize} \quad \sum_{B_i \in \mathcal{L}_2} y_i \tag{AUX-LP2}$$

$$\text{s.t.} \quad x_{ij} \leq y_i \qquad \forall p_j \in P_2,\ \forall B_i \in \mathcal{L}_2 \tag{14}$$

$$\sum_{p_j \in P_2} x_{ij} \leq y_i \cdot U'_i \qquad \forall B_i \in \mathcal{L}_2 \tag{15}$$

$$\sum_{B_i \in \mathcal{L}_2} x_{ij} \geq d_j \qquad \forall p_j \in P_2 \tag{16}$$

$$x_{ij} = 0 \qquad \forall p_j \in P_2,\ \forall B_i \in \mathcal{L}_2 \text{ such that } p_j \notin B_i \tag{17}$$

$$x_{ij} \geq 0 \qquad \forall p_j \in P_2,\ \forall B_i \in \mathcal{L}_2 \tag{18}$$

$$0 \leq y_i \leq 1 \qquad \forall B_i \in \mathcal{L}_2 \tag{19}$$

Note that the above LP has a variable y_i for each ball B_i in $\mathcal{L}_2$ and a variable x_{ij} for each ball B_i in $\mathcal{L}_2$ and each point $p_j \in P_2$. Again we are not going to solve this LP. Instead, we construct a solution to this LP using σ and round it. This LP is used to compare the cost of the rounded solution and the cost of σ^* in the end.

We construct an LP solution $\hat{\sigma} = (\hat{x}, \hat{y})$ from σ in the following manner. For $B_i \in \mathcal{L}_2$, $\hat{y}_i = 10 \cdot y_i \leq 10\alpha < 1$. For $p_j \in P_2$, $B_i \in \mathcal{L}_2$, $\hat{x}_{ij} = x_{ij}$.

▶ **Lemma 5.** *$\hat{\sigma} = (\hat{x}, \hat{y})$ is a feasible solution to AUX-LP2 with cost at most $10 \cdot \text{cost}(\sigma^*)$.*

Proof. First note that $\text{cost}(\hat{\sigma}) \leq 10 \sum_{B_i \in \mathcal{L}_2} y_i = 10 \sum_{B_i \in \mathcal{L}_2} y^*_i \leq 10 \cdot \text{cost}(\sigma^*)$. For $p_j \in P_2$, $B_i \in \mathcal{L}_2$, $\hat{x}_{ij} = x_{ij} \leq y_i < \hat{y}_i$. Thus, Constraint 14 is satisfied.

For $B_i \in \mathcal{L}_2$, $\sum_{p_j \in P_2} \hat{x}_{ij} = \sum_{p_j \in P_2} x_{ij} \leq y_i \cdot U_i = (10 \cdot y_i) \cdot (U_i/10) = \hat{y}_i \cdot U'_i$. Thus, Constraint 15 is satisfied.

For $p_j \in P_2$, $\sum_{B_i \in \mathcal{L}_2} \hat{x}_{ij} = \sum_{B_i \in \mathcal{L}_2} x_{ij} = d_j$. Thus, Constraint 16 is satisfied. Also, it is trivial to verify that Constraints 17-19 are also satisfied. Hence, the lemma follows. ◀

In the following, we give two algorithms for rounding the two auxilliary LPs. The rounded solution of the first LP satisfies all the constraints except the coverage constraint. The rounded solution of the second LP satisfies all the constraints except the coverage and capacity constraints. Then, we merge these two solutions to obtain a solution for MMCC-LP that does not violate any capacity constraints.

4.1 Rounding the First Auxilliary LP

Note that we are given a feasible LP solution $\overline{\sigma} = (\overline{x}, \overline{y})$ to AUX-LP1 that has the following properties.

1. For any $B_i \in \mathcal{H}_1$, $\overline{y}_i = 1$.
2. For any $B_i \in \mathcal{L}_1$, $\overline{y}_i \leq 10\alpha$.
3. For any $p_j \in P_1$, $\sum_{B_i \in \mathcal{H}_1} \overline{x}_{ij} \geq 1 - 4\alpha$.
4. $\text{cost}(\overline{\sigma}) \leq \text{cost}(\sigma^*)/\alpha$.

Note that Property (3) above states that for any point $p_j \in P_1$, the flow received by p_j from the balls in $\mathcal{H}_1$ is at least $1 - 4\alpha$. We will heavily use this property while performing the rounding. Indeed, we are going to use an algorithm similar to the one in [4] without the preprocessing step. In the algorithm of [4], preprocessing ensures that for any point p_j, the sum of the y values of the light balls that give non-zero flow to p_j is at most α. Note that this might not be true in our case for balls in $\mathcal{L}_1$. At first glance it is not clear how to do the

rounding without this assumption. However, as we show, a similar rounding scheme can be designed using the weaker assumption on the flow mentioned above. Another hurdle to adapt the algorithm of [4] is the monotonicity assumption, which might not be true in our case because of scaling of the capacities. However, we note that only light balls' capacities are scaled by a uniform constant scaling factor. Due to this fact, we show that their algorithm can be modified to handle our case. Next, we describe our rounding algorithm.

The first step in our algorithm is Cluster Formation. In this step, for each ball $B_i \in \mathcal{L}_1$, either B_i is opened fully (added to a set $\mathcal{O}$) and flow from other balls including the balls in $\mathcal{H}_1$ are rerouted to B_i only for points in B_i. Otherwise, B_i joins a cluster of a ball in $\mathcal{H}_1$ to which its entire flow is rerouted. $\mathcal{O}$ is initialized to the empty set. For each ball $B_i \in \mathcal{H}_1$, initialize the cluster of B_i, cluster(B_i) to $\{B_i\}$. During the course of the algorithm, let $\Lambda \subseteq \mathcal{L}_1$ be the set of balls which are not yet added to $\mathcal{O}$ or to a cluster of a ball in $\mathcal{H}_1$. Throughout the algorithm, we maintain the invariant that for any point p_j which is served by a ball in Λ, p_j receives a flow of at least $1 - 4\alpha$ from the balls in $\mathcal{H}_1$. Note that in the beginning of the algorithm this is true, as $\Lambda = \mathcal{L}_1$. At any point, the available capacity of a ball B_i, $AC(B_i) = U'_i - \sum_{j \in P_1} \overline{x}_{ij}$. While the set Λ is non-empty, apply the following steps.

While there is a ball $B_i \in \mathcal{H}_1$ and $B_{i'} \in \Lambda$ such that B_i intersects $B_{i'}$ and $AC(B_i)$ is at least the flow out $\sum_{j \in P_1} \overline{x}_{i'j}$ of $B_{i'}$, reroute the flow from $B_{i'}$ to B_i. Add $B_{i'}$ to cluster(B_i). If Λ becomes empty at this point, go to the Selection of Balls stage.

For any ball $B_j \in \Lambda$, let $\mathcal{A}_j$ be the set of points currently being served by B_j. Also, let $k_j = \min\{U'_j, |\mathcal{A}_j|\}$. We add a ball $B_t \in \Lambda$ to $\mathcal{O}$ such that k_t is the maximum over all k_j for $B_j \in \Lambda$.

Next we assign points up to larger extents to B_t to utilize its capacity. There are three cases.

1. $k_t > 2$. Note that the flow out of B_t, $\sum_{j \in P_1} \overline{x}_{tj} \leq 10\alpha U'_t$. Also, as $\overline{x}_{tj} = x_{tj} \leq y_t \leq \alpha$, $\sum_{j \in P_1} \overline{x}_{tj} \leq \alpha |\mathcal{A}_t| \leq 10\alpha |\mathcal{A}_t|$. Thus, $AC(B_t) \geq (1 - 10\alpha)k_t$. In this case, we arbitrarily select $\lfloor (1 - 10\alpha)k_t \rfloor$ points served by B_t and for each of those points p_ℓ, we reroute the maximum (whole) amount of flow possible from all other balls to B_t. Note that p_ℓ is no longer served by a ball in Λ, and thus the invariant is satisfied.
2. $1 \leq k_t \leq 2$. If $U'_t \geq |\mathcal{A}_t|$, then $|\mathcal{A}_t| = k_t$. In this case, for each of the k_t points served by B_t, we reroute the maximum amount of flow possible from all other balls to B_t. In the other case, $U'_t < |\mathcal{A}_t|$. Now, $AC(B_t) \geq (1 - 10\alpha)U'_t \geq 1 - 10\alpha$. The last inequality follows, as $U'_t \geq 1$. We arbitrarily select a point p_ℓ that is being served by B_t and reroute its flow from Λ to B_t. Let f be the amount of flow that now p_ℓ receives from B_t. Note that $f \leq 4\alpha$. Also, p_ℓ is no longer served by a ball in Λ. Now, $AC(B_t) \geq 1 - 10\alpha - 4\alpha = 1 - 14\alpha$. We reroute $\min\{AC(B_t), 1 - f\}$ amount of flow from $\mathcal{H}_1$ to B_t for p_ℓ. In any case, the points whose flow are routed to B_t in this step are no longer served by a ball in Λ, and thus the invariant is satisfied.
3. $0 < k_t < 1$. Note that, as $|\mathcal{A}_t| \geq 1$, $k_t = U'_t < 1$. Now, $AC(B_t) \geq (1 - 10\alpha)U'_t$. Consider any arbitrary point p_ℓ that is being served by B_t. First, reroute its flow from Λ to B_t. $AC(B_t) \geq (1 - 10\alpha)U'_t - 4\alpha$. Note that after this rerouting, p_ℓ is no longer served by balls in Λ, and thus the invariant is satisfied. Let p_ℓ gets a flow of f_1 from the balls in $\mathcal{H}_1$. By the invariant we maintain, f_1 is at least $1 - 4\alpha$. Reroute $\min\{AC(B_t), f_1\}$ amount of flow of p_ℓ from the balls in $\mathcal{H}_1$ to B_t.

When the while loop terminates each ball in $\mathcal{L}_1$ is either in $\mathcal{O}$ or added to a cluster. For each $B_i \in \mathcal{O}$, we set $\overline{y}_i = 1$ and cluster$(B_i) = \{B_i\}$.

We note that the third case ($0 < k_t < 1$) mentioned above does not occur in the context of [4], as in their case for each ball B_j, both U_j and $|\mathcal{A}_j|$ are at least 1. This case appears to be the bottleneck for our algorithm and leads to a larger constant of approximation as we will describe in the analysis.

The Selection of Balls step is more interesting in our case as the monotonicity property no longer holds in general. For a cluster of a ball in $\mathcal{O}$, we trivially select this ball. Consider the cluster of any ball $B_h \in \mathcal{H}_1$. If B_h is one of the top 10 largest balls in the cluster, then select all the balls larger than B_h and also B_h. Only B_h is expanded by a factor of 3. The flow rerouted from any selected ball of $\mathcal{L}_1$ to B_h in the Cluster Formation step is assigned to it. Note that for the remaining balls of $\mathcal{L}_1$ which are in the same cluster and not chosen, are smaller than B_h, and thus can be covered by a factor 3 expansion of B_h. The remaining flow is assigned to B_h. Otherwise, the top 10 largest balls are selected all of which are in $\mathcal{L}_1$. The flow rerouted from any selected ball to B_h in the Cluster Formation step is assigned to the ball. Now consider the remaining flow assigned to the cluster. Also consider a point p_j which receives a part of this flow and not in any of the selected balls. Then, by 5 factor expansion, any selected ball can cover p_j. We expand each selected ball by 5 factor and the remaining flow is assigned arbitrarily to selected balls respecting their capacity.

4.1.1 Analysis

Let I be the number of iterations of the outermost while loop. Also, let L_t be the ball of $\mathcal{L}_1$ added to $\mathcal{O}$ at iteration $1 \leq t \leq I$. For a ball $B_i \in \mathcal{H}_1$, let $F(L_t, B_i)$ be the amount of flow rerouted from B_i to L_t. Let $F_t = \sum_{B_i \in \mathcal{H}_1} F(L_t, B_i)$. The next lemma states that when L_t is added to $\mathcal{O}$ sufficient amount of flow is rerouted from the balls in $\mathcal{H}_1$ to L_t irrespective of the value of k_t.

▶ **Lemma 6.** *For $1 \leq i \leq I$, $F_t \geq k_t/60$ for $\alpha \leq 1/60$.*

Proof. To compute the flow rerouted from balls in $\mathcal{H}_1$ to B_t we refer to the three cases mentioned in Cluster Formation. In the first case, for $\lfloor (1-10\alpha)k_t \rfloor$ points, the flow is rerouted from $\mathcal{H}_1$ to B_t. Note that by the invariant we maintain, for each such point p_ℓ, p_ℓ receives at least $1-4\alpha$ amount of flow from the balls in $\mathcal{H}_1$. It follows that, at least $1-4\alpha$ amount of flow is rerouted for p_ℓ and $F_t \geq (1-4\alpha)\lfloor (1-10\alpha)k_t \rfloor \geq (14/15)\lfloor (5/6)k_t \rfloor \geq (14/15)(1/14)k_t = k_t/15 \geq k_t/60$. The second inequality follows as $\alpha \leq 1/60$ and the third inequality follows as $k_t > 2$.

In the second case, using the same argument as above, the amount of flow rerouted from $\mathcal{H}_1$ to B_t is at least $1-14\alpha$. As $k_t \leq 2$, F_t is at least $(1-14\alpha)k_t/2 \geq (23/60)k_t \geq k_t/60$. The first inequality is true for $\alpha \leq 1/60$.

In the third case, again using the same argument as above, the amount of flow rerouted from $\mathcal{H}_1$ to B_t is at least $\min\{(1-10\alpha)k_t - 4\alpha, 1-4\alpha\}$. As $k_t < 1$, $1-4\alpha \geq (1-4\alpha)k_t$. Thus, $F_t \geq (1-10\alpha)k_t - 4\alpha$. As $U_t \geq 1$, $k_t = U'_t \geq 1/10$, and hence $F_t \geq (1-10\alpha)/10 - 4\alpha = 1/10 - 5\alpha \geq 1/60$. The last inequality follows from the fact that $\alpha \leq 1/60$. ◀

Define the y-credit of a ball $B_i \in \mathcal{H}_1$ as $Y(L_t, B_i) = F(L_t, B_i)/k_t$. At any moment during the Cluster Formation stage, define the y-accumulation of B_i as $\tilde{y}(B_i) = \sum_{L_t \in \mathcal{O}} Y(L_t, B_i) - \sum_{B_i \in \mathcal{L}_1 \cap \text{cluster}(B_i)} \overline{y}_i$. The y-credit $Y(L_t, B_i)$ of B_i can be seen as a normalized load it transfers to L_t. The y-accumulation $\tilde{y}(B_i)$ is basically the difference between the total y-credit received by B_i and the sum of normalized flows of the balls absorbed by B_i. The next lemma gives a lower bound on the available capacities of the balls in $\mathcal{H}_1$, which is similar to Lemma 3.3 of [4].

▶ **Lemma 7.** *Consider a ball $B_i \in \mathcal{H}_1$ and any integer $1 \leq t \leq I$. Suppose the balls $L_1, \ldots, L_t$ have been added to $\mathcal{O}$ so far. Then, $AC(B_i) \geq \tilde{y}(B_i)k_t$.*

Proof. For any ball $B_i \in \mathcal{H}_1$, we prove the claim using induction on iteration number. In the base case, just after addition of L_1, $AC(B_i) \geq F(L_1, B_i) = Y(L_1, B_i)k_1 = \tilde{y}(B_i)k_1$. Now, suppose the claim is true for any $t-1$. We show that the claim is true for t as well.

Consider the iteration t. Note that $AC(B_i) \geq \tilde{y}(B_i)k_{t-1}$. Suppose a subset of balls have joined cluster of B_i. Let B_p be the first ball joined, which serves k points. To distinguish between the old and new value of $\tilde{y}(B_i)$, we refer to the new value by $\tilde{y}(B_i)'$. After B_p's joining to cluster of B_i, $\tilde{y}(B_i)' = \tilde{y}(B_i) - \overline{y}_p$. Now, the total flow out of B_p is at most $\min\{\overline{y}_p k, \overline{y}_p U_p'\} = \overline{y}_p \min\{k, U_p'\} \leq \overline{y}_p k_{t-1}$. Thus, $AC(B_i) \geq \tilde{y}(B_i)k_{t-1} - \overline{y}_p k_{t-1} = \tilde{y}(B_i)'k_{t-1}$. Using the same argument it can be shown that after each subsequent addition of a ball to cluster of B_i the claim is true.

In the next step, L_t is added to $\mathcal{O}$. Let $\tilde{y}(B_i)$ be the y-accumulation before this. After this addition, the new y-accumulation $\tilde{y}(B_i)' = \tilde{y}(B_i) + Y(L_t, B_i)$. If $\tilde{y}(B_i) \leq 0$, the new available capacity $A_i' \geq Y(L_t, B_i)k_t \geq \tilde{y}(B_i)'k_t$. Otherwise, $\tilde{y}(B_i) > 0$, the new available capacity by the induction hypothesis is, $A_i' = AC(B_i) + Y(L_t, B_i)k_t \geq \tilde{y}(B_i)k_{t-1} + Y(L_t, B_i)k_t \geq (\tilde{y}(B_i) + Y(L_t, B_i))k_t = \tilde{y}(B_i)'k_t$. ◀

The next lemma shows that for any ball $B_i \in \mathcal{H}_1$, y-accumulation is bounded, which is similar to Lemma 3.4 of [4].

▶ **Lemma 8.** *At any point, for any ball $B_i \in \mathcal{H}_1$, $\tilde{y}(B_i) < 1 + 10\alpha$.*

Intuitively, if the y-accumulation of B_i exceeds the bound, it must be due to selection of a ball L_t in $\mathcal{L}_1$. However, one can show that B_i had enough available capacity to absorb the flow from L_t. Hence, the bound follows.

The following lemma gives an upper bound on the number of balls of $\mathcal{L}_1$ that are fully opened.

▶ **Lemma 9.** *At the end of the Cluster Formation stage, $|\mathcal{O}| \leq 60((1+10\alpha)|\mathcal{H}_1| + \sum_{B_i \in \mathcal{L}_1} \overline{y}_i)$.*

Proof.

$$\begin{aligned}
\sum_{B_i \in \mathcal{H}_1} \tilde{y}(B_i) &= \sum_{B_i \in \mathcal{H}_1} \sum_{L_t \in \mathcal{O}} Y(L_t, B_i) - \sum_{B_i \in \mathcal{H}_1} \sum_{B_i \in \mathcal{L}_1 \cap \text{cluster}(B_i)} \overline{y}_i \\
&\geq \sum_{B_i \in \mathcal{H}_1} \sum_{L_t \in \mathcal{O}} F(L_t, B_i)/k_t - \sum_{B_i \in \mathcal{L}_1} \overline{y}_i \\
&= \sum_{t=1}^{I} F_t/k_t - \sum_{B_i \in \mathcal{L}_1} \overline{y}_i \\
&\geq |\mathcal{O}|/60 - \sum_{B_i \in \mathcal{L}_1} \overline{y}_i \qquad (F_t \geq k_t/60 \text{ by Lemma 6})
\end{aligned}$$

Also, by Lemma 8, $\sum_{B_i \in \mathcal{H}_1} \tilde{y}(B_i) \leq (1 + 10\alpha)|\mathcal{H}_1|$. It follows that, $|\mathcal{O}| \leq 60((1 + 10\alpha)|\mathcal{H}_1| + \sum_{B_i \in \mathcal{L}_1} \overline{y}_i)$. ◀

We obtain the following bound on the cost of the rounded solution.

▶ **Lemma 10.** *When the algorithm terminates the total cost of the solution is at most $10|\mathcal{H}_1| + |\mathcal{O}| \leq (70 + 600\alpha)\text{cost}(\sigma^*)/\alpha$.*

Proof. We note that from a heavy balls' cluster at most 10 balls are selected and all the balls in $\mathcal{O}$ are selected. Now, by Lemma 9,

$$\begin{aligned}10|\mathcal{H}_1| + |\mathcal{O}| &\leq 10|\mathcal{H}_1| + 60((1+10\alpha)|\mathcal{H}_1| + \sum_{B_i \in \mathcal{L}_1} \overline{y}_i) \\ &\leq (70 + 600\alpha)(|\mathcal{H}_1| + \sum_{B_i \in \mathcal{L}_1} \overline{y}_i) \\ &\leq (70 + 600\alpha)\text{cost}(\sigma^*)/\alpha\end{aligned}$$

◀

The following lemma shows that 5 factor expansion is sufficient to serve the points assigned to each cluster.

▶ **Lemma 11.** *Using factor 5 expansion of the balls the flow of any cluster can be assigned to the chosen balls without violating the capacities.*

Proof. It is clear from the algorithm that the coverage constraints are satisfied by expanding the balls by at most a factor of 5. Here we consider the capacity constraints. Note that in the first case the capacities of the selected light balls are trivially satisfied. Also, the remaining flow assigned to B_h must have an amount at most U_h due to the way balls are added to a cluster. Thus, its capacity constraint is satisfied. In the other case, let the total amount of flow rerouted from the selected 10 light balls to B_h in Cluster Formation step be f. Also, let B_ℓ be the smallest radius ball among these 10 balls. Thus, the available capacity of all these balls is at least $10U'_\ell - f$. Note that $U_h \leq U_\ell$, as B_ℓ is larger than B_h. Now, as each light balls' capacity is reduced to a factor 10 of the original capacity and the capacity of B_h remains unchanged, $U_h \leq 10U'_\ell$. Hence, the available capacity of all these 10 balls is at least $U_h - f$. As the remaining flow is at most $U_h - f$, it follows that the capacity constraints of these balls are satisfied. ◀

We summarize our findings in the following lemma.

▶ **Lemma 12.** *The solution $(\overline{x}, \overline{y})$ satisfies all the Constraints of AUX-LP1 except Constraint 11. Moreover,*

1. $\overline{y}_i = 1$ *for all* $B_i \in \mathcal{H}_1 \cup \mathcal{O}$ *and* $\overline{y}_i = 0$ *for all other balls.*
2. *For any* $p_j \in P_1$, $\sum_{B_i \in \mathcal{H}_1 \cup \mathcal{O}} \overline{x}_{ij} = 1$.
3. *For any point* $p_j \in P_1$, *if* $\overline{x}_{ij} > 0$, $d(c_i, p_j) \leq 5 \cdot r_i$.
4. $\text{cost}((\overline{x}, \overline{y})) \leq (70 + 600\alpha)\text{cost}(\sigma^*)/\alpha$.

4.2 Rounding the Second Auxilliary LP

Note that we are given a feasible LP solution $\hat{\sigma} = (\hat{x}, \hat{y})$ to AUX-LP2 that has the following properties.

1. For any $B_i \in \mathcal{L}_2$, $\hat{y}_i \leq 10\alpha$.
2. For any $p_j \in P_2$, $\sum_{B_i \in \mathcal{L}_2} \hat{x}_{ij} \geq 4\alpha$.
3. For any $p_j \in P_2$ and $B_i \in \mathcal{L}_2$, $\hat{x}_{ij} \leq \alpha$.
4. $\text{cost}(\hat{\sigma}) \leq 10 \cdot \text{cost}(\sigma^*)$.

First, we create a new solution to AUX-LP2 from $\hat{\sigma}$ which has cost at most two times that of $\hat{\sigma}$. We denote the new solution as well by $\hat{\sigma}$. Thus, for distinction, we denote the old values by $\hat{y}'_i$ and $\hat{x}'_{ij}$. For each y variable, its new value is twice the old value. Thus, $\hat{y}_i = 2\hat{y}'_i \leq 20\alpha < 1$. The last inequality follows for $\alpha \leq 1/60$. And, for each x variable, its new value is twice the old value. Thus, $\hat{x}_{ij} = 2\hat{x}'_{ij} \leq 2\alpha$. Note that, now, some points might receive flow of more than 1. We adjust the $\hat{x}$ values of these points so that each such point receives 1 amount of flow. We obtain the following lemma.

▶ **Lemma 13.** *There is a feasible LP solution $\hat{\sigma} = (\hat{x}, \hat{y})$ to AUX-LP2 that has the following properties.*

1. *For any $B_i \in \mathcal{L}_2$, $\hat{y}_i \leq 20\alpha$.*
2. *For any $p_j \in P_2$, $\sum_{B_i \in \mathcal{L}_2} \hat{x}_{ij} \geq 8\alpha$.*
3. *For any $p_j \in P_2$ and $B_i \in \mathcal{L}_2$, $\hat{x}_{ij} \leq 2\alpha$.*
4. *$\text{cost}(\hat{\sigma}) \leq 20 \cdot \text{cost}(\sigma^*)$.*

Proof. First note that $\text{cost}(\hat{\sigma}) \leq 20 \cdot \text{cost}(\sigma^*)$, as the values of the y variables are doubled. Next, we show that $\hat{\sigma}$ is feasible.

As the y variables are doubled and $\hat{x}_{ij} \leq 2\hat{x}'_{ij}$, $\hat{x}_{ij} \leq \hat{y}_i$. Thus, Constraint 14 is satisfied.

For $B_i \in \mathcal{L}_2$, $\sum_{p_j \in P_2} \hat{x}_{ij} \leq \sum_{p_j \in P_2} 2\hat{x}'_{ij} = 2\sum_{p_j \in P_2} \hat{x}'_{ij} \leq 2\hat{y}'_i \cdot U'_i = \hat{y}_i \cdot U'_i$. Thus, Constraint 15 is satisfied.

As we do not decrease the x variables, unless a point gets more than 1 amount of flow, Constraint 16 is also satisfied. Also, it is trivial to verify that Constraints 17-19 are also satisfied.

Properties 1, 3, and 4 follows immediately. Also, Property 2 follows from the fact that previously each point received a flow of at least 4α from the balls in $\mathcal{L}_2$. Hence, the lemma follows. ◀

We start with the fractional solution $\hat{\sigma} = (\hat{x}, \hat{y})$ and round it so that $\hat{y}$ becomes integral. Throughout our algorithm we modify $\hat{\sigma}$ over several steps to finally obtain the desired solution. Thus whenever we refer to $\hat{\sigma}$ we refer to its current value. For any $p_j \in P_2$, let $\delta_j = \sum_{B_i \in \mathcal{L}_2} \hat{x}_{ij}$. Note that $\delta_j \geq 8\alpha$. Let S and $\mathcal{O}'$ be two disjoint sets of balls which are initialized to $\mathcal{L}_2$ and $\emptyset$, respectively. Throughout we also maintain that $\sum_{B_i \in S \cup \mathcal{O}'} \hat{x}_{ij} = \delta_j$. Note that this is true in the beginning. Our algorithm is as follows.

While there is a point $p_j \in P_2$ such that $\sum_{B_i \in S} \hat{x}_{ij} > \alpha$, we do the following.

Let S_j be the set of balls in S that give flow to p_j, i.e., $S_j = \{B_i \in S : \hat{x}_{ij} > 0\}$. Note that as $\sum_{B_i \in S_j} \hat{x}_{ij} = \sum_{B_i \in S} \hat{x}_{ij} > \alpha$, $\sum_{B_i \in S_j} \hat{y}_i \geq \sum_{B_i \in S_j} \hat{x}_{ij} > \alpha$. Find $T \subseteq S_j$ such that $\alpha \leq \sum_{B_i \in T} \hat{y}_i \leq 21\alpha$. Such a subset can always be found using a linear scan of S_j, as $\sum_{B_i \in S_j} \hat{y}_i > \alpha$ and $\hat{y}_i \leq 20\alpha$ for all $B_i \in S_j$. Let B_t be the largest ball in T. Set $\hat{y}_t = 1$ and $\hat{y}_i = 0$ for each $B_i \in T$. Add B_t to $\mathcal{O}'$. Remove all balls in T from S. Reroute the flow from all balls in $T \setminus \{B_t\}$ to B_t.

▶ **Lemma 14.** *During the course of the above algorithm, the solution $\hat{\sigma}$ has cost at most $20 \cdot \text{cost}(\sigma^*)/\alpha$ and satisfies all the constraints of AUX-LP2 except Constraint 17. Moreover, for a point $p_j \in P_2$, if $\hat{x}_{ij} > 0$, $d(c_i, p_j) \leq 3 \cdot r_i$.*

Proof. First, we prove the feasibility of $\hat{\sigma}$ using induction on the iteration number. In the beginning, the claim holds. Now, consider a particular iteration. Note that the balls for which the $\hat{y}$ values are changed are in T and the points for which the $\hat{x}$ values are changed are the set of points P' that receive flow from a ball in T. It is sufficient to show that the constraints concerning these balls and points hold. Constraint 14 is satisfied as for each such point p_j, and the ball B_t, $\hat{x}_{tj} \leq \delta_j \leq 1 = \hat{y}_t$ and for a ball $B_i \in T \setminus \{B_t\}$, $\hat{x}_{ij} = 0$. Now, we argue that the capacity constraint of the ball B_t is satisfied. Note that in the beginning of the iteration, the total flow out of balls in T to all points is at most

$$\sum_{B_i \in T} \hat{y}_i \cdot U'_i \leq U'_t \sum_{B_i \in T} \hat{y}_i \leq U'_t \cdot 21\alpha < U'_t.$$

The first inequality follows from the fact that B_t is the largest ball in T and all the capacities of the balls in $\mathcal{L}_1$ are scaled by the same factor. The last inequality follows, as $\alpha \leq 1/60$.

Now, as this total flow is served by B_t the claim holds. Constraint 16 is also satisfied for all the points in P', as the flow is only rerouted from a ball to B_t. The other constraints except 17 are trivial to verify.

Note that whenever we set $\hat{y}_t = 1$, we also set $\hat{y}_i = 0$ for each $B_i \in T \setminus \{B_t\}$. Thus for each ball B_t we can charge all the balls in T. As $\sum_{B_i \in T} \hat{y}_i \geq \alpha$, the cost blow up is at most a factor of $1/\alpha$. Thus, the cost is at most $20 \cdot \text{cost}(\sigma^*)/\alpha$.

Whenever we reassign flow from balls in $T \setminus \{B_t\}$ to B_t, for a point $p_j \in P_2$, it holds that if $\hat{x}_{tj} > 0$, $d(c_t, p_j) \leq 3 \cdot r_t$. This is true, as B_t is the largest ball in T. As we remove B_t from S, no flow is ever rerouted again from or to B_t. Hence, the claim continues to hold for all points. ◀

Now, note that when the while loop of the above algorithm terminates, it holds that for any $p_j \in P_2$, $\sum_{B_i \in S} \hat{x}_{ij} \leq \alpha$. Thus, $\sum_{B_i \in \mathcal{O}'} \hat{x}_{ij} \geq \delta_j - \alpha \geq 7\alpha$. Using this fact, we compute a solution (x', y') to AUX-LP2 (that violates Constraint 17 and Constraint 15). For any ball B_i in $\mathcal{O}'$, set $y'_i = 1$. For any $p_j \in P_2$ and B_i in $\mathcal{O}'$, set $x'_{ij} = \min\{(1/(7\alpha)) \cdot \hat{x}_{ij}, 1\}$. All the other x' and y' values are set to zero. Note that, now, each point receives a flow of at least 1. We adjust the x' values so that each point receives exactly 1 amount of flow. We obtain the following lemma.

▶ **Lemma 15.** *The solution (x', y') satisfies all the constraints of AUX-LP2 except Constraint 17 and Constraint 15. Moreover,*

1. *$y'_i = 1$ for all $B_i \in \mathcal{O}'$ and $y'_i = 0$ for all $B_i \notin \mathcal{O}'$.*
2. *For any $p_j \in P_2$, $\sum_{B_i \in \mathcal{O}'} x'_{ij} = 1$.*
3. *For any $B_i \in \mathcal{O}'$, $\sum_{p_j \in P_2} x'_{ij} \leq (1/(7\alpha)) \cdot U'_i$.*
4. *For any point $p_j \in P_2$, if $x'_{ij} > 0$, $d(c_i, p_j) \leq 3 \cdot r_i$.*
5. *$\text{cost}((x', y')) \leq 20 \cdot \text{cost}(\sigma^*)/\alpha$.*

4.3 Combining the Two LP solutions

Next, we compose the two rounded solutions obtained in Lemma 12 and 15 to construct a solution for the original instance. In the new solution $(\tilde{x}, \tilde{y})$ we fully open the balls in $\mathcal{H}_1 \cup \mathcal{O} \cup \mathcal{O}'$. Also we keep all the x values unchanged. Note that a ball B_i of $\mathcal{L}_1 (= \mathcal{L}_2)$ can be opened in both solutions. However, as we had changed its capacity before, the total capacity that it can use is at most $U'_i + (1/(7\alpha)) \cdot U'_i \leq (1 + 1/(7\alpha))U_i/10 < U_i$. The last inequality follows by setting $\alpha = 1/60$. The total cost of the new solution is at most $(90 + 600\alpha)\text{cost}(\sigma^*)/\alpha \leq 6000 \cdot \text{cost}(\sigma^*)$. Hence, we obtain the following lemma.

▶ **Lemma 16.** *The solution $(\tilde{x}, \tilde{y})$ satisfies all the Constraints of MMCC-LP except Constraint 11. Moreover,*

1. *For any point $p_j \in P_1$, if $\overline{x}_{ij} > 0$, $d(c_i, p_j) \leq 5 \cdot r_i$.*
2. *$\text{cost}((\tilde{x}, \tilde{y})) \leq 6000 \cdot \text{cost}(\sigma^*)$.*

We note that by selecting different values of the parameters throughout the algorithm one can improve the constant in the approximation factor. However, as our main goal is to show any $O(1)$-approximation we did not pursue this.

▶ **Theorem 17.** *There is an $O(1)$-approximation for MMCC by expanding the balls by a factor of at most 5.*

5 Uniform Capacitated Case

The algorithm in the uniform case is same except the Selection of Balls step. The next lemma shows that the Selection of Balls can be performed with only 4.24 factor expansion of the balls.

▶ **Lemma 18.** *Using factor* 4.24 *expansion of the balls the flow of any cluster can be assigned to the chosen balls without violating the capacities.*

Proof. Consider any cluster of a heavy ball $B_h \in \mathcal{H}_1$. Let $c = (1+\sqrt{5})/2$. If B_h is one of the top 10 largest balls in the cluster, then select all the balls larger than B_h and also B_h. Only B_h is expanded by a factor of 3. The flow rerouted from any selected ball of $\mathcal{L}_1$ to B_h is assigned to the selected ball. Note that for the remaining balls of $\mathcal{L}_1$ which are in the same cluster and not chosen, are smaller than B_h and thus can be covered by a factor 3 expansion of B_h. The remaining flow is assigned to B_h. Note that in this case the capacities of the selected light balls are trivially satisfied. Also, the remaining flow assigned to B_h must have an amount at most U_h. Thus, the capacity constraint of B_h is satisfied.

Now, suppose B_h is not one of the top 10 largest balls. Let B_ℓ be the 10^{th} largest ball of this cluster. Also, let r_h and r_ℓ be the radius of B_h and B_ℓ, respectively. Now, there can be two cases (i) $r_h \geq r_\ell/c$ or (ii) $r_h < r_\ell/c$. In the first case, we select the top 9 largest balls all of which are in $\mathcal{L}_1$ and also B_h. The flow rerouted from any selected ball (except B_h) to B_h is assigned to the selected ball. Now consider the remaining flow assigned to the cluster. Also consider a point p_j which receives a part of this flow and not in any of the balls selected from $\mathcal{L}_1$. Then, by triangle inequality, the distance between p_j and the center c_h of B_h is at most $r_h + 2r_\ell \leq r_h + 2cr_h \leq 4.24r_h$. We expand B_h by the factor 4.24 and assign the remaining flow to B_h. Selected balls which are in $\mathcal{L}_1$ are not expanded. The capacity constraints are also satisfied due to the same reason mentioned above.

In the second case, the top 10 largest balls are selected all of which are in $\mathcal{L}_1$. The flow rerouted from any selected ball to B_h is assigned to the selected ball. Now consider the remaining flow assigned to the cluster. Also consider a point p_j which receives a part of this flow and not in any of the selected balls. Let $B_t = B(c_t, r_t)$ be a selected ball. Then, by triangle inequality, the distance between p_j and c_t is at most $r_t + 2r_h + 2r_\ell \leq r_t + 2r_\ell/c + 2r_\ell \leq (3 + 2/c)r_t \leq 4.24r_t$. The second last inequality follows, as r_ℓ is the smallest of the selected balls. We expand each selected ball by the factor 4.24. The remaining flow is assigned arbitrarily to selected balls respecting their capacity. Let the total amount of flow rerouted from the selected 10 light balls to B_h in Cluster Formation step be f. The total available capacity of all these balls is at least $10U'_\ell - f$, as B_ℓ is the smallest radius ball among these 10 balls. Now, as the capacity of each ball of $\mathcal{L}_1$ is reduced to a factor 10 of the original capacity and the capacity of B_h remains unchanged, $U_h \leq 10U'_\ell$. Hence, the available capacity of all these 10 balls is at least $U_h - f$. As the remaining flow is at most $U_h - f$, it follows that the capacity constraints of these balls are satisfied. ◀

▶ **Theorem 19.** *There is an $O(1)$-approximation for MCC by expanding the balls by a factor of at most* 4.24.

6 Conclusion

In this paper, we improve the expansion factor of the balls for MCC and MMCC to 4.24 and 5, respectively, in the context of obtaining constant approximation. Our approximation factor is a large constant. But, it is possible to improve this factor by setting different values

of parameters in the algorithm. Note that the lower bound on the expansion factor is still 3. So, one obvious problem is to reduce the gap further. Another interesting problem is to design a true constant approximation for the Euclidean version of MCC, which does not expand the balls. We note that this problem is open even in the plane.

Note that if the capacities are not monotonic, no $(O(1), O(1))$-approximation is known. On the other hand, the lower bound on the expansion factor even in this case is $3 - \epsilon$, similar to the uniform capacity case. So, a very natural and interesting direction of research is to study this most general version of the problem.

Abstract

We study a graph realization problem that pertains to degrees in vertex neighborhoods. The classical problem of *degree sequence realizability* asks whether or not a given sequence of n positive integers is equal to the degree sequence of some n-vertex undirected simple graph. While the realizability problem of degree sequences has been well studied for different classes of graphs, there has been relatively little work concerning the realizability of other types of information *profiles*, such as the vertex neighborhood profiles.

In this paper we introduce and explore the *minimum degrees in vertex neighborhood profile* as it is one of the most natural extensions of the classical degree profile to *vertex neighboring degree profiles*. Given a graph $G = (V, E)$, the min-degree of a vertex $v \in V$, namely $\textsc{MinND}(v)$, is given by $\min\{deg(w) \mid w \in N[v]\}$. Our input is a sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$, where $d_{i+1} > d_i$ and each n_i is a positive integer. We provide some necessary and sufficient conditions for σ to be realizable. Furthermore, under the restriction that the realization is acyclic, i.e., a tree or a forest, we provide a full characterization of realizable sequences, along with a corresponding constructive algorithm.

We believe our results are a crucial step towards understanding extremal neighborhood degree relations in graphs.

1 Introduction

Background and Motivation. Vertex degrees occur as a central and natural parameter in many network applications, and provide information on the significance, centrality, connectedness and influence of each vertex in the network, contributing to our understanding of the network structure and properties. The *m degree sequence* of an n-vertex graph G consists of its vertex degrees, $\textsc{Deg}(G) = (d_1, \ldots, d_n)$. It is a straightforwad task to extract the degree sequence of a given graph G from its adjacency matrix or adjacency lists. A more

interesting and challenging task, known as the *realization* problem, concerns the opposite situation where, given a sequence of non-negative integers D, it is necessary to decide whether there exists a graph whose degree sequence conforms to D. A sequence that admits such a realization is called *graphic*. A necessary and sufficient condition for a given sequence of integers to be graphic (also implying an $O(n)$ decision algorithm) was presented by Erdös and Gallai in [10]. Havel and Hakimi [12, 14] described an algorithm that given a sequence of integers computes in $O(m)$ time an m-edge graph realizing it, or proves that the given sequence is not graphic. Over the years, a number of extensions of the degree realization problem were studied as well, e.g., [1, 3, 23].

The current work is motivated by the fact that similar realization questions arise naturally in a variety of *other* contexts. Typically, some type of information profile, specifying some desired vertex property (related to degrees, distances, centrality, connectedness, etc), is given to us, and we are asked to find a graph conforming to the specified profile. Questions of this type span a wide research area, which was so far studied only sparsely. The current paper makes a step towards studying one specific information profile, from the family of *neighborhood degree* profiles. Such profiles arise in the context of social networks, where it is common to look at vertex degrees as representing influence or centrality, and neighboring degrees as representing proximity to power. Neighborhood degrees were considered before in [6], but there each vertex i is associated with the *list* of degrees of all vertices in its neighborhood. Our profiles are leaner, and provide a single parameter per vertex. In [5], we studied maximum-neighborhood-degree (MaxND) profiles, in which each vertex i is associated with the *maximum* degree of the vertices in its (closed) neighborhood.

A natural problem in this direction concerns the *minimum* degrees in the vertex neighborhoods. For each vertex i, let d_i denote the minimum vertex degree in i's closed neighborhood (i.e., including the vertex i itself). Then $\text{MinND}(G) = (d_1, \ldots, d_n)$ is the minimum-neighborhood-degree profile of G.

The same realizability questions asked above for degree sequences can be posed for neighborhood degree profiles as well. This brings us to the following central question of our work:

> Minimum Neighborhood Degree Realization
>
> **Input:** A sequence $D = (d_1, \ldots, d_n)$ of non-negative integers.
>
> **Question:** Is there a graph G of size n such that the *minimum* degree in the closed neighborhood of the *i-th* vertex in G is exactly equal to d_i ?

Our Contributions. We now discuss our contributions in detail. For simplicity, we represent the input vector D alternatively in a more compact format as $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$, where n_i's are positive integers with $n(\sigma) = \sum_{i=1}^{\ell} n_i = n$; here the specification requires that G contains exactly n_i vertices whose minimum degree in neighborhood is d_i. We may assume that $d_\ell > d_{\ell-1} > \cdots > d_1 \geq 1$ (noting that vertices with minimum-neighborhood-degree zero are necessarily singletons and can be handled separately).

Conditions. We show the following necessary and sufficient conditions for $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ to be MinND realizable. The necessary condition is that

$$d_i \leq n_1 + n_2 + \ldots + n_i - 1 \ , \text{ for } i \in [1, \ell], \quad \text{and} \tag{NC1}$$

$$d_\ell \leq \left\lfloor \frac{n_1 d_1}{d_1 + 1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2 + 1} \right\rfloor + \ldots + \left\lfloor \frac{n_\ell d_\ell}{d_\ell + 1} \right\rfloor . \tag{NC2}$$

The sufficient condition is that

$$d_i \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor + \ldots + \left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor \text{ , for } i \in [1,\ell] \text{ .} \tag{SC}$$

We remark that these conditions can be computed in polynomial time, and the realizing graphs, when any exist, can be constructed in polynomial time.

Approximation bound. For any sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying the first necessary condition (NC1), the sequence $\sigma^\gamma = (d_\ell^{\lceil \gamma n_\ell \rceil}, \ldots, d_1^{\lceil \gamma n_1 \rceil})$, where $\gamma = (d_1+1)/d_1$ satisfies[1] the sufficient condition (SC), thus our necessary and sufficient conditions differ by a factor of at most 2 in the n_i's.

We leave it as an open question to resolve the problem exactly over general graphs.

▶ **Open Question.** *Does there exist a closed-form characterization for realizing* MinND *profiles for general graphs?*

For the special case of ℓ bounded by 3, we show that $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ is MinND-realizable if and only if along with (NC1) and (NC2) the following condition is satisfied:

$$d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor, \text{ or } d_3 + 1 \leq n_1 + n_2 + n_3 - \left(1 + \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil \right) \tag{NC3}$$

Acyclic Realization. When the required graph G is acyclic (that is, G is a tree or a forest), we give tight bounds for realizability (in the form of a constructive algorithm as well as a matching lower bound). For a sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$, let

$$\phi(\sigma) = d_\ell^2 + 1 + \sum_{i=1}^{\ell} (n_i - 1)(d_i - 1)^2 + \sum_{i=1}^{\ell-1} d_i(d_i - 1) \text{ .}$$

We show that σ is MinND-realizable by a tree if and only if the following conditions are met:

$$d_1 = 1 \qquad \text{and} \qquad \phi(\sigma) \leq n(\sigma) \text{ .} \tag{NC-Tree}$$

Recall that $n(\sigma) = \sum_{i=1}^{\ell} n_i$. Observe that when the profile is (1^n), condition (NC-Tree) is equivalent to claiming that (1^n) is realizable for any $n \geq 2$. Indeed, the star graph provides such a realization. Next, note that d_1 and n_1 do not appear in $\phi(\sigma)$ when $\ell > 1$, because of the terms $d_i - 1$. However, n_1 is part of $n(\sigma)$, and it must be large enough to satisfy the condition. Therefore, condition (NC-Tree) can be rewritten as $\phi(\sigma) - \sum_{i=2}^{\ell} n_i \leq n_1$, where the left hand side is effectively independent of d_1 and n_1. That is, any sub-profile $\sigma' = (d_\ell^{n_\ell}, \cdots, d_2^{n_2})$ of σ can be realized if it is expanded into a full profile $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ for which n_1 is large enough. Hence in a sense, these n_1 vertices, which are leaves or neighbors of leaves, "control" the realizability of the profile.

[1] For further explanation, see the text just before Corollary 10.

The MaxND profile. We remark that in the companion paper [5] we studied the dual MaxND realization problem, which turns out to exhibit radically different behavior from the MinND realization problem, and requires different techniques. In the MaxND profile, d_i specifies the *maximum* degree in the neighborhood of the ith vertex in G. [5] gives tight bounds for realizations by an arbitrary graph and by a connected graph. However, the question of realizations with trees is left open.

It is interesting to contrast the behavior of the MinND and MaxND profiles. For general graphs, MinND appears to be more difficult, since it is nonmonotone when edges are added or deleted, while the MaxND profile is monotone. For trees, on the other hand, the realizability of the MinND profile depends only on the leaves and their parents, which simplifies the analysis; no analogous simplifying property was found for the MaxND profile.

Applicability. Realization questions may potentially be applicable in two general settings. The first involves scientific contexts, where the information profile may consist of measurement results obtained by observing some natural network of unknown structure and our goal is to build a model (possibly explaining the measurements). The second involves engineering contexts, where the profile is derived from a given specification and the goal is to implement a network abiding by the specification.

One of the concrete uses for degree realization techniques is within the framework of generating random graphs with specific given properties. In particular, given the ability to efficiently generate a graph with a given degree sequence, one can design methods for generating a random graph with a specific degree distribution based on first generating a random degree sequence from the given distribution. As happened with degree realization, one may expect that efficient solutions for the problem of realizing certain neighborhood degree profiles may lead to improved techniques for generating and simulating social networks with prescribed neighborhood degree profiles.

Finally, a popular sampling technique that takes advantage of the Friendship Paradox [11] is based on sampling a *random neighbor* of a *random vertex*. While the average of the degrees in the traditional degree profile is the expected degree of a random vertex, the lower and upper bounds on the expected degree of the random neighbor are the averages of the degrees in the MinND and MaxND profiles respectively. Providing realizations and characterizing realizable profiles may be useful in exploring and analyzing the performance of this sampling technique.

Related Work. Many works have addressed related questions such as finding all the (non-isomorphic) graphs that realize a given degree sequence, counting all the (non-isomorphic) realizing graphs of a given degree sequence, sampling a random realization for a given degree sequence as uniformly as possible, or determining the conditions under which a given degree sequence defines a unique realizing graph , cf. [8, 10, 12, 13, 14, 15, 18, 19, 21, 20, 22, 24]. Other works such as [7, 9, 16] studied interesting applications in the context of social networks.

To the best of our knowledge, the MinND realization problems have not been explored so far. There are two other related problems that we are aware of. The first is the *shotgun assembly* problem [17], where the characteristic associated with the vertex i is some description of its neighborhood up to radius r. The second is the *neighborhood degree lists* problem [6], where the characteristic associated with the vertex i is the list of degrees of all vertices in i's neighborhood. We point out that in contrast to these studies, our MinND problem applies to a more restricted profile (with a single number characterizing each vertex), and the techniques involved are totally different from those of [6, 17]. Several other realization problems are surveyed in [2, 4].

2 Preliminaries

Let H be an undirected graph. We use $V(H)$ and $E(H)$ to respectively denote the vertex set and the edge set of the graph H. For a vertex $x \in V(H)$, let $deg_H(x)$ denote the degree of x in H. Let $N_H[x] = \{x\} \cup \{y \mid (x,y) \in E(H)\}$ be the (closed) neighborhood of x in H. For a set $W \subseteq V(H)$, we denote by $N_H(W)$, the set of all the vertices lying outside the set W that are adjacent to some vertex in W, that is, $N_H(W) = (\bigcup_{w \in W} N[w]) \setminus W$. Given a vertex v in H, the minimum degree in the neighborhood of v, namely $\textsc{MinND}_H(v)$, is defined to be the minimum over the degrees of all the vertices in the neighborhood of v. Given a set of vertices A in a graph H, we denote by $H[A]$ the subgraph of H induced by the vertices of A. For a set A and a vertex $x \in V(H)$, we denote by $A \cup x$ and $A \setminus x$, respectively, the sets $A \cup \{x\}$ and $A \setminus \{x\}$. When the graph is clear from context, for simplicity, we omit the subscripts H in all our notations. Finally, given two integers $i \leq j$, we define $[i,j] = \{i, i+1, \ldots, j\}$.

Consider a profile $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying $d_\ell > d_{\ell-1} > \cdots > d_1 > 0$. Denote its size by $n(\sigma) = \sum_{i=1}^{\ell} n_i$. The profile σ is said to be *MinND realizable* if there exists an $n(\sigma)$-vertex graph G such that $|\{v \in V(G) : \textsc{MinND}(v) = d_i\}| = n_i$, namely, G contains exactly n_i vertices whose MinND is d_i, for every $i \in [1,\ell]$. Figure 1 depicts a MinND realization of $(2^3, 1^2)$. (The numbers represent vertex degrees.)

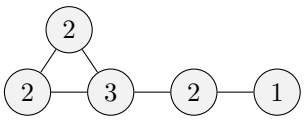

Figure 1 A MinND realization of $(2^3, 1^2)$.

3 Realizations on Acyclic graphs

In this section, we provide a complete characterisation for realizability on acyclic graphs.

3.1 Constructive Algorithm

▶ **Proposition 1.** *Any sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying $d_1 = 1$ and $\phi(\sigma) \leq n(\sigma)$ is MinND-realizable over trees.*

Proof. Initialize T to be a star with a root r and d_ℓ leaves. Let the initial set of $d_\ell + 1$ vertices be X_0. Notice $|X_0 \setminus \{r\}| = d_\ell > \ell - 1$, since $d_1 = 1$.

Partition $X_0 \setminus \{r\}$ into two sets Z_1 and Z_2, respectively of size $\ell - 1$ and $d_\ell - \ell + 1$. We label the $(i-1)^{th}$ vertex in Z_1 as $v_{i,1}$, for $i \in [2,\ell]$. Observe $|Z_2| \geq 1$.

Our algorithm (to iteratively build T) proceeds in ℓ rounds: $i = \ell, \ldots, 1$. (See Algorithm 1 for a pseudocode).

We will maintain the following invariant in our algorithm.

Invariant. *Before the beginning of round i, the vertex $v_{i,1}$ is a leaf node in the partially constructed tree T, and its neighbor r (always) has degree at least $d_\ell \geq d_i$.*

Description of round i ($i > 1$). Take the leaf node $v_{i,1} \in X_0$. Add $n_i - 1$ new vertices, namely $v_{i,2}, \ldots, v_{i,n_i}$ and connect each $v_{i,j}$ to $v_{i,j-1}$, for $2 \leq j \leq n_i$. Let V_i represent the set $\{v_{i,1}, v_{i,2}, \ldots, v_{i,n_i}\}$. Notice that V_i forms a simple path. Recall by our invariant that the neighbor of $v_{i,1}$ (other than $v_{i,2}$ in T) had degree already at least d_i. We will ensure next the following:

C1: All vertices in V_i have degree d_i.

C2: All neighbors of vertices in V_i have degree at least d_i.

To ensure condition C1, we proceed as follows: (i) Since the vertices $v_{i,1}, \ldots, v_{i,n_i-1}$ already have degree 2 in the current T_i, they are connected to $d_i - 2$ *new* vertices, and (ii) the vertex v_{i,n_i} is connected to $d_i - 1$ *new* vertices. In the process we add in total $n_i(d_i - 2) + 1$ new vertices. Let these be represented by the set A_i.

To ensure condition C2, we connect each $a \in A_i$ to an additional $d_i - 1$ *new* vertices. Let B_i be the set of new vertices added. Then, $|B_i| = |A_i| \cdot (d_i - 1)$.

We now compute the size of $V_i \cup A_i \cup B_i$.

$$\begin{aligned} |V_i \cup A_i \cup B_i| &= n_i + \big(n_i(d_i-2)+1\big) + \big(n_i(d_i-2)+1\big)\cdot(d_i-1) \\ &= n_i + d_i\big(n_i(d_i-2)+1\big) \\ &= n_i\big(d_i-1\big)^2 + d_i \end{aligned}$$

Description of round 1. Finally, in round $i = 1$, add a set Y_0 of $n(\sigma) - \phi(\sigma)$ *new* vertices to T. Observe that $n(\sigma) - \phi(\sigma) \geq 0$ due to the assumption. Connect the root node $r \in X_0$ in T to each of the vertices in Y_0.

We next show that our construction satisfies $|V(T)| = n(\sigma)$.

$$\begin{aligned} |V(T)| &= |X_0| + \sum_{i=2}^{\ell} \big(|V_i \cup A_i \cup B_i| - 1\big) + |Y_0| \\ &= d_\ell + 1 + \sum_{i=2}^{\ell} \big[n_i(d_i-1)^2 + d_i - 1\big] + n(\sigma) - \phi(\sigma) \\ &= d_\ell^2 + 1 + \sum_{i=2}^{\ell} (n_i - 1)(d_i-1)^2 + \sum_{i=2}^{\ell-1} d_i(d_i-1) + n(\sigma) - \phi(\sigma) \\ &= n(\sigma) \end{aligned}$$

Algorithm 1 Computing a tree MinND-realization for a given realizable σ.

Input: A sequence $\sigma = (d_\ell^{n_\ell} \cdots d_1^{n_1})$ satisfying $d_1 = 1$ and $n(\sigma) \geq \phi(\sigma)$.

```
Initialize T to be a star with a root r and d_ℓ leaves.
Label the i^th leaf in T as v_{i,1}, for i ∈ [2, ℓ].
for i = ℓ to 2 do
    Add n_i − 1 new vertices to T, namely v_{i,2}, ..., v_{i,n_i}.
    Connect each v_{i,j} to v_{i,j−1}, for 2 ≤ j ≤ n_i.
    Add to T a set A_i of n_i(d_i − 2) + 1 new vertices.
    Connect each v_{i,j}, for 1 ≤ j ≤ n_i − 1, to d_i − 2 isolated vertices in A_i.
    Connect v_{i,n_i} to d_i − 1 isolated vertices in A_i.
    Add to T a set B_i of |A_i| · (d_i − 1) new vertices.
    Connect each a ∈ A_i to d_i − 1 isolated vertices in B_i.
Add n(σ) − φ(σ) new vertices to T as children of the root r.
Output T.
```

Correctness Analysis

Let V_1 denote the set $V(T) \setminus \bigcup_{i=2}^{\ell} V_i$. Clearly, $|V_i| = n_i$ for $i \in [2, \ell]$, and since $|V(T)| = n(\sigma)$ it follows that $|V_1| = n(\sigma) - \sum_{i=2}^{\ell} n_i = n_1$. Therefore, if we show that for every $u \in V_i$, $\text{MinND}(u) = d_i$, for $i \in [1, \ell]$, then we are done.

Observe that the degrees of vertices in $V_i \cup A_i$ do not alter after round i, so C1 and C2 continue to hold for each V_i, $i \in [2, \ell]$. This shows that for every $u \in V_i$, $\text{MinND}(u) = d_i$, for $i \in [2, \ell]$. We are left to analyse set V_1. We have:

$$\begin{aligned} V_1 &= \left(X_0 \setminus \cup_{i=2}^{\ell}\{v_{i,1}\}\right) \cup Y_0 \cup \left(\cup_{i=2}^{\ell}(A_i \cup B_i)\right) \\ &= \{r\} \cup Z_2 \cup Y_0 \cup \left(\cup_{i=2}^{\ell}(A_i \cup B_i)\right) \end{aligned}$$

For $2 \le i \le \ell$, the set B_i contains only leaves, and each node in A_i must have a neighbor in B_i. Thus, vertices in $\cup_{i=2}^{\ell}(A_i \cup B_i)$ have MinND exactly 1.

So it is left to consider the vertices of $\{r\} \cup Z_2 \cup Y_0$, of which the vertices in $Z_2 \cup Y_0$ have already degree 1. Now recall $Z_2 \neq \emptyset$, and r is adjacent to degree-1 vertices in Z_2, thus MinND of r is 1 as well.

This completes the correctness analysis. ◀

3.2 Tightness Criterion

We next show that our construction is tight, i.e., a sequence is MinND-realizable over trees if and only if it is realizable by the procedure of Proposition 1.

▶ **Proposition 2.** *For a sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying $d_1 = 1$, a necessary condition of MinND-realizability over trees is $\phi(\sigma) \le n(\sigma)$.*

Proof. Consider a profile $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$, and let T be a MinND tree-realization of σ on V. Let $r \in V(T)$ be a vertex that satisfies $\text{MinND}(u) = d_\ell$. Root T at node r. For $i = 1, \ldots, \ell$, let $V_i = \{v \in V(T) \mid \text{MinND}(v) = d_i\}$. Observe that for each $i < \ell$, there exists (at least) one edge, denoted $(y_i, x_i) \in E(T)$, where y_i is the parent of x_i, satisfying the condition that (i) $x_i \in V_i$, and (ii) none of the vertices in the tree-path $(r \rightsquigarrow_T y_i)$ lie in V_i. These edges play a crucial role in our tight bound on $\phi(\sigma)$.

Let

$$\begin{aligned} A &= \{x_i \mid \text{MinND}(y_i) < d_i, \text{ for } i < \ell\}, \\ B &= \{x_i \mid \text{MinND}(y_i) > d_i, \text{ for } i < \ell\}. \end{aligned}$$

For each $w \in V(T)$, let $\mathcal{C}_w$ and $\mathcal{GC}_w$, respectively, be the set consisting of the children and grand-children of w in T. Also let $\mathcal{C}_A = \cup_{w \in A} \mathcal{C}_w$.

Now we define a function $\Gamma : V \mapsto 2^V$ as follows (see example in Figure 2):

$$\Gamma(w) = \begin{cases} \{r\} \cup \mathcal{C}_r \cup \mathcal{GC}_r, & \text{if } w = r, \\ \mathcal{C}_w \cup (\mathcal{GC}_w \setminus \mathcal{C}_A), & \text{if } w \in A, \\ \mathcal{GC}_w \setminus \mathcal{C}_A, & \text{otherwise.} \end{cases}$$

Figure 3 illustrates the subtree induced over $\{w\} \cup \mathcal{C}_w \cup \mathcal{GC}_w$, for some node w.

▷ Claim. $\Gamma(w) \cap \Gamma(v) = \emptyset$ for every $v, w \in V(T)$ such that $v \neq w$.

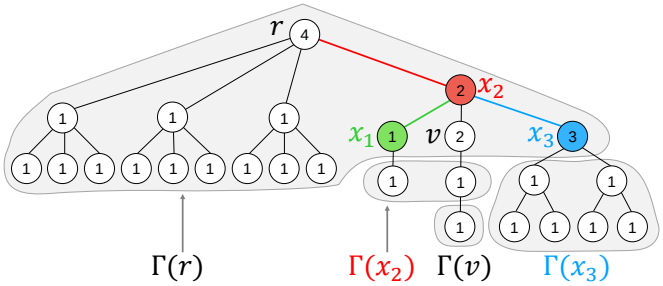

Figure 2 Tree MinND-realization of $\sigma = (4^1 3^1 2^2 1^{22})$. The number in each vertex denotes its MinND. The edges (y_1, x_1), (y_2, x_2) and (y_3, x_3) are colored green, red and blue, respectively. Further, $A = \{x_3\}$ and $B = \{x_1, x_2\}$.

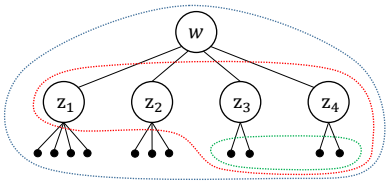

Figure 3 Illustration of a subtree induced over $\{w\} \cup \mathcal{C}_w \cup \mathcal{GC}_w$, for some node w. $\Gamma(w)$ is the set of vertices in the blue dotted line if $w = r$, in the red if $w \in A$, and in the green otherwise (assuming $z_1, z_2 \in A$).

Proof. Let us first consider the case $v = r$. The result is obviously true if $w \notin \mathcal{C}_r$, or $w \notin A$. Now if $w \in \mathcal{C}_r$, then $\text{MinND}(r) \geq \text{MinND}(w)$, thereby implying $w \notin A$.

Next consider any two vertices $v \neq w \in V(T) \setminus \{r\}$. Assume towards contradiction $\Gamma(v) \cap \Gamma(w)$ contains a node z. Then z must be a child of exactly one of the nodes v or w, and the corresponding node must lie in A. Assume $z \in \mathcal{C}_w$, and $w \in A$. Since $z \in \mathcal{C}_w \subseteq \mathcal{C}_A$, we have $z \notin \mathcal{GC}_v \setminus \mathcal{C}_A$, and also z cannot be a child of v, thereby implying $z \notin \Gamma(v)$. Hence, $\Gamma(v) \cap \Gamma(w)$ must be empty. ◁

▷ Claim. For every $v \in V_i$, $1 \leq i \leq \ell$, we have

$$|\Gamma(v)| \geq \begin{cases} d_i(d_i - 1), & \text{if } v \in A \cup B, \\ (d_i - 1)^2, & \text{if } v \notin \{r\} \cup A \cup B. \end{cases}$$

Proof. Consider a node $v \in V_i$, for some $i \leq \ell$. Observe that each $u \in \mathcal{C}_v$ must have degree at least d_i, and thus satisfy $|\mathcal{C}_u| \geq d_i - 1$. Let z_0 be v's parent and $z_1, \ldots, z_t$ be the nodes in $\mathcal{C}_v \cap A$. Since z_0 is an ancestor of $z_1, \ldots, z_t$, by definition of $A \cup B$, the MinND of all the vertices $z_0, z_1, \ldots, z_t$ must be distinct. Without loss of generality, we can assume $\text{MinND}(z_t) > \cdots > \text{MinND}(z_1)$. By definition of A, $\text{MinND}(z_1) > d_i$. Let $\Delta = \max_{j=0}^{t} \text{MinND}(z_j)$. Then $deg(v) \geq \Delta$. Consequently we have $\Delta \geq d_i + t$, since $\Delta \geq \text{MinND}(z_t) > \cdots > \text{MinND}(z_1) > d_i$. So

$$|\mathcal{C}_v \setminus A| = deg(v) - t - 1 \geq \Delta - t - 1 \geq (d_i - 1) \ . \tag{1}$$

We now consider three cases, according to whether v lies in A, B, or $V \setminus (\{r\} \cup A \cup B)$.

1. $v \in A$: By Eq. (1), $|\mathcal{GC}_v \setminus \mathcal{C}_A| \geq (d_i - 1)^2$, and also $|\mathcal{C}_v| \geq d_i - 1$. Combined, we get that $|\Gamma(v)| = |\mathcal{GC}_v \setminus \mathcal{C}_A| + |\mathcal{C}_v| \geq d_i(d_i - 1)$.

2. $v \in B$: By definition of B, MinND$(z_0) > d_i$. Thus, MinND$(z_j) > d_i$ for $j \in [0, t]$. Also, MinND of $z_0, \ldots, z_t$ are distinct. Hence, $\Delta \geq d_i + (t+1)$. So $|\mathcal{C}_v \setminus A| = deg(v) - t \geq \Delta - t \geq d_i$. This implies $|\Gamma(v)| = |\mathcal{GC}_v \setminus \mathcal{C}_A| \geq d_i(d_i - 1)$.
3. $v \notin \{r\} \cup A \cup B$: By Eq. (1), $|\mathcal{GC}_v \setminus \mathcal{C}_A| \geq (d_i - 1)^2$, implying $|\Gamma(v)| \geq (d_i - 1)^2$.

The claim follows. ◁

Note that $\Gamma(r)$ contains at least $d_\ell^2 + 1$ nodes, since the degrees of r and of its children are at least d_ℓ. Now, we are ready to prove the bound over $\phi(\sigma)$. In our calculations we use x_ℓ to denote the node r.

$$\begin{aligned} n(\sigma) = |V(T)| &\geq |\Gamma(r)| + \sum_{i=1}^{\ell} \sum_{v \in V_i \setminus \{x_i\}} |\Gamma(v)| + \sum_{i=1}^{\ell-1} |\Gamma(x_i)| \\ &\geq d_\ell^2 + 1 + \sum_{i=1}^{\ell} (n_i - 1)(d_i - 1)^2 + \sum_{i=1}^{\ell-1} d_i(d_i - 1) \\ &= \phi(\sigma) \ . \end{aligned}$$

This completes our proof of $n(\sigma) \geq \phi(\sigma)$. ◀

▶ **Corollary 3.** *For a sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying $d_1 = 1$, a necessary condition of MinND-realizability over forests is $\phi(\sigma) \leq n(\sigma)$.*

Proof. Given a sequence σ that is MinND-realizable as a forest, it can be partitioned into subsequences $\sigma_1, \ldots, \sigma_k$ corresponding to each of its connected components. By Proposition 2, $n(\sigma_i) \geq \phi(\sigma_i)$ for $i \in [1, k]$. Therefore, $n(\sigma) = \sum_{i=1}^{k} n(\sigma_i) \geq \sum_{i=1}^{k} \phi(\sigma_i) \geq \phi(\sigma)$, where the last inequality follows immediately from the definition of ϕ. ◀

By Proposition 1 and Corollary 3, and the fact that a tree always contains vertices of degree one (and hence also MinND one), the following is immediate.

▶ **Theorem 4.** *The sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ is MinND-realizable over acyclic graphs if and only if $d_1 = 1$, and $\phi(\sigma) \leq n(\sigma)$.*

4 Realizations in General graphs

We first define the notion of *leader* and *follower* crucial to our construction. Let $G = (V, E)$ be any graph. For any vertex $v \in V$, we define *leader*(v) to be a vertex in $N[v]$ of minimum degree, if there is more than one choice we pick the leader arbitrarily (these arbitrarily chosen leaders do not have to be consistent between neighbors, e.g., it is possible that two vertices u and v are the leaders of each other). In other words, *leader*$(v) \in \arg\min\{deg(w) \mid w \in N[v]\}$. Next let $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ be the min-degree sequence of G. We define V_i to be the set of those vertices in G whose minimum-degree in the closed neighborhood is exactly d_i, so $|V_i| = n_i$. Also, let L_i be the set of those vertices in G who are leaders of at least one vertex in V_i, equivalently, $L_i = \{leader(v) \mid v \in V_i\}$, and denote by $L = \cup_{i=1}^{\ell} L_i$ the set of all the leaders in G. Observe that the sets $V_1, \ldots, V_\ell$ form a partition of the vertex-set of G.

A vertex v in G is said to be a *follower*, if *leader*$(v) \neq v$. Let $F_i = \{v \in V_i \mid v \neq leader(v)\}$ be the set of all the followers in V_i. Finally we define $R = V \setminus L$ to be the set of all the non-leaders, and $F = \cup_{i=1}^{\ell} F_i$ to be the set of all the followers.

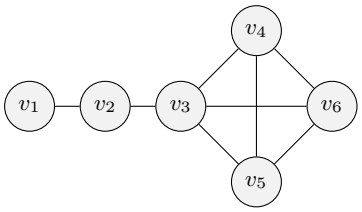

Figure 4 MinND-realization of sequence $\sigma = (3^3 2^1 1^2)$. Here $\text{MinND}(v_1) = \text{MinND}(v_2) = deg(v_1) = 1$, $\text{MinND}(v_3) = deg(v_2) = 2$, and $\text{MinND}(v_i) = 3$, for $i \in \{4, 5, 6\}$. Since $leader(v_2) = v_1$ and $leader(v_3) = v_2$, thus, v_2 is a leader as well as a follower.

We point here that there exist realizable sequences σ for which any graph G realizing σ and any leader function over G, the sets L and F have non-empty intersection. For example, consider the sequence $\sigma = (3^3 2^1 1^2)$ in Figure 4. It can be easily checked that σ has only one realizing graph, and in it, the leader-set and follower-set are non-disjoint.

We classify the sequences that admit disjoint leader and follower sets as follows.

▶ **Definition 5.** *A sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ is said to admit a Disjoint Leader-Follower (DLF) MinND-realization if there exists a graph G realizing σ and a leader function under which the sets L and F are mutually disjoint, that is, $L \cap F = \emptyset$.*[2]

▶ **Theorem 6.** *For any $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ that is MinND-realizable by a graph, say G, the following conditions must be satisfied.*
(NC1) *$d_i \leq \left(\sum_{j=1}^{i} n_j\right) - 1$, for $i \in [1, \ell]$;*
(NC2) *$d_\ell \leq \sum_{j=1}^{\ell} \left\lfloor \frac{n_j d_j}{d_j+1} \right\rfloor$.*
Further, for any leader function defined over G, and $i < \ell$, if $L_i \cap V_i \neq \emptyset$ then $d_i \leq \sum_{j=1}^{i} \left\lfloor \frac{n_j d_j}{d_j+1} \right\rfloor$.

Proof. We provide first a lower bound on the size of the leader set L_i. We show for each $i \in [1, \ell]$, we have $|L_i| \geq \left\lceil \frac{n_i}{d_i+1} \right\rceil$. Consider a vertex $a \in L_i$. Since $|N[a]| = d_i + 1$, vertex a can serve as leader for at most $d_i + 1$ vertices. This shows that $|L_i| \geq \frac{n_i}{d_i+1}$. The claim follows from the fact that $|L_i|$ is integer.

Proof of (NC1). Let w be any vertex in G such that $deg(w) = d_i$. Then w as well as all the neighbors of w must be contained in $\cup_{j=1}^{i} V_j$, therefore, we have: $d_i + 1 = |N[w]| \leq |\cup_{j=1}^{i} V_j| = \sum_{j=1}^{i} n_j$, thereby proving condition (NC1).

Proof of (NC2). Now suppose w is a vertex in G such that $\text{MinND}(w) = d_\ell$. Then $N[w]$ cannot contain vertices of degree less than d_ℓ, so $N[w] \cap L_i = \emptyset$, for each $i < \ell$. Therefore, $|N[w]| \leq n - \sum_{i=1}^{\ell-1} |L_i|$. Also $deg(w)$ must be at least d_ℓ. We thus get,

$$d_\ell + 1 \leq |N[w]| \leq n - \sum_{i=1}^{\ell-1} |L_i| = n_\ell + \sum_{i=1}^{\ell-1} (n_i - |L_i|) \leq n_\ell + \sum_{i=1}^{\ell} \left\lfloor \frac{n_i d_i}{d_i + 1} \right\rfloor .$$

Now if $n_\ell \leq d_\ell$, then $n_\ell - 1 = \left\lfloor \frac{n_\ell d_\ell}{d_\ell+1} \right\rfloor$, and so $d_\ell \leq \sum_{i=1}^{\ell} \left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor$. If $n_\ell \geq d_\ell + 1$, then $\frac{n_\ell d_\ell}{d_\ell+1} \geq d_\ell$ which implies $d_\ell \leq \left\lfloor \frac{n_\ell d_\ell}{d_\ell+1} \right\rfloor$ since d_ℓ is integral.

[2] In Section 4.1, we show that our construction realizes a DLF MinND-realization whenever one exists. In other words, the sufficient condition (SC) is also necessary for sequences that admit a DLF MinND-realization. Nevertheless, there exist MinND-realizable sequences that do not admit a DLF MinND-realization. These sequences may violate the sufficient condition (SC) despite being MinND-realizable.

Proof of last claim. Let w be any vertex lying in $L_i \cap V_i$, so $\text{MinND}(w) = deg(w) = d_i$. Recall for each $j < i$, vertices in the set L_j have degree strictly less than d_i. Since $N[w]$ cannot contain vertices of degree less than d_i, thus for each $j < i$, $N[w] \cap L_j = \emptyset$. Also vertices in $V_{i+1} \cup \ldots \cup V_\ell$ cannot be adjacent to any vertex in $\{w\} \cup \left(\cup_{j=1}^{i-1} L_j\right)$, therefore, $N[w]$ as well as $\cup_{j=1}^{i-1} L_j$ are contained in union $\cup_{j=1}^{i} V_j$. We thus get,

$$d_i + 1 = |N[w]| \leq \left|\bigcup_{j=1}^{i} V_j\right| - \left|\bigcup_{j=1}^{i-1} L_j\right| = n_i + \sum_{j=1}^{i-1}(n_i - |L_j|) \leq n_i + \sum_{j=1}^{i-1} \left\lfloor \frac{n_j d_j}{d_j + 1} \right\rfloor .$$

If $n_i \leq d_i$, then $n_i - 1 = n_i - \left\lceil \frac{n_i}{d_i+1} \right\rceil = \left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor$, and so $d_i \leq \sum_{j=1}^{i} \left\lfloor \frac{n_j d_j}{d_j+1} \right\rfloor$. If $n_i \geq d_i + 1$, then the bound trivially holds since $\frac{n_i d_i}{d_i+1} \geq d_i$ which from the fact that d_i is integral implies $d_i \leq \left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor$. ◀

We next prove the following theorem.

▶ **Theorem 7** (Sufficient condition SC). *Any sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying*

$$d_i \leq \sum_{j=1}^{i} \left\lfloor \frac{n_j d_j}{d_j + 1} \right\rfloor, \text{ for } i \in [1, \ell] ,$$

is MinND-realizable. Further, we can always compute a realizing graph, say G, and a leader function defined over G that satisfies $L \cap F = \emptyset$.

Proof. We begin with the simple case of realizing uniform sequences, and then consider the scenario of general sequences.

Uniform Sequences. Consider for simplicity first the sequence $\sigma = (d^n)$. We provide a realization for σ if $n \geq d+1$. Let $q \geq 1$ and $r \in [0, d]$ be integers satisfying $n = (q)(d+1) - r$. Take a set A of q vertices, namely a_i ($i \in [1, q]$), and another set B of dq vertices, namely b_{ij} ($i \in [1, q], j \in [1, d]$). Connect each a_i to the vertices $b_{i1}, \ldots, b_{id}$. So vertices in A have degree exactly d and vertices in B have in their neighborhood a vertex of degree d. Next if $r > 0$, then we merge b_{1j} with b_{2j}, for $j \in [1, r]$, thereby reducing r vertices in B. (Notice that b_{1j} and b_{2j} exists because $r > 0$ only when $q \geq 2$.) Thus $|A| + |B| = n$ and each vertex in A still has degree exactly d. So $|A| = \frac{n+r}{d+1} = \left\lceil \frac{n}{d+1} \right\rceil$ and $|B| = n - |A| = \left\lfloor \frac{nd}{d+1} \right\rfloor \geq d$. Finally, we add edges between each pair of vertices in B to make it a clique of size at least d; this will imply that the vertices in set B have degree at least d. It is easy to check that $\text{MinND}(v)$ for each $v \in A \cup B$ in our constructed graph is d. In our construction A forms the leader set, and B forms the follower set.

In the rest of proof, we use $\text{GRAPH}(n, d, A, B)$ to denote a function that returns the edges of the graph as constructed above (over A and B) whenever provided with four parameters n, d, A, B satisfying $n \geq d + 1$, $|A| = \left\lceil \frac{n}{d+1} \right\rceil$, and $|B| = \left\lfloor \frac{nd}{d+1} \right\rfloor$.

General Sequences. We now consider the case $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$. Initialize G to be an empty graph. Our algorithm proceeds in ℓ rounds. (See Algorithm 2 for a pseudocode.) In each round, we first add to G a set V_i of n_i new vertices and partition V_i into two sets L_i and R_i of sizes respectively $\left\lceil \frac{n_i}{d_i+1} \right\rceil$ and $\left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor$. Now if $n_i > d_i + 1$, then we solve this round independently by adding to G all the edges returned by $\text{GRAPH}(n_i, d_i, L_i, R_i)$. Notice that if $n_i \leq d_i + 1$, then L_i will contain only one vertex, say a_i. In such a case, we add edges between a_i and all the vertices in the set R_i. Also, we add edges between a_i and any arbitrarily chosen $d_i + 1 - n_i$ vertices in $\cup_{j<i} R_j$. This is possible since $d_i + 1 - n_i = d_i - \left\lfloor \frac{n_i d_i}{d_i+1} \right\rfloor \leq \sum_{j=1}^{i-1} \left\lfloor \frac{n_j d_j}{d_j+1} \right\rfloor = \sum_{j=1}^{i-1} |R_j|$. Finally, after the ℓ rounds are completed, we add edges between each pair of vertices in set $R = \cup_{i=1}^{\ell} R_i$ to make it a clique.

Let us now show bounds on the degree of vertices in sets L_i and R_i.

1. Each vertex in L_i has degree exactly d_i : Recall we add edges to vertices in L_i only in the i^{th} iteration of the for loop. If $n_i > d_i + 1$, then the degree of each vertex in L_i is exactly d_i. If $|L_i| = 1$ or, equivalently, $n_i \leq d_i + 1$, then $|R_i| = n_i - |L_i| = n_i - 1$, and so the degree of the vertex $a_i \in L_i$ is $(n_i - 1) + (d_i + 1 - n_i) = d_i$.
2. Vertices in R have degree at least d_ℓ : For any $i \in [1, \ell]$, if $n_i > d_i + 1$, then $|R_i| = \left\lceil \frac{n_i d_i}{d_i+1} \right\rceil$, and even in the case $n_i \leq d_i + 1$, we have $|R_i| = n_i - |L_i| = n_i - \left\lceil \frac{n_i}{d_i+1} \right\rceil = \left\lceil \frac{n_i d_i}{d_i+1} \right\rceil$. Thus $|R| = \sum_{i=1}^{\ell} |R_i| = \sum_{i=1}^{\ell} \left\lceil \frac{n_i d_i}{d_i+1} \right\rceil$ which is bounded below by d_i. Since $|R| \geq d_\ell$, and each vertex in R is adjacent to at least one vertex in $\cup_i L_i$, the degree of vertices in R is at least d_ℓ.

Algorithm 2 Computing a MinND-realization for a given special σ.

Input: A sequence $\sigma = (d_\ell^{n_\ell} \cdots d_1^{n_1})$ satisfying $d_i \leq \sum_{j=1}^{i} \left\lfloor \frac{n_j d_j}{d_j+1} \right\rfloor$, for $1 \leq i \leq \ell$.

```
Initialize G to be an empty graph.
for i = 1 to ℓ do
    Add to G a set V_i of n_i new vertices.
    Partition V_i in two sets L_i, R_i such that |L_i| = ⌈n_i/(d_i+1)⌉ and |R_i| = ⌊n_i d_i/(d_i+1)⌋.
    if (n_i > d_i + 1, or equivalently, |L_i| > 1) then
        Add to G all the edges returned by GRAPH(n_i, d_i, L_i, R_i).
    else if (|L_i| = 1) then
        Let a_i be the only vertex in L_i.
        Connect a_i to all vertices in R_i, and any arbitrary d_i + 1 − n_i vertices in
         ∪_{j<i} R_j.
Add edges between each pair of vertices in R = ∪_{i=1}^{ℓ} R_i to make it a clique.
Output G.
```

We next show that for any vertex $v \in V_i$, MinND$(v) = d_i$, where $i \in [1, \ell]$. If $v \in L_i$, then MinND$(v) = d_i$, since each vertex in L_i has degree d_i, and is adjacent to only vertices in R which have degree at least $d_\ell \geq d_i$. If $v \in R_i$, then also MinND$(v) = d_i$, since each vertex in R_i is adjacent to at least one vertex in L_i, and $N[v]$ is contained in the set $R \cup (\cup_{j \geq i} L_j)$, whose vertices have degree at least d_i.

The leader function over V is as follows. For each $v \in \cup_{i=1}^{\ell} L_i$, we set $leader(v) = v$, and for each $v \in R_i$, we set $leader(v)$ to any arbitrary neighbor of v in L_i. Since each vertex in $L = \cup_{i=1}^{\ell} L_i = \{leader(v) \mid v \in V\}$ is a leader of itself, the set L of leaders and the set F of followers must be mutually disjoint. ◀

As a corollary of the above results, the following is immediate.

▶ **Theorem 8.** *The sequence $\sigma = (d_2^{n_2}, d_1^{n_1})$ is MinND-realizable if and only if $d_1 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor$ and $d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$.*

Proof. Suppose $\sigma = (d_2^{n_2}, d_1^{n_1})$ is realizable. Then Theorem 6 implies (i) $n_1 \geq d_1 + 1$ which implies $d_1 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor$, and (ii) $d_\ell = d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$. The converse follows from Theorem 7. ◀

▶ Remark 9. In Appendix A, we additionally solve the more involved case of sequences of length three. That is, we provide a complete characterization of the realizability of sequences of the form $\sigma = (d_3^{n_3}, d_2^{n_2}, d_1^{n_1})$ over general graphs.

For a sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$, let $\gamma = (d_1+1)/d_1$. As $\lfloor \frac{\gamma n_1 d_1}{d_1+1} \rfloor + \ldots + \lfloor \frac{\gamma n_i d_i}{d_i+1} \rfloor \geq n_1 + \cdots + n_i \geq d_i$, we also have the following result providing a γ (≤ 2) approximation.

▶ **Corollary 10.** *For any sequence $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ satisfying the first necessary condition* (NC1)*, the sequence $\sigma^\gamma = (d_\ell^{\lceil \gamma n_\ell \rceil}, \ldots, d_1^{\lceil \gamma n_1 \rceil})$ satisfies the sufficient condition* (SC)*.*

4.1 Sequences admitting Disjoint-Leader-Follower Sets

Finally, we state our results on sequences admitting disjoint Leader-Follower sets.

▶ **Theorem 11.** *A sequence $\sigma = (n_\ell^{d_\ell} \ldots d_1^{n_1})$ is* MinND*-realizable by a graph G having disjoint leader-set (L) and follower-set (F) with respect to some leader function, if and only if, for each $i \in [1, \ell]$, $d_i \leq \sum_{j=1}^{i} \lfloor \frac{n_j d_j}{d_j+1} \rfloor$.*

Proof. Let us suppose there exists a leader function over G for which $L \cap F = \emptyset$, then for each $i \in [1, \ell]$, $L_i \subseteq V_i$. This is because if for some i, there exists $w \in L_i \setminus V_i$, then $deg(w) = d_i \neq \text{MinND}(d_i)$, which implies that w is a leader as well as a follower. Since $L_i \subseteq V_i$, by Theorem 6, $d_i \leq \sum_{j=1}^{i} \lfloor \frac{n_j d_j}{d_j+1} \rfloor$, for each $i \in [1, \ell]$. The converse claim follows from Theorem 7. ◀

A MinND realization of tri-sequences in General Graphs

Here we consider the scenario when a sequence has only three distinct degrees.

We now provide a complete characterization of sequence $\sigma = (d_3^{n_3}, d_2^{n_2}, d_1^{n_1})$.

▶ **Theorem 12.** *The necessary and sufficient conditions for* MinND*-realizability of the sequence* $\sigma = (d_\ell^{n_\ell}, \cdots, d_1^{n_1})$ *when* $\ell = 3$ *is*

1. $d_1 + 1 \leq n_1$,
2. $d_2 + 1 \leq n_1 + n_2$,
3. $d_3 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor + \left\lfloor \frac{n_3 d_3}{d_3+1} \right\rfloor$, *and*
4. *either* $d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$, *or* $d_3 + 1 \leq n_1 + n_2 + n_3 - \left(1 + \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil\right)$.

Proof. Suppose $\sigma = (d_3^{n_3}, d_2^{n_2}, d_1^{n_1})$ is realizable, then by Theorem 6, it follows that the first three conditions stated above are necessary.

To prove that all four conditions are necessary, we are left to show that if $d_2 > \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$, then $d_3 + 1 \leq n_1 + n_2 + n_3 - \left(1 + \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil\right)$. We consider a graph G that realizes σ. Let V_1, V_2, V_3 be the partition of $V(G)$ as defined in Section 4. Consider a vertex $w \in V_2$. Observe that $leader(w)$ must lie in V_1, because if $L_2 \cap V_2$ is non-empty, then Theorem 6 implies $d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$. We first show that $|L_1| \geq \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil$. The set $N(w) \cap V_1$ has size at least $d_2 - n_2$. Each vertex $x \in L_1$ can serve as a leader of at most d_1 vertices in open-neighborhood of w. Indeed, if $x \in N(w)$ then it can not count w (lying outside $N(w)$), and if $x \notin N(w)$ then it can not count itself (again lying outside $N(w)$). Thus to cover the set $N(w) \cap V_1$ at least $\left\lceil \frac{d_2 - n_2}{d_1} \right\rceil$ leaders are required, thereby showing $|L_1| \geq \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil$. Now consider a vertex $y \in V_3$, note that $N[y]$ excludes w (as degree of w is d_2), as well as L_1 (as vertices in L_1 have degree d_1). Therefore, we obtain the following relation.

$$d_3 + 1 = |\ N[y]\ | \leq |V_1 \setminus L_1| + |V_2 \setminus w| + |V_3| \leq n_1 + n_2 + n_3 - \left(1 + \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil\right)$$

We now prove the sufficiency claims. If $d_2 \leq \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$, then the conditions 1-4 are sufficient by Theorem 7. So let us focus on the scenario when $d_2 > \left\lfloor \frac{n_1 d_1}{d_1+1} \right\rfloor + \left\lfloor \frac{n_2 d_2}{d_2+1} \right\rfloor$. Let $N = n_1 + n_2 + n_3 - \left(1 + \left\lceil \frac{d_2 - n_2}{d_1} \right\rceil\right)$. The vertex-set of our realized graph $G = (V, E)$ will be a union of three disjoint sets $L_1, L_2 = \{w\}$, and Z of size respectively $\left\lceil \frac{d_2 - n_2}{d_1} \right\rceil$, 1, and N. Initially, the edge-set E is an empty-set. Between vertex pairs in Z, we add edges

so that the induced graph $G[Z]$ is identical to $\textsc{graph}(N, d_3, \left\lceil \frac{N}{d_3+1} \right\rceil, \left\lfloor \frac{Nd_3}{d_3+1} \right\rfloor)$. This step is possible since $d_3 + 1 \leq N$, and ensures that $\textsc{MinND}_{G[Z]}(z) = d_3$, for $z \in Z$. Let L_3 denote the set of those vertices in Z whose degree is equal to d_3. We connect w to arbitrary $N - n_3 = n_2 + (n_1 - |L_1 \cup L_2|)$ vertices in $Z \setminus L_3$, and any arbitrary $\alpha := d_2 - (n_1 + n_2 - |L_1 \cup L_2|)$ vertices in L_1. Since $deg_G(w) = d_2$, this step ensures that MinND of exactly n_2 vertices in Z decreases to d_2. Let Y be a subset of arbitrary $(n_1 - |L_1 \cup L_2|)$ neighbors of w in Z. Finally, we connect each $x \in L_1 \cap N[w]$ to arbitrary $d_1 - 1$ vertices in Y, and each $x' \in L_1 \setminus N[w]$ to arbitrary d_1 vertices in Y, so as to ensure each vertex in Y is adjacent to at least one leader in L_1. Since vertices in L_1 have degree d_1, this ensures $\textsc{MinND}_G(x) = d_1$, for each $x \in \{w\} \cup Y \cup L_1$. This completes the construction of G. ◀

Tight Approximation Algorithms for p-Mean Welfare Under Subadditive Valuations

Abstract

We develop polynomial-time algorithms for the fair and efficient allocation of indivisible goods among n agents that have subadditive valuations over the goods. We first consider the Nash social welfare as our objective and design a polynomial-time algorithm that, in the value oracle model, finds an $8n$-approximation to the Nash optimal allocation. Subadditive valuations include XOS (fractionally subadditive) and submodular valuations as special cases. Our result, even for the special case of submodular valuations, improves upon the previously best known $O(n \log n)$-approximation ratio of Garg et al. (2020).

More generally, we study maximization of p-mean welfare. The p-mean welfare is parameterized by an exponent term $p \in (-\infty, 1]$ and encompasses a range of welfare functions, such as social welfare ($p = 1$), Nash social welfare ($p \to 0$), and egalitarian welfare ($p \to -\infty$). We give an algorithm that, for subadditive valuations and any given $p \in (-\infty, 1]$, computes (in the value oracle model and in polynomial time) an allocation with p-mean welfare at least $1/8n$ times the optimal.

Further, we show that our approximation guarantees are essentially tight for XOS and, hence, subadditive valuations. We adapt a result of Dobzinski et al. (2010) to show that, under XOS valuations, an $O\left(n^{1-\varepsilon}\right)$ approximation for the p-mean welfare for any $p \in (-\infty, 1]$ (including the Nash social welfare) requires exponentially many value queries; here, $\varepsilon > 0$ is any fixed constant.

1 Introduction

In discrete fair division, given a set of m goods and n agents, the problem is to integrally allocate the set of goods to the agents in a fair and (economically) efficient manner [8, 17, 3]. In this thread of work, the Nash social welfare – defined as the geometric mean of the agents' valuations for their assigned bundles – has emerged as a fundamental and prominent measure of the quality of an allocation. It provides a balance between two central objectives: the social welfare (the sum of the agents' valuations) and the egalitarian welfare (the minimum valuation across the agents). Note that social welfare is a standard measure of (economic) efficiency, whereas egalitarian welfare is a fairness objective.

A Nash optimal allocation (i.e., an allocation that maximizes Nash social welfare) satisfies other fairness and efficiency criteria as well. Such an allocation is clearly Pareto optimal. Furthermore, if agents have additive valuations, then a Nash optimal allocation is known to be fair in the sense that it is guaranteed to be *envy-free up to one good* (EF1) [9] and *proportional up to one good* (Prop1) [15].[1]

As an objective, Nash social welfare is scale invariant: multiplicatively scaling any agent's valuation function by a nonnegative factor does not change the Nash optimal allocation. Furthermore, interesting connections have been established between market models and this welfare function; see, e.g., [13, 5]. As a practical application, the website `spliddit.org` uses the Nash social welfare as the optimization objective when partitioning indivisible goods [22, 9].

However, computing a Nash optimal allocation is APX-hard, even when the agents have additive valuations [24]. In terms of approximation algorithms, the problem of maximizing Nash social welfare has received considerable attention in recent years [14, 13, 2, 6, 1, 5, 19]. In particular, a polynomial-time $e^{1/e}$-approximation algorithm is known for additive valuations [5]. This algorithm preserves EF1, up to a factor of $(1+\varepsilon)$, and Pareto optimality. The approximation guarantee of $e^{1/e} \approx 1.45$ also holds for budget-additive valuations [11]. The work of Garg et al. [20] extends this line of work by considering Nash social welfare maximization under submodular valuations.

Submodular valuations capture the diminishing marginal returns property. They constitute a subclass of subadditive valuations, which, in turn, model complement-freeness. Formally, a set function v (defined over a set of indivisible goods) is subadditive if it satisfies $v(A \cup B) \leq v(A) + v(B)$, for all subsets of goods A and B. Complement-freeness is a very common assumption on valuation functions. Hence, fair division with subadditive valuations is an encompassing and important problem.

For Nash social welfare maximization under submodular valuations, Garg et al. [20] obtain an $O(n \log n)$-approximation algorithm. Prior to their work, the best known approximation ratio for submodular valuations was $(m - n + 1)$, which also extends to subadditive valuations [26]; here, m denotes the number of goods and n the number of agents. For a constant number of agents with submodular valuations, Garg et al. [20] provide an $e/(e-1)$-approximation algorithm and show that, even in this setting, improving upon $e/(e-1)$ is NP-hard.

[1] An allocation is said to be EF1 if for any pair of agents i and j, there exists a good g in j's bundle, such that i prefers her bundle to the one obtained after removing g from j's bundle. An allocation is said to be Prop1 if for each agent i there exists a good g with the property that including g into i's bundle ensures that i achieves a proportional share, i.e., her valuation ends up being at least $1/n$ times her value for all the goods.

In the context of allocating indivisible goods, two other well-studied welfare objectives are the social welfare and the egalitarian welfare. These represent, respectively, for an allocation, the average valuation of the agents and the minimum valuation of any agent. For the social welfare objective, a tight approximation factor of $e/(e-1)$ is known under submodular valuations [29]. For subadditive valuations, Feige [18] shows that social welfare maximization admits a polynomial-time 2-approximation, assuming oracle access to *demand queries*.[2]

For maximizing egalitarian welfare under additive valuations, Chakrabarty et al. [10] provide an $\widetilde{O}(n^{\varepsilon})$-approximation algorithm that runs in time $n^{O(1/\varepsilon)}$, for any $\varepsilon > 0$. Under submodular valuations, egalitarian welfare maximization admits an $\widetilde{O}(n^{1/4}m^{1/2})$-approximation algorithm [21]. Khot and Ponnuswami [23] provide a $2n$-approximation algorithm for maximizing egalitarian welfare under subadditive valuations. As a lower bound, with submodular valuations, egalitarian welfare cannot be approximated within a factor of 2, unless P = NP [7].

In this work we develop a unified treatment of fairness and efficiency objectives, including the welfare functions mentioned above. In particular, we develop an approximation algorithm for computing allocations that maximize the *generalized mean* of the agents' valuations. Formally, for exponent parameter $p \in \mathbb{R}$, the p^{th} *generalized mean* of a set of n positive reals $v_1, v_2, \ldots, v_n$ is defined as $\left(\frac{1}{n}\sum_{i=1}^{n} v_i^p\right)^{1/p}$. For an allocation (partition) $\mathcal{A} = (A_1, \ldots, A_n)$ of the indivisible goods among the n agents, we define the *p-mean welfare* of $\mathcal{A}$ as the generalized mean of the values $(v_i(A_i))_{i\in[n]}$; here $v_i(A_i)$ is the value that agent i has for the bundle A_i assigned to it. Indeed, with different values of p, the p-mean welfare encompasses a range of objectives: it corresponds to the social welfare (arithmetic mean) for $p = 1$, the Nash social welfare (geometric mean) for $p \to 0$, and the egalitarian welfare for $p \to -\infty$. In fact, p-mean welfare functions with $p \in (-\infty, 1]$ exactly correspond to the collection of functions characterized by a set of natural axioms, including the Pigou-Dalton transfer principle [25]. Hence, p-mean welfare functions, with $p \in (-\infty, 1]$, constitute an important and axiomatically-supported family of objectives.

Our Contributions. We develop a polynomial-time algorithm that, given a fair division instance with subadditive valuations and parameter $p \in (-\infty, 1]$, finds an allocation with p-mean welfare at least $1/8n$ times the optimal p-mean welfare (Theorem 9). Our algorithm uses the standard value oracle model which, when queried with any subset of goods and an agent i, returns the value that i has for the subset. For different values of p, our algorithm changes minimally, differing only in the weights of edges for a computed matching. We thus present a unified analysis for this broad class of welfare functions, suggesting further connections between these objectives than the previously mentioned axiomatization. Our result matches the best known $O(n)$-approximation for egalitarian welfare [23] and improves upon the $O(n \log n)$-approximation guarantee of Garg et al. [20] for Nash social welfare with submodular valuations. Arguably, our algorithm (and the analysis) is simpler than the one developed in [20] and simultaneously more robust, since it obtains an improved approximation ratio for subadditive valuations and a notably broader class of welfare objectives.

For clarity of exposition, we first present an $8n$-approximation algorithm for maximizing Nash social welfare under subadditive valuations (Theorem 2). We then generalize the algorithm to the class of p-mean welfare objectives.

[2] A demand-query oracle, when queried with prices $p_1, \ldots, p_m \in \mathbb{R}$ associated with the m goods, returns $\max_{S\subseteq[m]} \left(v(S) - \sum_{j\in S} p_j\right)$, for an underlying valuation function v. The current paper works with more basic value oracle, which when queried with a subset of goods returns the value this subset. Any value query can be simulated via a polynomial number of demand queries. However, the converse is not true [27].

We complement these algorithmic results by adapting a result of Dobzinski et al. [16] to show that for XOS valuations, any $O(n^{1-\varepsilon})$-approximation for p-mean welfare requires an exponential number of value queries (Section 5). Hence, in the value oracle model, our approximation guarantee is essentially tight for XOS and, hence, for subadditive valuations. We note that these are the first polynomial lower bounds on approximating either the Nash social welfare or the egalitarian welfare.

Nguyen and Rothe [26] obtain an $(m - n + 1)$-approximation guarantee for maximizing Nash social welfare with subadditive valuations. We establish two extensions of this result. First, we show that, under subadditive valuations, an $(m - n + 1)$-approximation for the p-mean welfare can be obtained for all $p \leq 0$. However, for $0 < p < 1$, we establish that it is NP-hard to obtain an $(m - n + 1)$-approximation, even under additive valuations. An analogous hardness result holds for $p = 1$ with submodular valuations.

Independent Work. In work independent of ours, Chaudhury et al. [12] also obtain an $O(n)$-approximation algorithm for maximizing generalized p-means under subadditive valuations. Their approach varies significantly from the current paper and, in particular, builds upon results on finding allocations that are approximately envy-free up to any good (EFX). Notably their algorithm computes allocations that satisfy additional fairness properties, including EF1 and either of two approximate versions of EFX.

Section 3 presents our approximation algorithm for maximizing Nash social welfare. Then, Section 4 shows that we can extend the algorithm for Nash social welfare to obtain the stated approximation bound for p-mean welfare. The tightness of these results is established in Section 5. Section 6 presents the results for the $(m - n + 1)$-approximation guarantees. All the missing proofs appear in the full version of this paper [4].

2 Notation and Preliminaries

An instance of a fair division problem is a tuple $\langle [m], [n], \{v_i\}_{i=1}^n \rangle$, where $[m] = \{1, 2, \ldots, m\}$ denotes the set of $m \in \mathbb{N}$ indivisible goods that have to be allocated (partitioned) among the set of $n \in \mathbb{N}$ agents, $[n] = \{1, 2, \ldots, n\}$. Here, $v_i : 2^{[m]} \mapsto \mathbb{R}_+$ represents the valuation function of agent $i \in [n]$. Specifically, $v_i(S) \in \mathbb{R}_+$ is the value that agent i has for a subset of goods $S \subseteq [m]$. For $g \in [m]$ and $i \in [n]$, write $v_i(g)$ to denote agent i's value for the good g, i.e., it denotes $v_i(\{g\})$.

We will assume throughout that the valuation function v_i for each agent $i \in [n]$ is (i) nonnegative: $v_i(S) \geq 0$ for all $S \subseteq [m]$, (ii) normalized: $v_i(\emptyset) = 0$, (iii) monotone: $v_i(A) \leq v_i(B)$ for all $A \subseteq B \subseteq [m]$, and (iv) subadditive: $v_i(A \cup B) \leq v_i(A) + v_i(B)$ for all subsets $A, B \subseteq [m]$.

Submodular and XOS (fractionally subadditive) valuations constitute subclasses of subadditive valuations. Formally, a set function $v : 2^{[m]} \mapsto \mathbb{R}_+$ is said to be submodular if it satisfies the *diminishing marginal returns* property: $v(A \cup \{g\}) - v(A) \geq v(B \cup \{g\}) - v(B)$, for all subsets $A \subseteq B \subsetneq [m]$ and $g \in [m] \setminus B$. A set function, $v : 2^{[m]} \mapsto \mathbb{R}_+$, is said to be XOS if it is obtained by evaluating the maximum over a collection of additive functions $\{f_r\}_{r \in [L]}$, i.e., $v(S) \coloneqq \max_{1 \leq j \leq L} \{f_r(S)\}$, for each subset $S \subseteq [m]$.[3]

We use $\Pi_n([m])$ to denote the collection of all n partitions of the indivisible goods $[m]$. An *allocation* is an n-partition $\mathcal{A} = (A_1, \ldots, A_n) \in \Pi_n([m])$ of the m goods. Here, A_i denotes the subset of goods allocated to agent $i \in [n]$ and will be referred to as a *bundle*.

[3] Here, L can be exponentially large in m.

Given a fair division instance $\mathcal{I} = \langle [m], [n], \{v_i\}_i \rangle$, the *Nash social welfare* of allocation $\mathcal{A}$ is defined as the geometric mean of the agents' valuations under $\mathcal{A}$: $\text{NSW}(\mathcal{A}) := (\prod_{i=1}^{n} v_i(A_i))^{\frac{1}{n}}$.

We will throughout use $\mathcal{N}^* = (N_1^*, \ldots, N_n^*)$ to denote an allocation that maximizes the Nash social welfare for a given fair division instance. We refer to $\mathcal{N}^*$ as a Nash optimal allocation. An allocation $\mathcal{P} = (P_1, \ldots, P_n)$ is an α-approximate solution (with $\alpha \geq 1$) of the Nash social welfare maximization problem if $\text{NSW}(\mathcal{P}) \geq \frac{1}{\alpha}\text{NSW}(\mathcal{N}^*)$.

Besides the Nash social welfare, we address a family of objectives defined by considering the *generalized means* of agents' valuations. In particular, for parameter $p \in \mathbb{R}$, the the p^{th} generalized (Hölder) mean $\text{M}_p(\cdot)$ of n nonnegative numbers $x_1, \ldots, x_n \in \mathbb{R}_+$ is defined as $\text{M}_p(x_1, \ldots, x_n) := \left(\frac{1}{n}\sum_{i=1}^{n} x_i^p\right)^{\frac{1}{p}}$.

Parameterized by p, this family of functions captures multiple fairness and efficiency measures. In particular, when $p = 1$, M_p reduces to the arithmetic mean. In the limit, M_p is equal to the geometric mean as p tends to zero. In addition, $\lim_{p\to-\infty} \text{M}_p(x_1, \ldots, x_n) = \min\{x_1, x_2, \ldots, x_n\}$.

We define the *p-mean welfare*, $\text{M}_p(\mathcal{A})$, of an allocation $\mathcal{A} = (A_1, A_2, \ldots, A_n)$ as

$$\text{M}_p(\mathcal{A}) := \text{M}_p(v_1(A_1), \ldots, v_n(A_n)) = \left(\frac{1}{n}\sum_{i=1}^{n} v_i(A_i)^p\right)^{1/p}.$$

With p equal to one, zero, and $-\infty$, the p-mean welfare corresponds to the (average) social welfare, Nash social welfare, and egalitarian welfare, respectively.

The following proposition implies that for any $p \leq -n\log n$, if instead of the p-mean welfare, we maximize the egalitarian welfare, then the resulting allocation loses a negligible factor in the approximation ratio.

▶ **Proposition 1.** *For any n nonnegative numbers $x_1, \ldots, x_n \in \mathbb{R}_+$ and $p \leq -n\log n$, we have*

$$\text{M}_{-\infty}(x_1, \ldots, x_n) \;\leq\; \text{M}_p(x_1, \ldots, x_n) \;\leq\; 2^{1/n}\,\text{M}_{-\infty}(x_1, \ldots, x_n).$$

3 An $8n$-Approximation for Nash Social Welfare

This section presents an efficient $8n$-approximation algorithm for the Nash social welfare maximization problem, under subadditive valuations. Our algorithm, Algorithm 1 (Alg), requires access to the valuation functions through basic value queries, i.e., it only requires an oracle which, when queried with a subset of goods $S \subseteq [m]$ and an agent $i \in [n]$, returns $v_i(S) \in \mathbb{R}_+$.

We first describe the ideas behind our algorithm. Write $\mathcal{N}^* = \{N_1^*, \ldots, N_n^*\}$ denote a Nash optimal allocation in the given instance and let us, for now, assume that the agents have additive valuations, i.e., for all agents $i \in [n]$ and subset of goods $S \subseteq [m]$, we have $v_i(S) = \sum_{g\in S} v_i(g)$. In the following two cases, we can readily obtain an $O(n)$ approximation. In the first case, each agent has a few "high-value" goods, i.e., each agent i has a good $g_i' \in N_i^*$ with the property that $v_i(g_i') \geq v_i(N_i^*)/n$. In such a setting, we can construct a complete bipartite graph with agents $[n]$ on one side and all the goods $[m]$ on the other. Here, the weight of edge $(i, g) \in [n] \times [m]$ is set to be $\log(v_i(g))$. In this bipartite graph, the matching $(i, g_i')_{i\in[n]}$ has Nash social welfare at least $1/n$ times the optimal and, hence, this also holds for a left-perfect maximum-weight matching in this graph.

Algorithm 1 ALG.

Input: Instance $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with value oracle access to the valuation functions v_is.

Output: An allocation $\mathcal{B} = (B_1, B_2, \ldots, B_n)$

Initialize iteration count $t = 0$ and define $\text{SAT}_t = \emptyset$ and $\text{UNSAT}_t = [n]$
for $i \in [n]$ **do**
  Sort the goods in $[m]$ in descending order of value such that $v_i(g_1) \geq \cdots \geq v_i(g_m)$
  if $v_i([m] \setminus \{g_1, \ldots, g_{2n}\}) = 0$ **then**
    Set $\gamma_i^t = 0$
  else
    $\gamma_i^t = v_i([m])$
  end if
end for
while $\text{UNSAT}_t \neq \emptyset$ **do**
  Consider the bipartite graph $\left([n] \cup [m], [n] \times [m], \{w(i,g)\}_{i \in [n], g \in [m]}\right)$ with weight of edge $(i, g) \in [n] \times [m]$ set as $w(i, g) = \log\left(v_i(g) + \gamma_i^t\right)$
  Compute a left-perfect maximum-weight matching, π^t, in this bipartite graph
  Set $G = [m] \setminus \{\pi^t(i)\}_{i \in [n]}$ and $A = [n]$
  while there exists $a' \in A$ and $g' \in G$ such that $v_{a'}(g') \geq \frac{1}{2n} v_{a'}(G)$ **do**
    Set $B_{a'}^t = \{g'\}$ and update $G \leftarrow G \setminus \{g'\}$ along with $A \leftarrow A \setminus \{a'\}$
  end while
  Set $(B_i^t)_{i \in A} = \text{MOVINGKNIFE}\left(G, A, \{v_i\}_{i \in A}\right)$
  Define $\text{SAT}_{t+1} = \{i \in [n] \mid v_i(B_i^t) \geq \gamma_i^t\}$ and set $\gamma_i^{t+1} = \gamma_i^t$ for each $i \in \text{SAT}_{t+1}$
  Define $\text{UNSAT}_{t+1} = \{i \in [n] \mid v_i(B_i^t) < \gamma_i^t\}$ and set $\gamma_i^{t+1} = \left(1 - \frac{1}{m}\right) \gamma_i^t$ for each $i \in \text{UNSAT}_{t+1}$
  Update $t \leftarrow t + 1$
end while
return allocation $\left(B_1^{t-1} \cup \{\pi^{t-1}(1)\}, B_2^{t-1} \cup \{\pi^{t-1}(2)\}, \ldots, B_n^{t-1} \cup \{\pi^{t-1}(n)\}\right)$

In the second case, all goods are of "low-value", i.e., for all $i \in [n]$ and $g \in [m]$ we have $v_i(g) \leq v_i(N_i^*)/(2n)$. Here again an $O(n)$ approximation can be obtained via a simple round-robin algorithm, wherein the agents (in an arbitrary order) repeatedly pick their highest valued good from those remaining. At a high level, our algorithm stitches together these two extreme cases by first matching high-value goods and then allocating the low-value ones.

We connect the two cases by considering the following quantity for each agent $i \in [n]$

$$\ell_i \coloneqq \min_{S \subseteq [m] : |S| \leq 2n} \frac{1}{2n} \, v_i\left([m] \setminus S\right) . \tag{1}$$

That is, ℓ_i is the value that each agent is guaranteed to achieve in a (near) proportional allocation, even after the removal of any $2n$-size subset of goods. Our algorithm leverages the following existential guarantee (Lemma 3): there necessarily exists a good $\widehat{g}_i \in N_i^*$ with the property that

$$v_i(\widehat{g}_i) + \ell_i \geq \frac{1}{4n} v_i(N_i^*) . \tag{2}$$

This result ensures that, a single high-value good (in particular, $\widehat{g}_i$) coupled with a $2n$-approximation to all the low-value goods (i.e., ℓ_i), is sufficient to ensure a $4n$-approximation *for each agent*. At this point, if we could (i) explicitly compute ℓ_i for each agent i and (ii)

for any size-n subset of goods S, assign the remaining goods $[m] \setminus S$ such that each agent gets a bundle of value at least ℓ_i, then we would be done. This follows from the observation that in the complete bipartite graph $([n] \cup [m], [n] \times [m])$ with weight of edge (i, g) set to $\log(v_i(g) + \ell_i)$, the weight of the matching $(i, \widehat{g}_i)_i$ is a $4n$ approximation to the optimal Nash social welfare by equation (2) and, hence, the same guarantee holds for a maximum-weight matching in the graph. Condition (ii) ensures that each agent also receives at least ℓ_i after the initial assignment of the n matched goods.

For additive valuations, both conditions (i) and (ii) can be satisfied. This template was employed in the SMatch algorithm (for additive valuations) of Garg et al. [20]. However, for submodular (and subadditive) valuations, the quantity ℓ_i is hard to approximate within a sub-linear factor [28].

Therefore, instead of satisfying condition (i) explicitly, we maintain an upper bound $\gamma_i \geq \ell_i$ for each agent i. Our algorithm first obtains a maximum weight matching in the bipartite graph between agents and goods with the weight of edge $(i, g) \in [n] \times [m]$ set to $\log(v_i(g) + \gamma_i)$. It assigns all the matched goods to the respective agents, removes these goods from further consideration in this iteration, and then carries out a procedure (described below) to ensure condition (ii). If, for agent i, the bundle obtained in this procedure (i.e., the bundle obtained for i after removing the matched goods) has value less than γ_i, then we multiplicatively reduce the (over) estimate γ_i for i and repeat the algorithm.

The procedure towards satisfying condition (ii) consists of two steps. Let G be the set of goods that remain once we remove the matched n goods from $[m]$. In the first step, if there exists an agent i and a good $g \in G$ such that $v_i(g) \geq v_i(G)/(2n)$, we assign g to i and remove both from further consideration. An agent thus removed has value ℓ_i from the assigned good; note that, by definition, $\ell_i \leq v_i(G)/(2n)$. After this step, we observe that $v_i(g) \leq v_i(G)/(2n)$ for each remaining agent i and good g. In the second step, we run a *moving knife* subroutine (Algorithm 2) on the goods that are still unassigned. In this subroutine, the goods are initially ordered in an arbitrary fashion. A hypothetical knife is then moved across the goods from one side until an agent i (who has yet to receive a bundle) calls out that the goods covered so far have a collective value of at least $v_i(G)/(2n)$ for her. These covered goods are then allocated to said agent i and both the agent as well as this bundle is removed from further consideration. We show that this allocation satisfies condition (ii), i.e., the bundle assigned to each agent in this procedure has value at least ℓ_i (but it may be lower than the overestimate γ_i).

Since we can guarantee ℓ_i for each agent i, irrespective of which goods are removed in the matching step, γ_i never goes below ℓ_i, for any agent. Hence, at some point, every agent i receives a bundle of value at least γ_i in the above two steps. We show that these bundles, with the goods matched with each agent, provide an $8n$ approximation to the optimal Nash social welfare.

It is relevant to note we use ℓ_i solely for the purposes of analysis. Our algorithm executes with the overestimate γ_i and keeps reducing this value till it is realized (in the two-step procedure) for all the agents.

As mentioned previously, the SMatch algorithm (developed for additive valuations) of Garg et al. [20] relies of conditions (i) and (ii). However, for submodular valuations their work diverges considerably from the current approach. In particular, the RepReMatch algorithm (developed for submodular valuations) in [20] first finds a set of goods $\mathcal{G}$ with the property that in the bipartite graph between all the agents and $\mathcal{G}$, there is a matching wherein every agent is matched to a good with value at least as much as her highest valued good in N_i^*. To ensure this property the cardinality of $\mathcal{G}$ needs to be $n \log n$. Intuitively,

Algorithm 2 MovingKnife.

Input: Instance $\mathcal{J} = \langle G, A, \{v_i\}_{i \in A} \rangle$ with value oracle access to the valuation functions v_is
Output: An allocation $\mathcal{P} = (P_1, P_2, \ldots, P_{|A|})$

Initialize $S = \emptyset$, $\widehat{G} = G$, $\widehat{A} = A$, and bundle $P_i = \emptyset$ for all $i \in A$.
while $\widehat{G} \neq \emptyset$ and $\widehat{A} \neq \emptyset$ **do**
  Select any arbitrary good $g \in \widehat{G}$ and update $S \leftarrow S \cup \{g\}$ along with $\widehat{G} \leftarrow \widehat{G} \setminus \{g\}$.
  if for some agent $\widehat{a} \in \widehat{A}$ we have $v_{\widehat{a}}(S) \geq \frac{1}{2n} v_{\widehat{a}}(G)$ **then**
    Set $P_{\widehat{a}} = S$ and update $\widehat{A} \leftarrow \widehat{A} \setminus \{\widehat{a}\}$ along with $S \leftarrow \emptyset$.
  end if
end while
if $\widehat{G} \neq \emptyset$ **then**
  $P_{|A|} \leftarrow P_{|A|} \cup \widehat{G}$
end if
return allocation $\mathcal{P} = (P_1, \ldots, P_{|A|})$.

this requirement leads to a lower bound of $\Omega(n \log n)$ on the approximation ratio obtained in [20]. Furthermore, the steps in their algorithm to ensure condition (ii) do not extend to subadditive valuations either. Specifically, Garg et al. [20] note that their algorithm gives an approximation ratio of $\Omega(m)$ for the case of subadditive valuations. The $2n$-approximation of Khot and Ponnuswami for egalitarian welfare [23] first guesses the optimal egalitarian welfare b, and uses this to partition the goods into "large" ones (those with value higher than b/n) and "small" ones, for each agent. It then tries to ensure every agent receives a bundle with valuation at least b/n. For Nash social welfare, guessing just a single value does not appear to help, since the Nash social welfare depends on the valuation of each agent.

The following theorem constitutes our main result for Nash social welfare.

▶ **Theorem 2.** *Let $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ be a fair division instance in which the valuation function v_i, of each agent $i \in [n]$, is nonnegative, monotone, and subadditive. Given value oracle access to v_is, the algorithm Alg computes an $8n$ approximation to the Nash optimal allocation in polynomial time.*

The following lemma proves inequality (2). We state and prove it for an arbitrary allocation $\mathcal{A}^* = (A_1^*, \ldots, A_n^*)$, rather than just for the Nash optimal allocation.

▶ **Lemma 3.** *Let $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ be a fair division instance with monotone, subadditive valuations and let $\mathcal{A}^* = (A_1^*, \ldots, A_n^*)$ be any allocation in $\mathcal{I}$. Let $\widehat{g}_i$ be the most valued (by i) good in A_i^* (i.e., $\widehat{g}_i \coloneqq \arg\max_{g \in A_i^*} v_i(g)$) and ℓ_i be as defined in (1). Then, for each agent $i \in [n]$*

$$v_i(\widehat{g}_i) + \ell_i \geq \frac{1}{4n} v_i(A_i^*).$$

Proof. Consider any agent $i \in [n]$ and note that $\ell_i \geq 0$. We will establish the lemma by considering two complementary cases.

Case 1. There exists a good $g_i \in A_i^*$ with the property that $v_i(g_i) \geq \frac{1}{4n} v_i(A_i^*)$. Since $\widehat{g}_i$ is the most valued good in A_i^*, we have $v_i(\widehat{g}_i) \geq v_i(g_i)$ and the desired inequality follows.

Case 2. For all goods $g \in A_i^*$, $v_i(g) < \frac{1}{4n} v_i(A_i^*)$. Recall that $\ell_i \coloneqq \min_{S \subseteq [m], |S| \leq 2n} \frac{1}{2n} v_i([m] \setminus S)$. Let S^* be the set S that induces ℓ_i, i.e., $\ell_i = \frac{1}{2n} v_i([m] \setminus S^*)$. Monotonicity of v_i ensures that $|S^*| = 2n$ and

$$\ell_i = \frac{1}{2n} v_i([m] \setminus S^*) \geq \frac{1}{2n} v_i(A_i^* \setminus S^*)\,. \tag{3}$$

Furthermore, given that in the current case $v_i(g) < \frac{1}{4n} v_i(A_i^*)$ for all $g \in A_i^*$, we have

$$v_i(A_i^* \cap S^*) \leq \sum_{g \in A_i^* \cap S^*} v_i(g) < \sum_{g \in A_i^* \cap S^*} \frac{1}{4n} v_i(A_i^*) \leq \frac{|S^*|}{4n} v_i(A_i^*) = \frac{1}{2} v_i(A_i^*)\,. \tag{4}$$

Here, the first inequality follows from the fact that v_i is subadditive and the last since $|S^*| = 2n$.

Therefore, we obtain the desired bound in terms of ℓ_i:

$$\begin{aligned}
\ell_i &\geq \frac{1}{2n} v_i(A_i^* \setminus S^*) && \text{(via inequality (3))} \\
&\geq \frac{1}{2n} \left(v_i(A_i^*) - v_i(A_i^* \cap S^*) \right) && (v_i \text{ is subadditive}) \\
&\geq \frac{1}{4n} v_i(A_i^*) && \text{(via inequality (4))}
\end{aligned}$$

Thus, the the stated inequality $v_i(\widehat{g}_i) + \ell_i \geq \frac{1}{4n} v_i(A_i^*)$ holds even in this case. ◀

The next lemma establishes the key property of Algorithm 2 (MovingKnife): if all the goods have low value for every agent, then MovingKnife returns a near-proportional allocation.

▶ **Lemma 4.** *Consider a fair division instance $\langle G, A, \{v_i\}_{i \in A} \rangle$ wherein the agents have monotone, subadditive valuations. In addition, suppose for each agent $i \in A$ and good $g \in G$ we have $v_i(g) < \frac{1}{2n} v_i(G)$, where $n \geq |A|$. Then the allocation $(P_1, \ldots, P_{|A|})$ returned by Algorithm 2 (MovingKnife) satisfies $v_i(P_i) \geq \frac{1}{2n} v_i(G)$ for all $i \in A$.*

Proof. Given instance $\langle G, A, \{v_i\}_{i \in A} \rangle$, the MovingKnife algorithm (Algorithm 2) considers the goods in an arbitrary order and adds these goods one by one into a bundle S until an agent $\widehat{a}$ calls out that its value for S is at least $\frac{1}{2n} v_{\widehat{a}}(G)$. We assign these goods to agent $\widehat{a}$ and remove them – along with $\widehat{a}$ – from consideration. The algorithm iterates over the remaining set of agents and goods. We will show that the while loop in the MovingKnife algorithm terminates with $\widehat{A} = \emptyset$ and, hence, assigns to each agent a bundle of desired value.

Consider an integer (count) $k \in \mathbb{N}$. Let $\widehat{G}$ and $\widehat{A}$ denote the set of goods and agents, respectively, that are left unassigned after k agents are assigned bundles in MovingKnife; note that $|\widehat{A}| = |A| - k$. The arguments below establish that for each remaining agent $i \in \widehat{A}$,

$$v_i(\widehat{G}) \geq \left(1 - \frac{k}{n}\right) v_i(G) \tag{5}$$

Therefore, for any $k < |A| \leq n$, the set of unassigned goods $\widehat{G}$ is nonempty and even the last agent (i.e., with $k = |A| - 1$) receives a bundle of sufficiently high value.

To prove (5), consider any agent $i \in \widehat{A}$. Indeed, agent i has not received any goods yet, but the k agents in $A \setminus \widehat{A}$ have been assigned bundles. Let S be a bundle assigned to some agent in $A \setminus \widehat{A}$ (i.e., $P_j = S$ for some $j \in A \setminus \widehat{A}$) and g' be the last good included in S. Step 4 of the algorithm ensures that $v_i(S \setminus \{g'\}) < \frac{1}{2n} v_i(G)$; otherwise, $S \setminus \{g'\}$ would have

been assigned to agent i. Furthermore, the assumption (in the Lemma statement) gives us $v_i(g') \leq \frac{1}{2n} v_i(G)$. Hence, using these inequalities and the subadditivity of v_i, we get $v_i(S) \leq v_i(S \setminus \{g'\}) + v_i(g') \leq \frac{1}{n} v_i(G)$.

This inequality provides an upper bound on $v_i(G \setminus \widehat{G}) = v_i\left(\cup_{j \in A \setminus \widehat{A}} P_j\right)$, the total value of the set of goods assigned among the k agents in $A \setminus \widehat{A}$. Specifically, by the subadditivity of v_i, $v_i(G \setminus \widehat{G}) \leq \frac{k}{n} v_i(G)$. Therefore, $v_i(\widehat{G}) \geq v_i(G) - v_i(G \setminus \widehat{G}) \geq \left(1 - \frac{k}{n}\right) v_i(G)$.

Overall, every agent $i \in A$ is eventually assigned a bundle of value at least $\frac{1}{2n} v_i(G)$ in the while loop. ◀

Next we show that in each iteration of the while loop in ALG (Algorithm 1), the value of the assigned bundle B_i^t is at least as large as ℓ_i.

▶ **Lemma 5.** *Given a fair division instance $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with subadditive valuations, let B_i^t be the bundle assigned to agent $i \in [n]$ in the t^{th} iteration (for $t \in \mathbb{N}$) of the outer while loop (Step 10) in ALG. Then, for all agents $i \in [n]$ and each iteration count t, we have $v_i(B_i^t) \geq \ell_i$.*

Proof. During any iteration t of the outer while loop (Step 10) in ALG and for any agent $i \in [n]$, the bundle B_i^t either consists of a single good of high value (Step 15), or of the set of goods assigned to agent i obtained after executing the MOVINGKNIFE subroutine (Step 17). We will show that in both cases the stated inequality holds.

Recall that $\ell_i \coloneqq \min_{S \subseteq [m] : |S| \leq 2n} \frac{1}{2n} v_i([m] \setminus S)$. Equivalently, $\ell_i = \min_{T \subseteq [m] : |T| \geq m - 2n} \frac{1}{2n} v_i(T)$. Therefore, we have

$$\frac{1}{2n} v_i(T) \geq \ell_i \qquad \text{for any subset } T \subseteq [m] \text{ of size at least } (m - 2n) \tag{6}$$

The relevant observation here is that, in any iteration t, the set of goods G from which the bundles B_i^ts are populated satisfies $|G| \geq m - 2n$. Specifically, in the t^{th} iteration, we start with $|G| = m - n$ (Step 13). Subsequently, the inner while loop (Step 14) assigns at most n goods and, hence, the number of goods passed on to the MOVINGKNIFE subroutine satisfies $|G| \geq m - 2n$.

First, we note that the lemma holds for any agent a' that receive a singleton bundle $B_{a'}^t = \{g'\}$ in Step 15: $v_{a'}(g') \geq \frac{1}{2n} v_{a'}(G) \geq \ell_{a'}$. Here, the first inequality follows from the selection criterion applied to g' and the second inequality from equation (6) and the fact that $|G| \geq m - 2n$.

Finally, we note that the bound also holds for the remaining agents i that receive a bundle B_i^t through the MOVINGKNIFE subroutine. As mentioned previously, at least $m - 2n$ goods are passed on as input to the subroutine, i.e., if MOVINGKNIFE is executed on instance $\mathcal{J} = \langle G, A, \{v_i\}_{i \in A} \rangle$, then we have $|G| \geq m - 2n$. Inequality (6) ensures that $\frac{1}{2n} v_i(G) \geq \ell_i$ for all $i \in A$. Finally, using Lemma 4, we get that the bundle assigned to agent $i \in A$ satisfies the stated inequality: $v_i(B_i^t) = v_i(P_i) \geq \frac{1}{2n} v_i(G) \geq \ell_i$.

Hence, the stated claim follows. ◀

We now show that the estimates γ_i^ts used in ALG also satisfy a lower bound similar to that in Lemma 5.

▶ **Lemma 6.** *Given a fair division instance $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with subadditive valuations, let $\gamma_i^t \in \mathbb{R}_+$ be the estimate associated with agent $i \in [n]$ in the t^{th} iteration (for $t \in \mathbb{N}$) of the outer while loop (Step 10) in ALG. Then, for all agents $i \in [n]$ and each iteration count t, we have $\gamma_i^t \geq \left(1 - \frac{1}{m}\right) \ell_i$.*

Proof. Note that for any agent $i \in [n]$, the quantity $\ell_i = 0$ iff i has positive value for at most $2n$ goods. This observation implies that the initial for loop in ALG correctly identifies agents i that have $\ell_i = 0$, and sets $\gamma_i^0 = 0$. For such agents $\gamma_i^t = 0$ for all t. Hence, the lemma holds for any agent i with $\ell_i = 0$.

We now consider agents $i \in [n]$ with $\ell_i > 0$. For such an agent i, the algorithm initially sets $\gamma_i^0 = v_i([m])$. Hence, for $t = 0$ we have $\gamma_i^t \geq \left(1 - \frac{1}{m}\right) \ell_i$. An inductive argument shows that this inequality continues to hold as the algorithm progresses. In particular, if in the t^{th} iteration the algorithm does not decrement the estimate (i.e., if $i \in \text{SAT}_{t+1}$), then $\gamma_i^{t+1} = \gamma_i^t \geq \left(1 - \frac{1}{m}\right) \ell_i$.

Even otherwise, if the algorithm multiplicatively decrements the estimate (in particular, sets $\gamma_i^{t+1} = (1 - 1/m)\ \gamma_i^t$), then it must be the case that $\gamma_i^t > v_i(B_i^t)$ (i.e., $i \in \text{UNSAT}_{t+1}$). That is, after the decrement we have $\gamma_i^{t+1} \geq \left(1 - \frac{1}{m}\right) v_i(B_i^t) \geq \left(1 - \frac{1}{m}\right) \ell_i$; the last inequality follows from Lemma 5. This completes the proof. ◀

3.1 Proof of Theorem 2

In this section we prove Theorem 2 by showing that ALG runs in polynomial time (Lemma 7) and the computed allocation achieves the stated approximation ratio of $8n$ (Lemma 8).

▶ **Lemma 7** (Runtime Analysis). *Given any fair division instance $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ in which the agents have monotone, subadditive valuations, ALG (Algorithm 1) terminates after $T = O\left(nm \log\left(nmV\right)\right)$ iterations of its outer while loop (Step 10); here,*

$$V = \max_{i \in [n]} \left(\frac{\max\limits_{g \in [m]} v_i(g)}{\min\limits_{g \in [m] : v_i(g) > 0} v_i(g)} \right) .$$

Proof. By design, ALG iterates as long as $\text{UNSAT}_t \neq \emptyset$. We will bound the number of times (i.e., the distinct values of t for which) any agent $i \in [n]$ is contained in UNSAT_t and, hence, establish the stated runtime bound.

Recall that for any agent $i \in [n]$, the quantity $\ell_i = 0$ iff i has positive value for at most $2n$ goods. For such agents ALG sets $\gamma_i^0 = 0$. Therefore, these agents are contained in SAT_t, for all iterations $t \geq 1$, and do not contribute to the repetitions of the outer while loop.

For the remaining agents, with $\ell_i > 0$, the algorithm initially sets $\gamma_i^0 = v_i([m])$ and we have

$$\ell_i \geq \frac{1}{2n} \min_{g \in [m] : v_i(g) > 0} v_i(g) \,. \tag{7}$$

Using Lemma 6 and the fact that the algorithm decrements γ_i^t by a multiplicative factor of $(1 - 1/m)$ whenever $i \in \text{UNSAT}_t$, we get that the number of times agent i can be in the UNSAT_t is at most

$$\begin{aligned}
m \log\left(\frac{v_i([m])}{\ell_i}\right) &\leq m \log\left(\frac{m\ \max_{g \in [m]} v_i(g)}{\ell_i}\right) \\
&\qquad \text{(since } v_i \text{ is subadditive, } v_i([m]) \leq m \max_{g \in [m]} v_i(g)\text{)} \\
&\leq m \log\left(\frac{2nm\ \max_{g \in [m]} v_i(g)}{\min\limits_{g \in [m] : v_i(g) > 0} v_i(g)}\right) \qquad \text{(via inequality (7))} \\
&\leq m \log\left(2nmV\right) .
\end{aligned}$$

Summing over all agents, we get that the number of times $\text{UNSAT}_t \neq \emptyset$ is at most $T = O\left(nm \log\left(nmV\right)\right)$. Hence, the stated lemma follows. ◀

We now show that the allocation computed by ALG achieves the required approximation guarantee.

▶ **Lemma 8** (Approximation Guarantee). *For any fair division instance $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with subadditive valuations, let $\mathcal{B} = (B_1, \ldots, B_n)$ denote the allocation computed by ALG. Then,* $\mathrm{NSW}(\mathcal{B}) \geq \frac{1}{8n}\mathrm{NSW}(\mathcal{N}^*)$*; here, $\mathcal{N}^*$ denotes the Nash optimal allocation in $\mathcal{I}$.*

Proof. For the given instance $\mathcal{I}$, say ALG terminates after $T+1$ iterations of the outer while loop. That is, we have $\mathrm{UNSAT}_{T+1} = \emptyset$ and, for each agent $i \in [n]$, the returned bundle $B_i = B_i^T \cup \{\pi^T(i)\}$. Here, $\pi^T(i)$ is the good assigned to agent i under the maximum weight matching π^T (considered in the last iteration) and B_i^T is the bundle populated for i (either in Step 15 or in Step 17).

The fact that $\mathrm{UNSAT}_{T+1} = \emptyset$ (i.e., $\mathrm{SAT}_{T+1} = [n]$) gives us

$$v_i(B_i^T) \geq \gamma_i^T \qquad \text{for all } i \in [n]\,. \tag{8}$$

Lemma 3 (instantiated with $\mathcal{A}^* = \mathcal{N}^*$) implies that there exists a matching – $\sigma(i) \coloneqq \widehat{g}_i \in N_i^*$, for all $i \in [n]$ – with the property that $v_i(\sigma(i)) + \ell_i \geq \frac{1}{4n} v_i(N_i^*)$. Using this inequality and Lemma 6 we get, for all $i \in [n]$:

$$v_i(\sigma(i)) + \gamma_i^T \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} v_i(N_i^*)\,. \tag{9}$$

Recall that π^T is a maximum weight matching in the bipartite graph (considered in Step 11 of ALG) with edge weights $\log\left(v_i(g) + \gamma_i^T\right)$. Given that $\sigma(\cdot)$ is some matching in the graph and π^T is a maximum weight matching, we get $\sum_{i=1}^n \log\left(v_i(\pi^T(i)) + \gamma_i^T\right) \geq \sum_{i=1}^n \log\left(v_i(\sigma(i)) + \gamma_i^T\right)$. That is,

$$\left(\prod_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)\right)^{\frac{1}{n}} \geq \left(\prod_{i=1}^n \left(v_i(\sigma(i)) + \gamma_i^T\right)\right)^{\frac{1}{n}} \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} \mathrm{NSW}(\mathcal{N}^*)\,. \tag{10}$$

The last inequality follows from equation (9). Also, as defined previously, the optimal Nash social welfare $\mathrm{NSW}(\mathcal{N}^*) = \left(\prod_i^n v_i\left(N_i^*\right)\right)^{1/n}$.

The monotonicity of the valuation function v_i implies $v_i\{\pi^T(i)\} \cup B_i^T) \geq 1/2(v_i(\pi^T(i)) + v_i(B_i^T))$ for each $i \in [n]$. Using these observations we can lower bound the Nash social welfare of the computed allocation $\left(B_i = \{\pi^T(i)\} \cup B_i^T\right)_i$ as follows

$$\begin{aligned}
\left(\prod_{i=1}^n v_i(B_i)\right)^{\frac{1}{n}} &\geq \frac{1}{2}\left(\prod_{i=1}^n \left(v_i(\pi^T(i)) + v_i(B_i^T)\right)\right)^{\frac{1}{n}} \\
&\geq \frac{1}{2}\left(\prod_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)\right)^{\frac{1}{n}} && \text{(via inequality (8))} \\
&\geq \left(1 - \frac{1}{m}\right) \frac{1}{8n} \mathrm{NSW}(\mathcal{N}^*)\,. && \text{(via inequality (10))}
\end{aligned}$$

This establishes the stated approximation guarantee and completes the proof of the lemma. ◀

▶ Remark. The result of Garg et al. [20] also holds for an asymmetric version of Nash social welfare maximization, in which each agent i has an associated weight $\eta_i \geq 0$ and the goal is to find an allocation $(A_1, \ldots, A_n)$ that maximizes $\left(\prod_{i \in [n]} \left(v_i(A_i)\right)^{\eta_i}\right)^{\frac{1}{\sum_{i \in [n]} \eta_i}}$. Our

approximation guarantee extends to this formulation. In particular, in Step 11 of ALG we can set the edges weights to be $\eta_i \log(v_i(g)+\gamma_i)$ (instead of $\log(v_i(g)+\gamma_i)$) and note that the subsequent arguments follow through to provide an $8n$-approximation ratio for maximizing Nash social welfare with asymmetric agents and subadditive valuations.

Also, one can use Theorem 2, in conjunction with the m/n approximation guarantee of Nguyen and Rothe [26],[4] to obtain an $O(\sqrt{m})$-approximation algorithm for maximizing Nash social welfare under subadditive valuations: for instances in which $m \geq n^2$, the $8n$ approximation suffices. Otherwise, if $m < n^2$ (i.e., $m/n < \sqrt{m}$), then we can invoke the result of Nguyen and Rothe [26].

4 An $8n$-Approximation for p-Mean Welfare

This section shows that we can extend Algorithm 1 and obtain an $8n$ approximation for maximizing the p-mean welfare as well.

For maximizing p-mean welfare, ALG (Algorithm 1) is modified as follows: In Step 11, the weight $w(i,g)$ of edge $(i,g) \in [n] \times [m]$ is set as $(v_i(g)+\gamma_i^t)^p$ (instead of $\log(v_i(g)+\gamma_i^t)$).[5] Furthermore,

- **(i)** For $p \in (0,1]$, in Step 12 we compute a left-perfect *maximum*-weight matching, π^t, otherwise
- **(ii)** For finite $p < 0$, we compute a left-perfect *minimum*-weight matching, π^t, in Step 12
- **(iii)** For maximizing egalitarian welfare (the $p = -\infty$ case), we set edge weights to be $(v_i(g)+\gamma_i^t)$ and compute a max-min matching[6] π^t with respect to these weights.

Theorem 9 below establishes that, with these changes in ALG (Algorithm 1), we can efficiently compute an allocation with p-mean welfare at least $\frac{1}{8n}$ times the optimal (p-mean welfare). Note that by Proposition 1, for $p \leq -n \log n$, we can maximize the egalitarian welfare, instead of the p-mean welfare, and the allocation thus obtained is an $8n$-approximation to the optimal p-mean welfare allocation.

▶ **Theorem 9.** *Let $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ be a fair division instance in which the valuation function v_i, of each agent $i \in [n]$, is nonnegative, monotone, and subadditive. Then, given value oracle access to v_is , one can efficiently compute an $8n$ approximation to the optimal p-mean welfare for any $p \in (-\infty, 1]$.*

Proof. We first note that Lemmas 3, 4, 5, 6, and 7 hold as is for p-mean welfare. In particular, using Lemma 7 we get that, even with the above-mentioned changes, the algorithm runs in polynomial time.

To complete the proof of the theorem, we will next show that the computed allocation $\mathcal{B} = (B_1, \ldots, B_n)$ satisfies $\mathrm{M}_p(\mathcal{B}) \geq \frac{1}{8n}\mathrm{M}_p(\mathcal{A}^*(p))$, where $\mathcal{A}^*(p)$ is a p-mean welfare maximizing allocation.

For the given instance $\mathcal{I}$, say the modified algorithm terminates after $T+1$ iterations of the outer while loop. That is, we have $\mathrm{UNSAT}_{T+1} = \emptyset$ and, for each agent $i \in [n]$, the returned bundle $B_i = B_i^T \cup \{\pi^T(i)\}$. Here, $\pi^T(i)$ is the good assigned to agent i under the matching π^T (considered in the last iteration) and B_i^T is the bundle populated for i in the final iteration.

[4] While Theorem 4 in [26] provides the above-mentioned approximation guarantee of $(m-n+1)$, its proof can in fact be easily modified to obtain an approximation ratio of m/n.

[5] Recall that the $p = 0$ case corresponds to Nash social welfare. Since we already have the desired approximation guarantee for this case, it is not explicitly addressed in this section.

[6] In particular, via binary search (over edge weights), we find a matching wherein the minimum edge weight (across agents) is as high as possible.

The fact that $\text{UNSAT}_{T+1} = \emptyset$ (i.e., $\text{SAT}_{T+1} = [n]$) gives us

$$v_i(B_i^T) \geq \gamma_i^T \qquad \text{for all } i \in [n] \tag{11}$$

Lemma 3 implies that there exists a matching – $\sigma(i) \coloneqq \widehat{g}_i \in A_i^*(p)$, for all $i \in [n]$ – with the property that $v_i(\sigma(i)) + \ell_i \geq \frac{1}{4n} v_i(A_i^*(p))$. Using this inequality and Lemma 6 we get, for all $i \in [n]$:

$$v_i(\sigma(i)) + \gamma_i^T \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} v_i(A_i^*(p)) \tag{12}$$

Recall that, given p, the modified algorithm computes π^T based on the sign of p. Hence, we split the proof of Theorem 9 into three cases depending on whether $p > 0$, $p < 0$, or $p = -\infty$.

Case (i). $p > 0$. In this case, π^T is a left-perfect maximum-weight matching in the bipartite graph $([n] \cup [m], [n] \times [m])$ with edge weights $\left(v_i(g) + \gamma_i^T\right)^p$. Given that $\sigma(\cdot)$ is some (left-perfect) matching in the graph and π^T is a maximum-weight matching, we get $\sum_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)^p \geq \sum_{i=1}^n \left(v_i(\sigma(i)) + \gamma_i^T\right)^p$. Therefore, with $p > 0$, the following inequality holds

$$\left(\frac{1}{n}\sum_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)^p\right)^{\frac{1}{p}} \geq \left(\frac{1}{n}\sum_{i=1}^n \left(v_i(\sigma(i)) + \gamma_i^T\right)^p\right)^{\frac{1}{p}} \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} \mathrm{M}_p(\mathcal{A}^*(p)) \,. \tag{13}$$

The last inequality follows from (12).

Case (ii). Finite $p < 0$. By design, in this case, π^T is a left-perfect minimum-weight matching in the bipartite graph $([n] \cup [m], [n] \times [m])$ with edge weights $\left(v_i(g) + \gamma_i^T\right)^p$. Given that $\sigma(\cdot)$ is some left-perfect matching in the graph and π^T is a minimum-weight matching, we get $\sum_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)^p \leq \sum_{i=1}^n \left(v_i(\sigma(i)) + \gamma_i^T\right)^p$. The fact that p is negative gives us

$$\left(\frac{1}{n}\sum_{i=1}^n \left(v_i(\pi^T(i)) + \gamma_i^T\right)^p\right)^{\frac{1}{p}} \geq \left(\frac{1}{n}\sum_{i=1}^n \left(v_i(\sigma(i)) + \gamma_i^T\right)^p\right)^{\frac{1}{p}} \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} \mathrm{M}_p(\mathcal{A}^*(p)) \tag{14}$$

The last inequality follows from (12).

Case (iii). $p = -\infty$. In this case, π^T is a max-min matching computed with edge weights $\left(v_i(\pi^T(i)) + \gamma_i^T\right)$. Given that $\sigma(\cdot)$ is some matching in the graph and matching π^T maximizes the value of the minimum matched edge, we get $\min_{i\in[n]}(v_i(\pi^T(i)) + \gamma_i^T) \geq \min_{i\in[n]}(v_i(\sigma^T(i)) + \gamma_i^T)$. Therefore,

$$\min_{i\in[n]}(v_i(\pi^T(i)) + \gamma_i^T) \geq \min_{i\in[n]}(v_i(\sigma^T(i)) + \gamma_i^T) \geq \left(1 - \frac{1}{m}\right) \frac{1}{4n} \mathrm{M}_p(\mathcal{A}^*(p)) \tag{15}$$

The last inequality follows from (12).

The monotonicity of the valuation function v_i implies $v_i(\{\pi^T(i)\} \cup B_i^T) \geq 1/2(v_i(\pi^T(i)) + v_i(B_i^T))$ for each $i \in [n]$. Using these observations we can lower bound the p-mean welfare of the computed allocation $\left(B_i = \{\pi^T(i)\} \cup B_i^T\right)_i$ as follows

$$\left(\sum_{i=1}^{n}(v_i(B_i))^p\right)^{\frac{1}{p}} \geq \frac{1}{2}\left(\sum_{i=1}^{n}\left(v_i(\pi^T(i))+v_i(B_i^T)\right)^p\right)^{\frac{1}{p}}$$
$$\geq \frac{1}{2}\left(\sum_{i=1}^{n}\left(v_i(\pi^T(i))+\gamma_i^T\right)^p\right)^{\frac{1}{p}} \qquad \text{(via inequality (11))}$$
$$\geq \left(1-\frac{1}{m}\right)\frac{1}{8n}\mathrm{M}_p(\mathcal{A}^*(p)) \qquad \text{(via inequality (13), (14), or (15))}$$

This establishes the stated approximation guarantee and completes the proof of the theorem. ◀

5 Lower Bound on Approximating p-Mean Welfare

This section shows that, under XOS valuations, maximizing the p-mean welfare for $p \in (-\infty, 1]$ within a sub-linear (in n) approximation factor necessarily requires an exponential number of value queries (Theorem 10). This result directly implies that the approximation ratio obtained in Theorems 2 and 9 (via polynomially many value queries) is essentially tight. We note that this query lower bound is unconditional, i.e., it does not depend on any complexity theoretic assumption.

We establish Theorem 10 by directly adapting a result of Dobzinski et al. [16], which provides a similar lower bound for social welfare. The impossibility result here holds under XOS valuations;[7] recall that XOS valuations constitute a special class of subadditive functions.

▶ **Theorem 10.** *For fair division instances $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with XOS valuations and $p \in (-\infty, 1]$, finding an allocation with p-mean welfare at least $1/n^{1-\varepsilon}$ times the optimal requires exponentially many value queries; here $\varepsilon > 0$ is any fixed constant.*

Here, we briefly explain the salient points of the proof of this lower bound and provide the details in the full version of the current paper [4]. Dobzinski et al. [16] construct two (families of) instances, both with n agents, $m = n^2$ goods, and XOS valuations for the agents. In the first instance, each agent has the same valuation function $f : 2^{[m]} \mapsto \mathbb{R}_+$ and maximum average social welfare (1-mean welfare) is $n^{4\delta}$, for a fixed constant $\delta > 0$. In the second instance, each agent has her own (non-identical) valuation function $v_i : 2^{[m]} \mapsto \mathbb{R}_+$ and there exists an allocation in which each agent has value n for her bundle. For any $p \leq 1$, it follows that in the first instance the optimal p-mean welfare is at most $n^{4\delta}$ (via the generalized mean inequality), while for the second instance, the optimal p-mean welfare is at least n (since there exists an allocation where every agent achieves value n). The proof of Dobzinski et al. [16] goes on to show that it takes an exponential number of value queries to distinguish between the two instances. However, given an $O(n^{1-\varepsilon})$-approximation algorithm for the p-mean welfare, one can readily distinguish between the two instances (by choosing $\delta < \varepsilon/4$). Hence such an algorithm must make an exponential number of value queries.

[7] Our results work under the value oracle model and do not require an explicit description of the underlying additive functions that define the XOS function at hand.

6 $(m - n + 1)$-Approximation Guarantees

This section provides two extensions of the result of Nguyen and Rothe [26], which shows the Nash social welfare maximization problem (under subadditive valuations) admits an $(m - n + 1)$-approximation algorithm. First, we show that an $(m - n + 1)$-approximation for the p-mean welfare can be obtained for all $p \leq 0$ and with subadditive valuations. Then, we establish that it is NP-hard to extend this positive result to any $p \in (0, 1)$, even under additive valuations, i.e., it is NP-hard to obtain an $(m - n + 1)$-approximation for $0 < p < 1$. The proofs of these two results are delegated to the full version of this paper [4].

▶ **Theorem 11.** *Let $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ be a fair division instance in which the valuation function v_i, of each agent $i \in [n]$, is nonnegative, monotone, and subadditive. Then, given value oracle access to v_is, one can efficiently compute an $(m - n + 1)$ approximation to the p-mean welfare maximization problem for any $p \in (-\infty, 0]$.*

The next theorem asserts that it is unlikely that Theorem 11 extends to $p \in (0, 1)$.

▶ **Theorem 12.** *For fair division instances $\mathcal{I} = \langle [m], [n], \{v_i\}_{i=1}^n \rangle$ with additive valuations and for any fixed $p \in (0, 1)$, computing an allocation with p-mean welfare at least $1/(m-n+1)$-times the optimal (for all m and n) is* NP*-hard.*

Note that this hardness result (in light of Theorem 9) is relevant for instances in which $m < 2n$.

Abstract

Let $G = (V, E)$ be an undirected graph on n vertices with non-negative capacities on its edges. The *mincut sensitivity problem* for the insertion of an edge is defined as follows.

Build a compact data structure for G and a given set $S \subseteq V$ of vertices that, on receiving any edge $(x, y) \in S \times S$ of positive capacity as query input, can efficiently report the set of all pairs from $S \times S$ whose mincut value increases upon insertion of the edge (x, y) to G.

The only result that exists for this problem is for a single pair of vertices (Picard and Queyranne, Mathematical Programming Study, 13 (1980), 8-16). We present the following results for the single source and the all-pairs versions of this problem.

1. *Single source*: Given any designated source vertex s, there exists a data structure of size $\mathcal{O}(|S|)$[1] that can output all those vertices from S whose mincut value to s increases upon insertion of any given edge. The time taken by the data structure to answer any query is $\mathcal{O}(|S|)$.
2. *All-pairs*: There exists an $\mathcal{O}(|S|^2)$ size data structure that can output all those pairs of vertices from $S \times S$ whose mincut value gets increased upon insertion of any given edge. The time taken by the data structure to answer any query is $\mathcal{O}(k)$, where k is the number of pairs of vertices whose mincut increases.

For both these versions, we also address the problem of reporting the values of the mincuts upon insertion of any given edge. To derive our results, we use interesting insights into the *nearest* and the *farthest* mincuts for a pair of vertices. In addition, a crucial result, that we establish and use in our data structures, is that there exists a directed acyclic graph of $\mathcal{O}(n)$ size that compactly stores the farthest mincuts from all vertices of V to a designated vertex s in the graph. We believe that this result is of independent interest, especially, because it also complements a previously existing result by Hariharan et al. (STOC 2007) that the nearest mincuts from all vertices of V to s is a laminar family, and hence, can be stored compactly in a tree of $\mathcal{O}(n)$ size.

1 Introduction

Let $G = (V, E)$ be a graph on $n = |V|$ vertices and $m = |E|$ edges with a non-negative capacity on each edge. A *mincut* for a pair of vertices u and v is a set of edges with least capacity whose removal disconnects v from u. It is a fundamental concept in graph theory. Moreover, the area of designing algorithms for the mincut and its variants has been extensively researched ever since the seminal result on the maxflow-mincut duality by Ford and Fulkerson [5].

It is often the case that one is more interested in the mincuts between vertices belonging to a relatively small part of the input graph than the mincuts between all vertices. Hence, consider a subset of vertices $S \subseteq V$ and any subset of pairs of vertices $Q \subseteq S \times S$ whose mincut we are interested in. The objective is to have the knowledge about how sensitive the mincuts of pairs of vertices from Q are, with respect to any change in the subgraph induced by S. This change could be a change in the capacity of an existing edge in the subgraph induced by S or insertion of a new edge between any two vertices in S. This knowledge of the impact on various mincuts due to any change in the network can make the network administrators well prepared for such changes when they indeed occur in future.

An important measure of the impact of a change in the capacity of an edge is the number of pairs of vertices whose mincut value changes. The change in the capacity of an edge could be either an increase or a decrease. We focus on the case when the capacity of an edge is allowed to increase only. For this data structure problem, the query input is a new edge with positive capacity or an existing edge whose capacity is increased. It can easily be observed that as far as the mincut between any pair of vertices is concerned, increasing the capacity of an existing edge (x, y) by amount Δ is equivalent to adding one more edge between x and y with capacity Δ. So henceforth, we only consider the insertion of an edge. On receiving any such edge, the objective is to efficiently report the pairs of vertices whose mincut increases.

Based on the discussion above, we now formally define the problem of mincut sensitivity.

▶ **Problem 1.** *Preprocess $G = (V, E)$, a set $S \subseteq V$, and a set $Q \subseteq S \times S$ to build a compact data structure that, on receiving any edge $(x, y) \in S \times S$ of positive capacity as query input, can efficiently report all those pairs from Q whose mincut value increases upon insertion of the edge (x, y) to G.*

We expect the bounds for the data structure of Problem 1 to depend on only the size of S instead of V. For simultaneously achieving efficient query time and compact space, the only previous solution that exists for this problem is for a single pair of vertices only, i.e., when $|Q| = 1$. It consists of a data structure that occupies $\mathcal{O}(|S|)$ space and achieves $\mathcal{O}(1)$ query time. This solution follows from an observation made by Picard and Queyranne in their seminal paper [11].

1.1 Our Contribution

We address the single source and the all-pairs versions of Problem 1, along with the problem of reporting the new value of the mincut between any pair of vertices after the edge insertion.

Single source all destinations: In the single source case, we are interested in the mincuts between a designated vertex $s \in S$ and all other vertices from set S, i.e., the (s,t)-mincut, for all $t \in S \setminus \{s\}$.

▶ **Theorem 2.** *For an undirected graph and any subset S of vertices with a designated vertex $s \in S$, there exists an $\mathcal{O}(|S|)$ size data structure that can report all those vertices from S whose mincut value to s increases upon insertion of any given edge from $S \times S$. The time taken by this data structure to answer any such query is $\mathcal{O}(|S|)$.*

The $\mathcal{O}(|S|)$ space and $\mathcal{O}(|S|)$ query time of our data structure for undirected graphs can be much less than $\mathcal{O}(|V|)$ for smaller S. Also, it is in sharp contrast with the following lower bound result for directed graphs that we also prove.

▶ **Theorem 3.** *Any data structure for a directed graph to answer a mincut sensitivity query from a designated source vertex to any designated subset of q vertices must use $\Omega(q^2)$ bits of space for at least one directed graph.*

The proof of Theorem 3 basically establishes that any such data structure can be used to store any balanced bipartite graph on $2|S|$ vertices implicitly. Interestingly, the same proof also establishes an $\Omega(|S|^2)$ lower bound for the single source version of two other fundamental problems for directed graphs, namely, *reachability sensitivity* as well as *distance sensitivity* for the insertion of an edge. These facts add more significance to the result stated in Theorem 2 for the single source mincut sensitivity.

All-pairs: When considering the mincuts between all pairs of vertices in S, i.e., the (u,v)-mincut, for all $u, v \in S$ such that $u \neq v$, we obtain the following result.

▶ **Theorem 4.** *For an undirected graph and any subset S of vertices, there exists an $\mathcal{O}(|S|^2)$ size data structure that can report all those pairs of vertices from $S \times S$ whose mincut value increases upon insertion of any given edge from $S \times S$. The time taken by the data structure to answer any such query is $\mathcal{O}(k)$, where k is the number of pairs whose mincut increases.*

Note that the query time of the data structure in Theorem 4 is optimal. Moreover, if the objective is to report just the number of all-pairs from the set $S \times S$ whose mincut increases upon insertion of any given edge, our data structure can accomplish this objective in $\mathcal{O}(\min(k, |S| \log |S|))$ time, which is $\mathcal{O}(|S| \log |S|)$ always.

▶ Remark 5. Our results for mincut sensitivity directly extend to maxflow sensitivity as well due to the equivalence between maxflow and mincut [5].

To achieve all our results, we use interesting insights into the *nearest* and the *farthest* mincuts for a pair of vertices – two concepts that exist since the seminal work of Ford and Fulkerson on maximum flow [5]. Additionally, a crucial result about the farthest mincuts that we establish and use in one of our data structures is the following.

▶ **Theorem 6.** *For an undirected graph on n vertices and a designated source vertex s, there exists a directed acyclic graph (DAG) of size $\mathcal{O}(n)$ that compactly stores the farthest mincuts from all vertices $v \in V \setminus \{s\}$ to s. For any v, the set of vertices defining the farthest mincut from v to s can be reported in time that is of the order of the size of the set.*

The graph theoretic result of Theorem 6 is of independent interest in addition to its applications in the mincut sensitivity problem. This is because, not only it adds to our understanding of mincuts, but it also complements an earlier result of Hariharan et al. [9] that showed that the nearest mincuts from all vertices to s form a laminar family, and hence, can be stored in a tree data structure occupying only $\mathcal{O}(n)$ space.

1.1.1 On reporting the value of mincut

In addition to reporting the pairs of vertices whose mincut increases upon insertion of a given edge, it may be important to output the new values of their mincuts. Indeed, if the edge capacities in the graph are integral and the inserted edge has unit capacity, our data structures from Theorems 2 and 4 can also report the new values of the affected mincuts upon insertion of an edge, i.e., the value of the mincut will be increased by one for the reported pairs of vertices. However, if there is no restriction on the capacity of the inserted edge, we show that even for the single source case it is not possible to accomplish this objective with any data structure of subquadratic size.

▶ **Theorem 7.** *There exists a set $\mathcal{G}$ of undirected graphs on n vertices with integer edge capacities in the range $[1, n^{2+\varepsilon}]$ (for any $\varepsilon > 0$) for which the following claim holds true. Any data structure for an undirected graph that can report the value of the mincut between a designated source vertex and any other vertex upon insertion of any edge of integer capacity polynomial in n must require $\Omega(n^2 \varepsilon \log n)$ bits of space for at least one graph from $\mathcal{G}$.*

For the all-pairs case, it turns out that any such data structure also provides a generalization of the flow-tree [6, 8]. That is, the data structure will also be able to report the mincut value between a vertex u and a pair $\{x, y\}$ of vertices for any $u, x, y \in V$. Chitnis, Kamma, and Krauthgamer [4] showed that there will be total $\mathcal{O}(n^2)$ distinct mincut values separating any vertex from any pair of vertices in an undirected graph. However, to the best of our knowledge, designing an $\mathcal{O}(n^2)$ size data structure that returns the value of any such mincut in non-trivial query time is still an open problem.

1.2 Overview of our results

We begin with the result of Picard and Queyranne [11] for mincut sensitivity for a source-destination pair (s, t). For any maximum flow f from s to t, let G_f be the corresponding residual graph. Notice that there is no path from s to t in G_f. Let R be the set of vertices which are reachable from s in G_f, and let T be the set of vertices from which t is reachable in G_f. Picard and Queyranne [11] made the following crucial observation.

▶ **Lemma 8** (Picard and Queyranne [11])**.** *The maxflow from s to t increases upon insertion of an edge (x, y) if and only if x belongs to R and y belongs to T.*

Without loss of generality, we can assume that the vertices of set S are labeled from 1 to $|S|$. Based on Lemma 8, the data structure for mincut sensitivity for a (s, t)-pair where $s, t \in S$, stores each of $R \cap S$ and $T \cap S$ in Boolean arrays indexed by the vertices of set S.

The subsets R and $V \backslash T$ in Lemma 8 turn out to be the smallest, and the largest subsets of vertices defining a mincut from s to t, respectively. In the literature on mincuts, R and $V \backslash T$ are respectively called the *nearest* and the *farthest* mincut from s to t; we define these notions more formally in the next section. Therefore, in order to design a compact and efficient data structure for the single source and the all-pairs versions of the mincut sensitivity problem, it is natural to explore if we can have a compact way to store these two types of cuts

for multiple pairs of vertices. We now provide an overview of the compact data structures for the nearest and the farthest mincuts, and the way these data structures are used to solve the mincut sensitivity problem.

Compact data structures for the nearest and the farthest mincuts

Interestingly, Hariharan et al. [9] showed that the nearest mincuts from all vertices to a designated vertex s in an undirected graph form a laminar family – If the subsets of vertices defining the nearest mincuts from u to s, and v to s intersect, then one of them must be a subset of the other. As a result, the nearest mincuts from all vertices to s can be stored compactly in a tree data structure occupying $\mathcal{O}(n)$ space only. However, the farthest mincuts do not constitute a laminar family. Let F_u and F_v be the subsets of vertices that define the farthest mincuts to s from u and v respectively. It is quite possible that F_u and F_v intersect each other but none of them is a subset of the other. In other words, two intersecting farthest mincuts to s may *cross* each other. Moreover, there may be $\Theta(n)$ vertices whose farthest mincuts to s cross the farthest mincut of a single vertex to s. This poses a challenge for designing a compact data structure for storing all the farthest mincuts to s. However, we overcome this challenge using crucial insights into the farthest mincuts.

Using the submodularity of cuts, we first establish the existence of a DAG on $\mathcal{O}(n)$ nodes that stores the farthest mincuts from all vertices to any designated vertex s. However, this DAG could have $\mathcal{O}(n^2)$ edges, and establishing the sparsity of the DAG turns out to be the main hurdle. We overcome this by proving the following interesting property of the farthest mincuts to s:

For any three vertices, either the intersection of their farthest mincuts to s is empty or the farthest mincut from at least one of them is a subset of one of the other two.

Using this property, we are able to prune away all the unnecessary edges from the DAG structure storing farthest mincuts to s. As a result, each node in the DAG turns out to have at most 2 incoming edges, so the size of the DAG is $\mathcal{O}(n)$.

For the objective of solving mincut sensitivity for a subset $S \subseteq V$, we present data structures for the nearest mincuts (likewise the farthest mincuts) that consist of vertices of S only instead of V. Their size is $\mathcal{O}(|S|)$. See Theorem 18 and Theorem 6.

Solving the mincut sensitivity problem

For solving the single source mincut sensitivity problem, we use the tree data structure storing the nearest mincuts and the DAG data structure storing the farthest mincuts, from all vertices of the set S to s. The size of the data structure is $\mathcal{O}(|S|)$. Following Lemma 8, it takes $\mathcal{O}(|S|)$ time using this data structure to determine whether the insertion of a given edge increases the (s, v)-mincut value for any vertex $v \in S$. This leads to $\mathcal{O}(|S|^2)$ time to find all vertices from S whose mincut value from s increases due to the insertion of a given edge. In order to reduce the query time to $\mathcal{O}(|S|)$, we make use of the following insight:

A vertex $x \in S$ belongs to the farthest mincut from v to s if and only if x is reachable from v in the DAG structure storing the farthest mincuts to s.

Solving the all-pairs version of the mincut sensitivity problem with optimal query time turns out to be more challenging. As the underlying graph is undirected, the subset of vertices that defines the farthest mincut from u to v is the complement of the subset of the vertices that defines the nearest mincut from v to u. As a result, keeping the nearest-mincut tree data structure for each vertex of S suffices to solve this problem. The data structure takes $\mathcal{O}(1)$ time to determine for any pair (u, v), whether insertion of an edge, say (x, y), increases

(u, v)-mincut value. This observation implies an $\mathcal{O}(|S|^2)$ time algorithm for computing all pairs of vertices from set S whose mincut value increases upon insertion of edge (x, y). But it is quite wasteful if k, the number of pairs whose mincut value increases, is much smaller than $|S|^2$. To accomplish $\mathcal{O}(k)$ query time, we make use of multiple insights into the structure of the nearest mincuts. The most crucial insight is the following:

The vertices whose mincut value to s increases upon insertion of an edge (x, y) lie contiguously on the paths from x and y to their lowest common ancestor in the tree that stores the nearest mincuts to s.

This insight leads to an $\mathcal{O}(|S| + k)$ query time. To get rid of the additive factor of $|S|$, we use another insight that helps finding the *right* pool of vertices whose nearest-mincut tree we need to query.

1.3 Related work

Our research is related to the field of dynamic graph algorithms that emphasizes on efficient data structures to handle changes in a network. For dynamic graph algorithms, the objective is to maintain the solution of a problem for an online sequence of edge insertions or deletions with worst case time complexity better than that of the best static algorithm. There do exist efficient dynamic algorithms for maintaining a global mincut – an incremental algorithm by Goranci, Henzinger, and Thorup [7], and a fully dynamic algorithm by Thorup [12]. However, there does not exist any dynamic algorithm for all-pairs mincuts whose worst case time complexity is better than the best static algorithm. Hartmann and Wagner [10] presented a fully dynamic algorithm for maintaining an all-pairs mincut tree for undirected graphs. Although it achieves a significant speedup over the best static algorithm on many real world graphs, its worst case asymptotic time complexity is not better than the best static algorithm for an all-pairs mincut tree.

1.4 Organization of the paper

Equipped with notations, definitions, and well known lemmas introduced in Section 2, we present the compact data structures for nearest and farthest mincuts in Sections 3 and Section 4, respectively. The data structures for the single source and the all-pairs versions of the mincut sensitivity problem are presented in Section 5 and 6 respectively. Due to the space constraint, the proofs of some theorems and lemmas had to be omitted from this version. So we recommend the reader to refer to the full version of this paper [2].

2 Preliminaries

Our results consider an undirected graph $G = (V, E)$ on n vertices where each edge is assigned a non-negative capacity through a function $c : E \to R^+$.

▶ **Definition 9** ((s, t)-cut). *A subset of edges whose removal disconnects t from s is called an (s, t)-cut. An (s, t)-mincut is an (s, t)-cut of smallest capacity.*

▶ **Definition 10** (set defining a cut). *A subset $A \subset V$ is said to define an (s, t)-cut if $s \in A$ and $t \notin A$. The corresponding cut is denoted by cut$(A, \bar{A})$ or more compactly cut(A).*

When there is no scope of confusion, we do not distinguish between a mincut and the set defining the mincut. We can extend the capacity function c on edges to any subset $A \subset V$ in a natural way as follows: $c(A)$ denotes the sum of the capacities of all those edges which have exactly one endpoint in A. With this generalization, we now state a well-known property of cuts, namely, the submodularity of cuts.

▶ **Lemma 11** (Submodularity of cuts). *Given an undirected graph $G = (V, E)$ with positive edge capacities, the following inequality holds true for any two subsets $A, B \subset V$.*

$$c(A) + c(B) \geq c(A \cup B) + c(A \cap B)$$

The following lemma states an important property of an (s,t)-mincut.

▶ **Lemma 12.** *Let $A \subset V$ define an (s,t)-mincut with $s \in A$. For any subset $A' \subset A$ with $s \notin A'$, if α is the number of edges incident on A' from $V \backslash A$, and β is the number of edges incident on A' from $A \backslash A'$, then $\alpha \leq \beta$.*

2.1 The nearest and the farthest mincuts

▶ **Definition 13** (Nearest and farthest mincuts from s to t). *The subset $A \subset V$ with $s \in A$ is said to define the nearest (likewise the farthest) mincut from s to t if (1) cut$(A, \bar{A})$ defines an (s,t)-mincut, and (2) For every other subset $A' \subset V$ that defines an (s,t)-mincut, $A \subset A'$ (likewise $A' \subset A$). We use s_t^N and s_t^F to denote the nearest and the farthest mincut from s to t, respectively.*

One can easily show using Lemma 11 that the nearest and the farthest mincut from s to t are unique. Additionally, t_s^N and s_t^F partition the set of vertices V as stated in the following lemma.

▶ **Lemma 14.** *For any pair of vertices $s, t \in V$, (i) $s_t^N \cap t_s^N = \emptyset$, and (ii) $s_t^F = V \backslash t_s^N$.*

In the light of Lemma 14, we can restate Lemma 8 for undirected graphs as follows.

▶ **Lemma 15** (Picard and Queyranne [11]). *The insertion of an edge (x, y) can increase the mincut between s and t if and only if $x \in s_t^N$ and $y \in t_s^N$ or vice versa.*

▶ Remark 16. In order to explore the relationship among the farthest mincuts from a set of vertices to a vertex s, we focus only on the connected component of s. This is because for each vertex outside this component, its farthest mincut to s is obvious. Therefore, without loss of generality we assume G to be connected in the rest of the paper.

3 A compact data structure for all nearest mincuts to vertex s

The following theorem plays the key role in compactly storing all nearest mincuts to s.

▶ **Theorem 17** (Hariharan et al. [9]). *For any two distinct vertices $u, v \in S$, either u_s^N and v_s^N are mutually disjoint or one of them is a subset of the other.*

For a given subset $S \subseteq V$, let $\mathcal{N} = \{x_s^N \cap S | x \in S \backslash \{s\}\}$. Using Theorem 17 we can arrange the sets of $\mathcal{N}$ in a forest of disjoint trees as follows. We refer to a vertex in this forest as *node*. For each set present in $\mathcal{N}$, we create a unique node in the forest. We assign each vertex $v \in S$ to the node ν corresponding to $v_s^N \cap S$. The parent of a node ν is defined as the unique node μ such that the set corresponding to μ is the smallest superset of the set corresponding to ν, if such a superset exists. If no such superset exists, ν will be the root of a tree. We create a dummy node and assign it as the parent of the root of every tree in this forest. Let us denote the resulting rooted tree by $\mathcal{T}(s)$. Figure 1 shows an example graph and the corresponding $\mathcal{T}(s)$ for the case $S = V$.

It can be observed that if a vertex $v \in S$ is assigned to node ν, then the subtree rooted at ν stores the set $v_s^N \cap S$. So it follows that a vertex, say x, belongs to $v_s^N \cap S$ if either x and v are assigned to the same node in $\mathcal{T}(s)$ or the node containing v is an ancestor of the

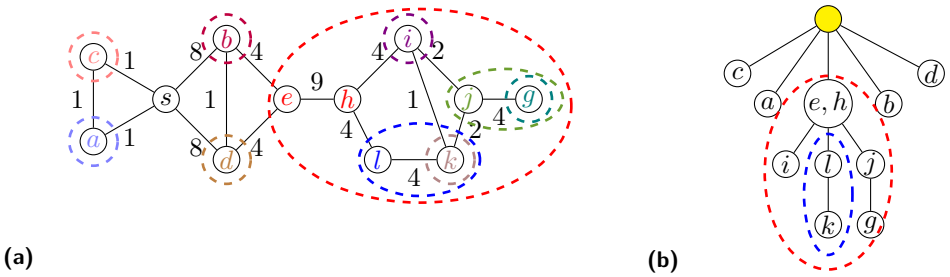

Figure 1 **(a)** The nearest mincut from a vertex to s is encircled with same color. **(b)** Tree $\mathcal{T}(s)$.

node containing x. This check can be easily done in $\mathcal{O}(1)$ time if we augment $\mathcal{T}(s)$ to answer lowest common ancestor (LCA) query for any pair of nodes (see [3]). We can thus state the following theorem.

▶ **Theorem 18.** *For an undirected graph $G = (V, E)$, a subset $S \subseteq V$, and any vertex $s \in S$, there exists an $\mathcal{O}(|S|)$ size data structure $\mathcal{T}(s)$ that can report in $\mathcal{O}(1)$ time whether $x \in v_s^N$ for any $x, v \in S$.*

4 A compact data structure for all farthest mincuts to vertex s

In this section, we present a novel data structure that compactly stores the farthest mincuts to vertex s from a subset of vertices. Our main result can be summarized as follows.

▶ **Theorem 19.** *For an undirected graph $G = (V, E)$, any subset $S \subseteq V$, and a designated vertex $s \in S$, there exists a directed acyclic graph $\mathcal{D}(s)$ having $\mathcal{O}(|S|)$ nodes and $\mathcal{O}(|S|)$ edges that can report $v_s^F \cap S$ in time of the order of the size of $v_s^F \cap S$ for any $v \in S \backslash \{s\}$.*

Lemma 14(ii) implies that $s_v^N = V \backslash v_s^F$. So we can compute $s_v^N \cap S$ in $\mathcal{O}(|S|)$ time once we have $v_s^F \cap S$. Therefore, we can state the following corollary of Theorem 19.

▶ **Corollary 20.** *For an undirected graph $G = (V, E)$, any subset $S \subseteq V$, and a designated vertex $s \in S$, there exists a data structure of $\mathcal{O}(|S|)$ size that takes just $\mathcal{O}(|S|)$ time to compute $s_v^N \cap S$ for any $v \in S \backslash \{s\}$.*

Next, we show how to compute a DAG storing all farthest mincuts to s in space $\mathcal{O}(|S|^2)$. Thereafter, we reduce its space complexity to $\mathcal{O}(|S|)$ only.

4.1 A DAG of size $\mathcal{O}(|S|^2)$

Our data structure to store all farthest mincuts to a designated vertex s uses the observation captured in Lemma 21. In its core, it tells us that certain farthest mincuts are related by a subset relation which can be exploited to store them compactly.

▶ **Lemma 21.** *Let x and v be any two vertices in G. If $x \in v_s^F$, then $x_s^F \subseteq v_s^F$.*

Proof. We use Lemma 11 on the submodularity of cuts and provide a proof by contradiction. Let A and B refer to the sets v_s^F and x_s^F, respectively. It is given that $x \in v_s^F$. Assume that $x_s^F \nsubseteq v_s^F$. This would imply that $B \backslash A \neq \emptyset$, hence A must be a proper subset of $A \cup B$.

Observe that $A \cap B$ defines a valid (x, s)-cut since x is present in both A and B, whereas $s \notin x_s^F$. This observation implies that $c(A \cap B) \geq c(B)$ since B defines an (x, s)-mincut. This inequality and Lemma 11 imply the following inequality.

$$c(A \cup B) \leq c(A) \tag{1}$$

Now observe that $A \cup B$ defines a valid (v,s)-cut since v belongs to A, whereas s belongs neither to A nor to B. Since A defines a (v,s)-mincut, so Inequality 1 implies that $c(A \cup B)$ must be equal to the capacity of an (v,s)-mincut. But A is a proper subset of $A \cup B$. This would imply that the cut defined by A is not the farthest mincut from v to s – a contradiction. ◀

Let $\mathcal{F} = \{v_s^F \cap S \mid v \in S \backslash \{s\}\}$. We now use Lemma 21 to build a directed acyclic graph $D = (\mathcal{V}, \mathcal{E})$ that stores $\mathcal{F}$ as follows. We use *node* to refer to a vertex of this DAG.

For each set present in $\mathcal{F}$, we create a unique node in D. The set of nodes thus created constitutes $\mathcal{V}$. We denote by $\mathcal{F}(\nu)$ the set in $\mathcal{F}$ corresponding to node ν. The edge set $\mathcal{E}$ of D is defined as follows.

$$\mathcal{E} = \{(\nu, \mu) \mid \mathcal{F}(\mu) \subset \mathcal{F}(\nu)\}$$

It can be observed that if $X \subset Y$ for any two sets X and Y in $\mathcal{F}$, then $|X| < |Y|$. Hence D is acyclic. To efficiently retrieve $x_s^F \cap S$ for any given $x \in S$, we can augment D as follows.

- We create an array J_s indexed by vertices of set S such that for any $v \in S \setminus \{s\}$, $J_s[v]$ stores the pointer to node μ that corresponds to $v_s^F \cap S$, that is, $\mathcal{F}(\mu) = v_s^F \cap S$.
- Each node μ of D stores a list $L(\mu)$ of all those vertices $v \in S$ such that $J_s[v] = \mu$.
- We introduce a dummy node and add an edge from it to every other node which has no incoming edge.

Lemma 22 follows immediately from Lemma 21 and the construction of D described above.

▶ **Lemma 22.** *Let x and u be any two vertices of set S. x is present in $u_s^F \cap S$ if and only if either $J_s[u] = J_s[x]$ or there is an edge from $J_s[u]$ to $J_s[x]$ in D.*

Lemma 22 implies that for each vertex $v \in S \backslash \{s\}$, $v_s^F \cap S$ is the set of vertices stored in the list $L(J_s[v])$ and the lists of all the nodes with an incoming edge from $J_s[v]$ in D.

The subset relation $\subset$ is transitive. So, if there is a path from a node ν to another node μ in D, then (ν, μ) is also an edge in D. In other words, the transitive closure of D is D itself. This observation in conjunction with Lemma 22 leads us to the following lemma which will be crucial for our data structure for the single source mincut sensitivity problem.

▶ **Lemma 23.** *Let x and u be any two vertices in set S. x is present in $u_s^F \cap S$ if and only if $J_s[x]$ is reachable from $J_s[u]$ in D.*

Notice that D has $\mathcal{O}(|S|)$ nodes, but it could have $\Theta(|S|^2)$ edges. So the total space occupied by D could be $\Theta(|S|^2)$. A natural idea to overcome this hurdle is to remove as many edges as possible from D without affecting the reachability between any pair of its vertices so that Lemma 23 continues to hold. In other words, we compute another DAG D^τ which is the transitive reduction of D. Aho, Garey, and Ullman [1] showed that computing the transitive reduction of a DAG is as easy as computing its transitive closure. While in general a transitive reduction does not always lead to a reduced number of edges, it does so in the case of D. In the following subsection we present crucial insights into crossing farthest mincuts that ensure that each node of D^τ will have at most two incoming edges. The data structure $\mathcal{D}(s)$ in Theorem 19 for storing all farthest mincuts to s is D^τ only.

4.2 Bounding the in-degree of D^τ by 2

A set of vertices $\mathcal{I} \subset V$ is said to be a set of *incomparable* vertices with respect to the mincuts to s if for each $u, v \in \mathcal{I}$ with $u \neq v$ it holds that $u \notin v_s^F$ and $v \notin u_s^F$. The following lemma highlights an important property for a pair of incomparable vertices.

▶ **Lemma 24.** *For any two incomparable vertices u and v, there does not exist any edge between the set $u_s^F \cap v_s^F$ and the set $V \backslash (u_s^F \cup v_s^F)$.*

We shall now use Lemma 12 and Lemma 24 to derive the following lemma which will play a crucial role in establishing that D^τ has indegree 2 only.

▶ **Lemma 25.** *For any three incomparable vertices $u, v, w \in V$, $u_s^F \cap v_s^F \cap w_s^F = \emptyset$.*

Proof. We give a proof by contradiction. Let B, L, and R denote the sets u_s^F, v_s^F, and w_s^F, respectively. Figure 2(i) illustrates these sets. For a clear distinction, we have used different colors for these sets in this figure, and correspondingly assigned the labels B (for blue), L (for light green), and R (for red) to these sets.

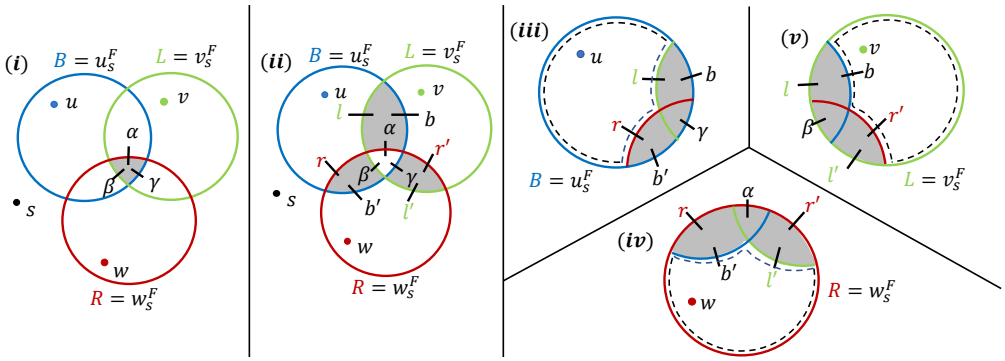

Figure 2 Intersection of the farthest mincuts to s.

Suppose the common intersection $B \cap L \cap R$ of these sets (shown shaded in Figure 2(i)) is not an empty set. By applying Lemma 24 for $B \cap L$, $L \cap R$, $R \cap B$, we can infer that each vertex in the common intersection will have edges incident only from the sets $B \cap L$, $L \cap R$, $R \cap B$. Considering the set $B \cap L \cap R$ as a single entity, let α, β, γ be the number of edges incident on it from $(B \cap L) \backslash R$, $(R \cap B) \backslash L$, $(L \cap R) \backslash B$, respectively. As the graph is connected (see Remark 16), we have:

$$\alpha + \beta + \gamma > 0. \tag{2}$$

Let us consider the set $(B \cap L) \backslash R$, that is, the set $B \cap L$ after removing the common intersection $B \cap L \cap R$. It follows from Lemma 24 that the edges incident on this set will be from $B \backslash L$ and $L \backslash B$ only, apart from the edges incident from $B \cap L \cap R$. Similar claims hold for the sets $(B \cap R) \backslash L$ and $(R \cap L) \backslash B$ as well. Figure 2(ii) shows these sets as shaded regions along with the edges incident on them. For example, l, b, α are the number of edges incident on $(B \cap L) \backslash R$ from $B \backslash L$, $L \backslash B$, and $B \cap R \cap L$, respectively.

The rest of the proof is as follows. Exploiting the fact that u, v, w are incomparable, we suitably apply Lemma 12 to arrive at inequalities that eventually leads to contradict Inequality 2.

B defines an (s, u)-mincut. Since u is incomparable with both v and w, it is not present in the set $B \cap (R \cup L)$ shown shaded in Figure 2(iii). Notice that the number of edges incident on this set from $V \backslash B$ is $b + b' + \gamma$ whereas the number of edges incident on this set from the rest of B, that is, the set $B \backslash (R \cup L)$ (enclosed by dotted boundary in Figure 2(iii)) is at most $l + r$. So we get the following inequality by substituting B and $B \cap (R \cup L)$ in place of A and A' respectively in Lemma 12:

$$b + b' + \gamma \leq l + r \tag{3}$$

In Figure 2, R defines an (s,w)-mincut and L defines an (s,v)-mincut. Hence, with similar arguments as above, analyzing the (s,w)-mincut in Figure 2(iv), and analyzing the (s,v)-mincut in Figure 2(v), we get the following inequalities, respectively:

$$r + r' + \alpha \leq b' + l', \qquad l + l' + \beta \leq b + r'$$

Adding the above inequalities with Inequality 3 and canceling identical terms on either sides we get $\alpha + \beta + \gamma \leq 0$. This contradicts Inequality 2 and completes the proof. ◀

The following is a simple corollary of Lemma 25.

▶ **Corollary 26.** *Let $A \in \mathcal{F}$. If U, V, W are any three distinct sets from $\mathcal{F}$ such that $A \subset U$, $A \subset V$, and $A \subset W$. Then at least one of the sets from $\{U, V, W\}$ must be a proper subset of one of the remaining two.*

We can use Corollary 26 to establish the following lemma.

▶ **Lemma 27.** *The indegree of any node in D^τ will be at most 2.*

Figure 3 shows farthest mincuts from a sample of vertices to s in our example graph. Notice that the farthest mincut b_s^F *crosses* the farthest mincut d_s^F. Also, the farthest mincuts from j and g to s are identical, so j and g are mapped to a single node in D^τ.

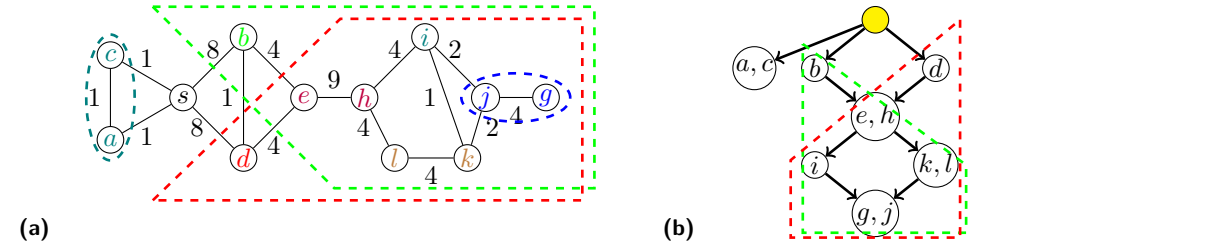

Figure 3 **(a)** A dotted boundary defines a farthest mincut to s from a vertex of the same color. **(b)** The DAG D^τ.

5 Single source mincut sensitivity for insertion of an edge

We now present an $\mathcal{O}(|S|)$ space data structure that can report all those vertices from S whose mincut value to s increases upon insertion of any given edge $(x,y) \in S \times S$. The data structure will consist of the tree structure $\mathcal{T}(s)$ from Theorem 18 and DAG structure $\mathcal{D}(s)$ from Theorem 19.

Let $A_x = \{v \in S | x \in s_v^N\}$ and $A_y = \{v \in S | y \in s_v^N\}$. It follows from Lemma 15 that if (s,v)-mincut increases, then v must belong to A_x or A_y. Furthermore, for any $v \in A_x$, (s,v)-mincut increases if $y \in v_s^N$. Using Theorem 18, it takes just $\mathcal{O}(1)$ time to do this check for any given $v \in A_x$ (likewise A_y). So, in order to report all vertices from S whose mincut from s increases upon insertion of edge (x,y) in $\mathcal{O}(|S|)$ time, all we need is an $\mathcal{O}(|S|)$ time algorithm to compute A_x and A_y. We now provide $\mathcal{O}(|S|)$ time algorithm to compute A_x; we can compute A_y in $\mathcal{O}(|S|)$ time in a similar manner.

It follows from Lemma 14(ii) that computing A_x is equivalent to computing the set $\bar{A_x} = \{v \in S | x \in v_s^F\}$. Recall that $J_s[x]$ is the node containing x in $\mathcal{D}(s)$. It follows from Lemma 23 that $x \in v_s^F$ if and only if $J_s[x]$ is reachable from $J_s[v]$ in $\mathcal{D}(s)$. Therefore, we can compute $\bar{A_x}$ by first reversing the edges of $\mathcal{D}(s)$ and then traversing all the nodes reachable

from $J_s[x]$. For each node λ reachable from $J_s[x]$ in the reversed $\mathcal{D}(s)$, x is present in v_s^F for each vertex $v \in L(\lambda)$. Since $\mathcal{D}(s)$ has $\mathcal{O}(|S|)$ edges, it takes $\mathcal{O}(|S|)$ time to reverse it and traverse it to compute $\bar{A}_x$. This establishes the proof of Theorem 2 for the single source mincut sensitivity problem.

6 All-pairs mincut sensitivity data structure for insertion of an edge

Our data structure consists of the nearest-mincut tree $\mathcal{T}(z)$ from Theorem 18 for each $z \in S$. Each of these trees occupies $\mathcal{O}(|S|)$ space, so the space occupied by the data structure is $\mathcal{O}(|S|^2)$. For the rest of this section, x, y, z are any arbitrary vertices from S. Upon insertion of edge (x, y), let k be the number of pairs of vertices from $S \times S$ whose mincut value increases. We present an $\mathcal{O}(k)$ time algorithm to output all these pairs using four insights into the nearest-mincut trees. Our first insight is stated in Lemma 28. It implies that for all vertices belonging to a node μ in $\mathcal{T}(z)$, it suffices to determine for any single vertex, say $u \in \mu$, whether the (z, u)-mincut value increases upon insertion of any given edge.

▶ **Lemma 28.** *Let $u, v \in S$ be any two vertices belonging to the same node in $\mathcal{T}(z)$. Upon insertion of any given edge, (u, z)-mincut value increases iff (v, z)-mincut value increases.*

Let μ and ν be the nodes in $\mathcal{T}(z)$ containing x and y respectively. Our second insight, stated in the following lemma, specifies the location of vertices in $\mathcal{T}(z)$ whose mincut value to s increases upon insertion of edge (x, y).

▶ **Lemma 29.** *Let $\omega = LCA(\mu, \nu)$ in $\mathcal{T}(z)$. Upon insertion of edge (x, y), the mincut value from z to only those vertices may increase that belong to the nodes of (1) the path from μ to ω but excluding ω, and (2) the path from ν to ω but excluding ω.*

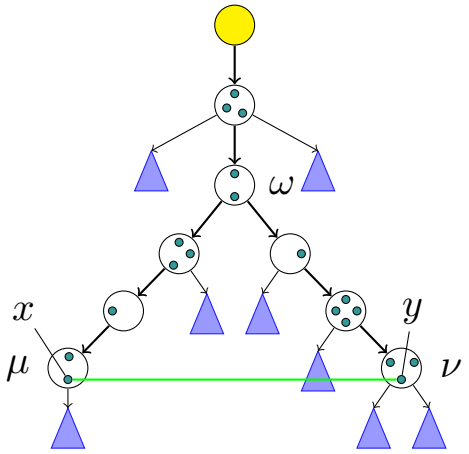

Figure 4 The tree $\mathcal{T}(z)$ from the perspective of μ and ν. If v is a vertex whose node in $\mathcal{T}(z)$ does not belong to either of ω-ν and ω-μ paths, then v must be present in one of the subtrees hanging from these paths (shown in blue). Now consider any node, say γ, lying on the path from ω to the root of $\mathcal{T}(z)$. Both x and y belong to the subtree rooted at γ.

Proof. Let us view $\mathcal{T}(z)$ from the perspective of the paths from μ and ν to the root of $\mathcal{T}(z)$. The reader is advised to refer to Figure 4 for a better understanding. If v is a vertex whose node in $\mathcal{T}(z)$ does not belong to these paths, then v must be present in one of the subtrees (shown in blue in Figure 4) hanging from these paths. Notice that neither x nor y belongs to

the subtree containing v. So it follows from Lemma 15 that the mincut from z to v is not affected by the insertion of edge (x, y). Now consider any node, say γ, lying on the path from ω to the root of $\mathcal{T}(z)$. Both x and y belong to the subtree rooted at γ. So using Lemma 15 again, the mincut from z to any vertex of γ remains unaffected by the insertion of edge (x, y). ◀

Our third and most crucial insight is that the vertices whose mincut value to z increases upon insertion of edge (x, y) belong to a *contiguous* sequence of nodes on the paths from the node containing y and the node containing x to their LCA in $\mathcal{T}(z)$. The following lemma states this insight for the node containing y.

▶ **Lemma 30.** *Let ω be the LCA of the nodes containing x and y in $\mathcal{T}(z)$. Let u and v be any two vertices lying on the path from the node containing y to ω in $\mathcal{T}(z)$ such that the node containing u is an ancestor of the node containing v. If (z, u)-mincut value increases upon insertion of edge (x, y), then (z, v)-mincut value also increases upon insertion of (x, y).*

Proof. It follows from the construction of $\mathcal{T}(z)$ that $y \in v_z^N$ and $v_z^N \subseteq u_z^N$. It is given that the insertion of edge (x, y) increases (z, u)-mincut value and u is an ancestor of y in $\mathcal{T}(z)$. So Lemma 15 implies:

$$x \in z_u^N \tag{4}$$

It follows from Lemma 14(i) that $z_u^N \cap u_z^N = \emptyset$. So $v \notin z_u^N$ since $v \in u_z^N$. Applying Lemma 14(ii), we get $v \in u_z^F$. So it follows from Lemma 21 that $v_z^F \subseteq u_z^F$. Applying Lemma 14(ii) again, it follows that $z_u^N \subseteq z_v^N$. Using this fact and Equation 4, we can infer that $x \in z_v^N$. Since we have already established that $y \in v_z^N$, so using Lemma 15 we can conclude that (z, v)-mincut value will also increase upon insertion of edge (x, y). ◀

It is a simple corollary of Lemma 30 that if (y, z)-mincut value does not increase upon insertion of edge (x, y), then for any vertex v present in any ancestor of the node containing y in $\mathcal{T}(z)$, (v, z)-mincut value will also not increase. So, to compute all-pairs of vertices whose mincut increases, we need to explore the nearest-mincut tree of only those vertices z whose mincut value to y (and likewise to x) increases.

We now describe how to process $\mathcal{T}(z)$ for a vertex z given that (y, z)-mincut value increases upon insertion of (x, y). For each such z, first we enumerate all vertices present in the node, say ν, to which y belongs. We then begin an upward traversal of $\mathcal{T}(z)$ starting from the parent of ν. For any node, say λ, that we traverse, we pick any arbitrary vertex from it, say v, and determine whether $x \in z_v^N$ by querying $\mathcal{T}(v)$. It takes $\mathcal{O}(1)$ time to answer this query (see Theorem 18). If $x \in z_v^N$, it follows from Lemma 28 that each vertex present in λ has its mincut value to z increased. So we enumerate all vertices from λ, and continue processing the parent of λ in a similar manner. If $x \notin z_v^N$, we stop the traversal. It follows from Lemma 30 that the vertices enumerated in this way are precisely the vertices whose mincut value to z increases. To efficiently identify each vertex z, such that the (y, z)-mincut value increases upon insertion of edge (x, y), we exploit the fourth insight into the nearest-mincut trees which is stated in the following lemma. This lemma can be seen as a corollary of Lemma 15.

▶ **Lemma 31.** *(y, z)-mincut value increases upon insertion of edge (x, y) iff $x \in z_y^N$.*

It follows from Lemma 31 that the vertices present in the node containing x and its ancestors in $\mathcal{T}(y)$ are precisely the vertices whose mincut value to y increases. We can identify all these vertices in optimal time by traversing $\mathcal{T}(y)$ upward from the node containing x.

We have described above the processing of each z such that the (y, z)-mincut value increases due to the insertion of edge (x, y). A similar processing must be carried out for all vertices z, such that the (x, z)-mincut value increases due to the insertion of edge (x, y).

It follows from the description given above that we can compute all those pairs of vertices from $S \times S$ whose mincut value increases upon the insertion of any given edge in $\mathcal{O}(k)$ time, where k is the number of these pairs. If our goal is to just report the value of k, we can accomplish it in $\mathcal{O}(\min(k, |S| \log |S|))$ time by suitably augmenting the nearest-mincut trees. We can thus conclude with Theorem 32 which extends Theorem 4.

▶ **Theorem 32.** *For an undirected graph $G = (V, E)$, and a subset S of vertices, there exists an $\mathcal{O}(|S|^2)$ size data structure that can report all pairs of vertices whose mincut increases upon insertion of a query edge. The guaranteed query time is $\mathcal{O}(k)$, where k is the number of pairs whose mincut increases. We can also report k in $\mathcal{O}(\min(k, |S| \log |S|))$ time.*

Abstract

Lexicographic Depth First Search (LexDFS) is a special variant of a Depth First Search (DFS), which was introduced by Corneil and Krueger in 2008. While this search has been used in various applications, in contrast to other graph searches, no general linear time implementation is known to date. In 2014, Köhler and Mouatadid achieved linear running time to compute some special LexDFS orderings for cocomparability graphs. In this paper, we present a linear time implementation of LexDFS for chordal graphs. Our algorithm even implements the extended version LexDFS$^+$ and is, therefore, able to find any LexDFS ordering for this graph class. To the best of our knowledge this is the first unrestricted linear time implementation of LexDFS on a non-trivial graph class. In the algorithm we use a search tree computed by Lexicographic Breadth First Search (LexBFS).

1 Introduction

Graph searches are among the most basic algorithms in computer science. Nevertheless, they are very powerful tools and can be used to compute many important graph properties. For example, *Breadth First Search* (BFS) is the standard procedure for testing bipartiteness or computing shortest paths with respect to the number of edges. Similarly, *Depth First Search* (DFS) can be used in algorithms to find strongly connected components in directed graphs [24] or to test for planarity [14].

In 1976, Rose, Tarjan, and Lueker [21] proposed a modified variant of BFS to compute perfect vertex elimination orderings of chordal graphs. This search, since named *Lexicographic Breadth First Search* (LexBFS), uses the ordering of the already visited vertices and visits the vertex with lexicographically largest neighborhood next. Rose, Tarjan, and Lueker also gave a linear time implementation of LexBFS using partition refinement, which, for example, also provides a linear time greedy algorithm for finding minimum colorings of chordal graphs.

It was only in 2008 that a corresponding lexicographical variant for DFS was introduced by Corneil and Krueger [8]. Similar to LexBFS, this search computes perfect elimination orderings on chordal graphs. Therefore, it can be used to find minimum colorings as well as all minimal separators and all maximal cliques on this graph class [25]. Besides this, LexDFS was used in the field of data mining to design an efficient hierarchical clustering algorithm [10]. However, no general linear time implementation of LexDFS is known to date. An implementation with running time in $\mathcal{O}(\min\{n^2, n + m \log n\})$ is given in [17]. Spinrad announced an $\mathcal{O}(m \log \log n)$-implementation [23] which has not been published as of yet. In [15], Köhler and Mouatadid present the first linear time algorithm to compute a LexDFS cocomparability ordering, that is, a special class of LexDFS orderings can be computed in linear time on cocomparability graphs using modular decomposition. However, there are LexDFS orderings of cocomparability graphs that cannot be computed by this approach. Even more restricting, it is not possible to choose an arbitrary start vertex for the search. Nevertheless, this result can be used to design linear time algorithms which find minimum path covers [5], maximum matchings [20] as well as maximum independent sets, minimum clique covers and minimum vertex covers [6] on cocomparability graphs.

Search trees are an important concept in the theory of graph searches. Already in 1972, Tarjan [24] gave a complete characterization of DFS-trees as so-called palm trees. However, no algorithm that determines whether a given spanning tree of a graph G is a DFS-tree of G was specified in that work. Using the concept of palm trees, Hopcroft and Tarjan developed a linear time algorithm for testing planarity of a graph [14]. In 1985, Hagerup [12] formulated the problem of checking whether a given spanning tree of G can be obtained by a DFS and presented a linear time algorithm for this problem. In the same year, Hagerup and Novak [13] presented a linear time algorithm for the recognition of BFS-trees. Similar results were obtained by Korach and Ostfeld [16] for DFS-trees and Manber [19] for BFS-trees. Recently, Beisegel et al. [1, 2] studied the search tree recognition problem for LexBFS, LexDFS and other searches.

Our Contribution

In this paper, we give the first linear time implementation of LexDFS on chordal graphs. We show for all graphs that the computation of a LexDFS ordering is linear time equivalent to the construction of a LexDFS search tree, i.e., there are linear time reductions between both problems. The combination of this result with some properties of search trees of LexBFS on chordal graphs yields a linear time implementation of LexDFS$^+$, an extended version of LexDFS, which uses vertex orderings to break ties during the search. This implementation is able to compute any LexDFS ordering of a given chordal graph. To the best of our knowledge this is the first unrestricted linear time implementation of LexDFS on a non-trivial graph class. Furthermore, we show that testing whether a given ordering is in fact a LexDFS ordering is linear time equivalent to the recognition of LexDFS search trees.

2 Preliminaries

Throughout this paper, we consider finite, simple, undirected and connected graphs $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges. An edge between u and v is simply denoted by uv. For a vertex $v \in V$, the *neighborhood* of v is denoted by $N(v)$, i.e., $N(v) = \{u \in V \mid uv \in E\}$. For a subset $S \subseteq V$, we define the neighborhood as $N(S) = \{v \in V \setminus S \mid \exists u \in S : uv \in E\}$.

Given a subset S of vertices in G, the *subgraph of G induced by S* is denoted by $G[S]$, where $V(G[S]) = S$ and $E(G[S]) = \{uv \in E(G) \mid u \in S,\ v \in S\}$. The subgraph induced by $V(G) \setminus S$ is denoted by $G - S$ and, in the case where S contains just one element, we simply write $G - v$ instead of $G - \{v\}$.

A graph G that contains no induced cycle of length larger than 3 is called *chordal*. Other equivalent definitions of chordal graphs can be found in [4]. A *tree* is an acyclic connected graph and a *spanning tree* of a graph G is an acyclic connected subgraph of G which contains all vertices of G. A tree together with a distinguished *root vertex* s is said to be *rooted*. In such a rooted tree a vertex v is an *ancestor* of vertex w if v is an element of the unique path from w to the root s. In particular, if v is adjacent to w, it is called the *parent* of w. A vertex w is called a *descendant (child)* of v if v is an ancestor (the parent) of w.

A (connected) graph search is, in the most general sense, a mechanism for systematically visiting all vertices of a graph. Starting at a vertex $s \in V$, we expand the set of vertices S beginning with $S = \{s\}$ by moving a vertex from $N(S)$ to S, which may also add new neighbors to $N(S)$ in consequence. The result of this procedure is a *search ordering* $\sigma = (v_1 = s, v_2, \ldots, v_n)$ of the vertices of the graph listing the vertices in order of occurrence. For any linear vertex ordering σ we write $u \prec_\sigma v$ if u appears before v in the ordering and say that u is *to the left* of v and that v is *to the right* of u. Furthermore, σ^- denotes the reverse ordering of σ, that is, $\sigma^- = (v_n, v_{n-1}, \ldots, v_1)$.

There are many graph search protocols which differ in the way in which a vertex from $N(S)$ is chosen next. The two most common graph searches are *Breadth First Search* and *Depth First Search* which can be simply described as using a queue and a stack to store the vertices in $N(S)$, respectively. Given a graph search protocol $\mathcal{P}$ and a vertex ordering σ, we say that σ is a *$\mathcal{P}$-ordering* if there exists a valid $\mathcal{P}$ search on G that returns σ.

In [8], Corneil and Krueger present a characterizing *four point property* of DFS orderings.

▶ **Lemma 1** ([8]). *A vertex ordering σ is a DFS ordering of a graph $G = (V, E)$ if and only if for every triple $a \prec_\sigma b \prec_\sigma c$ where $ac \in E$ and $ab \notin E$ there is a vertex d with $a \prec_\sigma d \prec_\sigma b$ such that $db \in E$.*

In the same paper, the authors introduced *Lexicographic Depth First Search* (LexDFS, see Algorithm 1), a variant of DFS which uses labels and their lexicographic order to break ties during the search.

Algorithm 1 Lexicographic Depth First Search.

Input: Connected graph $G = (V, E)$ and a distinguished vertex $s \in V$
Output: Ordering σ of V starting at s

```
1 begin
2     label(s) ← (0);
3     foreach vertex v ∈ V − s do assign to v the empty label;
4     for i ← 1 to n do
5         pick an unnumbered vertex v with lexicographically largest label;
6         σ(i) ← v;
7         foreach unnumbered vertex w ∈ N(v) do prepend i to label(w);
```

The idea of using such a lexicographic order of labels originates from an algorithm for the calculation of perfect elimination orderings of chordal graphs, given by Rose, Lueker, and Tarjan [21], since named *Lexicographic Breadth First Search* (LexBFS, see Algorithm 2).

Both LexDFS and LexBFS are special variants of the standard searches and, thus, every LexDFS ordering is also a DFS ordering and every LexBFS ordering is also a BFS ordering. In both algorithms, the vertices are labeled by their already visited neighbors (see line 7

Algorithm 2 Lexicographic Breadth First Search.

Input: Connected graph $G = (V, E)$ and a distinguished vertex $s \in V$
Output: Ordering σ of V starting at s

```
1 begin
2     label(s) ← (n);
3     foreach vertex v ∈ V − s do assign to v the empty label;
4     for i ← 1 to n do
5         pick an unnumbered vertex v with lexicographically largest label;
6         σ(i) ← v;
7         foreach unnumbered vertex w ∈ N(v) do append (n − i) to label(w);
```

in Algorithm 1 and 2). While in LexDFS vertices visited later in the search have a larger significance for the lexicographic order of the label, in LexBFS it is the opposite, i.e., vertices visited earlier have a larger impact.

Corneil and Krueger [8] also present a four point property of LexDFS orderings.

▶ **Lemma 2** ([8]). *A vertex ordering σ is a LexDFS ordering of a graph $G = (V, E)$ if and only if for every triple $a \prec_\sigma b \prec_\sigma c$ where $ac \in E$ and $ab \notin E$ there is a vertex d with $a \prec_\sigma d \prec_\sigma b$ such that $db \in E$ and $dc \notin E$.*

A variant of LexDFS and LexBFS is the technique of "multisweeping". This describes the multiple application of some graph search, where each run of the search uses the ordering given by the previous application as a so-called *"tie-break" rule*, that is, a priority list which decides which vertex can be visited next in those cases where the given search paradigm allows several different options. It was first used by Simon [22] in an algorithm for the recognition of interval graphs which is flawed as was shown by Ma [18]. Nevertheless, "multisweeping" has proven to be very fruitful in recent years [5, 9]. In the case of LexDFS, this technique implies a new search scheme known as LexDFS$^+$: Given a ordering ρ of the vertices, LexDFS$^+(\rho)$ is computed by executing a regular LexDFS with the modification that in line 5 of Algorithm 1 the rightmost element with regard to ρ is chosen among all vertices with lexicographically largest label. The searches DFS$^+$, BFS$^+$ and LexBFS$^+$ are defined analogously. Note that all these searches yield unique orderings, as there are no more ties to break in the algorithms.

It is not difficult to see that, given the reverse of a search ordering as tie break, such a procedure yields that same ordering again. For a more general result see Corneil et al. [7].

▶ **Observation 3.** *Let $G = (V, E)$ be a graph and let σ be a vertex ordering of G. The ordering σ is a LexDFS ordering of G if and only if LexDFS$^+(\sigma^-)$ is equal to σ. This also holds for LexBFS and LexBFS$^+(\sigma^-)$.*

Using a technique called *partition refinement*, LexBFS can be implemented in linear time [11, 21]. Given a set S, we call $\mathcal{Q} = (Q_1, Q_2, \ldots, Q_k)$ a partition of S if $S = \bigcup_{i=1}^{k} Q_i$ with non-empty, pairwise disjoint sets Q_i ($Q_i \cap Q_j = \emptyset$ for $i \neq j$). Note that a partition is an *ordered* list of subsets. We say that a subset $S' \subseteq S$ refines $\mathcal{Q}$ if Q_i is replaced by a subpartition (A_i, B_i) where $A_i = Q_i \cap S'$ and $B_i = Q_i \setminus A_i$ whenever both sets are non-empty. In particular, for LexBFS we start with $\mathcal{Q} = (V)$ and starting vertex s. Now, we refine $\mathcal{Q}$ with $\{s\}$ which separates s in a single set. Afterwards, we refine with $N(s)$. In the first iteration, this yields the partition $(\{s\}, N(s), V \setminus (N(s) \cup \{s\}))$. The vertex whose neighborhood is used to refine the partition classes is called a *pivot*. Choose the next pivot v from $N(s)$ and

refine with $\{v\}$ and then $N(v)$. For $Q_i = \{v\}$, repeat refining using an element from the set Q_{i+1} as the next pivot, maintaining the order of the partition classes created so far. As shown in [11], this final partition can be computed in linear time and it is actually a LexBFS ordering. The pivot is just the vertex visited by the search and it *pulls* its neighbors to the front of each set. Unfortunately, no linear time implementation of partition refinement for LexDFS is known to date.

Usually, a graph search is associated with a search tree which is a spanning tree of the graph. Given a BFS ordering $\sigma = (v_1, \ldots, v_n)$, a vertex v_i is typically connected to the leftmost neighbor in $(v_1, \ldots, v_{i-1})$, i.e., it is connected to the vertex that was current at the point at which v_i was added to $N(S)$. On the contrary, given a DFS ordering $\sigma = (v_1, \ldots, v_n)$, a vertex v_i is connected to the rightmost neighbor in $(v_1, \ldots, v_{i-1})$, i.e., it is connected to the neighbor which occurred last before v_i itself was visited. These two different approaches of constructing a search tree give rise to the following definition.

▶ **Definition 4** ([2]). *Given a search ordering $\sigma = (v_1, \ldots, v_n)$ of a given search on a connected graph $G = (V, E)$, the* first-in tree *(or $\mathcal{F}$-tree) of σ is the tree consisting of the vertex set V and an edge from each vertex different from v_1 to its leftmost neighbor in σ. The* last-in tree *(or $\mathcal{L}$-tree) of σ is the tree consisting of the vertex set V and an edge from each vertex v_i different from v_1 to its rightmost neighbor v_j in σ with $j < i$. In both cases, v_1 is the* root *of the search tree.*

The notation of $\mathcal{F}$-trees and $\mathcal{L}$-trees was introduced in [2], where the recognition problem of these search trees was studied. In contrast to the original definition, we always assume that a search tree has a designated root. In particular, two search trees on a graph G are equal if they use the same edge set and if they have the same root. Given a search protocol $\mathcal{P}$ and a spanning tree T of G rooted in s, we say that T is an *$\mathcal{L}$-tree* (*$\mathcal{F}$-tree*) of $\mathcal{P}$ on G if there is a $\mathcal{P}$-ordering of G starting at s with $\mathcal{L}$-tree ($\mathcal{F}$-tree) T.

Although, it would be most natural to consider the $\mathcal{F}$-tree for LexBFS, the $\mathcal{L}$-tree of LexBFS is a key ingredient in our procedure on chordal graphs.

3 Search Orderings and Trees of LexDFS

Given a search ordering, it is easy to construct the corresponding search tree in linear time by simply using Definition 4. However, if we are only given a search tree, then it is not immediately clear how to find a search ordering that results in this tree. In this section, we present a linear time algorithm that computes a LexDFS ordering for a given $\mathcal{L}$-tree of LexDFS. Using this result we prove that both recognition and creation of search orderings and $\mathcal{L}$-trees are linear time equivalent in the case of LexDFS.

The main idea of this algorithm is to use a special tie-break rule in form of a ordering of the vertices τ such that a simple run of DFS$^+(\tau)$ on the tree is a LexDFS ordering of G with tree T. This tie-break rule τ is computed by using a form of partition refinement which moves from the leaves of the tree towards its root. The pseudo code of this procedure is given in Algorithm 3.

Before we begin with the analysis of this algorithm we present some general results on $\mathcal{L}$-trees of DFS. The first is a lemma by Tarjan [24] which characterizes $\mathcal{L}$-trees of DFS.

▶ **Lemma 5** ([24]). *Let $G = (V, E)$ be a graph and let T be a spanning tree of G. Then T is an $\mathcal{L}$-tree of G generated by DFS if and only if for each edge $uv \in E$ it holds that either u is an ancestor of v in T or v is an ancestor of u in T.*

Algorithm 3 ORDERING(G, T, s, ρ).

Input: Connected graph $G = (V, E)$, an $\mathcal{L}$-tree T of DFS on G rooted in $s \in V$, ordering ρ of V ending with vertex s
Output: ordering σ of V starting at s

```
1  begin
2      β ← reverse of a BFS ordering of T starting at s;
3      Q ← (V);
4      for i ← 1 to n do
5          v ← β(i);
6          refine Q with {w ∈ N(v) | w ≺_β v};
7      order every set in Q with respect to ρ⁻ and move {s} to the leftmost position;
8      τ ← reverse of the final order of vertices in Q;
9      σ ← DFS⁺(τ) on T;
10     return σ;
```

In order to make sure that Algorithm 3 returns a DFS ordering of G with $\mathcal{L}$-tree T, we prove the following statement.

▶ **Lemma 6.** *Let T be an $\mathcal{L}$-tree of some DFS on G rooted in s and let σ be a DFS ordering of T starting at s. Then σ is a DFS ordering of G with $\mathcal{L}$-tree T.*

Proof. We show that σ is a DFS ordering of G by proving that it fulfills the characterization given in Lemma 1. Let a, b and c be three vertices in G with $a \prec_\sigma b \prec_\sigma c$, $ac \in E(G)$ and $ab \notin E(G)$. We have to show that there is a vertex d with $a \prec_\sigma d \prec_\sigma b$ such that $db \in E(G)$. Assume that $ac \in E(T)$. As σ is a DFS ordering of the tree T, there is a vertex d with $a \prec_\sigma d \prec_\sigma b$ and $db \in E(T) \subseteq E(G)$ due to Lemma 1. Therefore, we can assume that ac is not contained in $E(T)$. By Lemma 5 this implies that a is an ancestor of c in T. Let $P = (a = w_1, \ldots, w_k = c)$ be the unique path between a and c in T. As σ is a DFS ordering of T, it holds that $a \prec_\sigma w_2 \prec_\sigma \ldots \prec_\sigma c$. If there is an $1 < i < k$ such that $w_i = b$, then w_{i-1} is a vertex between a and b in σ with $w_{i-1}b \in E(G)$. Otherwise, there exists an $1 \leq i < k$ with $w_i \prec_\sigma b \prec_\sigma w_{i+1}$ and $w_iw_{i+1} \in E(T)$. As in the first case there exists a vertex d with $a \preceq_\sigma w_i \prec_\sigma d \prec_\sigma b$ and $db \in E(T) \subseteq E(G)$. By Lemma 1, this proves that σ is a DFS ordering.

Let T' be the $\mathcal{L}$-tree of σ with regard to G and assume for contradiction that there is an edge uv in T' that is not part of T. Due to Lemma 5, we can assume without loss of generality that u is an ancestor of v in T. Since uv is not part of T, vertex u is not the parent of v in T. Let w be the parent of v in T. Note that this means that w is a descendant of u in T. Since σ is a DFS ordering on T, vertex w must be to the left of v and to the right of u in σ. Since $vw \in E(G)$, edge uv cannot be part of T', as T' is the $\mathcal{L}$-tree of σ; a contradiction. ◀

With these results on DFS we can proceed to the analysis of Algorithm 3. First we will prove correctness.

▶ **Theorem 7.** *Let T be an $\mathcal{L}$-tree of some DFS on G rooted in s and let ρ be an arbitrary ordering of V ending in s. Let σ be the ordering produced by Algorithm 3 with input (G, T, s, ρ). Then T is an $\mathcal{L}$-tree of LexDFS rooted in s if and only if σ is a LexDFS ordering of G.*

Proof. Assume σ is a LexDFS ordering of G. Due to Lemma 6, the $\mathcal{L}$-tree of σ is T and, therefore, it is an $\mathcal{L}$-tree of LexDFS.

For the other direction, assume that T is an $\mathcal{L}$-tree of LexDFS. Let σ^* be a LexDFS ordering of G such that the $\mathcal{L}$-tree of σ^* is T and the common prefix of σ and σ^* is maximal among all LexDFS orderings with $\mathcal{L}$-tree T. If σ and σ^* are equal, then we are done. Otherwise let $i \in \{1, \dots, n\}$ be the first index for which $v = \sigma(i) \neq \sigma^*(i) = v^*$. By Lemma 6, both σ and σ^* are DFS orderings with $\mathcal{L}$-tree T and v and v^* have the same parent p in T. If v and v^* have the same neighborhood in the set $S = \{\sigma(j) \mid j < i\}$, then v could have been taken by LexDFS instead of v^* and this choice would not have had an impact on the $\mathcal{L}$-tree of the ordering, due to Lemma 5. Hence, there must be a vertex $w \in S$ with $wv^* \in E(G)$ and $wv \notin E(G)$ and for all vertices x with $w \prec_\sigma x \prec_\sigma v$ it holds that both v and v^* are adjacent to x or both are not adjacent to x. Note that w is an ancestor of both v and v^* in T and therefore, it is to the right of both vertices in β.

However, this means that before the iteration of the `for`-loop in lines 4–6, where we consider vertex w, both v and v^* are in the same set of $\mathcal{Q}$. After this iteration, vertex v^* is in a set of $\mathcal{Q}$ to the left of the set containing v. Therefore, v^* is to the right of v in τ, as τ uses the reverse ordering of $\mathcal{Q}$. Thus, the search $\mathrm{DFS}^+(\tau)$ visits v^* before v, as both are children of p; a contradiction to v being to the left of v^* in σ. ◀

As seen in the proof, it is not necessary to use the reverse of a BFS ordering for β. Any ordering will suffice, where for every vertex w all ancestors in T are to the right of w in the ordering. Having shown that Algorithm 3 returns a correct LexDFS ordering for any $\mathcal{L}$-tree of LexDFS, we will now evaluate its running time.

▶ **Lemma 8.** *Algorithm 3 has running time in $\mathcal{O}(n + m)$.*

Proof. Algorithm 3 begins with an execution of BFS which can be done in linear time. In the `for`-loop we iterate through the neighborhood of every vertex exactly once. Thus, the overall costs are in $\mathcal{O}(n + m)$. To sort the sets of $\mathcal{Q}$ with respect to ρ^- we iterate through ρ^- and move the considered vertex to the end of its set. The final $\mathrm{DFS}^+(\tau)$ can be executed in linear time by first sorting the neighborhoods of all vertices with respect to τ. ◀

The last results imply that the construction of an $\mathcal{L}$-tree of LexDFS is linear time equivalent to the computation of a LexDFS ordering.

▶ **Theorem 9.** *For a given graph family $\mathcal{G}$ and $\mathcal{O}(M) \supseteq \mathcal{O}(n + m)$ the following two statements are equivalent:*

1. *There is an algorithm with running time in $\mathcal{O}(M)$ that computes a LexDFS ordering for any graph in $\mathcal{G}$ and any starting vertex s.*
2. *There is an algorithm with running time in $\mathcal{O}(M)$ that creates an $\mathcal{L}$-tree of LexDFS for any graph in $\mathcal{G}$ and any root s.*

Proof. It is easy to see that the $\mathcal{L}$-tree of an arbitrary vertex ordering can be constructed in $\mathcal{O}(n + m)$. Therefore, an $\mathcal{O}(M)$-algorithm for the computation of a LexDFS ordering starting at s directly implies an $\mathcal{O}(M)$-algorithm for the creation of an $\mathcal{L}$-tree of LexDFS rooted in s.

If, on the other hand, we can compute an $\mathcal{L}$-tree of LexDFS rooted in s in time $\mathcal{O}(M)$, then we can use Algorithm 3 to create a corresponding LexDFS ordering in linear time, due to Theorem 7 and Lemma 8. ◀

This linear time equivalence does not only hold for the computation but also for the recognition of $\mathcal{L}$-trees and orderings of LexDFS. To prove this we need the following two technical lemmas.

▶ **Lemma 10.** *Let T be an $\mathcal{L}$-tree of a DFS on G rooted in s, let ρ be an arbitrary ordering of V ending with s and let σ be the ordering produced by Algorithm 3 with input (G, T, s, ρ). Furthermore, let v and w be two vertices in G with $v \prec_\sigma w$ which have the same parent in T and the same neighborhood in the set $Y = \{x \mid x \prec_\sigma v\}$. Then v is to the right of w in ρ.*

Proof. As v is to the left of w in σ by assumption, vertex v was taken before w in $DFS^+(\tau)$. Since v and w have the same parent in T, it holds that v is to the right of w in τ. If the vertex v is pulled by a vertex x in the `for`-loop of Algorithm 3, then x is adjacent to v and has a smaller distance to the root s in T. By Lemma 5, vertex x is an ancestor of v in T and x is to the left of v in σ. As v and w have the same neighborhood in Y, the vertex x is also adjacent to w and pulls it, too. This implies that v and w are in the same set of $\mathcal{Q}$ after the `for`-loop. Therefore, v has to be to the right of w in ρ, as it is to the right of w in τ. ◀

▶ **Lemma 11.** *Let T be an $\mathcal{L}$-tree of LexDFS on G rooted in s and let σ be a vertex ordering of a graph G starting at s whose corresponding $\mathcal{L}$-tree is T. Algorithm 3 returns σ for input (G, T, s, σ^-) if and only if σ is a LexDFS ordering of G.*

Proof. If Algorithm 3 returns σ for input (G, T, s, σ^-), then, by Theorem 7, σ is a LexDFS ordering of G.

Therefore, we assume that σ is a LexDFS ordering and Algorithm 3 returns the LexDFS ordering σ^* for input (G, T, s, σ^-) with $\sigma \neq \sigma^*$. Let $i \in \{1, \ldots, n\}$ be the first index where $v = \sigma(i) \neq \sigma^*(i) = v^*$ and let σ_i be the prefix of the first $i-1$ elements of σ (and σ^*). It follows that v and v^* have the same neighborhood in σ_i and, thus, the same parent in T. Since v is to the right of v^* in σ^- it follows from Lemma 10 that v must be to the left of v^* in σ^*; a contradiction. ◀

Now we can prove the linear time equivalence of tree recognition and ordering verification for LexDFS.

▶ **Theorem 12.** *For a given graph family $\mathcal{G}$ and $\mathcal{O}(M) \supseteq \mathcal{O}(n+m)$ the following two statements are equivalent:*

1. *There is an algorithm with running time in $\mathcal{O}(M)$ that checks for any graph G in $\mathcal{G}$ and any vertex s whether a given ordering beginning in s is a LexDFS ordering of G.*
2. *There is an algorithm with running time in $\mathcal{O}(M)$ for any graph G in $\mathcal{G}$ and any vertex s that checks whether a given spanning tree rooted in s is an $\mathcal{L}$-tree of LexDFS on G.*

Proof. Assume we have an algorithm $\mathcal{A}$ for the recognition of LexDFS orderings with running time in $\mathcal{O}(M)$. For a given spanning tree T of G rooted in s we first decide in linear time whether T is an $\mathcal{L}$-tree of DFS (see [12, 16]). If not, then it is not an $\mathcal{L}$-tree of LexDFS. Otherwise, we execute Algorithm 3 with the input (G, T, s, ρ), where ρ is an arbitrary ordering of the vertices of G, and get the vertex ordering σ as result in linear time. Due to Theorem 7, T is an $\mathcal{L}$-tree of LexDFS if and only if σ is an LexDFS ordering of G. We use $\mathcal{A}$ to decide this in time $\mathcal{O}(M)$.

Now assume we have an algorithm $\mathcal{A}$ for the recognition of $\mathcal{L}$-trees of LexDFS with running time in $\mathcal{O}(M)$ and get a vertex ordering σ starting at s. We first create the $\mathcal{L}$-tree T of σ in linear time and check whether T is an $\mathcal{L}$-tree of LexDFS in time $\mathcal{O}(M)$. If not, σ is not an LexDFS ordering of G. Otherwise, we call Algorithm 3 with input (G, T, s, σ^-). Due to Lemma 11, the resulting vertex ordering is equal to σ if and only if σ is a LexDFS ordering of G. ◀

Note that this result does not hold for search orderings and their corresponding trees in general (if $\mathcal{P} \neq \mathcal{NP}$). Beisegel et al. [1, 2] show for example that the recognition problem of $\mathcal{F}$-trees of both LexBFS and LexDFS is $\mathcal{NP}$-complete, whereas it is easy to recognize the corresponding orderings.

4 LexDFS on Chordal Graphs

We will now use the results of the last section to derive a linear time implementation of LexDFS for chordal graphs. We first show that LexBFS and LexDFS have the same set of $\mathcal{L}$-trees on chordal graphs. This fact is also implied by a more general result in [1]. Since this work has not been published yet and we only need a special case here, we give an alternative proof for the sake of completeness.

In [3], Berry et al. show that a whole range of different graph search schemes share the same set of search orderings on chordal graphs. Among these searches are variants of both LexDFS and LexBFS, called *CompLexDFS* and *CompLexBFS*, respectively. For these algorithms we replace line 5 in both Algorithm 1 and 2 by "choose a component C of the graph induced by the unnumbered vertices and take a vertex in C with lexicographically largest label".

▶ **Lemma 13** ([3]). *For any chordal graph G a linear vertex ordering is a CompLexDFS ordering if and only if it is a CompLexBFS ordering.*

We now show that both LexDFS and LexBFS compute the same $\mathcal{L}$-trees as their respective Comp-variants for any graph.

▶ **Lemma 14.** *A spanning tree T of a graph G rooted in s is an $\mathcal{L}$-tree of LexDFS (LexBFS) on G if and only if T is an $\mathcal{L}$-tree of CompLexDFS (CompLexBFS) on G.*

Proof. Since every ordering of LexDFS is also an ordering of CompLexDFS, every $\mathcal{L}$-tree of LexDFS on G is also an $\mathcal{L}$-tree of CompLexDFS.

For the reverse we first introduce some technical definitions. Let $\tau = (w_1, \dots, w_n)$ be some ordering of the vertices of G. We define $C_\tau(w_i)$ to be the connected component of $G - \{w_1, \dots, w_{i-1}\}$ containing w_i. Now, consider a CompLexDFS ordering σ of G with $\mathcal{L}$-tree T. Let σ^* be the LexDFS$^+(\sigma^-)$ ordering of G. We claim that T is the $\mathcal{L}$-tree of σ^*. To this end, we show that $C_\sigma(v) = C_{\sigma^*}(v)$ for every vertex $v \in V$. Furthermore, we show that for every vertex $w \in C_\sigma(v) = C_{\sigma^*}(v)$ it holds that the label of w at point where v is chosen in σ is the same as the label of w when v is chosen in σ^*.

Assume for contradiction that v is the leftmost vertex in σ which does not fulfill both of these properties. Let w be the rightmost vertex in σ with $w \prec_\sigma v$ such that w has a neighbor in $C_\sigma(v)$. Due to choice of v, it holds that $C_\sigma(w) = C_{\sigma^*}(w)$ and both components are labeled the same at the moment w is chosen in the respective search. As the labels cannot be changed from outside of the component, there must be a vertex in $C_\sigma(v)$ that is between w and v in σ^*. Let x be the leftmost vertex in σ^* with this property. At the point where x is chosen by σ^* the labels of both x and v are the same as in σ at the point when v was chosen. Therefore, the labels of x and v must be the same at the point where x was chosen in σ^*. However, v is to the right of x in σ^- and it has to be chosen before x in σ^*; a contradiction.

Now, let T^* be the $\mathcal{L}$-tree of σ^* and assume that the parent of vertex y in T is p and the parent of y in T^* is $p^* \neq p$. Due to the observation above, both p and p^* must be to the left of y in both σ and σ^*. Therefore, it holds that $p \prec_{\sigma^*} p^*$ and $p^* \prec_\sigma p$. However, this is a contradiction to the observation above since p would be in $C_\sigma(p^*)$ but not in $C_{\sigma^*}(p^*)$.

Since no special property of LexDFS and CompLexDFS is used in the proof above, the claim also holds for LexBFS and CompLexBFS. ◀

Combining Lemmas 13 and 14 yields the following corollary.

▶ **Corollary 15.** *Let $G = (V, E)$ be a chordal graph and T be a spanning tree of G rooted in $s \in V$. The tree T is an $\mathcal{L}$-tree of LexDFS of G if and only if T is an $\mathcal{L}$-tree of LexBFS of G.*

Using this corollary, we can compute an $\mathcal{L}$-tree of LexDFS rooted in vertex s for any chordal graph G by using LexBFS. This tree can then be used as the input for Algorithm 3 to return a LexDFS ordering for G. Furthermore, it is possible to implement LexDFS$^+$ in linear time for chordal graphs using the same approach (see Algorithm 4).

Algorithm 4 LexDFS$^+$ on chordal graphs.

Input: Chordal graph $G = (V, E)$, vertex $s \in V$, ordering ρ of V ending with s
Output: The LexDFS$^+(\rho)$ ordering σ of G

```
1 begin
2     π ← LexBFS+(ρ) ordering of G;
3     T ← L-tree of π;
4     σ ← Ordering(G, T, s, ρ);
5     return σ;
```

▶ **Theorem 16.** *Let $G = (V, E)$ be a chordal graph, s be a vertex in V and ρ be an arbitrary ordering of V ending in s. Then for input (G, s, ρ) Algorithm 4 produces the LexDFS$^+(\rho)$ ordering of G in time $\mathcal{O}(n + m)$.*

Proof. Due to Corollary 15, the tree T is an $\mathcal{L}$-tree of LexDFS. By Theorem 7, Ordering(G, T, s, ρ) produces a LexDFS ordering of G starting at s.

It remains to show that σ is also the LexDFS$^+(\rho)$ ordering. Let σ^* be the LexDFS$^+(\rho)$ ordering of G and assume that $\sigma \neq \sigma^*$. Let $i \in \{1, \ldots, n\}$ be the first index where $v = \sigma(i) \neq \sigma^*(i) = v^*$ and let σ_i be the prefix of the first $i - 1$ elements of σ (and σ^*). It follows that v and v^* have the same neighborhood in σ_i and v^* must be to the right of v in ρ.

Assume that v is to the left of v^* in the LexBFS$^+(\rho)$ ordering π. Since $v \prec_\rho v^*$, vertex v had a larger label than v^* at the point where it was chosen in π. This implies that there is a vertex w with $w \prec_\pi v \prec_\pi v^*$ such that $wv \in E(G)$ but $wv^* \notin E(G)$. Due to Lemma 5, vertex w has to be an ancestor of v in T and, therefore, w is in σ_i. This is a contradiction as v and v^* have the same neighbors in σ_i.

Therefore, we can assume that v^* is to the left of v in π. If v and v^* have the same parent in T, then vertex v has to be to the right of v^* in ρ, due to Lemma 10; a contradiction. Thus, assume that p is the parent of v but not the parent of v^* in T. However since p is in σ_i, vertex v^* is adjacent to p in G and, therefore, is a descendant of p in T, due to Lemma 5. Let x be the unique child of p in T, which is an ancestor of v^*. Note that $x \neq v$ since otherwise $v \prec_\pi v^*$. Furthermore, it holds that both $x \prec_\pi v^*$ and $v \prec_\sigma x$ and every neighbor of x which is to the left of x in π is an element of σ_i, due to the choice of i. If x has the same neighborhood in σ_i as v and v^*, then $v^* \prec_\rho x$ and, due to Lemma 10, it holds that $x \prec_\sigma v$; a contradiction. Thus, x has a neighbor in σ_i which is neither a neighbor of v nor of v^*. Let y be the rightmost vertex in σ_i with this property. Since σ is a LexDFS ordering there must be a vertex z with $y \prec_\sigma z \prec_\sigma v$ such that $vz \in E(G)$ and $xz \notin E(G)$, due to Lemma 2. Since z is also adjacent to v^* we can use Lemma 2 again leading to a vertex u with $z \prec_\sigma u \prec_\sigma x$ that is adjacent to x but not to v^*. Due to the choice of y, vertex u must be to the right of v in σ. This is contradiction to p being the parent of x in the $\mathcal{L}$-tree T of σ.

Since all three steps can be executed in linear time (see Lemma 8), the algorithm has linear running time in total. ◀

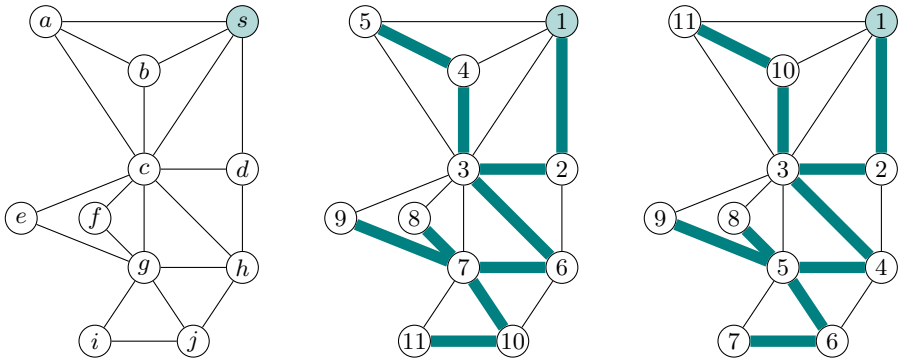

Figure 1 The graph $G = (V, E)$ on the left side is chordal. In the middle, the $\mathcal{L}$-tree of a LexBFS starting at s is shown. Vertex labels correspond to the index in the search ordering. On the right side, the same tree is shown, but now the labeling fits to a LexDFS starting at s.

It follows from Observation 3 that Algorithm 4 is able to compute any LexDFS ordering of a chordal graph G.

▶ **Corollary 17.** *Algorithm 4 can compute any LexDFS ordering of a chordal graph G.*

This result does not hold for efficient implementations of graph searches in general. One example is *Maximal Neighborhood Search (MNS)* introduced by Corneil and Krueger in 2008 [8] as a generalization of both LexBFS and LexDFS. This search can be implemented with linear running time by implementing LexBFS. However, not every MNS ordering is a LexBFS ordering, so this approach can only compute a subset of the MNS orderings of a graph. Observation 3 also leads to an easy recognition algorithm of LexDFS orderings.

▶ **Corollary 18.** *LexDFS orderings can be recognized in linear time on chordal graphs.*

Note that this result can also be achieved using Theorem 12 and the fact that $\mathcal{L}$-trees of LexDFS on chordal graphs can be recognized in linear time (see [1]).

To illustrate the final procedure of Algorithm 4, we give the following example.

▶ **Example 19.** Given the chordal graph in Figure 1, start vertex s and $\rho = (a, b, \ldots, j, s)$, we begin by computing a LexBFS$^+(\rho)$ ordering using partition refinement. The first pivot is s with neighborhood $N(s) = \{d, c, b, a\}$, which yields the partition $(s)(d, c, b, a)(j, i, h, g, f, e)$. With d as the next pivot, we obtain $(s)(d)(c)(b, a)(h)(j, i, g, f, e)$. After a few more steps, we have $\pi = (s, d, c, b, a, h, g, f, e, j, i)$ which is the LexBFS$^+(\rho)$ ordering. Now, we consider the $\mathcal{L}$-tree T induced by this ordering, which is shown in Figure 1.

By Corollary 15, we see that T is also an $\mathcal{L}$-tree of LexDFS rooted in s. We first compute the ordering β and, as seen before, we can use any ordering where the children of a vertex are always to the left of their parent. Thus, we can use $\beta = \pi^-$, although it is not a BFS ordering of T, since T is an $\mathcal{L}$-tree and not a standard $\mathcal{F}$-tree.

Now, we iterate through β and use partition refinement, beginning with $\mathcal{Q} = \beta$, to compute a final tie-breaking rule τ (see Algorithm 3). Vertex i has an empty neighborhood to the left so nothing has to be done. Vertex j as neighbor i to the left in β, so the first refinement of $\mathcal{Q}$ occurs. After processing vertices e and f with empty left neighborhoods, we refine for g with $\{e, f, i, j\}$. This yields the intermediate partition $(i)(j, e, f)(g, h, a, b, c, d, s)$. Finally, we obtain $\mathcal{Q} = (i)(j)(e, f)(a)(g)(h)(b)(c)(d)(s)$.

$\mathcal{Q}$ is post-processed to compute τ. Here, we sort (e, f) with respect to ρ^-, which is the only part of $\mathcal{Q}$ with more than one vertex. Furthermore, we move s to the leftmost position and reverse the whole ordering. This yields $\tau = (d, c, b, h, g, a, e, f, j, i, s)$. Now, we perform

a final DFS$^+(\tau)$ on the tree T. We start in s and follow the unique path to c. Vertex c has two children in T and τ forces us to take h, since h is to the right of b in τ. Similarly, j is chosen after g due to τ. The final LexDFS$^+(\rho)$ ordering is $(s, d, c, h, g, j, i, f, e, b, a)$. It is shown on the right side of Figure 1.

5 Conclusion

In this paper, we have presented the first linear time implementation of LexDFS on chordal graphs. This is already the second important subclass of perfect graphs, the other being cocomparability graphs, that admits a linear time implementation of LexDFS. In contrast to the algorithm for cocomparability graphs [15], however, our approach can compute any LexDFS ordering with arbitrary start vertices. Thus, it also yields the first unrestricted linear time implementation of LexDFS on interval graphs, which are the intersection of cocomparability graphs and chordal graphs. It remains an open question whether this result can be algorithmically exploited to efficiently solve problems on other subclasses of chordal graphs besides interval graphs in linear time.

In the light of these results, the question of whether LexDFS can be executed in linear time in general is even more interesting. There are several open questions. Can the search tree approach be extended? Are there other graph classes where rooted $\mathcal{L}$-trees of LexBFS and LexDFS coincide or is this a characteristic property of chordal graphs? It is also possible that there are other graph classes and other modifications of graph searches that produce a tree equal to an $\mathcal{L}$-tree of LexDFS in linear time on graphs of this particular class.

However, if the answer was "no", that is, we cannot find a general linear time algorithm for LexDFS, it is an interesting question whether recognizing LexDFS orderings can be done faster than actually generating one. In particular, is it possible to check in linear time whether a given vertex ordering or a search tree belongs to LexDFS?

Abstract

Structural graph parameters, such as treewidth, pathwidth, and clique-width, are a central topic of study in parameterized complexity. A main aim of research in this area is to understand the "price of generality" of these widths: as we transition from more restrictive to more general notions, which are the problems that see their complexity status deteriorate from fixed-parameter tractable to intractable? This type of question is by now very well-studied, but, somewhat strikingly, the algorithmic frontier between the two (arguably) most central width notions, treewidth and pathwidth, is still not understood: currently, no natural graph problem is known to be W-hard for one but FPT for the other. Indeed, a surprising development of the last few years has been the observation that for many of the most paradigmatic problems, their complexities for the two parameters actually coincide exactly, despite the fact that treewidth is a much more general parameter. It would thus appear that the extra generality of treewidth over pathwidth often comes "for free".

Our main contribution in this paper is to uncover the first natural example where this generality comes with a high price. We consider Grundy Coloring, a variation of coloring where one seeks to calculate the worst possible coloring that could be assigned to a graph by a greedy First-Fit algorithm. We show that this well-studied problem is FPT parameterized by pathwidth; however, it becomes significantly harder (W[1]-hard) when parameterized by treewidth. Furthermore, we show that Grundy Coloring makes a second complexity jump for more general widths, as it becomes para-NP-hard for clique-width. Hence, Grundy Coloring nicely captures the complexity trade-offs between the three most well-studied parameters. Completing the picture, we show that Grundy Coloring is FPT parameterized by modular-width.

1 Introduction

The study of the algorithmic properties of *structural graph parameters* has been one of the most vibrant research areas of parameterized complexity in the last few years. In this area we consider graph complexity measures ("graph width parameters"), such as treewidth, and attempt to characterize the class of problems which become tractable for each notion of width. The most important graph widths are often comparable to each other in terms of their generality. Hence, one of the main goals of this area is to understand which problems separate two comparable parameters, that is, which problems transition from being FPT for a more restrictive parameter to W-hard for a more general one[1]. This endeavor is sometimes referred to as determining the "price of generality" of the more general parameter.

The two most widely studied graph widths are probably treewidth and pathwidth, which have an obvious containment relationship to each other. Despite this, to the best of our knowledge, no natural problem is currently known to delineate their complexity border in the sense we just described. Our main contribution is exactly to uncover a natural, well-known problem which fills this gap. Specifically, we show that Grundy Coloring, the problem of ordering the vertices of a graph to maximize the number of colors used by the First-Fit coloring algorithm, is FPT parameterized by pathwidth, but W[1]-hard parameterized by treewidth. We then show that Grundy Coloring makes a further complexity jump if one considers clique-width, as in this case the problem is para-NP-complete. Hence, Grundy Coloring turns out to be an interesting specimen, nicely demonstrating the algorithmic trade-offs involved among the three most central graph widths.

Graph widths and the price of generality. Much of modern parameterized complexity theory is centered around studying graph widths, especially treewidth and its variants. In this paper we focus on the parameters summarized in Figure 1, and especially the parameters that form a linear hierarchy, from vertex cover, to tree-depth, pathwidth, treewidth, and clique-width. Each of these parameters is a strict generalization of the previous ones in this list. On the algorithmic level we would expect this relation to manifest itself by the appearance of more and more problems which become *intractable* as we move towards the more general parameters. Indeed, a search through the literature reveals that for each step in this list of parameters, several *natural* problems have been discovered which distinguish the two consecutive parameters (we give more details below). The one glaring exception to this rule seems to be the relation between treewidth and pathwidth.

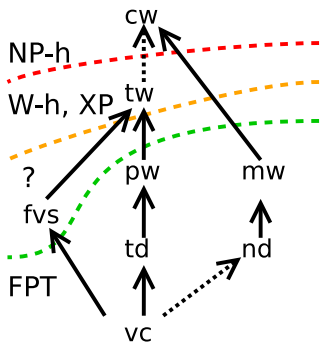
Treewidth is a parameter of central importance to parameterized algorithmics, in part because wide classes of problems (notably all MSO_2-expressible problems [18]) are FPT for this parameter. Treewidth is usually defined in terms of tree decompositions of graphs, which naturally leads to the equally well-known notion of pathwidth, defined by forcing the decomposition to be a path. On a graph-theoretic level, the difference between the two

[1] We assume the reader is familiar with the basics of parameterized complexity theory, such as the classes FPT and W[1], as given in standard textbooks [21].

notions is well-understood and treewidth is known to describe a much richer class of graphs. In particular, while all graphs of pathwidth k have treewidth at most k, there exist graphs of constant treewidth (in fact, even trees) of unbounded pathwidth. Naturally, one would expect this added richness of treewidth to come with some negative algorithmic consequences in the form of problems which are FPT for pathwidth but W-hard for treewidth. Furthermore, since treewidth and pathwidth are probably the most studied parameters in our list, one might expect the problems that distinguish the two to be the first ones to be discovered.

Nevertheless, so far this (surprisingly) does not seem to have been the case: on the one hand, FPT algorithms for pathwidth are DPs which also extend to treewidth; on the other hand, we give (in Section 1.1) a semi-exhaustive list of dozens of natural problems which are W[1]-hard for treewidth and turn out without exception to also be hard for pathwidth. In fact, even when this is sometimes not explicitly stated in the literature, the same reduction that establishes W-hardness by treewidth also does so for pathwidth. Intuitively, an explanation for this phenomenon is that the basic structure of such reductions typically resembles a $k \times n$ (or smaller) grid, which has both treewidth and pathwidth bounded by k.

Our main motivation in this paper is to take a closer look at the algorithmic barrier between pathwidth and treewidth and try to locate a natural (that is, not artificially contrived) problem whose complexity transitions from FPT to W-hard at this barrier. Our main result is the proof that Grundy Coloring is such a problem. This puts in the picture the last missing piece of the puzzle, as we now have natural problems that distinguish the parameterized complexity of any two consecutive parameters in our main hierarchy.



Parameter	Result	Ref
Clique-width	para-NP-hard	Theorem 25
Treewidth	W[1]-hard	Theorem 16
Pathwidth	FPT	Theorem 20
Modular-width	FPT	Theorem 26

In the figure, clique-width, treewidth, pathwidth, tree-depth, vertex cover, feedback vertex set, neighborhood diversity, and modular-width are indicated as cw, tw, pw, td, vc, fvs, nd, and mw respectively. Arrows indicate more general parameters. Dotted arrows indicate that the parameter may increase exponentially, (e.g. graphs of vc k have nd at most $2^k + k$).

Figure 1 Summary of considered graph parameters and results.

Grundy Coloring. In the Grundy Coloring problem we are given a graph $G = (V, E)$ and are asked to order V in a way that maximizes the number of colors used by the greedy (First-Fit) coloring algorithm. The notion of Grundy coloring was first introduced by Grundy in the 1930s, and later formalized in [17]. Since then, the complexity of Grundy Coloring has been very well-studied (see [1, 3, 14, 30, 44, 46, 52, 55, 73, 74, 76, 77, 78] and the references therein). For the natural parameter, namely the number of colors to be used, Grundy coloring was recently proved to be W[1]-hard in [1]. An XP algorithm for Grundy Coloring parameterized by treewidth was given in [74], using the fact that the Grundy number of any graph is at most $\log n$ times its treewidth. In [13] Bonnet et al. explicitly asked whether this can be improved to an FPT algorithm. They also observed that the problem is FPT parameterized by vertex cover. It appears that the complexity of Grundy Coloring parameterized by pathwidth was never explicitly posed as a question and it was

not suspected that it may differ from that for treewidth. We note that, since the problem (as given in Definition 1) is easily seen to be MSO_1 expressible for a fixed Grundy number, it is FPT for all considered parameters if the Grundy number is also a parameter [19], so we intuitively want to concentrate on cases where the Grundy number is large.

Our results. Our results illuminate the complexity of Grundy Coloring parameterized by pathwidth and treewidth, as well as clique-width and modular-width. More specifically:

1. We show that Grundy Coloring is W[1]-hard parameterized by treewidth via a reduction from k-Multi-Colored Clique. The main building block of our reduction is the structure of binomial trees, which have treewidth one but unbounded pathwidth, which explains the complexity jump between the two parameters. As mentioned, an XP algorithm is known in this case [74], so this result is in a sense tight.
2. We show that Grundy Coloring is FPT parameterized by pathwidth. Our main tool here is a combinatorial lemma, which draws heavily from known combinatorial bounds on the performance of First-Fit coloring on intervals graphs [53, 65]. We use this lemma to show that on any graph the Grundy number is at most a linear function of the pathwidth.
3. We show that Grundy Coloring is para-NP-complete parameterized by clique-width, that is, NP-complete for graphs of constant clique-width (specifically, clique-width 6).
4. We show that Grundy Coloring is FPT parameterized by neighborhood diversity (which is defined in [56]) and leverage this result to obtain an FPT algorithm parameterized by modular-width (which is defined in [38]).

Our main interest is concentrated in the first two results, which achieve our goal of finding a natural problem distinguishing pathwidth from treewidth. The result for clique-width nicely fills out the picture by giving an intuitive view of the evolution of the complexity of the problem and showing that in a case where no non-trivial bound can be shown on the optimal value, the problem becomes hopelessly hard from the parameterized point of view.

Other related work. Let us now give a brief survey of "price of generality" results involving our considered parameters, that is, results showing that a problem is efficient for one parameter but hard for a more general one. In this area, the results of Fomin et al. [35], introducing the term "price of generality", have been particularly impactful. This work and its follow-ups [36, 37], were the first to show that four natural graph problems (Coloring, Edge Dominating Set, Max Cut, Hamiltonicity) which are FPT for treewidth, become W[1]-hard for clique-width. In this sense, these problems, as well as problems discovered later such as counting perfect matchings [20], SAT [68, 23], $\exists\forall$-SAT [59], Orientable Deletion [45], and d-Regular Induced Subgraph [16], form part of the "price" we have to pay for considering a more general parameter. This line of research has thus helped to illuminate the complexity border between the two most important sparse and dense parameters (treewidth and clique-width), by giving a list of *natural* problems distinguishing the two. (An artificial MSO_2-expressible such problem was already known much earlier [19, 58]).

Let us now focus in the area below treewidth in Figure 1 by considering problems which are in XP but W[1]-hard parameterized by treewidth. By now, there is a small number of problems in this category which are known to be W[1]-hard even for vertex cover: List Coloring [31] was the first such problem, followed by CSP (for the vertex cover of the dual graph) [70], and more recently by (k, r)-Center, d-Scattered Set, and Min Power Steiner Tree [49, 48, 50] on weighted graphs. Intuitively, it is not surprising that problems W[1]-hard by vertex cover are few and far between, since this is a very restricted parameter.

Indeed, for most problems in the literature which are W[1]-hard by treewidth, vertex cover is the only parameter (among the ones considered here) for which the problem becomes FPT.

A second interesting category are problems which are FPT for tree-depth ([66]) but W[1]-hard for pathwidth. Mixed Chinese Postman Problem was the first discovered problem of this type [43], followed by Min Bounded-Length Cut [25, 10], ILP [40], Geodetic Set [51] and unweighted (k, r)-Center and d-Scattered Set [49, 48].

To the best of our knowledge, for all remaining problems which are known to be W[1]-hard by treewidth, the reductions that exist in the literature also establish W[1]-hardness for pathwidth. Below we give a (semi-exhaustive) list of problems which are known to be W[1]-hard by treewidth. After reviewing the relevant works we have verified that all of the following problems are in fact shown to be W[1]-hard parameterized by pathwidth (and in many case by feedback vertex set and tree-depth), even if this is not explicitly claimed.

1.1 Known problems which are W-hard for treewidth and for pathwidth

- Precoloring Extension and Equitable Coloring are shown to be W[1]-hard for both tree-depth and feedback vertex set in [31] (though the result is claimed only for treewidth). This is important, because Equitable Coloring often serves as a starting point for reductions to other problems. A second hardness proof for this problem was recently given in [22]. These two problems are FPT by vertex cover [33].
- Capacitated Dominating Set and Capacitated Vertex Cover are W[1]-hard for both tree-depth and feedback vertex set [24] (though again the result is claimed for treewidth).
- Min Maximum Out-degree on weighted graphs is W[1]-hard by tree-depth and feedback vertex set [72].
- General Factors is W[1]-hard by tree-depth and feedback vertex set [71].
- Target Set Selection is W[1]-hard by tree-depth and feedback vertex set [9] but FPT for vertex cover [67].
- Bounded Degree Deletion is W[1]-hard by tree-depth and feedback vertex set, but FPT for vertex cover [11, 39].
- Fair Vertex Cover is W[1]-hard by tree-depth and feedback vertex set [54].
- Fixing Corrupted Colorings is W[1]-hard by tree-depth and feedback vertex set [12] (reduction from Precoloring Extension).
- Max Node Disjoint Paths is W[1]-hard by tree-depth and feedback vertex set [29, 34].
- Defective Coloring is W[1]-hard by tree-depth and feedback vertex set [8].
- Power Vertex Cover is W[1]-hard by tree-depth but open for feedback vertex set [2].
- Majority CSP is W[1]-hard parameterized by the tree-depth of the incidence graph [23].
- List Hamiltonian Path is W[1]-hard for pathwidth [62].
- L(1,1)-Coloring is W[1]-hard for pathwidth, FPT for vertex cover [33].
- Counting Linear Extensions of a poset is W[1]-hard (under Turing reductions) for pathwidth [26].
- Equitable Connected Partition is W[1]-hard by pathwidth and feedback vertex set, FPT by vertex cover [28].
- Safe Set is W[1]-hard parameterized by pathwidth, FPT by vertex cover [7].
- Matching with Lower Quotas is W[1]-hard parameterized by pathwidth [4].
- Subgraph Isomorphism is W[1]-hard parameterized by the pathwidth of G, even when G, H are connected planar graphs of maximum degree 3 and H is a tree [61].
- Metric Dimension is W[1]-hard by pathwidth [15].
- Simple Comprehensive Activity Selection is W[1]-hard by pathwidth [27].

- Defensive Stackelberg Game for IGL is W[1]-hard by pathwidth (reduction from Equitable Coloring) [5].
- Directed (p, q)-Edge Dominating Set is W[1]-hard parameterized by pathwidth [6].
- Maximum Path Coloring is W[1]-hard for pathwidth [57].
- Unweighted k-Sparsest Cut is W[1]-hard parameterized by the three combined parameters tree-depth, feedback vertex set, and k [47].
- Graph Modularity is W[1]-hard parameterized by pathwidth plus feedback vertex set [63].

Let us also mention in passing that the algorithmic differences of pathwidth and treewidth may also be studied in the context of problems which are hard for constant treewidth. Such problems also generally remain hard for constant pathwidth (examples are Steiner Forest [42], Bandwidth [64], Minimum mcut [41]). One could also potentially try to distinguish between pathwidth and treewidth by considering the parameter dependence of a problem that is FPT for both. Indeed, for a long time the best-known algorithm for Dominating Set had complexity 3^k for pathwidth, but 4^k for treewidth. Nevertheless, the advent of fast subset convolution techniques [75], together with tight SETH-based lower bounds [60] has, for most problems, shown that the complexities on the two parameters coincide exactly.

Finally, let us mention a case where pathwidth and treewidth have been shown to be quite different in a sense similar to our framework. In [69] Razgon showed that a CNF can be compiled into an OBDD (Ordered Binary Decision Diagram) of size FPT in the pathwidth of its incidence graphs, but there exist formulas that always need OBDDs of size XP in the treewidth. Although this result does separate the two parameters, it is somewhat adjacent to what we are looking for, as it does not speak about the complexity of a decision problem, but rather shows that an OBDD-producing algorithm parameterized by treewidth would need XP time simply because it would have to produce a huge output in some cases.

2 Definitions and Preliminaries

For non-negative integers i, j, we use $[i, j]$ to denote the set $\{k \mid i \leq k \leq j\}$. Note that if $j < i$, then the set $[i, j]$ is empty. We will also write simply $[i]$ to denote the set $[1, i]$.

We give two equivalent definitions of our main problem.

▶ **Definition 1.** *A k-Grundy Coloring of a graph $G = (V, E)$ is a partition of V into k non-empty sets $V_1, \ldots, V_k$ such that: (i) for each $i \in [k]$ the set V_i induces an independent set; (ii) for each $i \in [k-1]$ the set V_i dominates the set $\bigcup_{i<j\leq k} V_j$.*

▶ **Definition 2.** *A k-Grundy Coloring of a graph $G = (V, E)$ is a proper k-coloring $c : V \to [k]$ that results by applying the First-Fit algorithm on an ordering of V; the First-Fit algorithm colors one by one the vertices in the given ordering, assigning to a vertex the minimum color that is not already assigned to one of its preceding neighbors.*

The Grundy number of a graph G, denoted by $\Gamma(G)$, is the maximum k such that G admits a k-Grundy Coloring. In a given Grundy Coloring, if $u \in V_i$ (equiv. if $c(u) = i$) we will say that u was given color i. The Grundy Coloring problem is the problem of determining the maximum k for which a graph G admits a k-Grundy Coloring. It is not hard to see that a proper coloring is a Grundy coloring if and only if every vertex assigned color i has at least one neighbor assigned color j, for each $j < i$.

3 W[1]-Hardness for Treewidth

In this section we prove that Grundy Coloring parameterized by treewidth is W[1]-hard (Theorem 16). Our proof relies on a reduction from k-Multi-Colored Clique and initially establishes W[1]-hardness for a more general problem where we are given a target color for a set of vertices (Lemma 8); we then reduce this to Grundy Coloring. Interestingly, this intermediate problem turns out to be W[1]-hard even for pathwidth (Lemma 12), since our reduction uses the standard strategy of constructing a grid-like structure of dimensions $k \times n$. The reason this reduction fails to prove that Grundy Coloring is W[1]-hard by pathwidth is that we use some gadgets to implement the targets and a support operation (which "pre-colors" some vertices) and for these gadgets we use trees of unbounded pathwidth. The results of Section 4 show that this is essential: our reduction *needs* some part that causes it to have high pathwidth, otherwise the Grundy number of the constructed graph would be bounded by the parameter, resulting in an instance that can be solved in FPT time.

Let us now present the different parts of our construction. We will make use of the structure of binomial trees T_i.

▶ **Definition 3.** *The binomial tree T_i with root r_i is a rooted tree defined recursively in the following way: T_1 consists simply of its root r_1; in order to construct T_i for $i > 1$, we construct one copy of T_j for all $j < i$ and a special vertex r_i, then we connect r_j with r_i. An alternative equivalent definition of the binomial tree T_i, $i \geq 2$ is that we construct two trees T_{i-1} , T'_{i-1}, we connect their roots r_{i-1}, r'_{i-1} and select one of them as the new root r_i.*

▶ **Proposition 4.** *Let $i \geq 2$, T_i be a binomial tree and $1 \leq t < i$. There exist 2^{i-t-1} binomial trees T_t which are vertex-disjoint and non-adjacent subtrees in T_i, where no T_t contains the root r_i of T_i.*

▶ **Proposition 5.** *$\Gamma(T_i) \leq i$. Furthermore, for all $j \leq i$ there exists a Grundy coloring which assigns color j to the root of T_i.*

The proofs of Propositions 4 and 5 can be found in the full version of this paper.

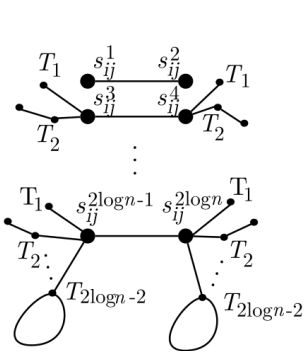
A Grundy coloring of T_i that assigns color i to r_i is called *optimal*. If r_i is assigned color $j < i$ then we call the Grundy coloring *sub-optimal*.

We now define a generalization of the Grundy coloring problem with target colors and show that it is W[1]-hard parameterized by treewidth. We later describe how to reduce this problem to Grundy Coloring such that the treewidth does not increase by a lot.

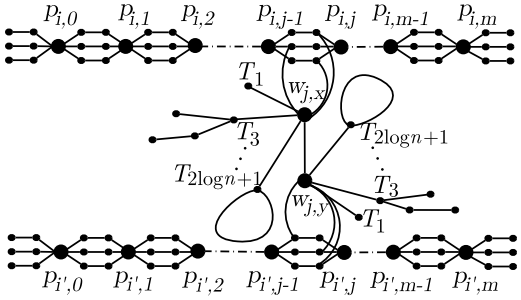
▶ **Definition 6** (Grundy Coloring with Targets)**.** *We are given a graph $G(V, E)$, an integer $t \in \mathbb{N}$ called the target and a subset $S \subset V$. (For simplicity we will say that vertices of S have target t.) If G admits a Grundy Coloring which assigns color t to some vertex $s \in S$ we say that, for this coloring, vertex s* achieves its target*. If there exists a Grundy Coloring of G which assigns to all vertices of S color t, then we say that G admits a* Target-achieving Grundy Coloring*. Grundy Coloring with Targets is the decision problem associated to the question "given G, S, t as defined above, does G admit a Target-achieving Grundy Coloring ?".*

We will also make use of the following operation:

▶ **Definition 7** (Tree-support)**.** *Given a graph $G = (V, E)$, a vertex $u \in V$ and a set N of positive integers, we define the* tree-support *operation as follows: (a) for all $i \in N$ we add a copy of T_i in the graph; (b) we connect u to the root r_i of each of the T_i. We say that we* add supports *N on u. The trees T_i will be called the* supporting trees *or* supports *of u. Slightly abusing notation, we also call* supports *the numbers $i \in N$.*



(a) Vertex Selection gadget $S_{i,j}$.



(b) Propagators $p_{i,j}$ and Edge Selection gadget W_j. The edge selection checkers and the supports of the $p_{i,j}$ and $s^l_{i,j}$ are not depicted. In the example $B_x = 010$ and $B_y = 100$.

Figure 2 The gadgets. Figure 2a is an enlargment of Figure 2b between $p_{i,j-1}$ and $p_{i,j}$.

Intuitively, the tree-support operation ensures that vertex u may have at least one neighbor of color i for each $i \in N$ in a Grundy coloring, and thus increase the color u can take. Observe that adding supporting trees to a vertex does not increase the treewidth, but does increase the pathwidth (binomial trees have unbounded pathwidth).

Our reduction is from k-Multi-Colored Clique, proven to be W[1]-hard in [32]: given a k-multipartite graph $G = (V_1, V_2, \ldots, V_k, E)$, decide if for every $i \in [k]$ we can pick $u_i \in V_i$ forming a clique, where k is the parameter. We can also assume that $\forall i \in [k], |V_i| = n$, that n is a power of 2, and that $V_i = \{v_{i,0}, v_{i,1}, \ldots, v_{i,n-1}\}$. Furthermore, let $|E| = m$. We construct an instance of Grundy Coloring with Targets $G' = (V', E')$ and $t = 2\log n + 4$ (where all logarithms are base two) using the following gadgets:

Vertex selection $S_{i,j}$. See Figure 2a. This gadget consists of $2\log n$ vertices $S^1_{i,j} \cup S^2_{i,j} = \bigcup_{l\in[\log n]}\{s^{2l-1}_{i,j}\} \cup \bigcup_{l\in[\log n]}\{s^{2l}_{i,j}\}$, where for each $l \in [\log n]$ we connect vertex $s^{2l-1}_{i,j}$ to $s^{2l}_{i,j}$ thus forming a matching. Furthermore, for each $l \in [2, \log n]$, we add supports $[2l-2]$ to vertices $s^{2l-1}_{i,j}$ and $s^{2l}_{i,j}$. Observe that the vertices $s^{2l-1}_{i,j}$ and $s^{2l}_{i,j}$ together with their supports form a binomial tree T_{2l} with either of these vertices as the root. We construct $k(m+2)$ gadgets $S_{i,j}$, one for each $i \in [k], j \in [0, m+1]$.

The vertex selection gadget $S_{i,1}$ encodes in binary the vertex that is selected in the clique from V_i. In particular, for each pair $s^{2l-1}_{i,1}, s^{2l}_{i,1}$, $l \in [\log n]$ either of these vertices can take the maximum color in an optimal grundy coloring of the binomial tree T_{2l} (that is, a coloring that gives the root of the binomial tree T_{2l} color $2l$). A selection corresponds to bit 0 or 1 for the l^{th} binary position. In order to ensure that for each $j \in [m]$ all (middle) $S_{i,j}$ encode the same vertex, we use propagators.

Propagators $p_{i,j}$. See Figure 2b. For $i \in [k]$ and $j \in [0, m]$, a propagator $p_{i,j}$ is a single vertex connected to all vertices of $S^2_{i,j} \cup S^1_{i,j+1}$. To each $p_{i,j}$, we also add supports $\{2\log n + 1, 2\log n + 2, 2\log n + 3\}$. The propagators have target $t = 2\log n + 4$.

Edge selection W_j. See Figure 2b. Let $j = (v_{i,x}, v_{i',y}) \in E$, where $v_{i,x} \in V_i$ and $v_{i',y} \in V_{i'}$. The gadget W_j consists of four vertices $w_{j,x}, w_{j,y}, w'_{j,x}, w'_{j,y}$. We call $w'_{j,x}, w'_{j,y}$ the *edge selection checkers*. We have the edges $(w_{j,x}, w_{j,y}), (w'_{j,x}, w_{j,x}), (w'_{j,y}, w_{j,y})$. Let us now describe the connections of these vertices with the rest of the graph. Let $B_x = b_1 b_2 \ldots b_{\log n}$ be the binary representation of x. We connect $w_{j,x}$ to each vertex $s^{2l-b_l}_{ij}$, $l \in [\log n]$ (we do similarly for $w_{j,y}, S_{i',j}$, and B_y). We add to each of $w_{j,x}, w_{j,y}$ supports $\bigcup_{l\in[\log n+1]}\{2l-1\}$. We add to each of $w'_{j,x}, w'_{j,y}$ supports $[2\log n + 3] \setminus \{2\log n + 1\}$ and set the target $t = 2\log n + 4$ for these two vertices. We construct m such gadgets, one for each edge. We say that W_j *is activated* if at least one of $w_{j,x}, w_{j,y}$ receives color $2\log n + 3$.

Edge validators $q_{i,i'}$. We construct $\binom{k}{2}$ of them, one for each pair $(i, i'), i < i' \in [k]$. The edge validator is a single vertex that is connected to all vertices $w_{j,x}$ for which j is an edge between V_i and $V_{i'}$. We add supports $[2\log n + 1]$ and a target of $t = 2\log n + 4$.

The edge validator plays the role of an "or" gadget: in order for it to achieve its target, at least one of its neighboring edge selection gadgets should be activated.

▶ **Lemma 8.** *G has a clique of size k if and only if G' has a target-achieving Grundy coloring.*

Proof. $\Rightarrow$) Suppose that G has a clique. We color the vertices of G' in the following order: First, we color the vertex selection gadget $S_{i,j}$. We start from the supports which we color optimally. We then color the matchings as follows: let $v_{i,x}$ be the vertex that was selected in the clique from V_i and $b_1 b_2 \dots b_{\log n}$ be the binary representation of x; we color vertices $s_{i,j}^{2l-(1-b_l)}$, $l \in [\log n]$ with color $2l-1$ and vertices $s_{i,j}^{2l-b_l}$, $l \in [\log n]$ will receive color $2l$. For the propagators, we color their supports optimally. Propagators have $2\log n + 3$ neighbors each, all with different colors, so they receive color $2\log n + 4$, thus achieving the targets.

Then, we color the edge validators $q_{i,i'}$ and the edge selection gadgets W_j that correspond to edges of the clique (that is, $j = (v_{i,x}, v_{i',y}) \in E$ and $v_{i,x} \in V_i$, $v_{i',y} \in V_{i'}$ are selected in the clique). We first color the supports of $q_{i,i'}, w_{j,x}, w_{j,y}$ optimally. From the construction, vertex $w_{j,x}$ is connected with vertices $s_{i,j}^{2l-b_l}$ which have already been colored $2l$, $l \in [\log n]$ and with supports $\bigcup_{l\in[\log n+1]}\{2l-1\}$, thus $w_{j,x}$ will receive color $2\log n + 2$. Similarly $w_{j,y}$ already has neighbors which are colored $[2\log n + 1]$, but also $w_{j,x}$, thus it will receive color $2\log n + 3$. These W_j will be activated. Since both $w_{j,x}, w_{j,y}$ connect to $q_{i,i'}$, the latter will be assigned color $2\log n + 4$, thus achieving its target. As for $w'_{j,x}$ and $w'_{j,y}$, these vertices have one neighbor colored c, where $c = 2\log n + 2$ or $c = 2\log n + 3$. We color their support T_c sub-optimally so that the root receives color $2\log n + 1$; we color their remaining supports optimally. This way, vertices $w'_{j,x}, w'_{j,y}$ can be assigned color $t = 2\log n + 4$, achieving the target.

Finally, for the remaining W_j, we claim that we can assign to both $w_{j,x}, w_{j,y}$ a color that is at least as high as $2\log n + 1$. Indeed, we assign to each supporting tree T_r of $w_{j,x}$ a coloring that gives its root the maximum color that is $\leq r$ and does not appear in any neighbor of $w_{j,x}$ in the vertex selection gadget. We claim that in this case $w_{j,x}$ will have neighbors with all colors in $[2\log n]$, because in every interval $[2l-1, 2l]$ for $l \in [\log n]$, $w_{j,x}$ has a neighbor with a color in that interval and a support tree T_{2l+1}. If $w_{j,x}$ has color $2\log n + 1$ then we color the supports of $w'_{j,x}$ optimally and achieve its target, while if $w_{j,x}$ has color higher than $2\log n + 1$, we achieve the target of $w'_{j,x}$ as in the previous paragraph.

$\Leftarrow$) Suppose that G' admits a coloring that achieves the target for all propagators, edge selection checkers, and edge validators. We will prove the following three claims:

▷ Claim 9. The coloring of the vertex selection gadgets is consistent throughout. This corresponds to a selection of k vertices of G.

▷ Claim 10. $\binom{k}{2}$ edge selection gadgets have been activated. That correspond to $\binom{k}{2}$ edges of G being selected.

▷ Claim 11. If an edge selection gadget $W_j = \{w_{j,x}, w_{j,y}\}$ with $j = (v_{i,x}, v_{i',y})$ has been activated then the coloring of the vertex selection gadgets $S_{i,j}$ and $S_{i',j}$ corresponds to the selection of vertices $v_{i,x}$ and $v_{i',y}$. In other words, selected vertices and edges form indeed a clique of size k in G.

Proof of Claim 9. Suppose that an edge selection checker $w'_{j,x}$ achieved its target. We claim that this implies that $w_{j,x}$ has color at least $2\log n+1$. Indeed, $w'_{j,x}$ has degree $2\log n+3$, so its neighbors must have all distinct colors in $[2\log n+3]$, but among the supports there are only 2 neighbors which may have colors in $[2\log n+1, 2\log n+3]$. Therefore, the missing color must come from $w_{j,x}$. We now observe that vertices from the vertex selection gadgets have color at most $2\log n$, because if we exclude from their neighbors the vertices $w_{j,x}$ (which we argued have color at least $2\log n+1$) and the propagators (which have target $2\log n+4$), these vertices have degree at most $2\log n-1$.

Suppose that a propagator $p_{i,j}$ achieves its target of $2\log n+4$. Since this vertex has a degree of $2\log n+3$, that means that all of its neighbors should receive all the colors in $[2\log n+3]$. As argued, colors $[2\log n+1, 2\log n+3]$ must come from the supports. Therefore, the colors $[2\log n]$ come from the neighbors of $p_{i,j}$ in the vertex selection gadgets.

We now note that, because of the degrees of vertices in vertex selection gadgets, only vertices $s_{i,j}^{2\log n}, s_{i,j+1}^{2\log n-1}$ can receive colors $2\log n, 2\log n-1$; from the rest, only $s_{i,j}^{2\log n-2}, s_{i,j+1}^{2\log n-3}$ can receive colors $2\log n-2, 2\log n-3$ etc. Thus, for each $l\in[\log n]$, if $s_{i,j}^{2l}$ receives color $2l-1$ then $s_{i,j+1}^{2l-1}$ should receive color $2l$ and vice versa. With similar reasoning, in all vertex selection gadgets we have that $s_{i,j}^{2l-1}, s_{i,j}^{2l}$ received the two colors $\{2l-1, 2l\}$ since they are neighbors. As a result, the colors of $s_{i,j+1}^{2l-1}$, $s_{i,j}^{2l-1}$ (and thus the colors of $s_{i,j+1}^{2l}$, $s_{i,j}^{2l}$) are the same, therefore, the coloring is consistent, for all values of $j\in[m]$. ◁

Proof of Claim 10. If an edge validator achieves its target of $2\log n+4$, then at least one of its neighbors from an edge selection gadget has received color $2\log n+3$. We know that each edge selection gadget only connects to a unique edge validator, so there should be $\binom{k}{2}$ edge selection gadgets which have been activated in order for all edge validators to achieve the target. ◁

Proof of Claim 11. Suppose that an edge validator $q_{i,i'}$ achieves its target. That means that there exists an edge selection gadget $W_j=\{w_{j,x}, w_{j,y}, w'_{j,x}, w'_{j,y}\}$ for which at least one of its vertices $\{w_{j,x}, w_{j,y}\}$, say vertex $w_{j,x}$, has received color $2\log n+3$. Let j be an edge connecting $v_{i,x}\in V_i$ to $v_{i',y}\in V_{i'}$. Since the degree of $w_{j,x}$ is $2\log n+4$ and we have already assumed that two of its neighbors ($q_{i,i'}$ and $w'_{j,x}$) have color $2\log n+4$, in order for it to receive color $2\log n+3$ all its other neighbors should receive all colors in $[2\log n+2]$. The only possible assignment is to give colors $2l$, $l\in[\log n]$ to its neighbors from $S_{i,j}$ and color $2\log n+2$ to $w_{j,y}$. The latter is, in turn, only possible if the neighbors of $w_{j,y}$ from $S_{i',j}$ receive all colors $2l$, $l\in[\log n]$. The above corresponds to selecting vertex $v_{i,x}$ from V_i and $v_{i',y}$ from $V_{i'}$. ◁

◀

▶ **Lemma 12.** *Let G'' be the graph that results from G' if we remove all the tree-supports. Then G'' has pathwidth at most $\binom{k}{2}+2k+3$.*

The proof of Lemma 12 can be found in the full version of the paper.

We will now show how to implement the targets using the tree-filling operation below.

▶ **Definition 13** (Tree-filling). *Let $G=(V,E)$ be a graph and $S=\{s_1,s_2,\ldots,s_j\}\subset V$ a set of vertices with target t. The* tree-filling *operation is the following. First, we add in G a binomial tree T_i, where $i=\lceil\log j\rceil+t+1$. Observe that, by Proposition 4, there exist $2^{i-t-1}>j$ vertex-disjoint and non-adjacent sub-trees T_t in T_i. For each $s\in S$, we find such a copy of T_t in T_i, identify s with its root r_t, and delete all other vertices of the sub-tree T_t.*

The tree-filling operation might in general increase treewidth, but we will do it in a way that it only increases by a constant factor in regards to the pathwidth of G.

▶ **Lemma 14.** *Let $G = (V, E)$ be a graph of pathwidth w and $S = \{s_1, \ldots, s_j\} \subset V$ a subset of vertices having target t. Then there is a way to apply the tree-filling operation such that the resulting graph H has $tw(H) \leq 4w + 5$.*

Proof. Construction of H. Let $(\mathcal{P}, \mathcal{B})$ be a path-decomposition of G whose largest bag has size $w + 1$ and $B_1, B_2, \ldots, B_j \in \mathcal{B}$ distinct bags where $\forall a, s_a \in B_a$ (assigning a distinct bag to each s_a is always possible, as we can duplicate bags if necessary). We call those bags *important*. We define an ordering $o : S \to \mathbb{N}$ of the vertices of S that follows the order of the important bags from left to right, that is $o(s_a) < o(s_b)$ if B_a is on the left of B_b in $\mathcal{P}$. For simplicity, let us assume that $o(s_a) = a$ and that B_a is to the left of B_b if $a < b$.

We describe a recursive way to do the substitution of the trees in the tree-filling operation. Crucially, when $j > 2$ we will have to select an appropriate mapping between the vertices of S and the disjoint subtrees T_t in the added binomial tree T_i, so that we will be able to keep the treewidth of the new graph bounded.

- If $j = 1$ then $i = t + 1$. We add to the graph a copy of T_i, arbitrarily select the root of a copy of T_t contained in T_i, and perform the tree-filling operation as described.
- Suppose that we know how to perform the substitution for sets of size at most $\lceil j/2 \rceil$, we will describe the substitution process for a set of size j. We have $i = \lceil \log j \rceil + t + 1$ and for all j we have $\lceil \log \lceil j/2 \rceil \rceil = \lceil \log j \rceil - 1$. Split the set S into two (almost) equal disjoint sets S^L and S^R of size at most $\lceil j/2 \rceil$, where for all $s_a \in S^L$ and for all $s_b \in S^R$, $a < b$. We perform the tree-filling on each of these sets by constructing two binomial trees T^L_{i-1}, T^R_{i-1} and doing the substitution; then, we connect their roots and set the root of the left tree as the root r_i of T_i, thus creating the substitution of a tree T_i.

Small treewidth. We now prove that the new graph H that results from applying the tree-filling operation on G and S as described above has a tree decomposition $(\mathcal{T}, \mathcal{B}')$ of width $4w + 5$; in fact we prove by induction on j a stronger statement: if $A, Z \in \mathcal{B}$ are the left-most and right-most bags of $\mathcal{P}$, then there exists a tree decomposition $(\mathcal{T}, \mathcal{B}')$ of H of width $4w + 5$ with the added property that there exists $R \in \mathcal{B}'$ such that $A \cup Z \cup \{r_i\} \subset R$, where r_i is the root of the tree T_i.

For the base case, if $j = 1$ we have added to our graph a T_i of which we have selected an arbitrary sub-tree T_t, and identified the root r_t of T_t with the unique vertex of S that has a target. Take the path decomposition $(\mathcal{P}, \mathcal{B})$ of the initial graph and add all vertices of A (its first bag) and the vertex r_i (the root of T_i) to all bags. Take an optimal tree decomposition of T_i of width 1 and add r_i to each bag, obtaining a decomposition of width 2. We add an edge between the bag of $\mathcal{P}$ that contains the unique vertex of S, and a bag of the decomposition of T_i that contains the selected r_t. We now have a tree decomposition of the new graph of width $2w + 2 < 4w + 5$. Observe that the last bag of $\mathcal{P}$ now contains all of A, Z and r_i.

For the inductive step, suppose we applied the tree-filling operation for a set S of size $j > 1$. Furthermore, suppose we know how to construct a tree decomposition with the desired properties (width $4w + 5$, one bag contains the first and last bags of the path decomposition $\mathcal{P}$ and r_i), if we apply the tree-filling operation on a target set of size at most $j - 1$. We show how to obtain a tree decompostition with the desired properties if the target set has size j.

By construction, we have split the set S into two sets S^L, S^R and have applied the tree-filling operation to each set separately. Then, we connected the roots of the two added trees to obtain a larger binomial tree. Observe that for $|S| = j > 1$ we have $|S^L|, |S^R| < j$.

Let us first cut $\mathcal{P}$ in two parts, in such a way that the important bags of S^L are on the left and the important bags of S^R are on the right. We call $A^L = A$ and Z^L the leftmost and rightmost bags of the left part and A^R, $Z^R = Z$ the leftmost and rightmost bags of the right part. We define as G^L (respectively G^R) the graph that contains all the vertices of the left (respectively right) part. Let r_i be the root of T_i and r_{i-1} the root of its subtree T_{i-1}. From the inductive hypothesis, we can construct tree decompositions $(\mathcal{T}^{\mathcal{L}}, \mathcal{B}^{\mathcal{L}})$, $(\mathcal{T}^{\mathcal{R}}, \mathcal{B}^{\mathcal{R}})$ of width $4w + 5$ for the graphs H^L, H^R that occur after applying tree-filling on G^L, S^L and G^R, S^R; furthermore, there exist $R^L \in \mathcal{B}^{\mathcal{L}}, R^R \in \mathcal{B}^{\mathcal{R}}$ such that $R^L \supseteq A \cup Z^L \cup \{r_i\}$ and $R^R \supseteq A^R \cup Z \cup \{r_{i-1}\}$.

We construct a new bag $R' = A \cup A^R \cup Z^L \cup Z \cup \{r_{i-1}, r_i\}$, and we connect R' to both R^L and R^R, thus combining the two tree-decompositions into one. Last we create a bag $R = A \cup Z \cup \{r_i\}$ and attach it to R'. This completes the construction of $(\mathcal{T}, \mathcal{B}')$.

Observe that $(\mathcal{T}, \mathcal{B}')$ is a valid tree-decomposition for H:

- $V(H) = V(H^L) \cup V(H^R)$, thus $\forall v \in V(H), v \in \mathcal{B}^{\mathcal{L}} \cup \mathcal{B}^{\mathcal{R}} \subset \mathcal{B}$.
- $E(H) = E(H^L) \cup E(H^R) \cup \{(r_{i-1}, r_i)\}$. We have that $r_{i-1}, r_i \in R' \in \mathcal{B}$. All other edges were dealt with in $\mathcal{T}^{\mathcal{L}}, \mathcal{T}^{\mathcal{R}}$.
- Each vertex $v \in V(H)$ that belongs in exactly one of H^L, H^R trivially satisfied the connectivity requirement: bags that contain v are either fully contained in $\mathcal{T}^{\mathcal{L}}$ or $\mathcal{T}^{\mathcal{R}}$. A vertex v that is in both H^L and H^R is also in $Z^L \cap A^R$ due to the properties of path-decompositions, hence in R'. Therefore, the sub-trees of bags that contain v in $\mathcal{T}^{\mathcal{L}}, \mathcal{T}^{\mathcal{R}}$, form a connected sub-tree in $\mathcal{T}$.

The width of $\mathcal{T}$ is $\max\{tw(H^L), tw(H^R), |R'| - 1\} = 4w + 5$. ◀

The last thing that remains to do in order to complete the proof is to show the equivalence between achieving the targets and finding a Grundy coloring.

▶ **Lemma 15.** *Let G and G' be two graphs as described in Lemma 8 and let H be constructed from G' by using the tree-filling operation. Then G has a clique of size k iff $\Gamma(H) \geq \lceil \log(k(m+1) + \binom{k}{2} + 2m) \rceil + 2\log n + 5$. Furthermore, $tw(H) \leq 4\binom{k}{2} + 8k + 17$.*

The proof of Lemma 15 can be found in the full version of the paper.

▶ **Theorem 16.** *Grundy Coloring parameterized by treewidth is W[1]-hard.*

4 FPT for pathwidth

In this section, we show that, in contrast to treewidth, Grundy Coloring is FPT parameterized by pathwidth. We achieve this by providing an upper bound on the Grundy number of any graph as a function of its pathwidth. Pipelining this with the algorithm of [74], we obtain a dependency on pathwidth alone. In order to obtain our bound, we rely on the following result on the performance ratio of the first-fit coloring algorithm on interval graphs.

▶ **Theorem 17** ([65]). *First-Fit is 8-competitive for online coloring interval graphs.*

In other words, interval graphs satisfy $\Gamma(G) \leq 8 \cdot \chi(G)$. Since for any interval graph G we have $\chi(G) = pw(G) + 1$, we immediately obtain the following:

▶ **Corollary 18.** *For every interval graph G, $\Gamma(G) \leq 8 \cdot (pw(G) + 1)$.*

▶ **Lemma 19.** *For every graph G, $\Gamma(G) \leq 8 \cdot (pw(G) + 1)$.*

Proof. For a contradiction, suppose there exists G such that $\Gamma(G) > 8 \cdot (pw(G)+1)$, and let $c : V(G) \to \{1, \ldots, \Gamma(G)\}$ be a Grundy coloring using $\Gamma(G)$ colors. In addition, let G have the smallest possible number of vertices, i.e., there is no G' satisfying those conditions with $|V(G')| < |V(G)|$. This implies that, for every optimal path decomposition of G, there is no bag B and vertices $u, v \in B$ such that $c(u) = c(v)$.

Indeed, if such vertices exist, adding the edge uv to G and contracting uv yields a new graph G' such that $pw(G') \leq pw(G)$ (edge contraction does not increase the pathwidth), $\Gamma(G') \geq \Gamma(G)$ (since c when limited to V(G') is a valid Grundy coloring of G') and $|V(G')| < |V(G)|$, contradicting the assumption that G is smallest possible.

In addition, for any u, v such that $c(u) \neq c(v)$ and $v \notin N(u)$, adding edge uv to G does not decrease the Grundy number of G since c remains a valid Grundy coloring of the new graph. In particular, since, as previously observed, vertices in any bag of an optimal path decomposition of G all have pairwise different colors, turning every bag of such a decomposition into a clique does not decrease the Grundy number of G. More precisely, this yields a graph G' such that $pw(G') = pw(G)$ and $\Gamma(G') \geq \Gamma(G)$, where G' is an interval graph. Applying Corollary 18 we obtain $\Gamma(G) \leq \Gamma(G') \leq 8 \cdot (pw(G')+1)$, contradiction. ◀

Combining Lemma 19 with the $O^*(2^{O(tw(G)\cdot\Gamma(G))})$ algorithm of [74], we have:

▶ **Theorem 20.** *Grundy Coloring can be solved in time* $O^*(2^{O(pw(G)^2)})$.

Finally, note that there exist interval graphs that satisfy $\Gamma(G) \geq r \cdot pw(G)$, for any $r < 5$ [53], therefore, the constant in Lemma 19 cannot be improved below 5.

5 NP-hardness for Constant Clique-width

In this section we prove that Grundy Coloring is NP-hard even for constant clique-width via a reduction from 3-SAT. We use a similar idea of adding supports as in Section 3, but supports now will be cliques instead of binomial trees. The support operation is defined as:

▶ **Definition 21.** *Given a graph $G = (V, E)$, a vertex $u \in V$ and a set of positive integers S, we define the **support** operation as follows: for each $i \in S$, we add to G a clique of size i (using new vertices) and we connect one arbitrary vertex of each such clique to u.*

When applying the support operation we will say that we support vertex u with set S and we will call the vertices introduced supporting vertices. Intuitively, the support operation ensures that the vertex u may have at least one neighbor with color i for each $i \in S$.

We are now ready to describe our construction. Suppose we are given a 3CNF formula ϕ with n variables $x_1, \ldots, x_n$ and m clauses $c_1, \ldots, c_m$. We assume without loss of generality that each clause contains exactly three variables. We construct a graph $G(\phi)$ as follows:

1. For each $i \in [n]$ we construct two vertices x_i^P, x_i^N and the edge (x_i^P, x_i^N).
2. For each $i \in [n]$ we support the vertices x_i^P, x_i^N with the set $[2i-2]$. (Note that x_1^P, x_1^N have empty support).
3. For each $i \in [n], j \in [m]$, if variable x_i appears in clause c_j then we construct a vertex $x_{i,j}$. Furthermore, if x_i appears positive in c_j, we connect $x_{i,j}$ to $x_{i'}^P$ for all $i' \in [n]$; otherwise we connect $x_{i,j}$ to $x_{i'}^N$ for all $i' \in [n]$.
4. For each $i \in [n], j \in [m]$ for which we constructed a vertex $x_{i,j}$ in the previous step, we support that vertex with the set $(\{2k \mid k \in [n]\} \cup \{2i-1, 2n+1, 2n+2\}) \setminus \{2i\}$.
5. For each $j \in [m]$ we construct a vertex c_j and connect to all (three) vertices $x_{i,j}$ already constructed. We support the vertex c_j with the set $[2n]$.

6. For each $j \in [m]$ we construct a vertex d_j and connect it to c_j. We support d_j with the set $[2n+3] \cup [2n+5, 2n+3+j]$.
7. We construct a vertex u and connect it to d_j for all $j \in [m]$. We support u with the set $[2n+4] \cup [2n+5+m, 10n+10m]$.

This completes the construction. Before we proceed, let us give some intuition. Observe that we have constructed two vertices x_i^P, x_i^N for each variable. The support of these vertices and the fact that they are adjacent, allow us to give them colors $\{2i-1, 2i\}$. The choice of which gets the higher color encodes an assignment to variable x_i. The vertices $x_{i,j}$ are now supported in such a way that they can "ignore" the values of all variables except x_i; for x_i, however, $x_{i,j}$ "prefers" to be connected to a vertex with color $2i$ (since $2i-1$ appears in the support of $x_{i,j}$, but $2i$ does not). Now, the idea is that c_j will be able to get color $2n+4$ if and only if one of its literal vertices $x_{i,j}$ was "satisfied" (has a neighbor with color $2i$). The rest of the construction checks if all clause vertices are satisfied in this way.

We now state the lemmata that certify the correctness of our reduction. Their proofs appear in the full version of the paper.

▶ **Lemma 22.** *If ϕ is satisfiable then $G(\phi)$ has a Grundy coloring with $10n+10m+1$ colors.*

▶ **Lemma 23.** *If $G(\phi)$ has a Grundy coloring with $10n+10m+1$ colors, then ϕ is satisfiable.*

▶ **Lemma 24.** *The graph $G(\phi)$ has constant clique-width.*

▶ **Theorem 25.** *Given graph $G=(V,E)$, k-Grundy Coloring is NP-hard even when the clique-width of the graph $cw(G)$ is a constant.*

6 FPT for modular-width

In this section we show that Grundy Coloring is FPT parameterized by modular-width. Recall that $G=(V,E)$ has modular-width w if V can be partitioned into at most w modules, such that each module is a singleton or induces a graph of modular-width w. Neighborhood diversity is the restricted version of this measure where modules are required to be cliques or independent sets. We sketch the main ideas of the algorithm (a full proof is in the full version of the paper).

The first step is to show that Grundy Coloring is FPT parameterized by neighborhood diversity. Similarly to the standard Coloring algorithm for this parameter [56], we observe that, without loss of generality, all modules can be assumed to be cliques, and hence any color class has one of 2^w possible types. We would like to use this to reduce the problem to an ILP with 2^w variables, but unlike Coloring, the ordering of color classes matters. We thus prove that the optimal solution can be assumed to have a "canonical" structure where each color type only appears in consecutive colors. We then extend the neighborhood diversity algorithm to modular-width using the idea that we can calculate the Grundy number of each module separately, and then replace it with an appropriately-sized clique.

▶ **Theorem 26.** *Let $G=(V,E)$ be a graph of modular-width w. The Grundy number of G can be computed in time $2^{O(w2^w)}n^{O(1)}$.*

Abstract

The Burrows-Wheeler Transform (BWT) has been an essential tool in text compression and indexing. First introduced in 1994, it went on to provide the backbone for the first encoding of the classic suffix tree data structure in space close to entropy-based lower bound. Within the last decade, it has seen its role further enhanced with the development of compact suffix trees in space proportional to "r", the number of runs in the BWT. While r would superficially appear to be only a measure of space complexity, it is actually appearing increasingly often in the time complexity of new algorithms as well. This makes having the smallest value of r of growing importance. Interestingly, unlike other popular measures of compression, the parameter r is sensitive to the lexicographic ordering given to the text's alphabet. Despite several past attempts to exploit this fact, a provably efficient algorithm for finding, or approximating, an alphabet ordering which minimizes r has been open for years.

We help to explain this lack of progress by presenting the first set of results on the computational complexity of minimizing BWT-runs via alphabet reordering. We prove that the decision version of this problem is NP-complete and cannot be solved in time $poly(n) \cdot 2^{o(\sigma)}$ unless the Exponential Time Hypothesis fails, where σ is the size of the alphabet and n is the length of the text. Moreover, we show that the optimization variant is APX-hard. In doing so, we relate two previously disparate topics: the optimal traveling salesperson path of a graph and the number of runs in the BWT of a text. In addition, by relating recent results in the field of dictionary compression, we illustrate that an arbitrary alphabet ordering provides an $O(\log^2 n)$-approximation. Lastly, we provide an optimal linear-time algorithm for a more restricted problem of finding an optimal ordering on a subset of symbols (occurring only once) under ordering constraints.

1 Introduction and Related Work

The Burrows-Wheeler Transform (BWT) is an essential building block in the fields of text compression and indexing with a myriad of applications in bioinformatics and information retrieval [24, 25, 26, 30]. Since it first arose in 1994 [6], it has been utilized to provide the popular compression algorithm bzip2 and has been adapted to provide powerful compressed text indexing data structures, such as the FM-index [12]. Hence, improvements to the algorithmic aspects of this transformation and related data structures can have a significant impact on the research community.

The BWT of a text $T[1, n]$, denoted by $BWT(T)$ is a reversible transformation which can be defined as follows: sort the circular shifts of T in lexicographical order and place the sorted circular shifts in a matrix. By reading the last column of this matrix from top to bottom we obtain $BWT(T)$. To make the transformation invertible a new symbol \$ (lexicographically smaller than others) is appended to T prior to sorting the circular shifts. See Figure 1 for an example. Historically, the BWT was introduced for the purpose of text compression [6], where its effectiveness is based on symbols with shared preceding context forming long *runs* (maximal unary substrings).

F		L
\$	mississipp	i
i	\$mississip	p
i	ppi\$missis	s
i	ssippi\$mis	s
i	ssissippi\$	m
m	ississippi	\$
p	i\$mississi	p
p	pi\$mississ	i
s	ippi\$missi	s
s	issippi\$mi	s
s	sippi\$miss	i
s	sissippi\$m	i

Figure 1 Column L shows the BWT of *mississippi*. The number of runs $r = 9$.

Recently, the number of runs "r" in the BWT has become of increasing interest. This can be attributed to the fact that many modern text collections are highly repetitive, which makes their compression effective via the BWT followed by Run-Length encoding (i.e., in space proportional to r). This raised an interesting question: can we also index the text in space propositional to r? Note that the FM-index needs space proportional to n (i.e., $\approx n \log \sigma$ bits, where σ is the alphabet size). The data-structure community has made great strides in answering this question [3, 5, 14, 21, 23, 31]. The first such index was developed by Mäkinen and Navarro in 2005 [28]. However, it lacked the ability to efficiently locate the occurrences of a pattern within space $\tilde{O}(r)$. After a decade of related research [29, 14], we now have fully functional suffix trees in space proportional to r, developed by Gagie et al. [15]. Also note that the recent optimal BWT construction algorithm for highly repetitive texts is parameterized by r [19]. A technique reducing the value of this parameter r would have a significant impact on a large body of work.

A natural way to minimize r is to change the lexicographic ordering assigned to symbols of the alphabet. To demonstrate that this can have an impact on r, consider as an example the text *mississippi* with the usual ordering $\$ < i < m < p < s$ where $r = 9$, but with the ordering $\$ < s < i < p < m$ we have $r = 8$. In fact, there exist string families in which r differs by a factor of $\Omega(\log n)$ for different orderings. This problem of reordering the alphabet is clearly fixed-parameter tractable in alphabet size σ and has a trivial $O(\sigma!\ n)$ time solution. This may be adequate when σ is small as in DNA sequences. However, this is far from satisfactory from a theoretical point of view, or even from a practical point when the alphabet is slightly larger, such as in protein sequences, natural language texts, ascii texts, etc.

1.1 Related Work

The work in 2018 on block sorting based transformations by Giancarlo et al. gives a theoretical treatment of alphabet ordering in the context of the Generalized BWT [16]. It was shown that for any alphabet ordering, r is at most twice the number of runs in the original text, a result which then holds for the standard BWT as well. Note however that this gives no lower bound on r, and thus gives no results on the approximability of the run minimization problem. There have been multiple previous attempts to develop other approaches to alphabet ordering. In bioinformatics, the role of ordering on proteins was considered in [34] with approaches evaluated experimentally. Similar heuristic approaches evaluated through experiments were done in [1]. Researchers have also considered more restricted versions of this problem. For example, one can try to order a restricted subset of the alphabet, or limit wherein the ordering symbols can be placed. On this problem, heuristics have been utilized. Software tools like BEETL utilize these techniques to handle collections of billions of reads [8]. Another related work in [7] shows, how to permute a given set of strings in linear time, such that the number of runs in the BWT of the (long) string obtained by concatenating the input strings, separated by the same delimiter symbol is minimized.

Even more recently, a work by Giancarlo *et al.,* considered the case where ordering is assigned to the nodes of a string's suffix tree, to minimize the number of runs in the BWT [17]. Interestingly, this problem can be solved in polynomial time. Although their technique can potentially minimize the number of runs in the BWT to an even greater extent than modifying the ordering on the alphabet, it also requires storing the order for each of these nodes, which can require more space. We leave open the problem of finding a trade-off between the strategy of ordering the alphabet and ordering the nodes of the suffix tree.

Given the lack of success with attacking the main problem from the upper bound side, perhaps it is best to approach the problem from the perspective of lower bounds and hardness. To this end, we show why a provably efficient algorithm has been evasive.

2 Problem Definitions and Our Results

Let Σ denotes the alphabet and $\sigma = |\Sigma|$. A run in a string T is a maximal unary sub-string. Let $\rho(T)$ be the number of runs in T.

▶ **Problem 1** (Alphabet Ordering (AO)). *Given a string $T[1, n]$ and an integer t, decide whether there exists an ordering of the symbols in its alphabet such that $\rho(BWT(T)) \leq t$.*

▶ **Theorem 2.** *The alphabet ordering problem is NP-complete and its corresponding minimization problem is APX-hard.*

The problem can be solved in $n \cdot \sigma! = n \cdot 2^{O(\sigma \log \sigma)}$ time naively. However, any significant improvement seems unlikely as per the Exponential Time Hypothesis (ETH) [27].

▶ **Corollary 3.** *Under ETH, AO cannot be solved in time* $poly(n) \cdot 2^{o(\sigma)}$.

It is known that $\rho(BWT(T))$ can be lower bounded by the size of string attractor γ, a recently proposed compressibility measure [22]. Kempa and Kociumaka showed that $\rho(BWT(T))$ can be upper bounded by $O(\gamma \log^2 n)$ [20]. However, γ is independent of the alphabet ordering and the following result is immediate.

▶ **Corollary 4.** *Any alphabet ordering is an* $O(\log^2 n)$*-approximation for AO.*

We also introduce a specialization of AO, one where we impose more constraints on the ordering given to alphabet symbols.

▶ **Problem 5** (Constrained Alphabet Ordering (CAO))**.** *Given a set of* d *strings* $T_1, \ldots, T_d$ *of total length* N*, find an ordering* π *on the symbols* $\$_i$ $(1 \leq i \leq d)$ *such that* $\$_{\pi(1)} \prec \$_{\pi(2)} \ldots \prec \$_{\pi(d)} \prec 0 \ldots \prec \sigma - 1$ *and* $\rho(BWT(T_1\$_1T_2\$_2 \ldots T_d\$_d))$ *is minimized.*

We call $\$_1, \$_2, \ldots, \$_d$ *special symbols*. In Section 5.3, we provide an example where an optimal ordering of special symbols removes a factor of $\Omega(\log_\sigma d)$ in the number of runs, demonstrating that this can be a worthwhile preprocessing step. We refer to [8] for an immediate use case in bioinformatics, where the input is a large collection of DNA reads.

▶ **Theorem 6.** *The constrained alphabet ordering problem can be solved in linear time.*

In the full version [4] of this paper, we extend these hardness results to the related problem of ordering source vertex on Wheeler graphs. Wheeler graphs are a recently introduced class of graphs which allow for BWT based indexing [2, 13, 18].

3 Preliminaries: L-reductions

Our inapproximability results use L-reductions [9]. We will be reducing a problem A, with some known inapproximability results, to a new problem B. We will use the following notation:

- $\mathrm{OPT}_A(x)$ denotes the cost of an optimal solution to the instance x of Problem A.
- $c_A(y)$ denotes the cost of a solution y to an instance x of Problem A (suppressing the x in the notation $c_A(x, y)$).
- Since all problems presented here are minimization problems the approximation ratio can be written as $R_A(x, y) = \frac{c_A(y)}{\mathrm{OPT}_A(x)}$, which is ≥ 1.
- Let $f_A(x) = x'$ be a mapping of an instance x of Problem A to instance x' of Problem B.
- Let y' be a solution to instance $x' = f_A(x)$ and $g_B(y') = y$ be the mapping of a solution y' to a solution y for instance x.

Taking x, y, x' y' as above, an L-reduction is defined by the pair of functions (f_A, g_B), computable in polynomial time, such that there exist constants $\alpha, \beta > 0$, where for all x and y the following two conditions hold:

$$\mathrm{OPT}_B(f_A(x)) \leq \alpha\, \mathrm{OPT}_A(x) \quad \text{and} \quad c_A(g_B(y')) - \mathrm{OPT}_A(x) \leq \beta\Big(c_B(y') - \mathrm{OPT}_B(f_A(x))\Big).$$

As a result, $R_B(x', y') = 1 + \varepsilon$ implies $R_A(x, y) \leq 1 + \alpha\beta\varepsilon = 1 + O(\varepsilon)$. L-reductions preserve APX-hardness [32].

4 Hardness of Alphabet Ordering

We will demonstrate a sequence of L-reductions from the $(1,2)$-TSP Cycle problem, where the aim is to find a Hamiltonian cycle of minimum weight through an undirected *complete graph* on n vertices where all edges have weights either 1 or 2. The $(1,2)$-TSP Cycle problem is APX-hard, even with only $\Theta(n)$ edges of weight 1 [33]. The first reduction is to $(1,2)$-TSP Path, where the goal is to find a Hamiltonian path of minimum weight, rather than a cycle.

▶ **Lemma 7.** *(1,2)-TSP Path is APX-hard, even with only $\Theta(n)$ edges of weight 1.*

Proof. We will give an approximation preserving reduction from $(1,2)$-TSP to $(1,2)$-TSP Path. By the APX-hardness of $(1,2)$-TSP Cycle, we obtain Lemma 7.

Let x be the input graph G for $(1,2)$-TSP Cycle and let f_A map the graph G to an identical graph G'. Let g_B map the $(1,2)$-TSP Path y' given to G' to the cycle in G obtained by connecting the end points of the path with an edge of weight at most 2. Hence the cost $c_B(y')$ is always at most the cost $c_A(g_B(y'))$. At the same time, the weight $\mathrm{OPT}_A(x)$ of an optimal cycle in G is bound above by the weight $\mathrm{OPT}_B(f_A(x))$ of an optimal path in G' plus 2. Thus, $c_B(y') \leq c_A(g_B(y'))$ and $\mathrm{OPT}_A(x) \leq \mathrm{OPT}_B(f_A(x)) + 2$. Therefore,

$$\frac{\mathrm{OPT}_B(f_A(x))}{c_B(y')} \leq 1+\varepsilon \implies \frac{\mathrm{OPT}_A(x)}{c_A(g_B(y'))} \leq \frac{\mathrm{OPT}_B(f_A(x))+2}{c_B(y')} \leq 1+\varepsilon+\frac{2}{n} \leq 1+O(\varepsilon). \quad \blacktriangleleft$$

We proceed to present our reduction which consists of two phases.

4.1 Reduction Phase 1

Given a complete graph on n vertices and $m = \Theta(n)$ edges of weight 1 as input to (1,2)-TSP Path, remove all edges of weight 2. We call the resulting graph G. Construct the incidence matrix for G (a row for each edge, and a column for each vertex, where the two 1's in a row indicate which two vertices are incident to the edge for that row). Then add 2ℓ rows of all 0's to bottom of the matrix, where $\ell = 4m$. Next, add two additional columns c_s and c_t where $c_s[i] = 1$ if $i \in \{m+2, m+4, \ldots, m+2\ell\}$ and 0 otherwise, and $c_t[i] = 1$ if $i \in \{m+1, m+3, \ldots, m+2\ell-1\}$ and 0 otherwise (see Figure 2). We call this matrix M.

$$\begin{array}{c} \boldsymbol{c_s} \quad\quad\quad\quad\quad \boldsymbol{c_t} \\ \left[\begin{array}{ccccc} 0 & ? & \ldots & ? & 0 \\ 0 & ? & \ldots & ? & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & ? & \ldots & ? & 0 \end{array}\right]_{m} \\ \left[\begin{array}{ccccc} 0 & 0 & \ldots & 0 & 1 \\ 1 & 0 & \ldots & 0 & 0 \\ 0 & 0 & \ldots & 0 & 1 \\ 1 & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \ldots & 0 & 1 \\ 1 & 0 & \ldots & 0 & 0 \end{array}\right]_{2\ell} \end{array}$$

Figure 2 The modified incidence matrix for the graph G. Each of the first m rows is for an edge. The bottom $2\ell = 8m$ rows are added as are the outer two most columns.

We now present an intermediate problem that we call Column Ordering (CO), which is: given a matrix M constructed as above, find an optimal ordering on the columns so as to *minimize the number of runs in its linearization.* We will use M_π to denote the matrix M with the ordering π applied to its columns and $L(M_\pi)$ to denote the string obtained by concatenating the rows of M_π from top to bottom. We call $L(M_\pi)$ the linearization of M_π.

Next, we describe the function which maps solutions of our instance of Column Ordering back to a solution of $(1,2)$-TSP Path. Ignoring the added columns c_s and c_t, the ordering π induces a collection of disjoint paths in G, which we call P, where two vertices form an edge if their columns are adjacent and there exists a row with 1's in both columns. Given P we create a (1,2)-TSP Path by connecting the paths in P with $|P|-1$ edges of weight 2. Note that this can be done in linear time.

▶ **Lemma 8.** *If c_s and c_t are the first and last columns of M_π respectively, then the cost of our CO solution is $\rho(L(M_\pi)) = 2m_1 + 4(m-m_1) + 2\ell + 1 = 4m - 2m_1 + 2\ell + 1$, where m_1 is the number of rows whose edges are in the collection of paths P. The corresponding cost of the solution to (1,2)-TSP Path is $m_1 + 2(n-1-m_1) = 2(n-1) - m_1$.*

Proof. Ignoring the first run of $L(M_\pi)$ for the moment, every row in M_π corresponding to an edge in P contributes two runs to $\rho(L(M_\pi))$ (e.g. $0\ldots0110\ldots0$). Any row whose edge is not in P and not in the bottom 2ℓ rows, contributes four (e.g. $0\ldots010\ldots010\ldots0$) and there are $m-m_1$ such (rows) edges. The extra 2ℓ rows in total contribute 2ℓ runs. Adding the "+1" term for the start of $L(M_\pi)$ gives the desired expression. The second statement follows from the TSP Path having m_1 edges of weight 1 and the $n-1$ edges in total needed to form a Hamiltonian path. ◀

▶ **Lemma 9.** *If c_s and c_t are not the first and last columns respectively, then the solution to CO is sub-optimal.*

Proof. If c_t is first and c_s is last, then one extra run is contributed over c_s being first and c_t last, while maintaining the rest of the ordering to be the same. In any configuration where either c_s or c_t are not ends of the matrix, the bottom rows will contribute at least 3ℓ runs. Letting m_1^* denote the optimal number of edges of P, then the optimal $\rho(L(M_{\pi^*}))$ is $4m - 2m_1^* + 2\ell + 1 < 4m + 2\ell \leq 3\ell$. Note that the first inequality is strict since we can always find at least one edge for P. ◀

It is immediate from Lemmas 8 and 9 that an optimal solution for CO is one which maximizes m_1, and this provides an optimal solution for (1,2)-TSP Path. We now must show that our reduction is also an L-reduction. Lemmas 10 and 11 consider the two possible cases.

▶ **Lemma 10.** *If c_s and c_t are the first and last columns respectively in a solution to CO, then the L-reduction conditions hold.*

Proof. By Lemmas 8 and 9, the optimal cost for the instance of CO can be expressed as $4m - 2m_1^* + 2\ell + 1$ and the optimal cost for the instance of (1,2)-TSP Path as $2(n-1) - m_1^*$. To prove Condition (i), we need to show there exists an $\alpha > 0$ such that

$$4m - 2m_1^* + 2\ell + 1 \leq \alpha(2(n-1) - m_1^*)$$

Since $m = \Theta(n)$ there exists a constant $C > 1$, such that for n large enough $m \leq Cn$. The left hand side can be bounded above by $4Cn - 2m_1^* + 8Cn + 1 = 12Cn - 2m_1^* + 1$ (recall $\ell = 4m$). Since $m_1^* \leq n-1$ it is easy to find such an α for $n \geq 2$. Below is the inequality for Condition (ii), which is true for $\beta \geq 1/2$.

$$(2(n-1) - m_1) - (2(n-1) - m_1^*) \leq \beta\Big((4m - 2m_1 + 2\ell + 1) - (4m - 2m_1^* + 2\ell + 1)\Big)$$ ◀

▶ **Lemma 11.** *If c_s and c_t are not the first and last columns respectively in a solution to CO, the L-reduction conditions still hold.*

Proof. Condition (i) holds since the optimal solution values to the overall problem have not changed. For Condition (ii), we consider the two scenarios:

- **Scenario 1**: c_s or c_t are not at the far ends of M_π. Then the cost of the solution for CO, which is at least 3ℓ, exceeds the cost for any solution considered in Lemma 10. Furthermore, any corresponding solution for (1,2)-TSP Path has already been considered in Lemma 10, where now the right-hand is larger than it was in Lemma 10.
- **Scenario 2**: c_t is the first column of M_π and c_s is the last. Then, again, we have already considered a solution in Lemma 10 which has solution cost one less for CO and yet had the same solution cost for (1,2)-TSP Path.

This completes the proof. ◀

4.2 Reduction Phase 2

Given the matrix M as constructed in Phase 1 from G, we will now construct a string T as input to the problem AO. It is easier to describe T in terms of its substrings, which are created by iterating through the matrix M as follows:

- For $1 \leq j \leq n+2$, $1 \leq i \leq m+2\ell$: if $M_{i,j} = 1$ output the substring $10^{i+1}2C_j$
- For $1 \leq j \leq n+2$: output the substring $0^{m+2\ell+2}2C_j$
- Append to each substring created above a unique $\$_i$ symbol ($1 \leq i \leq 2m+2\ell+n+2$).

The string T is the concatenation of these substrings in any order and $|T| = O(n^2)$. The alphabet set Σ is $\{0,1,2\} \cup \{C_1, C_2, \ldots, C_{n+2}\} \cup \{\$_1, \$_2, \ldots, \$_{2m+2\ell+n+2}\}$ and $\sigma = \Theta(n)$.

Given a solution π to this instance of AO we use the relative ordering given to the C_i symbols as the ordering for the columns of M_π. For the analysis of why this works, we define some properties that we would like $BWT(T)$ and π to have. For any symbol $a \in \Sigma$ we will call the maximal set of indices where the F column of the sorted circular shift matrix has only a's as the *a-block*. Our goal will be to"simulate" the linearization of $L(M_\pi)$ within the 0-block of $BWT(T)$. We let C_s and C_t denote the symbols for columns c_s and c_t respectively.

The following are the key properties that an optimal solution π^* will have:

1. For a fixed j, all C_j symbols are placed adjacently in $BWT(T)$;
2. All 2 symbols are placed adjacently in $BWT(T)$;
3. The symbol 2 is adjacent to the symbol 0 in the ordering;
4. The $\$_i$ symbols are ordered in such a way as to minimize the number of runs of 1 in the 0-block of $BWT(T)$.
5. The symbols C_s and C_t are both positioned at the beginning and end respectively of the alphabet ordering given to the C_i symbols.

The 0-block of $BWT(T)$ will consist of 0's, 1's, and $\$_i$ symbols. All $\$_i$ symbols will be adjacent within the 0-block. This is since the $\$_i$ symbols succeeded by 0, are all succeeded by the substring $0^{m+2\ell+2}2$ and every occurrence of $0^{m+2\ell+2}2$ preceded by a $\$_i$ symbol (when T is viewed as a circular string). Let r_0 denote the number of runs created in the 0-block of $BWT(T)$, minus the number of $\$_i$ symbols in the 0-block of $BWT(T)$.

▶ **Lemma 12.** *Unless all of the above properties hold, the solution to AO is suboptimal.*

Proof. If any of Properties 1–3 are violated, we can exchange our solution with one which maintains the value r_0 but reduces the runs created in other blocks. This is since the alphabet ordering can be modified to have these properties, while at the same time maintaining the relative orderings of symbols within the 0-block. In the case of Property 4, given that

Properties 1–3 hold, modifying the solution so that the property holds can only decrease r_0, while it maintains the number of runs created in other blocks. Assuming properties 1–4 hold, there are two possibilities, either C_s and C_t are extremal or they are not.

- In the case of being extremal, if $C_s < C_t$, then by Property 4, the $2\ell = 8m$ instances of 1's in the bottom 2ℓ rows of M_π shall correspond to $4m$ runs of two consecutive 1's in the 0-block of $BWT(T)$. The upper rows of M_π shall correspond to at most $2m$ runs of 1's in the 0-block of $BWT(T)$. Hence, in the 0-block there are at most $6m + 1$ runs of 1's making at most $6m + 2$ runs of zeros to surround them, so that $r_0 \leq 12m + 3$. In the case where $C_t < C_s$, one additional run of 1's is created over the same configuration where the positions of C_s and C_t are swapped.
- In the case of them not being extremal, considering only the last 2ℓ rows of M_π, there are $8m$ runs of lonely 1's in the 0-block of $BWT(T)$, and at least $8m + 1$ runs of 0's to surround them, leading to $r_0 \geq 16m + 1$.

This completes the proof. ◀

As mentioned earlier, we aim to have a substring of $BWT(T)$ within the 0-block which is the same as $L(M_\pi)$ except for the lengths of its runs, i.e., the number of runs will be the same. We will call this substring the simulation of $L(M_\pi)$.

▶ **Lemma 13.** *If all Properties 1–5 hold, then* $r_0 = \rho(L(M_\pi)) - 1$ *and* $\rho(BWT(T)) = r_0 + \sigma - 1$.

Proof. We will first show that when Properties 1–5 hold, $r_0 = \rho(L(M_\pi)) - 1$, i.e., that the simulation works. Within the 0-block of $BWT(T)$, row i is simulated by the characters preceding each substring $0^{i+1}2$. Note that they all appear consecutively in the 0-block. Within the simulation of the i^{th} row, if the value of the j^{th} column of M_π is 0, then the characters preceding substrings of the form $0^{i+1}2C_j$ are all 0. If the value of the j^{th} column of M is 1, then there exists a single substring of the form $0^{i+1}2C_j$ preceded by a 1, and the remaining substrings of the form $0^{i+1}2C_j$ are all preceded by 0. Note that all characters preceding $0^{i+1}2C_j$ are consecutive within the i^{th} row, however, the unique \$'s following each substring allow the characters following each $0^{i+1}2C_j$ to have their orders swapped. Because of Property 5, in the column ordering of M_π there will never be a run of more than two consecutive 1's in $L(M_\pi)$. Hence, when Property 4 is applied, we know that 1's which would are adjacent in $L(M_\pi)$ are adjacent in the 0-block. Combining all these observations gives us that $L(M_\pi)$ is successfully simulated within the 0-block. The "-1" term in the expression for r_0 arises due to Property 2. This is since the 0 symbol in 0-block of $BWT(T)$ that is adjacent to the 2-block does not contribute a run. We have shown $r_0 = L(M_\pi) - 1$.

Finally, the fact that $\rho(BWT(T)) = r_0 + \sigma - 1$ follows from Properties 1–3 which cause every symbol except 1 to contribute exactly one run to $\rho(BWT(T))$ outside of the simulation (1's first appearance is within the simulation). ◀

▶ **Lemma 14.** *If all Properties 1–5 hold, the L-reduction conditions are satisfied.*

Proof. By Lemma's 12 and 13 we have the optimal cost for AO being $r_0^* + \sigma - 1$ and optimal cost for CO as $r_0^* + 1$. For Condition (i) note that $\sigma = \Theta(n)$ and because there are at most 5 runs created by each row, $m + 2\ell \leq r_0^* \leq 5(m + 2\ell)$, so that $r_0^* = \Theta(n)$. Hence, we can find an α such that $r_0^* + \sigma - 1 \leq \alpha(r_0^* + 1)$. For Condition (ii), we have $(r_0 + 1) - (r_0^* + 1) \leq \beta((r_0 + \sigma - 1) - (r_0^* + \sigma - 1))$ with $\beta = 1$. ◀

▶ **Lemma 15.** *If any of Properties 1–5 are violated, the L-reduction conditions are satisfied.*

Proof. Condition (i) is satisfied since optimal values for the overall problem are unchanged. For Condition (ii), if any of the first four properties are violated, we have already shown in Lemma 14 that the inequality holds in the harder case where $\rho(L(M_\pi))$ has the same value but the overall number of runs in $BWT(T)$ is less. If the first four properties hold and the fifth property does not hold, there are two cases. In the first case, if C_t is ordered first and C_s last, then swapping C_s and C_t modifies both sides of the inequality for Condition (ii) by the same amount. In the second case, if either C_s or C_t are not ordered first or last, the left hand side of the inequality in Condition (ii), that is $\Big(\rho(L(M_\pi)) - \rho(L(M_{\pi^*}))\Big)$, will be large, as this corresponds to the columns c_s and c_t not being first or last. However, the right-hand side $\Big((r_0 + \sigma - 1) - (r_0^* + \sigma - 1)\Big)$ will be large as well, perhaps even larger as there may exist runs of three of four 1's in $L(M_\pi)$ that cannot be simulated in the 0-block of $BWT(T)$. In particular, $r_0 \geq \rho(L(M_\pi)) - 1$ and $\rho(L(M_{\pi^*})) = r_0^* + 1$, so that with $\beta = 1$

$$\rho(L(M_\pi)) - \rho(L(M_{\pi^*})) \leq (r_0 + 1) - \rho(L(M_{\pi^*})) \leq \beta\Big((r_0 + \sigma - 1) - (r_0^* + \sigma - 1)\Big). \quad \blacktriangleleft$$

We have shown an L-reduction from (1,2)-TSP Path to AO. This combined with Lemma 7 completes the proof for Theorem 2.

4.3 Proof of Corollary 3

Assuming ETH, there exists no $2^{o(n)}$ time algorithm for Hamiltonian Path Problem [10]. Our reduction allows us to determine the minimum number of paths in G needed to cover all the vertices and can hence solve Hamiltonian Path. This can be done by first constructing an incidence matrix for G and then applying the rest of the reduction as in Section 4. Since the alphabet size σ is linear in n and $|T| = \Theta(n^2)$, an $|T|^{O(1)} \cdot 2^{o(\sigma)}$ time algorithm for AO would imply an $2^{o(n)}$ time algorithm for Hamiltonian Path, a contradiction.

5 Constrained Alphabet Ordering

5.1 Reducing to a Simpler Problem

Recall that we wish to find an ordering on the special symbols $\$_1, \ldots, \$_d$ such that the number of runs in the BWT of $T = T_1\$_1 \ldots T_d\$_d$ is minimized and the \$ symbols are lexicographically before other symbols. We will consider our alphabet to be over integers that are bounded by $N^{O(1)}$, where $N = |T|$. Let s be an arbitrary substring of T without \$ symbols. The symbols in T which are followed by $s\$_i$ will form a contiguous portion of $BWT(T)$. However, their ordering within that contiguous portion is determined by the relative ordering given to $\$_i$ symbols. Hence, we can arrange the symbols within this portion of $BWT(T)$ so that identical symbols are placed adjacently.

For example, let $c_1 s\$_1$, $c_2 s\$_2$, ..., $c_t s\$_t$ be substrings of T. The symbols c_1, c_2, ... c_t will be contiguous in $BWT(T)$ in some order. Now, suppose that $c_2 = c_4 = c_7$. By rearranging the $\$_2$, $\$_4$, and $\$_7$ to be adjacent within the relative ordering of the \$ symbols, we can make c_2, c_4, and c_7 appear consecutively. Taking this one step further, we can also change the relative ordering of $\$_2$, $\$_4$, and $\$_7$, so that if the substrings $\alpha c_2 s\$_2$, $\beta c_4\$_4$, and $\alpha s\$_7$ occur in T, then the two α's will be adjacent in the contiguous portion of $BWT(T)$ corresponding to the substrings $c_2 s\$_2$, $c_4 s\$_4$, and $c_7 s\$_7$.

Hence, the set of symbols $B_s = \{x \mid xs\$_i \text{ is a substring of } T \text{ for some } i \in [1, d]\}$ can be modeled as a tuple where each symbol appears only once within the tuple. Along with each symbol x in B_s, we will maintain a set $\Delta_s^x = \{\$_i \mid xs\$_i \text{ is a substring of } T\}$. We will arrange

all non-empty tuples B_s in the lexicographic ordering of s. As such, these tuples can be constructed by first assigning any ordering to the \$ symbols (where they are lexicographically first in the alphabet) and then using the longest common prefix (LCP) between consecutive suffixes in lexicographic order. These values are obtained directly from the longest common prefix array. The suffix array and longest common prefix array can both be constructed in linear time assuming an integer alphabet of size $N^{O(1)}$ [11]. We will define the problem of ordering the symbols within these tuples as a new problem.

▶ **Problem 16** (Tuple Ordering (TO)). *Given a list of tuples $t_1, \ldots, t_q$ in a fixed order, each containing a subset of symbols from Σ, order the symbols in each tuple such that the total number of runs in the string formed by their concatenation $t_1 \cdot t_2 \cdot \ldots \cdot t_q$ is minimized (not considering '(', ')' and commas, of course).*

We will show that TO can be solved in linear time. To map solutions of TO back to solutions of CAO, a tuple for B_s needs to maintain pointers to each tuple B_{xs}, where x is a symbol. Then given a solution to TO, we start with the tuple for B_ε. The ordering given to symbols within this tuple provides us with a partial ordering on the \$ symbols. The symbols in Δ_ε^x associated with the first symbol x within the tuple are ordered before the symbols Δ_ε^y associated with the second symbol y, etc. Then for a symbol x, the tuple for B_x provides a refinement of this partial ordering. In particular, it provides a partial ordering on Δ_ε^x. To recover the total ordering on \$ symbols, we recursively refine the partial ordering at our current tuple by examining all of the tuples which the current tuple points to. Note that this works since for a given tuple for B_s, the sets Δ_s^x are disjoint. The time required to recover this solution is proportional to N.

5.2 Solving the Tuple Ordering Problem in Linear Time

We show how to reduce the TO problem to the single-source shortest path problem on a DAG G, which is constructed as follows. For each tuple t_i, create two sets of vertices L_i and R_i, both of size $|t_i|$, such that for each symbol $c \in t_i$, there exists a vertex with label c in L_i as well as in R_i. Between each pair of vertices $u \in L_i$ and $v \in R_i$, where the label of u is not equal to the label of v, create a directed edge of weight 1 from u to v. If $|t_i| = 1$, then create a directed edge of weight 1 from the unique vertex in L_i to the unique vertex in R_i. For each R_i and L_{i+1} $(1 \leq i \leq q-1)$, and each pair $u \in R_i$ and $v \in L_{i+1}$, create a directed edge from u to v, with weight 1 if they have the same label, and weight 2 otherwise. Finally, create a start vertex s and directed edges of weight 1 from s to each vertex in L_1, and an end vertex e with directed edges of weight 1 from each vertex in R_q to e. See Figure 3 for an illustration.

Clearly, the shortest path from s to e is the one with the fewest edges of weight 2, and this path gives us a tuple ordering which minimizes the number of runs created by the tuples. To obtain this ordering, for a tuple t_i, place as the left-most symbol the label of the vertex used in L_i within the shortest path, and the right-most symbol the label of the vertex used in R_i within the shortest path. The other symbols can be ordered arbitrarily. Because G a DAG, this shortest path can be found in time proportional to the number of edges, which is $O(\sigma^2 q)$. Next, we show how to solve this in time proportional to the number of vertices of G.

Rather than constructing the edges in G, we can work from left-to-right maintaining the shortest path from s to the vertices in our current level of G, either L_i or R_i. Suppose our current level is L_i and we wish to extend the solution to the level R_i. Assuming $|t_i| \geq 2$, we identify the vertices v_1 and v_2 in L_i with the first and second shortest paths (they may have the same length) from s, respectively. For each vertex u in R_i, if the label of u is not the same as the label for v_1, we make the shortest path to u the path from s to v_1, then the edge

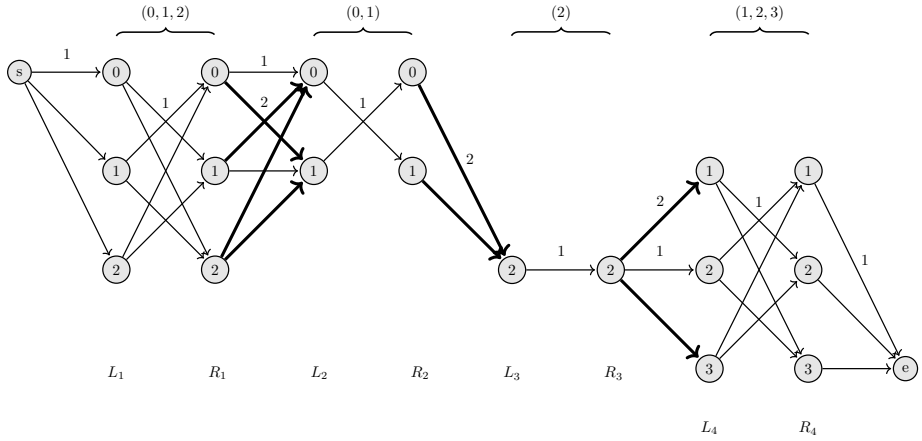

Figure 3 The graph G constructed for the tuple ordering instance $(0, 1, 2), (0, 1), (2), (1, 2, 3)$.

from v_1 to u, otherwise we make it the path from s to v_2, then the edge from v_2 to u. If $|t_i| = 1$, we make the shortest path from s to u the path from s to the unique vertex v in L_i, then the edge from v to the unique vertex u. To extend a solution from R_i to L_{i+1}, we first identify the vertex v_1 in R_i with the shortest path from s. For each vertex u in L_{i+1}, if a vertex with matching label v_u exists in R_i, we take as the shortest path to u the shorter of the following two paths: (i) the path from s to v_1, then from v_1 to u, or (ii) the path from s to v_u, then from v_u to u. If no such vertex with matching label exists in R_i, take as the shortest path from s to u the path from s to v_1, then from v_1 to u.

5.3 An Example of the Effectiveness of CAO

Lastly, we provide an example where the \$ symbol ordering greatly reduces the number of runs in the BWT. Let d be the number of strings and n the length of the strings. It is possible for a set of special symbols to be ordered such that the number of runs is $\Omega(nd)$. Let $\sigma = 2$ and $d = \sigma^n$. Consider the d distinct binary strings concatenated with special symbols in lexicographic order. Under the ordering $\$_1 < \$_2 \ldots < \$_d$, the string $BWT(T)$ alternates between the \$'s, 0's, and 1's, yielding $\Omega(nd)$ runs. On the other hand, for this same case, arranging the \$'s in the optimal ordering will give $O(d)$ runs in total. This is since for any substring s of T, the contiguous section of $BWT(T)$ containing the characters preceding $s\$_i$ for $i \in [1, d]$ contains at most the start of two runs. For example, with $n = 3$, we would have $T = 000\$_1001\$_2010\$_3011\$_4100\$_5101\$_6110\$_7111\$_8$. The number of runs in $BWT(T)$ under the naive ordering $\$_1 < \$_2 < \ldots < \$_8$, is 32 with $BWT(T) = 010101010101\$_8\$_101\$_2\$_3010101\$_4\$_501\$_6\$_7$. The number of runs using an optimal ordering $\$_3 < \$_5 < \$_2 < \$_7 < \$_4 < \$_6 < \$_1 < \$_8$ is 19 with $BWT(T) = 000011111100 01\$_8\$_101\$_2\$_3001110\$_4\$_501\$_6\$_7$.

Abstract

We consider the efficient simulation of population protocols. In the population model, we are given a system of n agents modeled as identical finite-state machines. In each step, two agents are selected uniformly at random to interact by updating their states according to a common transition function. We empirically and analytically analyze two classes of simulators for this model. First, we consider sequential simulators executing one interaction after the other. Key to the performance of these simulators is the data structure storing the agents' states. For our analysis, we consider plain arrays, binary search trees, and a novel Dynamic Alias Table data structure. Secondly, we consider batch processing to efficiently update the states of multiple independent agents in one step. For many protocols considered in literature, our simulator requires amortized sub-constant time per interaction and is fast in practice: given a fixed time budget, the implementation of our batched simulator is able to simulate population protocols several orders of magnitude larger compared to the sequential competitors, and can carry out 2^{50} interactions among the same number of agents in less than 400 s.

1 Introduction

We consider the *population model*, introduced by Angluin et al. [5] to model systems of resource-limited mobile agents that interact to solve a common task. Agents are modeled as finite-state machines. The computation of a *population protocol* is a sequence of pairwise interactions of agents. In each interaction, the two participating agents observe each other's states and update their own state according to a transition function common to all agents.

Typical applications of population protocols are networks of passively mobile sensors [5]. As an example, consider a flock of birds, where each bird is equipped with a simple sensor. Two sensors communicate whenever their birds are sufficiently close. An application could be a distributed disease monitoring system raising an alarm if the number of birds with high temperature rises above some threshold. Further processes which resemble properties of population protocols include chemical reaction networks [38], programmable chemical controllers at the level of DNA [22], or biochemical regulatory processes in living cells [21].

While the computational power of population protocols with constantly many states per agent is well understood by now (see below), less is known about the power of protocols with state spaces growing with the population size. In this setting, much interest has been on analyzing the runtime and state space requirements for *probabilistic* population protocols, where the two interacting agents are sampled in each time step independently and uniformly at random from the population. This notion of a probabilistic scheduler allows the definition of a *runtime* of a population protocol. The runtime and the number of states are the main performance measures used in the theoretical analysis of population protocols.

For the theoretical analysis of population protocols, a large toolkit is available in the literature. Consequently, the remaining gaps between upper and lower bounds for many quantities of interest have been narrowed down: for many protocols, the required number of states has become sub-logarithmic, while the runtime approaches more and more the (trivial) lower bounds for any meaningful protocol. So far, when designing new protocols, simulations have always proven a versatile tool in getting an intuition for these stochastic processes. However, once observables are of order $\log\log n$ and below, naive population protocol simulators fail to deliver the necessary insights (e.g., $\log\log n \leq 5$ for typical input sizes of $n \leq 2^{32}$). Our main contribution in this paper is a new simulation approach allowing to execute a large number of interactions even if the population size exceeds 2^{40}. In the remainder of this section, we first give a formal model definition in Section 1.1 and then describe our main contributions and related work in Sections 1.2 and 1.3.

1.1 Formal Model Definition

In the *population model*, we are given a distributed system of n agents modeled as finite-state machines. A *population protocol* is specified by a state space $Q = \{q_1, \ldots, q_{|Q|}\}$, an output domain Y, a transition function $\delta\colon Q \times Q \to Q \times Q$, and an output function $\gamma\colon Q \to Y$. At time t, each agent i has a state $s_i(t) \in Q$, which is updated during the execution of the protocol. The current output of agent i in state $s_i(t)$ is $\gamma(s_i(t))$. The *configuration* $C(t) = \{s_1(t), \ldots, s_n(t)\}$ of the system at time t contains the states of the agents after t interactions. For the sake of readability, we omit the parameter t in $C(t)$ and $s_i(t)$ when it is clear from the context. The *initial configuration* is denoted $C(0) = C_0$.

The *computation* of a population protocol runs in a sequence of discrete time steps. In each time step, a *probabilistic scheduler* selects an ordered pair of agents (u, v) independently and uniformly at random to *interact*. Agent u is called the *initiator* and agent v is the *responder*. During this *interaction*, both agents u and v observe each other's state and update their states according to the transition function δ such that $(s_u(t{+}1),\ s_v(t{+}1)) \leftarrow \delta(s_u(t),\ s_v(t))$.

Sequential	$\text{SEQ}_{\text{Array}}$	Section 2	$\Theta(N)$	$\Theta(n \log \lvert Q\rvert)$
	$\text{SEQ}_{\text{Linear}}$	Section 2	$\mathrm{O}(N\lvert Q\rvert)$	$\Theta(\lvert Q\rvert \log n)$
	SEQ_{BST}	Section 2	$\Theta(N \log \lvert Q\rvert)$	$\Theta(\lvert Q\rvert \log n)$
	$\text{SEQ}_{\text{Alias}}$	Section 2	$\Theta(N)$ w.h.p.	$\Theta(\lvert Q\rvert \log n)$
Batch	BATCHED	Section 4	$\mathrm{O}(N(\log n + \lvert Q\rvert^2)/\sqrt{n})^\dagger$	$\Theta(\lvert Q\rvert \log n)$
	MULTIBATCHED	Section 5	$\mathrm{O}(N\lvert Q\rvert\sqrt{\log n}/\sqrt{n})^\dagger$	$\Theta(\lvert Q\rvert \log n)$

A given problem for the population model specifies the agents' initial states, the output domain O, and (a set of) *desired (output) configurations* for a given input. As an example, consider the MAJORITY problem. Each agent is initially in one of two states q_A and q_B corresponding to two opinions A and B. Assuming that A is the initially dominant opinion, the protocol concludes once all agents u give $\gamma(s_u) = A$ as their output. Any configuration in which all agents output the initially dominant opinion is a desired configuration.

This notion of a desired configuration allows to formally define two notions of a *runtime* of a population protocol. The *convergence time* T_C is the number of interactions until the system enters a desired configuration and never leaves the desired configurations in a given run. The *stabilization time* T_S is the number of interactions until the system enters a desired *stable* configuration for which there does not exist any sequence of interactions due to which the system leaves the desired configurations. A population protocol is *stable*, if it always eventually reaches a desired output configuration.

A number of variants of this model are commonly used. For *symmetric protocols*, the order of the interacting agents is irrelevant for the transition. In particular, this means that if $\delta(q_u, q_v) = (q'_u, q'_v)$, then $\delta(q_v, q_u) = (q'_v, q'_u)$. In *protocols with probabilistic transition functions*, the outcome of an interaction may be a random variable. In *one-way protocols*, only the initiator updates its states such that $\delta(q_u, q_v) = (q'_u, q_v)$ for any interaction.

Model Assumptions. We assume a *meaningful* protocol which converges after at most $N = \text{poly}(n)$ interactions, has an $\mathrm{O}(1)$ time transition function δ, and uses $|Q| < \sqrt{n}$ states (observe that many relevant protocols only use $|Q| = \mathrm{O}(\text{polylog}\, n)$ states; see Section 1.3).

1.2 Our Contributions

In this paper, we present a new approach for simulating population protocols. Our simulator allows us to efficiently simulate a large number, N, of interactions for large populations of size n. Our findings are summarized in Table 1.

Sequential Simulators. As a baseline, we directly translate the population model into a sequential algorithm framework SEQ: SEQ selects for each interaction two agents uniformly at random, updates their states, and repeats. We analyze the runtime and memory consumption of various variants in Section 2.

Batch Processing. To speed up the simulation, we introduce and exploit *collision-free runs*, a sequence of interactions where no agent participates more than once. Our algorithms BATCHED and MULTIBATCHED coalesce these independent interactions into batches for

improved efficiency. BATCHED first samples the length ℓ of a collision-free run. It then randomly pairs ℓ independent agents, adds one more interaction – the collision – reusing one of the run's agents, and finally repeats. BATCHED is presented in Section 4 and extended into MULTIBATCHED in Section 5. We discuss practical details and heuristics in Section 6.

Dynamic Alias Tables. The simulation of population protocols often needs an *urn-like* data structure to efficiently sample random agents (marbles) and update their states (colors). The *alias method* [41, 40] enables random sampling from arbitrary discrete distributions in $O(1)$ time. However, it is static in that the distribution may not change over time. Thus, we extend it and analyze a *Dynamic Alias Table* in Section 2. It supports sampling with and without replacement uniformly at random (u.a.r.) and addition of elements (if the urn is sufficiently full). Due to its practical performance and simplicity compared to more general solutions [30, 33], we believe this data structure might be of independent interest and show:

▶ **Theorem 1.** *Let U be a Dynamic Alias Table that stores an urn of n marbles, where each marble has one of k possible colors. U requires $\Theta(k \log n)$ bits of storage. If $n \geq k^2$, we can*

- *select a marble u.a.r. from U with replacement in expected constant time,*
- *select a marble u.a.r. from U without replacement in expected amortized constant time,*
- *and add a marble of a given color to U in amortized constant time.*

1.3 Related Work

Population Protocols. The population model was introduced in [5], assuming a constant number of states per agent. Together with [6, 9], they show that all semilinear predicates are stably computable in this model. In the following, we focus on two prominent problems, MAJORITY and LEADER ELECTION. For a broad overview, we refer to surveys [12] and [26].

In [8] a MAJORITY protocol with three states is presented where the agents agree on the majority after $O(n \log n)$ interactions w.h.p. (*with high probability* $1 - n^{-\Omega(1)}$), if the initial numbers of agents holding each opinion differ by at least $\omega(\sqrt{n} \log n)$. In [34, 25], four-state protocols are analyzed that stabilize in expectation in $O(n^2 \log n)$ interactions. In a recent series of papers [35, 1, 2, 4, 19, 15, 14, 13], bounds for the MAJORITY problem have been gradually improved. The currently best known protocol [13] solves MAJORITY w.h.p. in $O(n \log^{3/2} n)$ interactions using $O(\log n)$ states. Regarding lower bounds, [1] shows that protocols with less than $(\log \log n)/2$ states require in expectation $\Omega(n^2/\operatorname{polylog}(n))$ interactions to stabilize. In [2] it is shown that any MAJORITY protocol that stabilizes in $n^{2-\Omega(1)}$ expected interactions requires $\Omega(\log n)$ states under some natural assumptions.

The goal for LEADER ELECTION protocols is that exactly one agent is in a designated leader state. Doty and Soloveichik [24] show that any population protocol with a constant number of states that stably elects a leader requires $\Omega(n^2)$ expected interactions, a bound matched by a natural two-state protocol. Upper bounds for protocols with a non-constant number of states per agent were presented in [3, 1, 19, 2, 18, 28, 29, 16]. In [28] a LEADER ELECTION protocol that stabilizes w.h.p. in $O(n \log^2 n)$ interactions, using $O(\log \log n)$ states (matching a corresponding lower bound [1]) is presented. The core idea is to synchronize the agents using a *phase-clock*. The currently best known protocol for LEADER ELECTION is due to [16], stabilizing in expected $O(n \log n)$ interactions using $O(\log \log n)$ states per agent.

As a tool for self-synchronization, so-called *phase-clocks* have been explored in a wide range of related areas, see, e.g., the seminal paper [10]. In the population model, the concept of phase-clocks was first introduced in [7] under the assumption that a leader is present. These clocks were generalized in [28] to a *junta* of n^ε agents. In Section 7 we empirically analyze a variant of this phase-clock process.

Simulations have proven a versatile tool to get an intuitive understanding of population protocols. This is also reflected in the related work: See, e.g., [7, 8, 4, 3] for some examples of papers that also present empirical data. However, to the best of our knowledge, our paper is the first systematic analysis of simulators for population protocols.

Sampling from Discrete Distributions. The methods to sample non-uniform variates heavily depend on the modeling and properties of the required probability distributions.

If the distribution is governed by a closed-form density function $f(x)$, "numerical tricks" can yield efficient algorithms with small memory footprints; this is the case for most well-known distributions [23, 20]. A standard approach is the *inverse sampling technique* [23]. It needs to compute the inverse F^{-1} of f's cumulative density function $F(x) = \int_{-\infty}^{x} f(y)\mathrm{d}y$ (cf. Section 6.1). Another concept is *rejection sampling* [20, Sec. 5.2.5/6]. It obtains a sample x from a suitable simpler distribution g. In order to generate the distribution f, the sample is accepted only with probability proportional to $f(x)/g(x)$. The process repeats until a sample is obtained (cf. Section 3). A special case is the *ratio-of-uniforms* method, commonly used to obtain hypergeometric random variates [39].

Dedicated data structures support sampling from arbitrary discrete distributions. Given a finite universe $U = \{1, \ldots, u\}$ with probabilities $(p_1, \ldots, p_u)$ with $\sum_i p_i = 1$, Walker's *alias tables* [41] allow sampling in constant expected time, and can be constructed in $\mathrm{O}(u)$ time [40]; recently Hübschle-Schneider et al. [31] discussed engineering aspects and parallel construction.

In this paper, we model an urn with n balls with $\mathrm{O}(\sqrt{n})$ colors (typically much less) as a distribution over k colors where p_i is proportional to the number of balls with color i. While alias tables work in the static case, they do neither support removal nor insertion of balls without rebuilding the data structure.

A suited binary tree can be constructed in $\mathrm{O}(k)$ time, and supports updates and sampling in $\mathrm{O}(\log k)$ time. Two independent but similar data structures by [30] and [33] support updates and sampling in expected constant time. They partition the input into groups such that the probabilities of elements within a group differ by at most a factor of two. This allows rejection sampling *within* a group with an acceptance rate of at least 1/2. Since updates to the distribution can affect the partition sizes, over-provisioning and table doubling involving garbage collection [33, App. B] is used.

The approaches differ in the way they select a group to sample from. They are however both recursive in the sense that the group selection is carried out with another instance of the data structure itself. To achieve constant access times, the recursion is stopped after constantly many layers, and the remaining very small problem is treated as a special case. As a result, the data structures are quite complex, and were excluded in preliminary experiments due to performance considerations. By constraining the supported distributions, simpler schemes can be obtained [36, 27]. However, in our use case, they incur impractically high rejection rates, as we cannot give non-trivial bounds on the number of balls per color.

It is note-worthy that Hagerup et al. [30] operate on integer weights (modeled as *generalized distributions* lacking the normalization constraint), and require integer arithmetic only.

2 Sequential Simulation

As a baseline, we first consider variants of Seq, a sequential approach defined in Algorithm 1. It is a direct translation of the machine model discussed in Section 1.1. Seq carries out N steps in a fully serialized manner. For each interaction, it selects two agents uniformly at random, computes their new states based on their current ones, and updates the configuration.

Algorithm 1 SEQ: The algorithmic framework for sequential simulation.

input: configuration C, transition function δ, number of steps N
for $t \leftarrow 1$ **to** N **do**
  sample and remove agents i and j without replacement from C
  add agents in states $\delta(s_i, s_j)$ to C

Under the realistic assumption that the transition function δ can be evaluated in constant time, SEQ's runtime and memory footprint is dominated by storing, sampling from, and updating the configuration C. We therefore consider appropriate data structures. In the population model, agents typically are anonymous, i.e., we cannot distinguish two agents in the same state. Hence, we can store a configuration C as an unordered multiset $\hat{C}$ and maintain multiplicities rather than individual states. To this end, SEQ requires an *urn-like* data structure which efficiently supports (i) weighted sampling (with and without replacement) and (ii) adding of single agents. In the following, we consider various data structures and their impact on the complexity of the sequential approach.

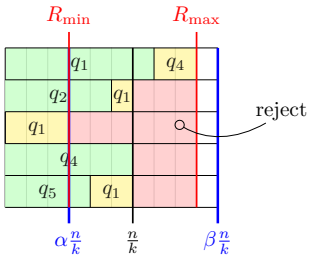
Array. $\text{SEQ}_{\mathsf{Array}}$ maintains the configuration C in an array $A[1 \dots n]$ where $A[i]$ holds s_i, the state of the i-th agent. Sampling with replacement is trivial, as we only draw a uniform variate $X \in [n]$ and return $A[X]$. Sampling without replacement works analogously: we overwrite $A[i]$ with $A[n]$ and remove the array's last element $A[n]$. Adding new elements is possible by appending. (Note that we do not grow the memory since we always store at most n agents in the array.) This leads to an $\mathrm{O}(N)$ time algorithm and a memory footprint of $\mathrm{O}(n \log |Q|)$ bits, which can be prohibitively large if simulating large populations in parallel.

Linear Search. $\text{SEQ}_{\mathsf{Linear}}$ maintains the multiset $\hat{C}$ in an array A such that $A[i]$ holds the number of agents in state q_i. Sampling requires a linear search on A in $\mathrm{O}(|Q|)$ per sample. This results in a worst-case simulation time of $\Theta(N|Q|)$. Nevertheless, in practice $\text{SEQ}_{\mathsf{Linear}}$ is among the fastest sequential variants for small $|Q|$ (see Section 7). Compared to $\text{SEQ}_{\mathsf{Array}}$, it has a significantly smaller memory footprint of $\mathrm{O}(|Q| \log n)$ bits.

Binary Search Tree. $\text{SEQ}_{\mathsf{BST}}$ maintains the multiset $\hat{C}$ using a balanced binary search tree. The i-th leaf (from left to right) encodes $\hat{C}_i$, the number of agents in state i. Each inner node v stores the number ℓ_v of agents in its left subtree. To randomly sample an agent, we draw an integer X from $\{0, \dots, n-1\}$ uniformly at random and compare it to the root's value ℓ_r. If $X < \ell_r$, the sample is in the interval covered by the left sub-tree, and we descend accordingly. Otherwise, we update $X \leftarrow X - \ell_r$ and descend into the right subtree. We recurse until some leaf i is reached, where we emit an agent of state i.

Each operation on the tree involves a simple path from the root to a leaf of length $\Theta(\log |Q|)$. Since the work per level is constant, all operations take $\Theta(\log |Q|)$ time. Thus, $\text{SEQ}_{\mathsf{BST}}$ requires $\Theta(N \log |Q|)$ total time and $\mathrm{O}(|Q| \log n)$ bits of memory.

$\text{SEQ}_{\mathsf{Alias}}$ combines the linear runtime of $\text{SEQ}_{\mathsf{Array}}$ (w.h.p.) with the small memory footprint of $\text{SEQ}_{\mathsf{BST}}$, provided $|Q| < \sqrt{n}$. At the heart of $\text{SEQ}_{\mathsf{Alias}}$ lies a *Dynamic Alias Table* introduced in the following section.



$F[i]$	$S[i]$	$A[i]$	rejection probability
7	2	q_4	0
5	1	q_1	$3/9$
0	3	q_1	$6/9$
6	0	q_1	$3/9$
4	2	q_1	$3/9$

Figure 1 Dynamic Alias Table storing $\hat{C} = (q_1 : 13,\ q_2 : 5,\ q_3 : 0,\ q_4 : 8,\ q_5 : 4)$, i.e., $n = 30$ and $k = 5$. This imbalanced configuration will soon need rebuilding, e.g., after the next decrease of q_1 in row 3, or after adding two more agents in state q_1 in row 1.

3 Dynamic Alias Tables

Dynamic Alias Tables. In this section we introduce our Dynamic Alias Table data structure. Our goal is to model an urn which initially contains n marbles, each of which has one of k possible colors. We assume that the colors are identified by numbers in $\{1, \ldots, k\}$. The urn defines a probability distribution D for the color of a marble drawn uniformly at random: let p_i be the probability that we sample a marble of color i.

Original Alias Method. The alias method [41] uses a table with two columns and k rows, one row for each element (color) in the distribution D. Each row i has two entries corresponding to two elements. Each element has a weight in $[0, 1]$, and the two weights sum up to 1 in each row. The first element of row i is always element i. It has weight $F[i]$. The second element of row i is stored in $A[i]$. It has a weight of $1 - F[i]$. This means that the original alias method uses only the two arrays, F and A, to store the distribution $p_1, \ldots, p_k$.

To sample from D in the original alias method, we first sample a row i uniformly at random from $\{1, \ldots, k\}$. Then we draw a random real $X \in [0, 1)$. If $X < F[i]$, we return the left element, i. Otherwise, we return the right element, $A[i]$. In the following, we modify the alias method and call the resulting data structure Dynamic Alias Table.

Dynamic Alias Tables. Recall that we assume that our distribution corresponds to an urn storing n marbles of k different colors. First, we explicitly add a second weight array $S[i]$ which stores the weight of the alias. Now instead of storing just one real value $F[i]$ for each row i, we store the exact numbers of marbles as integers for the first and the second entry of row i in $F[i]$ and $S[i]$, respectively (cf. generalized distributions of [30]). As before, the first entry of row i corresponds to color i and the second entry of row i corresponds to color $A[i]$. As illustrated in Figure 1, the rows are constructed in such a way that the total weight of each row no longer adds up to the real value 1, but to the integer value $\lfloor n/k \rfloor$ or $\lceil n/k \rceil$ such that all rows in total add up to n.

▶ **Observation 2.** *Let U be a Dynamic Alias Table encoding an urn with n marbles and k colors. The data structure U can be constructed in $O(k)$ time.*

Proof. The algorithm by Vose [40] can generate an (original) alias table representation of such a discrete probability distribution D in $O(k)$ time. It is straightforward to define a mapping between the weights of the original alias method as computed in [40] and the two integer values used in our Dynamic Alias Table. It follows that the Dynamic Alias Table (using integer weights) can be constructed in $O(k)$ time. ◀

Updating and Sampling from Dynamic Alias Tables. Our modified data structure now allows us to sample elements with and without replacement. Let $R_i = F[i] + S[i]$ denote the weight of row i and define $R_{\min}$ and $R_{\max}$ as smallest and largest row weights, respectively. Observe that in general $R_{\min} \neq R_{\max}$.

In order to sample from U, we first select row i uniformly at random from $\{1, \ldots, k\}$. Then we draw a uniform variate X from $\{0, \ldots, R_{\max} - 1\}$.[1] There are three possible events: If $X < F[i]$, we emit the first element i. If $F[i] \leq X < R_i$, we emit the second element $A[i]$. Otherwise, we reject the trial and restart the sampling process.

If we sample from U without replacement, we decrement the weight of the element just sampled. This is always possible, since only elements with strictly positive weights can be sampled in the first place. If we add a new element with color i to U, we increment the weight of the first element of row i.

In order to guarantee expected constant sampling time, we ensure that the fraction between $R_{\min}$ and $R_{\max}$ does not exceed a certain value. Let $0 < \alpha < 1$ and $\beta > 1$ be two parameters chosen such that $\beta/\alpha = \mathrm{O}(1)$. After each update to U we require

$$\alpha\lfloor n/k \rfloor \leq R_{\min} \leq R_{max} \leq \beta\lceil n/k \rceil. \tag{1}$$

Otherwise, we rebuild the data structure in $\mathrm{O}(k)$ time.

We are now ready to show Theorem 1.

Proof of Theorem 1. We start with the memory complexity. The Dynamic Alias Table U stores the values of k, n, and $R_{\max}$ as well as three arrays. Array $F[1 \ldots k]$ stores the weight of the first column, array $S[1 \ldots k]$ stores the weight of the second column, and array $A[1 \ldots k]$ stores the alias, i.e., the element of the second column. All entries are integers from $\{0, \ldots, n\}$ (recall that we assume $k \leq \sqrt{n}$). Thus, the Dynamic Alias Table requires $\Theta(k \log n)$ bits of memory.

Let us now consider the sampling procedure. First, we consider the rejection probability. Recall that we first sample a row i and then draw a uniform variate X from $\{0, \ldots, R_{\max} - 1\}$. As before, we denote the total weight of row i as R_i with $R_i = F[i] + S[i]$. A sampling trial in row i is rejected if $X \geq R_i$, i.e., with probability $R_i/R_{\max}$. Therefore, the probability to reject a sample from any row is at most $R_{\min}/R_{\max}$. From the conditions in Equation (1) we get that the rejection probability is at most $\alpha/\beta = \mathrm{O}(1)$ and, conversely, we have at least a constant success probability of $(\beta - \alpha)/\beta$. The number of trials until we emit an element is therefore geometrically distributed and has an expected value of at most $\beta/(\beta - \alpha) = \mathrm{O}(1)$.

It remains to show that we emit an element of color i with probability $p_i = \hat{C}_i/n$, where $\hat{C}_i$ is the number of marbles of color i in the Dynamic Alias Table U. We consider a single sampling trial. Observe that in each trial we are given a uniform probability space $\mathbf{\Omega} = \{(i, x) \ : \ 1 \leq i \leq k \text{ and } 0 \leq x < R_{\max}\}$. From this probability space we draw the row i and the value X uniformly at random. Fix a color c and let $\mathcal{S}_c$ be the set of all events (i, x) which lead to emission of an element of color c for this probability space $\mathbf{\Omega}$. An event (i, x) is in $\mathcal{S}_c$ if and only if (i) $i = c$ and $x < F[i]$ or (ii) $A[i] = c$ and $F[i] \leq x < F[i] + S[i]$.

The Dynamic Alias Table U is constructed such that the total weight for each color c always equals $\hat{C}_c$. Therefore, counting all elementary events gives us $|\mathcal{S}_c| = \hat{C}_c$. Observe that $\mathbf{\Omega}$ is a uniform probability space since the row i and the value X are drawn uniformly. It has size $|\mathbf{\Omega}| = kR_{\max}$. Hence, all events in $\mathcal{S}_c$ have equal probability $1/(kR_{\max})$, and we get $\Pr[\mathcal{S}_c] = |\mathcal{S}_c|/(kR_{\max}) = \hat{C}_c/(kR_{\max})$.

[1] Observe that in a practical implementation one can draw a single uniform variate U' from $\{1, \ldots, k \cdot R_{\max} - 1\}$, and derive U and X from it.

Let $\mathcal{R}$ be the event that a trial is rejected. Analogously to before, we enumerate over all elementary events and obtain $|\mathcal{R}| = \sum_i (R_{\max} - R_i) = kR_{\max} - n$. For the complementary event $\overline{\mathcal{R}}$ we get $|\overline{\mathcal{R}}| = n$, which matches the intuition that the urn contains n marbles. Hence, we have $\Pr[\overline{\mathcal{R}}] = n/(kR_{\max})$. Observe that $\mathcal{S}_c$ and $\mathcal{R}$ are mutually exclusive and hence $\mathcal{S}_c \cap \overline{\mathcal{R}} = \mathcal{S}_c \setminus \mathcal{R} = \mathcal{S}_c$.

Rejected trials emit no element, but are repeated. Hence, we condition on $\overline{\mathcal{R}}$ and obtain

$$p_c = \Pr[\mathcal{S}_c \mid \overline{\mathcal{R}}] = \frac{\Pr[\mathcal{S}_c \cap \overline{\mathcal{R}}]}{\Pr[\overline{\mathcal{R}}]} = \frac{\Pr[S_c]}{\Pr[\overline{\mathcal{R}}]} = \frac{\hat{C}_c}{kR_{\max}} \cdot \frac{kR_{\max}}{n} = \frac{\hat{C}_c}{n}.$$

This means that a color c is indeed emitted with the correct probability $p_c = \hat{C}_c/n$.

Finally, we consider the amortized costs of rebuilding the Dynamic Alias Table U ever so often. Observe that U has to be rebuilt whenever the condition in Equation (1) is violated. This can happen in two possible ways.

- Case 1: $R_{\min} < \alpha\lfloor n/k \rfloor$.
  In this case there must exist a row i for which $R_i < \alpha\lfloor n/k \rfloor$. Observe that by assumption of the theorem we have $n \geq k^2$, and after rebuilding U we have $R_{\min} = \lfloor n/k \rfloor$. In order to have $R_i < \alpha\lfloor n/k \rfloor$, at least $\lfloor n/k \rfloor - \alpha\lfloor n/k \rfloor \geq k(1-\alpha)$ elements must have been deleted from row i. As $0 < \alpha < 1$, this happens only after at least $k(1-\alpha) = \Omega(k)$ sampling operations. Now according to Observation 2, rebuilding takes time $\mathrm{O}(k)$. Together this implies that rebuilding U takes amortized constant time per update of U.
- Case 2: $R_{\max} > \beta\lceil n/k \rceil$.
  The second case follows analogously to the first case. If $R_{\max} > \beta\lceil n/k \rceil$, at least $\beta\lceil n/k \rceil - \lceil n/k \rceil \geq k(\beta-1)$ elements must have been added. This takes at least $k(\beta-1) = \Omega(k)$ insertions, and hence rebuilding U takes amortized constant time per insertion.

Removal and insertion operations can be arbitrarily mixed and interact only beneficially towards the amortization arguments. This concludes the proof of the theorem. ◀

4 Batch Processing

So far, we discussed algorithms to simulate a population protocol step-by-step. These simulators can output the population's configuration $C(t)$ for each time step $1 \leq t \leq N$. With a time complexity of $\mathrm{O}(N)$, the simulators $\textsc{Seq}_{\mathsf{Array}}$ and $\textsc{Seq}_{\mathsf{Alias}}$ are optimal in this sense. In practice, however, it often suffices to obtain a configuration snapshot every $\Theta(n)$ steps. In this setting, we can achieve sub-constant work per interaction under mild assumptions.

Recall that $\textsc{Seq}_{\mathsf{BST}}$ has a small memory footprint but a sub-optimal time complexity of $\Theta(N \log |Q|)$. Observe, however, that the underlying binary search tree can update the multiplicity of any existing state in time $\mathrm{O}(\log |Q|)$ *independently* of the changed quantity. Here, we introduce the new algorithm Batched (see Algorithm 2) to exploit this observation. The algorithm uses a binary search tree to store the configuration. It updates $\Omega(\sqrt{n})$ agents in expectation with each access and therefore reduces the time complexity to $\mathrm{O}(N(\log n + |Q|^2)/\sqrt{n})$ which is $\mathrm{o}(N)$ for $|Q| = \mathrm{o}(n^{1/4})$ and $N = \Theta(\mathrm{poly}(n))$.

Batching interactions. In order to coalesce individual updates into batches, Batched uses the notion of *collision-free runs* as illustrated in Figure 2. We interpret the execution of a protocol as a sequence $i_1, i_2, \ldots$ where at time t agents i_{2t-1} and i_{2t} interact.

Let ℓ be the largest index such that all $i_1, \ldots, i_\ell$ are distinct. Then, the first $\lfloor \ell/2 \rfloor$ interactions are independent of each other and can be rearranged in any order. We refer to them as a collision-free run of length ℓ. If ℓ is odd, the first agent of the $(\lfloor \ell/2 \rfloor + 1)$-th

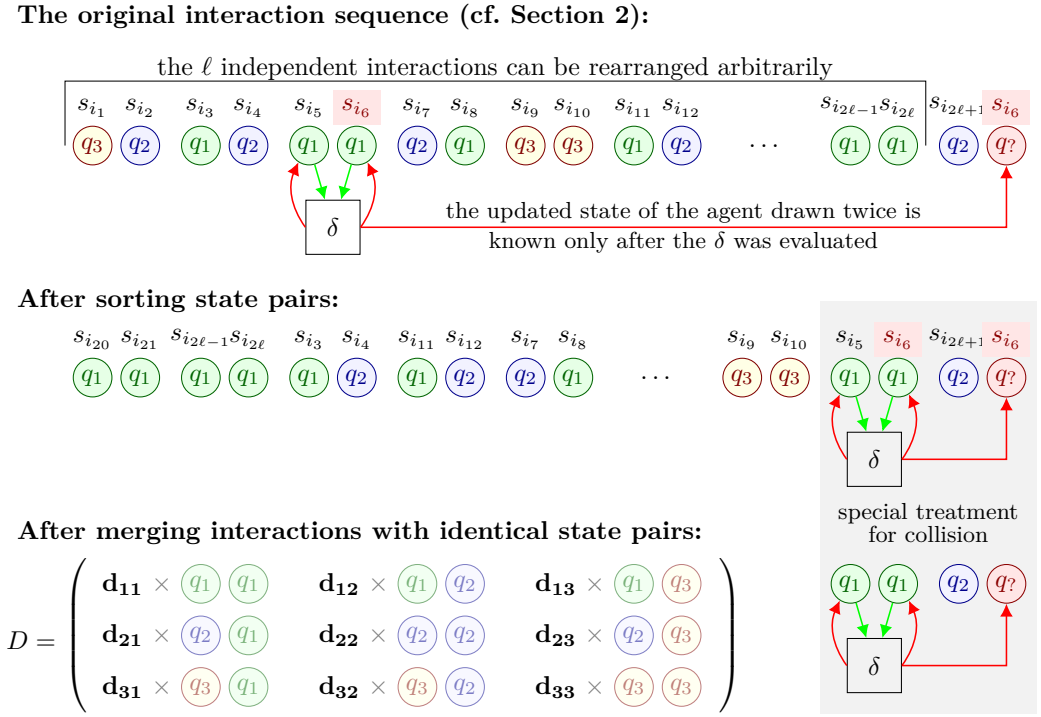


Figure 2 Batch processing uses collision-free runs, long sequences of independent interactions, which can be rearranged and grouped together.

interaction is also considered collision-free. Since we are free to reorder the interactions, we can group all interactions of states (q_i, q_j) together, evaluate $\delta(q_i, q_j)$, and update all accordingly affected states in one step.

Now instead of sampling a sequence of agents and partitioning the sequence into collision-free runs, we take the opposite direction. We first sample only the length ℓ of a collision-free run from the appropriate probability distribution (see below). Then, we randomly match ℓ agents as discussed below. Finally, we reuse one of the agents from the matching in order to plant a collision. These steps are repeated until at least N interactions are simulated.

Matching Agents. We simulate sampling ℓ agents without replacement to construct a collision-free run of length ℓ. While we cannot afford to draw the agents individually, we only need to know how many interactions n_{ij} of each state pair (q_i, q_j) we encountered. Thus, a run can be modeled by a $|Q|\times|Q|$ matrix $D = (n_{ij})$ with $\sum_{ij} n_{ij} = \lfloor \ell/2 \rfloor$. (If ℓ is odd, we remove one agent and treat it individually.)

To obtain D, we first sample the row sums $D_i = \sum_j n_{ij}$ of the matrix from a multivariate hypergeometric distribution. This simulates sampling $\lfloor \ell/2 \rfloor$ initiating agents without replacement. We then sample values within each row analogously to find the matching responding agents. Sampling D takes $\mathrm{O}(|Q|^2)$ time in total since each individual sample from a hypergeometric distribution can be computed in $\mathrm{O}(1)$ time [39].

For correctness, note that our sampling approach corresponds to first selecting $\lfloor \ell/2 \rfloor$ agents as initiators and then $\lfloor \ell/2 \rfloor$ agents as responders. That is, we first sample agents $i_1, i_3, \ldots, i_{2\lfloor \ell/2 \rfloor - 1}$ and then agents $i_2, i_4, \ldots, i_{2\lfloor \ell/2 \rfloor}$ (instead of the natural interleaved variant $i_1, i_2, \ldots, i_{2\lfloor \ell/2 \rfloor}$). Since, each draw is taken uniformly at random, the permutation does not change the distribution (see full version [17] for a formal proof).

Algorithm 2 BATCHED: The algorithmic framework for simulation in batches.

input: configuration C, transition function δ, number of steps N
$t \leftarrow 0$
while $t < N$ **do**
  $\ell \leftarrow$ sample length of a collision-free run
  let $D = (d_{ij})$ be a $|Q| \times |Q|$ matrix and sample d_{ij} as the number of interactions (q_i, q_j) among ℓ interactions ▷ `batch processing`
  let C' be an empty configuration
  foreach $(q_i, q_j) \in Q^2$ **do**
    remove from C: d_{ij} agents in states q_i, and d_{ij} agents in states q_j
    $(q_i', q_j') \leftarrow \delta(q_i, q_j)$
    add to C': d_{ij} agents in states q_i', and d_{ij} agents in states q_j'
  if ℓ *is even* **then** ▷ `plant a collision`
    sample agent c_1 without replacement from C' ▷ `collision at` c_1
    merge C' into C
    sample agent c_2 without replacement from C
  else
    sample agent c_1 without replacement from C
    sample agent c_2 without replacement from C' ▷ `collision at` c_2
    merge C' into C
  add agents $\delta(c_1, c_2)$ to C
  $t \leftarrow t + \ell + 1$

Length of a Collision-Free Run. In the following, we analyze the length ℓ of a collision-free run. Observe that the following analysis is similar to the analysis of a generalized variant of the birthday problem [32]. We consider a generalization which we also use in Section 5. We assume that r agents have already interacted and ask how many more collision-free agents can be added. Formally we define the distribution $\mathsf{coll}(n, r)$ as follows.

▶ **Definition 3.** Consider a sequence $a_1, a_2, \ldots$ of agents sampled independently and uniformly at random. Let A_0 be a set of r initially prescribed agents and let $A_i = A_{i-1} \cup \{a_i\}$ be the set of agents after i draws. We define the random variable ℓ as the smallest index s.t. $a_\ell \in A_{\ell-1}$. We say $\ell \sim \mathsf{coll}(n, r)$, where n is the total number of agents and r is the number of prescribed agents.

In Section 6.1 we discuss how we can sample from this distribution using the inverse sampling technique [23]. We find that sampling ℓ takes $\mathrm{O}(\log n)$ time. In practice, this is comparable to the time it takes to sample a hypergeometric random variate. In the following, we show basic properties of $\mathsf{coll}(n, r)$ in order to show bounds on the runtime of BATCHED.

▶ **Lemma 4.** *Let $\ell \sim \mathsf{coll}(n, r)$. Then ℓ has support $\{1, \ldots, n - r\}$ and distribution* $\Pr[\ell = k] = n^{-(k+1)}(n - r)!(r + k)/(n - r - k)!$.

Proof. Consider an urn with n marbles. Initially, r marbles are red, while the remaining $n - r$ marbles are green. We now take out one marble at a time: if it is green, we keep on going (think of a traffic light) and put a red one back in. If we take a red marble, we stop. Observe that the number of marbles we take out is exactly ℓ as above, as the green marbles represent new unconsidered agents while the red ones represent agents in $A_{\ell-1}$.
This directly leads to the acclaimed distribution:

$$\Pr[\ell = k] = \underbrace{\prod_{i=0}^{k-1} \frac{(n-r)-i}{n}}_{\text{select } k \text{ out of } n-r} \cdot \underbrace{\frac{r+k}{n}}_{(k+1)\text{-th is red}}$$

◀

▶ **Lemma 5.** *Let $\ell \sim \mathsf{coll}(n, 0)$. Then $\mathbb{E}[\ell] = \Theta(\sqrt{n})$.*

Proof. We first upper bound $\mathbb{E}[\ell] = \mathrm{O}(\sqrt{n})$ and then give a matching lower bound $\mathbb{E}[\ell] = \Omega(\sqrt{n})$. In both cases, we write $\mathbb{E}[\ell] = \sum_{i=0}^{n} \Pr[\ell \geq i]$ and split the sum at $\sqrt{n}$. Then we bound both terms appropriately. Observe that for some fixed value i we have $\Pr[\ell \geq i] = \prod_{j=0}^{i-1}(1 - j/n)$. For the upper bound on $\mathbb{E}[\ell]$ we get

$$\mathbb{E}[\ell] = \sum_{i=0}^{n} \Pr[\ell \geq i] = \sum_{i=0}^{n} \prod_{j=0}^{i-1} \left(1 - \frac{j}{n}\right) \leq \sum_{i=0}^{\sqrt{n}-1} 1 + \sum_{i=\sqrt{n}}^{\infty} \left(1 - \frac{\sqrt{n}}{n}\right)^{i} \leq 2\sqrt{n}.$$

Similarly, we get for the lower bound on $\mathbb{E}[\ell]$ that

$$\begin{aligned}\mathbb{E}[\ell] &= \sum_{i=0}^{n} \Pr[\ell \geq i] = \sum_{i=0}^{n} \prod_{j=0}^{i-1} \left(1 - \frac{j}{n}\right) \geq \sum_{i=0}^{\sqrt{n}} \prod_{j=0}^{i-1} \left(1 - \frac{\sqrt{n}}{n}\right) = \sum_{i=0}^{\sqrt{n}} \left(1 - \frac{1}{\sqrt{n}}\right)^{i} \\ &= \sqrt{n}\left(1 - \left(1 - \frac{1}{\sqrt{n}}\right)^{\sqrt{n}+1}\right) \geq \sqrt{n}\left(1 - e^{-1}\right).\end{aligned}$$

Therefore we have $\mathbb{E}[\ell] = \Theta(\sqrt{n})$. ◀

Using Lemma 5, we are now ready to bound the runtime and space complexity of Batched.

▶ **Theorem 6.** *Let n be the number of agents and $|Q|$ the number of states. Batched simulates N interactions in $\mathrm{O}(N(|Q|^2 + \log n)/\sqrt{n})$ expected time using $\Theta(|Q| \log n)$ bits.*

Proof. According to Lemma 5, each batch simulates $\Theta(\sqrt{n})$ interactions in expectation. It takes $\mathrm{O}(\log n)$ time to sample the length of a collision-free run ℓ (see Section 6.1) and $\mathrm{O}(|Q|^2)$ time (cf. [39]) to sample the interaction numbers and process the interactions for all pairs of states. This implies the runtime complexity. The space complexity follows immediately from the binary search tree used to store the configuration. ◀

5 Merging Batches

In an empirical evaluation, we found that our implementation of algorithm Batched spends most time in the batch processing step (to sample and transition the $|Q| \times |Q|$ matrix D); this is especially true for complex protocols with non-trivial state space sizes. As the matrix sampling cost is independent of the length ℓ of the underlying collision-free run, we modify the algorithm to support more than one collision per batch processing step.

Introducing Epochs. An execution of the improved algorithm MultiBatched logically consists of several epochs. For each epoch, the algorithm samples the *lengths* $\ell_1, \ell_2, \ldots, \ell_\rho$ of multiple collision-free runs $R_1, \ldots, R_\rho$. As no agent may appear twice in the union of those collision-free sequences, later runs become shorter in expectation ($\mathbb{E}[\ell_{i+1}] < \mathbb{E}[\ell_i]$), naturally limiting the number ρ of runs per epoch. After each run R_i, we plant one collision, i.e., an interaction with an agent that was already considered in the current epoch. An epoch concludes with a single batch processing step, in which matrix D is sampled and processed analogously to algorithm Batched.

Tracking Dependencies. While algorithm Batched only reorders and groups together independent interactions, our improved algorithm MultiBatched delays most interactions until the end of the epoch. To do so, the algorithm conceptually assigns each agent one of three types, and updates these labels as it progresses through the epoch:

- untouched agents did not interact in the current epoch. Hence, all agents are labeled untouched at the beginning of an epoch.
- updated agents took part in at least one interaction that was already evaluated. Thus, updated agents are already assigned their most recent state.
- delayed agents took part in *exactly one* interaction that was not yet evaluated. Thus, delayed agents are still in the same state they had at the beginning of the epoch, but are scheduled to interact at a later point in time. We additionally require that their interaction partner is also labeled delayed.

Analogously to algorithm Batched, we maintain two urns C and C'. Urn C' contains updated agents, while urn C stores untouched and delayed agents (or in other words, all agents whose state was not updated in the current epoch). At any point in time, an agent is either in C or C' meaning that $|C| + |C'| = n$. Due to symmetry, we do not explicitly differentiate untouched from delayed agents. We rather maintain only the number T of delayed agents and lazily select them while planting collisions or during batch processing.

If a delayed agent a is selected while planting a collision, it takes part in a second interaction and – by definition – cannot be labeled delayed any more. Thus, we randomly draw a second delayed agent b, evaluate their transition, store the updated state of b in C', and directly evaluate a again in the planted collision. Finally, we decrease $T \leftarrow T - 2$ as agents a and b changed their labels from delayed to updated. Observe that we might repeat this step in the (unlikely) case that a planted collision involved two formerly delayed agents.

Length of an Epoch. We now analyze the length of an epoch. We start by extending the analysis of $\mathsf{coll}(n, r)$ to the $r = \Omega(\sqrt{n})$ regime (reached after $\mathrm{O}(1)$ runs w.h.p.). The following lemmas establish expected value and concentration.

▶ **Lemma 7.** *Let $\ell \sim \mathsf{coll}(n, r)$ and $r = \Omega(\sqrt{n})$. Then $\mathbb{E}[\ell] = \Theta(n/r)$.*

Proof. The proof follows analogously to Lemma 5. Again, we start with the upper bound.

$$\mathbb{E}[\ell] = \sum_{i=0}^{n-r} \Pr[\ell \geq i] = \sum_{i=0}^{n-r} \prod_{j=0}^{i-1} \left(1 - \frac{j+r}{n}\right) \leq \sum_{i=0}^{\infty} \left(1 - \frac{r}{n}\right)^i = \frac{n}{r}.$$

For the lower bound we derive a general result for arbitrary r.

$$\begin{aligned}\mathbb{E}[\ell] &= \sum_{i=0}^{n-r} \Pr[\ell \geq i] = \sum_{i=0}^{n-r} \prod_{j=0}^{i-1} \left(1 - \frac{j+r}{n}\right) \geq \sum_{i=0}^{r-1} \prod_{j=0}^{i-1} \left(1 - \frac{j+r}{n}\right) \geq \sum_{i=0}^{r-1} \left(1 - \frac{2r}{n}\right)^i \\ &= \frac{n}{2r}\left(1 - \left(1 - \frac{2r}{n}\right)^r\right) \geq \frac{n}{2r}(1 - e^{-2r^2/n}).\end{aligned}$$

The last inequality holds since $e^{-2r^2/n}$ constitutes an upper bound on $(1 - 2r/n)^r$ as it can be rewritten as $(1 - 2r/n)^{n \cdot r/n}$ and $(1 - 2r/n)^n \leq e^{-2r}$. For $r = \Omega(\sqrt{n})$ the second factor $(1 - \exp(-2r^2/n))$ is $\Omega(1)$ which proves the claim. ◀

▶ **Lemma 8.** *Let $\ell \sim \mathsf{coll}(n, r)$ and $r = \Omega(\sqrt{n})$. Then $\ell = \Theta(n/r)$ with probability $1 - o(1)$.*

Proof. We prove the claim by showing that $\Pr[\ell < t]$ and $\Pr[\ell > t]$ are $o(1)$ for $t = o(n/r)$ and $t = \omega(n/r)$, respectively. We have

$$\Pr[\ell < t] = 1 - \Pr[\ell \geq t] = 1 - \prod_{i=0}^{t-1}\left(1 - \frac{i+r}{n}\right) \leq 1 - \left(1 - \sum_{i=0}^{t-1}\frac{i+r}{n}\right) \leq \frac{2tr + t^2}{2n},$$

where the first inequality follows from the Weierstrass product inequality. Furthermore, with $r = \Omega(\sqrt{n})$ we have $n/r = O(\sqrt{n})$ and thus $t = o(n/r)$ such that $t^2 = o(n)$ and $tr = o(n)$. For the second part, we have

$$\Pr[\ell > t] = \prod_{i=0}^{t}\left(1 - \frac{i+r}{n}\right) \leq \left(1 - \frac{r}{n}\right)^t \leq e^{-rt/n},$$

and for $t = \omega(n/r)$ and thus $rt/n = \omega(1)$ the claim follows. ◀

Intuitively, Lemma 7 shows that for sufficiently many prescribed agents r, the probability of drawing a colliding agent remains approximately r/n throughout the run. Similar to a geometric distribution, this results in a concentrated expected length of $\Theta(n/r)$. We now estimate the number of agents sampled after ρ runs.

▶ **Lemma 9.** *Let $L_k = \sum_{i=1}^{k} \ell_i$ be the number of agents drawn in an epoch with k runs. Then, for $|Q| = \omega(\sqrt{\log n})$, $|Q| = o(\sqrt{n \log n})$ and $\rho = \mathrm{O}(|Q|^2/\log n)$ we have $\mathbb{E}[L_\rho] = \Theta(\sqrt{\rho n})$.*

Proof. The variable L_k equivalently corresponds to the number of marbles $B(k, n)$ that need to be drawn in the birthday problem s.t. k coincidences occur. The asymptotics of $\mathbb{E}[B(k, n)]$ have first been studied by Kuhn and Struik [32] for the cases that $k = o(n^{1/4})$. Their results have since been improved by Arratia et al. [11] where the asymptotic bounds on the moments of $B(k, n)$ have been calculated for more general conditions on k. By [11, Corollary 12] for k a function of n, i.e., $k = k_n$ where $k_n \to \infty$ and $k_n/n \to 0$ it holds that

$$\mathbb{E}[B(k_n, n)] \sim \sqrt{2nk_n} \quad \text{as } n \to \infty.$$

By assumption the conditions are met since $\rho = \omega(1)$ and $\rho = o(n)$, thus $\mathbb{E}[L_\rho] = \Theta(|Q|\sqrt{n/\log n}) = \Theta(\sqrt{\rho n})$. ◀

Complexity. In order to analyze MultiBatched's runtime, we first establish the time required per epoch, and then bound the total expected runtime and memory requirements.

▶ **Lemma 10.** *MultiBatched takes time $\mathrm{O}(\rho \log n + |Q|^2)$ for an epoch of ρ runs.*

Proof. Planting a collision is done by drawing the two interacting agents from the appropriate urns and setting them to be updated which requires $\mathrm{O}(1)$ time. Sampling the length of a single collision-free run takes time $\mathrm{O}(\log n)$ (see Section 6.1). For the final batch-processing step MultiBatched takes $\Theta(|Q|^2)$ time independently of the number of delayed agents. ◀

▶ **Theorem 11.** *Let n be the number of agents and $|Q|$ the number of states. MultiBatched simulates N interactions in $\mathrm{O}(N|Q|/\sqrt{n/\log n})$ expected time if $|Q| = \omega(\sqrt{\log n})$ and $|Q| = \mathrm{o}(\sqrt{n \log n})$.*

Proof. Combining Lemmas 9 and 10, we find a runtime of $\mathrm{O}(N(\rho \log n + |Q|^2)/\sqrt{\rho n})$. Setting $\rho = \Theta(|Q|^2/\log n)$ balances the cost of sampling runs and planting collisions with the cost of batch processing, and thus does not increase the asymptotic cost per epoch. Higher values of ρ only increase the expected time complexity. ◀

MultiBatched has sub-constant work per interaction for $|Q| = \mathrm{o}\left(\sqrt{\frac{n}{\log n}}\right)$ and $N = \Theta(\mathrm{poly}\, n)$.

6 Heuristics and Implementation Details

Implementations of all discussed simulators (including scripts to reproduce figures and numbers included in this paper) are freely available. In the following, we highlight important aspects necessary to obtain simulators that are both fast in practice and highly customizable.

All simulators are implemented in C++ and use compile-time specializations to implement specific protocols and experimental setups.

In contrast to pure deterministic functions, non-deterministic transition functions (possibly with side-effects) have to be informed about every interaction carried out.[2] To allow for batch processing, we cannot use the natural invocation order. Instead, we inform the protocol how often a state pair will interact within an epoch. It is then expected to assign all participating agents to the appropriate states. See the full version of this paper [17] for more details and listings.

6.1 Sampling the Length of a Collision-Free Run

Recall that Batched and MultiBatched repeatedly sample the length ℓ of a collision-free run. In the following we discuss how this sampling can be implemented using the inverse sampling technique (Ist) [23]: let $\mathrm{cdf}(x)$ be the cumulative density function of a target distribution. Then, Ist draws a uniform variate U from $[0;1]$, solves $U = \mathrm{cdf}(x)$ for x, and returns it as the sample. We denote the CDF of $\mathsf{coll}(n,k)$ as $F_{n,k}(t)$. Lemma 4 yields:

$$1 - F_{n,k}(t) = \Pr[\ell > t] = \prod_{i}^{t} \frac{n-k-i}{n} = \frac{1}{n^t} \frac{(n-k)!}{(n-k-t-1)!} \overset{(x-1)!=\Gamma(x)}{=} n^{-t} \frac{\Gamma(n-k+1)}{\Gamma(n-k-t)}.$$

Since we are not aware of an inverse that can be evaluated fast, we numerically solve $U = F_{n,k}(t)$ for t. To avoid numerical instabilities, we rewrite the expression in terms of $\log\Gamma(x)$, which is available as the C standard function `lgamma`(x):

$$U = 1 - n^{-t} \frac{\Gamma(n-k+1)}{\Gamma(n-k-t)} \quad \Leftrightarrow \quad \log(1-U) = \log\Gamma(n-k+1) - \log\Gamma(n-k-t) - t\log n$$

Lacking a cheap derivative of the RHS, we rely on first-order numerical inversion methods only. In this context, an ad-hoc combination of binary search and regula-falsi gave most consistent results. We jump-start the search using a small look-up table containing lower and upper bounds on t for intervals of U and k.

While the method requires $\mathrm{O}(\log n)$ evaluations of $F_{n,k}(\cdot)$, we observe less than ten calls on average for $n = 2^{50}$. The resulting sampling algorithm has a practical runtime comparable to the sampling of hypergeometric random variates. Since the latter is sampled much more frequently, further optimizations will yield limited results to the total runtimes of Batched and MultiBatched.

6.2 Heuristics

The frequent sampling of hypergeometric random variates, dominates MultiBatched's runtime. In the following, we discuss three heuristics to reduce this number.

[2] Observe that many protocols with non-deterministic transition functions have been derandomized, see, e.g., the notion of (biased) synthetic coins in [1, 18]. While this is supported by the simulator, we feel it is more convenient to offer the most expressive interface possible.

	0	1	2	3
0	0	1	0	0
1	1	1	2	1
2	2	2	2	3
3	0	3	3	3

Figure 3 Simplified transition matrix Δ' for a clock with period m=4. The initiator's phase (row) is circularly incremented only when matched with a suitable responder (column).

Renaming. In the *renaming heuristic* we exploit the observation that agents are typically not uniformly distributed over all states. Instead there are often sparsely populated states which are seldom hit when sampling an agent.

It can be beneficial to consider these states last. SEQ$_{\mathsf{Linear}}$'s linear search, for instance, stops as soon as the sampled state is found. The same is true when sampling BATCHED's and MULTIBATCHED's interaction matrices: for row i, we draw D_i agents from a multivariate hypergeometric distribution. This is implemented by obtaining $|Q|-1$ properly parametrized hypergeometric variates; the process terminates early once all D_i agents have been sampled.

In both examples, we maximize the probability of early stopping by considering highly populated states first. To this end, we maintain a permutation $\pi\colon [|Q|] \to [|Q|]$ that sorts states decreasingly by their sizes. We then process states in the order indicated by π. If this permutation is updated once every $\Omega(|Q| \log |Q|)$ interactions, the sorting step becomes asymptotically negligible for sequential simulators. For BATCHED and MULTIBATCHED, π can be updated once every $\Omega(\log q)$ batches.

Partitioning. If δ is a deterministic function, we can model it as a matrix $\Delta \in (Q \times Q)^{|Q|\times|Q|}$. The matrix of a deterministic one-way protocol can be further simplified to $\Delta' \in Q^{|Q|\times|Q|}$ since the states of the responders remain unchanged.

For many meaningful protocols, the entries of Δ' are not random but exhibit some structure. As an example, consider the simplified[3] phase-clock transition matrix illustrated in Figure 3. Here, each row contains only two different output states. The *partitioning heuristic* uses this observation during the batch steps of BATCHED and MULTIBATCHED. When sampling D_i responders for initiators in state q_i, we group together all entries in the i-th row of Δ' that assign the same new state to the initiating agents. It then suffices to draw one random hypergeometric variate per group.

Note that the heuristic does not reduce the runtime complexity of the algorithm – even if we precompute the partitioning. This is due the fact that we still need to compute the population sizes for each group which involves $\Theta(|Q|)$ additions per row. For pathological protocols, the number of hypergeometric random variates required for each row remains $\Omega(|Q|)$. A simple worst-case protocol is the transition function $\delta(q_u, q_v) = (q_v, q_v)$.

Skipping. Generalizing *partitioning heuristic* to two-way protocols tends to be ineffective in practice: since initiator and responder may both update their states, the transition matrix is often more fragmented. The partitioning overhead then easily exceeds the potential savings. For such protocols MULTIBATCHED uses a coarser partitioning, and only detects and skips transitions that preserve the configuration (i.e., $\delta(q_u, q_v) = (q_u, q_v)$ or $\delta(q_u, q_v) = (q_v, q_u)$).

[3] Formally the states of the phase-clock are pairs (x, b) where x represents the *phase*, and b marks an agent as *leader*. For the sake of simplicity we assume that all agents are followers.

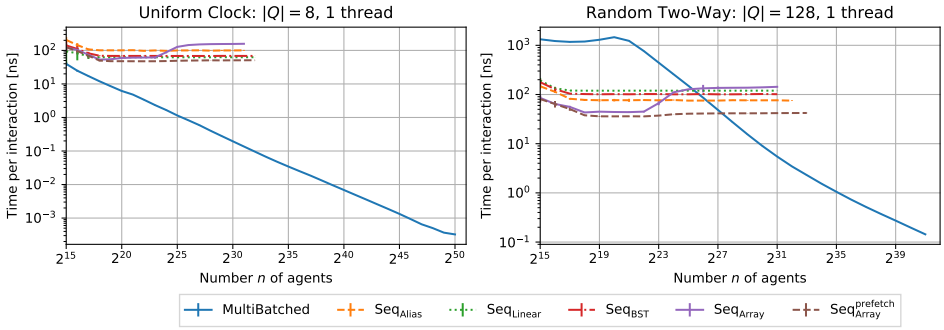

Figure 4 Processing time per interaction as function of the number of agents n. Each series ends with the largest value n for which the median of the total processing time is below 400 s.

6.3 Dynamic Epoch Lengths

Recall that MultiBatched is split into several epochs that each consist of multiple collision-free runs. In our implementation, we add runs to an epoch until the number of interactions exceeds a specified threshold T. The value of T has to be chosen as a trade-off between the cost of adding another run (i.e., sampling the run length and planting a collision) versus the diminishing return it yields (as later runs become shorter in expectation). This trade-off depends on the protocol and its configuration. For instance, the batch processing cost of a convergent protocol may become smaller compared to the initial costs (e.g., when most agents are in only a small fraction of the states).

As the trade-off is dynamic, we maximize the throughput using a control loop that dynamically optimizes the length of an epoch. Given the currently best value known for T, it increases (and later decreases) T to $1.1T$ and $0.9T$, respectively. For each of the three values, we measure the throughput, chose the T which maximizes it and repeat. Since the throughput response curve is single-peaked, the process will find a nearly optimal T.

7 Experimental Evaluation

In the following, we empirically evaluate the various simulation algorithms. The code is compiled using `g++-8.3` with flags `-O3 -march=native` and executed on the following system: 2× Intel Xeon Gold 6148 CPU @ 2.4 GHz (40 cores/80 hardware threads in total), 192 GiB DDR4 RAM @ 2666 MHz. Each data point is the median of at least five measurements (using different random seeds); error bars indicate their standard deviation.

Seq_{BST}'s search tree is implemented as an array with breath-first-indexing (i.e., the weight of node $i \geq 1$ is stored at $A[i]$; its left child is at index $2i$, its right child at $2i+1$). In order to reduce pipeline stalls, we implement a branch-free traversal similarly to [37]. $\text{Seq}_{\text{Array}}$ uses an array with 32 bit words to store states. We additionally consider $\text{Seq}_{\text{Array}}^{\text{prefetch}}$ which prefetches states for eight[4] interactions ahead of time as a latency hiding technique. If our Dynamic Alias Table implementation detects an imbalance necessitating rebuilding of the data structure, it will first attempt to quickly solve the problem by swapping the alias of the affected row with up to five randomly selected partners; only if this fails a rebuild is issued. This heuristic does not change the asymptotic time complexity of the data structure.

[4] This is the optimal value measured for this CPU type and slightly varies between machines.

The runtime of most simulators has non-trivial dependencies on the input parameters, protocol, and state distribution. Hence, we simulate a small number $N = n$ of interactions to prevent measuring artifacts caused by significant changes in the state distributions. MultiBatched typically simulates slightly more interactions due to the batching granularity. Since the runtime of all simulators is linear in N, we always report the time *per interaction* to ease extrapolation.

Three different protocols are used to highlight certain aspects of the algorithms.

- *Uniform Clock* and *Running Clock* implement the same deterministic one-way protocol phase-clock protocol inspired by [28]. In the *running* variant, all agents start in the first phase, and $\sqrt{n}$ of them are marked. Due to the choice of parameters, we expect only one out of $\Theta(\sqrt{n})$ interactions to change states. Thus, even at the end of the benchmark, the population is still highly concentrated in the lowest phase. The *uniform* variant, in contrast, evenly distributes marked and unmarked agents over all phases. This results in a constant update probability per interaction.
- The *Random Two-Way* protocol uses a deterministic transition function $\delta(q_i, q_j) = d_{ij}$ where each d_{ij} is initially drawn independently and uniformly at random from Q. Initially agents are evenly distributed over all states.

To ensure the correctness of our implementations, we rely on unit tests (e.g., using a family of protocols that count the number of interactions of each agent). Additionally, we cross-reference the results of various algorithms. Since we cannot expect two simulators to yield the same set of interactions, we compare their simulated dynamics. We, for instance, monitor the number of interactions required until a Uniform Clock starts running.

Number of Agents. We begin our experimental study by investigating the dependencies on the problem size n. To this end, we search for the largest number n of agents that a simulator can simulate within a fixed time budget of 400 s. Figure 4 reports such measurements for two different settings (see the full version of this paper [17] for the full set).

For the *Uniform Clock* protocol with $|Q| = 8$ states, the fastest Seq variant reaches $n = 2^{32}$ within the time budget. In the same time, MultiBatched simulates $N = n = 2^{50}$ interactions. For *Random Two-Way*, the ratio between the achievable population sizes is smaller but still exceeds three orders of magnitude. We attribute the different ratios mainly to the batching step. MultiBatched requires $\Theta(|Q|^2)$ hypergeometric variates per batching step for the latter protocol, since neither the partitioning nor the skipping heuristics (see Section 6) are effective on a featureless transition matrix with uniformly random states. For the *Uniform Clock* protocol, the partitioning heuristic reduces the number of hypergeometric random variates to less than $2|Q|$ per batch.

Number of States. As summarized in Table 1, the number $|Q|$ of states crucially affects the algorithms' runtimes. To quantify the practical impact, we carry out scaling experiments for $4 \leq |Q| \leq 128$ while fixing all remaining parameters. Figure 5 visualizes the results.

MultiBatched performs best in all cases supporting our previous analysis. It shows almost no scaling behavior for both clock protocols. For *Random Two-Way*, the algorithm is almost one order of magnitude faster than its competitors despite a slow-down of 40 between the smallest and largest state sizes.

$\text{Seq}^{\mathsf{prefetch}}_{\mathsf{Array}}$ is the second fastest solution in almost all settings. In the *Running Clock* campaign, it is however outperformed by $\text{Seq}_{\mathsf{Linear}}$. This can be explained by the fact that initially almost all agents are in state 0 which results in a constant time look-up despite the usage of a linear search. This behavior motivates the renaming heuristic.

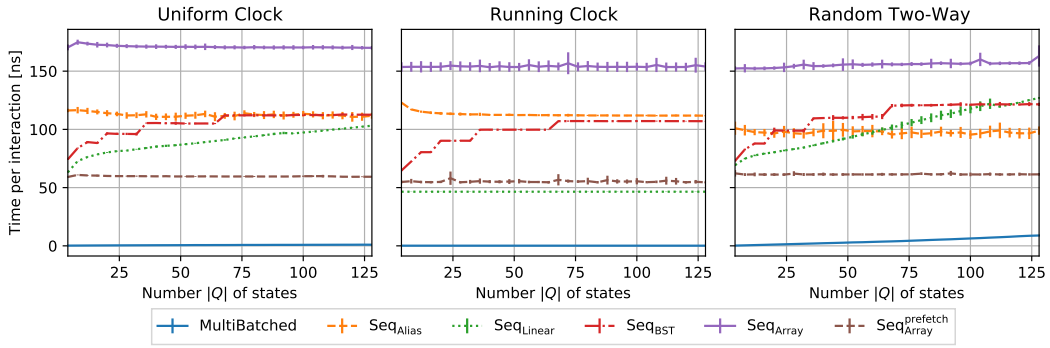

Figure 5 Processing time per interaction as function of the number of states $|Q|$ with $n = 2^{30}$.

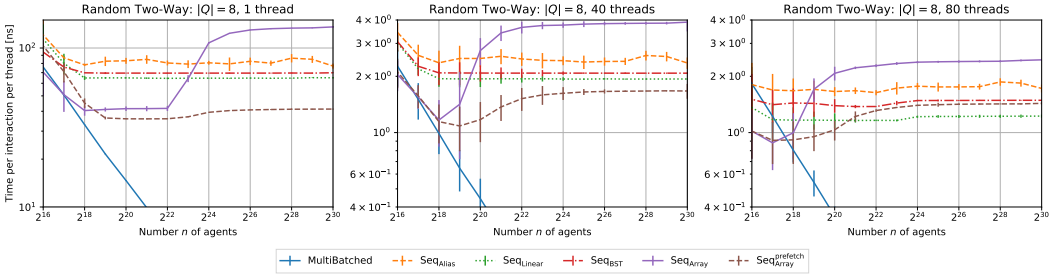

Figure 6 Effect of process parallelism on a machine with 40 CPU cores (plus HyperThreading).

We observe no systematic dependency on $|Q|$ for $\textsc{Seq}_{\textsf{Alias}}$ rendering it a good choice for very large state spaces. While it is up to a factor of 2.0 slower compared to $\textsc{Seq}^{\textsf{prefetch}}_{\textsf{Array}}$, the algorithm might be preferable in a parallel setting.

Memory Footprint and Parallelism. Due to the stochastic nature of the protocols, we expect that in almost all applications several runs of the same protocol are required to derive statistically significant results. On modern machines with many processor cores, one should be able to maximize the throughput by executing multiple independent simulations in parallel. As visualized in Figure 6, most simulators scale well with the number of threads and typically achieve a self-speedup of 40 to 50 times using 40 cores (plus HyperThreading) at $n = 2^{30}$. A notable exception is $\textsc{Seq}^{\textsf{prefetch}}_{\textsf{Array}}$, which reaches only a speedup of 30 as it saturates the memory controllers of both CPU sockets.

Another aspect of parallel execution is the memory footprint. Since $\textsc{Seq}_{\textsf{Array}}$ requires constant memory per agent, our implementations of $\textsc{Seq}_{\textsf{Array}}$ and $\textsc{Seq}^{\textsf{prefetch}}_{\textsf{Array}}$ allocate in excess of 320 GB main memory to execute 80 processes in parallel. Although, this number can be reduced by constant factors using a more efficient representation of states, it has to be contrasted to the competing algorithms with a state space of only a few kilobytes[5] for the same campaign.

[5] We report no exact numbers as the system's process overheads exceed the simulators' internal states.

8 Conclusions and Open Problems

We considered the simulation of large population protocols to allow the experimental investigation of slowly scaling observables in such systems. Two algorithm classes are discussed.

Sequential simulators carry out each interaction one after the other. We analyze the variants $\text{SEQ}_{\mathsf{Array}}$, $\text{SEQ}_{\mathsf{Linear}}$, $\text{SEQ}_{\mathsf{BST}}$, and $\text{SEQ}_{\mathsf{Alias}}$ which differ in the data structures maintaining the agents' states, and demonstrate substantial differences in their practical performances. As a by-product, we describe the Dynamic Alias Table which might be independently applicable.

Batched simulators coalesce interactions to achieve asymptotical speed-ups for protocols with a limited number of states. Our implementation then simulates more than 2^{50} interactions in 400 s which is several orders of magnitudes larger than the fastest sequential simulator.

Possible Extensions. In some variants of the population model it is assumed that interactions are limited to some communication network. Since we store the configurations in our batched simulators as a multiset, it is not clear how to directly adapt our approach. We believe this might be an interesting extension of our work.

Further variants are concerned with the way how agents interact. It is straightforward to adapt our simulator software to a setting where, e.g., a random matching of agents interacts in each time step. Furthermore, our approach could be generalized to a setting where more than two agents interact. In this case we are in need of good heuristics for partitioning the transition-tensor, since the work for updating a batch grows exponentially in the number of interacting agents. In general, sampling the interaction counters is a frequent and costly task. Therefore, any improved heuristic to sample from the $|Q| \times |Q|$ matrix using only $o(|Q|^2)$ variates would yield a measureable benefit for the total runtime of a simulation.

Abstract

Consider the following simple coloring algorithm for a graph on n vertices. Each vertex chooses a color from $\{1, \ldots, \Delta(G) + 1\}$ uniformly at random. While there exists a conflicted vertex choose one such vertex uniformly at random and recolor it with a randomly chosen color. This algorithm was introduced by Bhartia et al. [MOBIHOC'16] for channel selection in WIFI-networks. We show that this algorithm always converges to a proper coloring in expected $O(n \log \Delta)$ steps, which is optimal and proves a conjecture of Chakrabarty and de Supinski [SOSA'20].

1 Introduction

It is well known that an undirected graph $G = (V, E)$ with maximum degree $\Delta = \Delta(G)$ can be properly colored by using $\Delta + 1$ colors. In fact, a simple greedy algorithm which assigns the colors successively achieves this bound by just touching each vertex once. Note that the bound $\Delta + 1$ is tight, as cliques and odd cycles require this number of colors.

In [1] Bhartia et al. introduced the use of a simple decentralized coloring algorithm as an efficient solution to the channel selection problem in wireless networks. Their algorithm can be formulated as follows.

Decentralized Graph Coloring

For a graph $G = (V, E)$

1. choose for each vertex $v \in V$ a color from $\{1, \ldots, \Delta + 1\}$ independently and uniformly at random;
2. choose a vertex $v \in V$ uniformly at random among all vertices which have a neighbor in the same color;
3. recolor v into a color chosen from $\{1, \ldots, \Delta + 1\}$ uniformly at random;
4. repeat steps 2 and 3 until a proper coloring of G is found.

They showed that this algorithm finds a proper coloring in $O(n\Delta)$ rounds in expectation. Chakrabarty and de Supinski [2] introduced a variant of the coloring algorithm: instead of recoloring a vertex v once as above, in their "Persistent Decentralized Coloring Algorithm" such a vertex v persistently (hence the name) gets recolored until it has no neighbor in the same color. They showed that this modified algorithm only requires $O(n \log \Delta)$ recolorings and conjectured that the same bound also holds for the original algorithm. In this paper we prove their conjecture.

▶ **Theorem 1.1.** *The decentralized coloring algorithm converges in expectation to a proper* $(\Delta + 1)$*-coloring in* $O(n \log \Delta)$ *recoloring steps.*

In fact, our argument shows that the same runtime bound holds true if the initial coloring is chosen adversarially. This is in contrast with the persistent version of the algorithm mentioned above, as that one takes $\Theta(n\Delta)$ recolorings in expectation when starting with an adversarial coloring (see [1, Theorem 3]). However, the question raised in [2] of 'which algorithm is faster in the random setting' remains open.

We note that the bound in Theorem 1.1 is best possible, as for the complete graph K_n the decentralized coloring algorithm essentially performs a *Coupon Collector* process. Indeed, once a color (coupon) has been acquired it remains in the graph until the end of the process and we need to see all colors. The claim thus follows from the well known fact that in expectation the coupon collector process with n coupons requires $nH_n = \Theta(n \log n)$ rounds, where $H_k = \sum_{i=1}^{k} \frac{1}{i}$ is the k-th Harmonic number. Moreover, the result is tight for every combination of n and Δ. Namely, consider a vertex-disjoint union of n/Δ complete graphs K_Δ and by the same argument the process requires $\Theta(n/\Delta \cdot \Delta \log \Delta) = \Theta(n \log \Delta)$ rounds.

Our proof of Theorem 1.1 is short and elegant, and is based on *drift analysis* [8]. It is presented in an expository way and provides insight in why our potential function is appropriate for the analysis. We complement the analyis by tail bounds in Section 3.

Finally, we conclude the paper by a brief discussion of the parallelized version of this algorithm, where all "conflicted" vertices get recolored simultaneously (instead of Step 3), and we prove that this variant takes exponential time.

2 Proof of Theorem 1.1

We start with introducing some notation. We use c_t to denote the coloring of the graph after t recoloring steps, that is c_t is a function $c_t \colon V(G) \to \{1, \ldots, \Delta + 1\}$. With $M_t \subseteq E$ we denote the set of *monochromatic edges* in c_t. Observe that c_t is a proper coloring of G if and only if $|M_t| = 0$. Our main goal is thus to establish good bounds on (the reduction of) the size of the sets M_t. In order to do so it is helpful to view the recoloring step(s) (i.e. Step 2 and Step 3) as a (slightly different) three step process:

Recoloring Step

For every $t \geqslant 1$,

- **S1** choose a monochromatic connected component $C \subseteq M_{t-1}$ at random proportional to the number of vertices in C;
- **S2** choose a vertex $v \in V(C)$ uniformly at random;
- **S3** let $c_t(v)$ be a uniformly at random chosen color from $\{1, \dots, \Delta + 1\}$ and set $c_t(u) = c_{t-1}(u)$ for all $u \neq v$.

As a main tool in bounding the expected number of recoloring steps we use a so-called drift theorem (see [8, Theorem 2.3.1]).

▶ **Theorem 2.1** (Additive Drift Theorem [6]). *Let $(X_t)_{t \geqslant 0}$ be a sequence of non-negative random variables with a finite state space $\mathcal{S} \subset \mathbb{R}_0^+$ such that $0 \in \mathcal{S}$. Let $T := \inf\{t \geqslant 0 \mid X_t = 0\}$. If there exists $\delta > 0$ such that for all $s \in \mathcal{S} \setminus \{0\}$ and for all $t > 0$,*

$$\mathbb{E}[X_t - X_{t-1} \mid X_t = s] \leqslant -\delta, \tag{1}$$

then

$$\mathbb{E}[T] \leqslant \mathbb{E}[X_0] \,/\, \delta.$$

By *drift* we refer to the expectation $\mathbb{E}[X_t - X_{t-1} \mid X_t = s]$. (For a more extensive introduction to drift analyis, we refer the reader to [8].) Our goal is to apply Theorem 2.1 by assigning to each coloring c_t a real value $\Phi(t)$ (which we plug in for X_t) so that $\Phi(t) = 0$ if and only if c_t is a proper coloring. The *potential function* $\Phi(\cdot)$ we eventually use to prove Theorem 1.1 consists of several terms (see equation (3) below) and in order to motivate each of the terms we introduce them one by one. The simplest and most natural choice is to consider just the number of monochromatic edges, i.e. $\Phi(t) := |M_t|$. (Mind that this is only for explanatory purposes and will not be the final definition of Φ.) To apply Theorem 2.1 we need to estimate the drift from a single recoloring step. In the following claim (and in fact all similar ones in this section), the expectation is always taken with respect to a single recoloring step. That is, we (implicitly) condition on the coloring c_{t-1} without stating it every time. Note that this formulation implies what is required by equation (1).

As it turns out, in the case of $\Phi(t) := |M_t|$ we do not need to make use of the fact that the component C is chosen randomly, we may assume that the component C is given arbitrarily or even by an adversary.

▷ Claim 2.2. For all $t \geqslant 1$ and any connected component C in M_{t-1} we have

$$\mathbb{E}\left[|M_t| \,\middle|\, C\right] \leqslant |M_{t-1}| - \bar{d}(C) + 1 - \frac{1}{\Delta + 1},$$

where $\bar{d}(C)$ denotes the average degree of the graph induced by $V(C)$.

Proof. The claim follows easily from the following two observations. As v is chosen uniformly at random within C (as in Step 2), we decrease the number of monochromatic edges within C by $\bar{d}(C)$ whenever the newly chosen color is different from the current color of C, which happens with probability $\Delta/(\Delta + 1)$. All edges incident to v that do not belong to C become monochromatic with probability $1/(\Delta + 1)$. Thus we have

$$\mathbb{E}\left[|M_t| \,\middle|\, C\right] \leqslant |M_{t-1}| - \bar{d}(C) \cdot \frac{\Delta}{\Delta + 1} + \frac{\Delta - \bar{d}(C)}{\Delta + 1} = |M_{t-1}| - \bar{d}(C) + 1 - \frac{1}{\Delta + 1},$$

as claimed. ◁

As the average degree of every monochromatic component in M_t is at least one, Claim 2.2 implies $\mathbb{E}[|M_t|] \leqslant |M_{t-1}| - 1/(\Delta+1)$ whenever $|M_{t-1}| > 0$. The following proposition then easily follows from Theorem 2.1.

▶ **Proposition 2.3.** *Let $D > 0$ be any fixed constant. For every graph G and every coloring c_0 of G such that $|M_0| \leqslant Dn/\Delta$ the decentralized coloring algorithm reaches a proper $(\Delta+1)$-coloring in expectation after $O(n)$ recoloring steps.*

Unfortunately, a random coloring of a graph G with $\Delta + 1$ colors has in expectation $\Theta(n)$ monochromatic edges, so Proposition 2.3 is not immediately applicable. Instead, Claim 2.2 together with Theorem 2.1 only provide us with the bound of $O(n\Delta)$ (see Bhartia et al. [1]). In order to go beyond this, observe that Claim 2.2 actually gives a drift of $-1/3$ whenever $|V(C)| \geqslant 3$, as the average degree of a connected graph on $s \geqslant 3$ vertices is at least $4/3$. Thus, the only critical case are components C that consist of only one edge. To handle these we introduce some more notation.

We denote by $I_t \subseteq M_t$ the set of *isolated edges*, that is all edges which are monochromatic components of size two. We also let $P_t \subseteq V$ stand for the set of all properly colored vertices, i.e. the vertices that are not incident to any edge in M_t. Akin to Claim 2.2, the next claim gives a bound on the expected change in the number of isolated edges in one recoloring step.

▷ Claim 2.4. For all $t \geqslant 1$ and any connected component C in M_{t-1} we have

$$\mathbb{E}\left[|I_t| \;\middle|\; C\right] \leqslant |I_{t-1}| + \bar{d}(C) + 1.$$

For components C that form an isolated edge, we have in addition

$$\mathbb{E}\left[|I_t| \;\middle|\; C = uw\right] \leqslant |I_{t-1}| - \frac{\Delta}{\Delta+1} + \frac{|N(u) \cap P_{t-1}| + |N(w) \cap P_{t-1}|}{2(\Delta+1)}.$$

Proof. By recoloring a vertex v, the only isolated edges that can be created are edges that are incident to neighbors of v within C (at most one isolated edge per neighbor of v) and edges between v and P_{t-1} (naturally at most one edge incident to v can be isolated and monochromatic). This proves the first inequality. For the second assume that $C = uw$. Clearly, after recoloring one of u and w with a different color (which happens with probability $\Delta/(\Delta+1)$), the isolated edge $C = uw$ disappears. Observe, also that a new isolated edge can only be generated if we choose as a new color for u (or w) a color of a vertex in $N(u) \cap P_{t-1}$ (or $N(w) \cap P_{t-1}$) respectively. This, together with the fact that each of u or w is chosen in Step 2 with probability $1/2$, proves the second inequality. ◁

We pause for a moment from the proof of Theorem 1.1 to showcase the use of previous claims for proving a positive result about complete bipartite graphs.

▶ **Proposition 2.5.** *For complete bipartite graphs $G = K_{n,m}$ the decentralized coloring algorithm reaches a proper $(\Delta+1)$-coloring in expectation after $O(\min\{n,m\})$ recoloring steps.*

Proof. Observe that for complete bipartite graphs vertices of $P_{t-1} \cap A$ and $P_{t-1} \cap B$ need to be colored with *different* colors (here A and B denote the two parts of the bipartite graph). Also note that an isolated edge can only be generated if a color appears only once in $P_{t-1} \cap A$ (and $P_{t-1} \cap B$). Therefore, for a monochromatic edge uv we have $|N(u) \cap P_{t-1}| + |N(w) \cap P_{t-1}| \leqslant \Delta$. We can thus replace the bound in the second inequality of Claim 2.4 by

$$\mathbb{E}\left[|I_t| \;\middle|\; C = uw\right] \leqslant |I_{t-1}| - \frac{\Delta}{\Delta+1} + \frac{\Delta}{2(\Delta+1)} \leqslant |I_{t-1}| - \frac{\Delta}{2(\Delta+1)}. \tag{2}$$

Consider now the potential function $\Phi(t) := |M_t| + \frac{1}{10}|I_t|$. In case $|V(C)| \geqslant 3$, from Claim 2.2 and Claim 2.4, we get (with room to spare)

$$\begin{aligned}\mathbb{E}\left[\Phi(t) \mid C, |V(C)| \geqslant 3\right] &\leqslant |M_{t-1}| - \bar{d}(C) + 1 - \frac{1}{\Delta+1} + \frac{1}{10}|I_{t-1}| + \frac{1}{10}\bar{d}(C) + \frac{1}{10} \\ &\leqslant \Phi(t-1) - \frac{9}{10}\bar{d}(C) + \frac{11}{10} \leqslant \Phi(t-1) - \frac{1}{20},\end{aligned}$$

where we used the fact that $\bar{d}(C) \geqslant 4/3$. On the other hand, if $C = uw$ then by Claim 2.2 and (2) we have

$$\begin{aligned}\mathbb{E}\left[\Phi(t) \mid C = uw\right] &\leqslant |M_{t-1}| - \bar{d}(C) + 1 - \frac{1}{\Delta+1} + \frac{1}{10}|I_{t-1}| - \frac{1}{10}\frac{\Delta}{2(\Delta+1)} \\ &\leqslant \Phi(t-1) - \frac{1}{20}\Big(\frac{20}{\Delta+1} + \frac{\Delta}{\Delta+1}\Big) \leqslant \Phi(t-1) - \frac{1}{20}.\end{aligned}$$

In conclusion,

$$\mathbb{E}\left[\Phi(t) \mid C\right] \leqslant \Phi(t-1) - \frac{1}{20},$$

for every component C. The proposition now follows from Theorem 2.1 together with the fact that in a random x-coloring an edge is monochromatic with probability $1/x$ and thus

$$\mathbb{E}[\Phi(0)] \leqslant \mathbb{E}[|M_0|] + \mathbb{E}[|I_0|] \leqslant 2 \cdot \frac{n \cdot m}{\max\{n,m\}+1} \leqslant 4\min\{n,m\},$$

with room to spare. ◀

We note that this proof actually shows that the assertion of Proposition 2.5 remains true, for sufficiently small $\varepsilon > 0$, if we reduce the number of colors to be used by the algorithm to $(1-\varepsilon)\Delta$, that is $(1-\varepsilon)\max\{n,m\}$. We do not elaborate further on this.

After this short detour we come back to the proof of Theorem 1.1. What one could conclude from the two claims above is that if we were to choose a component C in Step 1 which is of size at least three throughout the process, then the drift obtained (Claim 2.2) would always be less than $-1/3$. However, this is far too optimistic to hope for.

Consider an isolated edge uv and assume we recolor v. If the new color chosen *does not* belong to its properly-colored neighborhood $N(v) \cap P_{t-1}$, then the number of monochromatic isolated edges decreases by one. This happens with constant probability unless the size of $N(v) \cap P_{t-1}$ is close to Δ.

Since in Step 1 we choose C *randomly*, we expect a strong drift "towards the target" as long as we are in one of the situations from the paragraphs above. In other words, we have a desired drift unless M_{t-1} comprises mostly of isolated edges *and* most vertices $u \in V(I_{t-1})$ have almost Δ neighbors in $N(u) \cap P_{t-1}$.

Let us hence analyze what happens if in such a case we recolor a vertex v belonging to an isolated edge uv. Suppose we set $c_t(v) := c_{t-1}(x)$ for some $x \in N(v) \cap P_{t-1}$. If the color $c_{t-1}(x)$ appears multiple times in $N(v) \cap P_{t-1}$, we do not create a new isolated edge. Otherwise, the edge xv becomes isolated and $P_t := (P_{t-1} \setminus \{x\}) \cup \{u\}$. However, crucially, as we assumed that every vertex $u \in V(I_{t-1})$ had roughly Δ neighbors in P_{t-1}, we conversely have that an average vertex in P_{t-1} has roughly $\Delta|V(I_{t-1})|/|P_{t-1}|$ neighbors in $V(I_{t-1})$. Thus, we may expect that $N(x) \cap P_t$ is *smaller* than Δ. In other words, we expect that $e(V(I_t), P_t)$ is smaller than $e(V(I_{t-1}), P_{t-1})$. Here and throughout we use $e(X,Y)$ to denote the number of edges between two disjoint vertex sets X and Y.

Previous considerations motivate keeping track of $e(V(I_t), P_t)$ as well and lead us to formulate the following potential function:

$$\Phi(t) := |M_t| + \frac{|I_t|}{10} + \frac{e(V(I_t), P_t)}{100\Delta}. \tag{3}$$

Note that the value of $\Phi(t)$ is always proportional to the number of monochromatic edges.

▷ Claim 2.6. For all $t \geqslant 1$ we have

$$|M_t| \leqslant \Phi(t) \leqslant 2|M_t|.$$

Proof. The first inequality is trivial. The second follows, with room to spare, as $I_t \subseteq M_t$ and $e(V(I_t), P_t) \leqslant 2|I_t| \cdot \Delta$. ◁

With Claim 2.6 at hand we deduce from Proposition 2.3 that in order to complete the proof of Theorem 1.1 it suffices to show that the algorithm reduces the potential Φ to a value of Dn/Δ in $O(n \log \Delta)$ steps, for some arbitrarily large but fixed constant $D > 0$. This is what we do in the remainder of this section.

Note also that there is no hope to always get a *constant* drift, as by Theorem 2.1 this would then lead to a bound of $O(n)$ recoloring steps, which would contradict the bound of $\Omega(n \log n)$ for K_n. Instead we show a *multiplicative* drift.

▷ Claim 2.7. For any $t \geqslant 1$ with $\Phi(t-1) > 0$, we have

$$\mathbb{E}[\Phi(t)] \leqslant \Phi(t-1)\Big(1 - \frac{1}{1000n}\Big).$$

Proof. By linearity of expectation we can consider each term of $\Phi(\cdot)$ in (3) independently. The first two terms are handled by Claim 2.2 and Claim 2.4, so we first establish some bounds on the third. Observe that in order for an edge to be counted in $e(V(I_t), P_t)$ but not in $e(V(I_{t-1}), P_{t-1})$ it must be incident to a vertex in either $V(I_t) \setminus V(I_{t-1})$ or $P_t \setminus P_{t-1}$. Let C be a component chosen in Step 1 and v a vertex chosen in Step 2. For any vertex in $\{v\} \cup (N(v) \cap V(C))$, we either get one new isolated edge or one new properly colored vertex (or neither). In the former, the other endpoint of that edge potentially contributes by Δ to $e(V(I_t), P_t)$, and in the latter each monochromatic edge with one endpoint in $N(v) \cap V(C)$ potentially contribute by Δ to $e(V(I_t), P_t)$ for each of its endpoints. Thus we have

$$\mathbb{E}[e(V(I_t), P_t) \mid C] \leqslant e(V(I_{t-1}), P_{t-1}) + (\bar{d}(C) + 1) \cdot 2\Delta,$$

where as before $\bar{d}(C)$ denotes the average degree of the component C. Together with Claim 2.2 and Claim 2.4, for all components C on at least three vertices we get

$$\begin{aligned} \mathbb{E}\left[\Phi(t) \mid C, |V(C)| \geqslant 3\right] &\leqslant \Phi(t-1) - \Big(1 - \frac{1}{10} - \frac{2}{100}\Big)\bar{d}(C) + 1 + \frac{1}{10} + \frac{2}{100} \\ &\leqslant \Phi(t-1) - \frac{1}{25}\bar{d}(C), \end{aligned} \tag{4}$$

where the last inequality follows from $\bar{d}(C) \geqslant 4/3$.

Next we consider the third term of $\Phi(\cdot)$ conditioned on choosing a component $C \subseteq I_{t-1}$, i.e. C is an isolated edge. We first let $d(v, X) := |N(v) \cap X|$ for all $v \in V$ and sets $X \subseteq V$ and denote by

$$\bar{d}_{IP} := \frac{1}{|V(I_{t-1})|} \sum_{u \in V(I_{t-1})} d(u, P_{t-1}) \qquad \text{and} \qquad \bar{d}_{PI} := \frac{1}{|P_{t-1}|} \sum_{u \in P_{t-1}} d(u, V(I_{t-1}))$$

the average degree of vertices in $V(I_{t-1})$ into P_{t-1}, and the average degree of vertices in P_{t-1} into $V(I_{t-1})$, respectively. Note that, of course, we have $\sum_{u\in V(I_{t-1})} d(u,P_{t-1}) = \sum_{u\in P_{t-1}} d(u,V(I_{t-1}))$, and hence $\bar{d}_{IP}|V(I_{t-1})| = \bar{d}_{PI}|P_{t-1}|$.

Consider an isolated edge wv and assume v gets recolored with a new color. Then, since w is now properly colored, all $d(w,P_{t-1})$ edges incident to w which contributed to $e(V(I_{t-1}),P_{t-1})$ are not counted in $e(V(I_t),P_t)$, except possibly one in case v forms a new isolated edge with a neighbor of w. Moreover, any new edge counted in $e(V(I_t),P_t)$ must be incident to either v, w, or a vertex $x \in P_{t-1}$ for which $vx \in I_t$. There are at most $\Delta - d(v,P_{t-1})$, $\Delta - d(w,P_{t-1})$, and $\Delta - d(x,V(I_{t-1}))$ such edges respectively not already counted in $e(V(I_{t-1}),P_{t-1})$. Combining all this we get

$$\begin{aligned} e(V(I_t),P_t) \leqslant e(V(I_{t-1}),P_{t-1}) - d(w,P_{t-1}) + 1 + \Delta - d(v,P_{t-1}) \\ + \Delta - d(w,P_{t-1}) + \sum_{x\in P_{t-1}} \mathbb{1}_{vx\in I_t}\big(\Delta - d(x,V(I_{t-1}))\big), \end{aligned}$$

if $c_t(v) \neq c_{t-1}(v)$, and of course $e(V(I_t),P_t) = e(V(I_{t-1}),P_{t-1})$ if $c_t(v) = c_{t-1}(v)$.

We conclude that

$$\begin{aligned} \mathbb{E}\left[e(V(I_t),P_t) \mid C \subseteq I_{t-1}\right] \leqslant e(V(I_{t-1}),P_{t-1}) + \frac{\Delta}{\Delta+1}(2\Delta + 1 - 3\bar{d}_{IP}) \\ + \frac{1}{|V(I_{t-1})|}\sum_{x\in P_{t-1}}\sum_{v\in V(I_{t-1})\cap N(x)} \frac{1}{\Delta+1}\big(\Delta - d(x,V(I_{t-1}))\big), \end{aligned}$$

where the last term can be rewritten as

$$\frac{1}{|V(I_{t-1})|}\sum_{x\in P_{t-1}} \frac{d(x,V(I_{t-1}))\big(\Delta - d(x,V(I_{t-1}))\big)}{\Delta+1}.$$

We note that the summand above can be written as $f(d(x,V(I_{t-1}))$ where $f(y) := y(\Delta - y)/(\Delta+1)$ is a concave function. Hence, by Jensen's inequality, we can upper bound the expression by $|P_{t-1}|f(\bar{d}_{PI})/|V(I_{t-1})| = \bar{d}_{IP}(\Delta - \bar{d}_{PI})/(\Delta+1)$. Altogether we get

$$\begin{aligned} \mathbb{E}\left[e(V(I_t),P_t) \mid C \subseteq I_{t-1}\right] &\leqslant e(V(I_{t-1}),P_{t-1}) + \frac{\Delta(2\Delta+1-3\bar{d}_{IP})}{\Delta+1} + \frac{\bar{d}_{IP}(\Delta-\bar{d}_{PI})}{\Delta+1} \\ &\leqslant e(V(I_{t-1}),P_{t-1}) + \frac{\Delta}{\Delta+1}(2\Delta+1-2\bar{d}_{IP} - \bar{d}_{IP}\bar{d}_{PI}/\Delta). \end{aligned}$$

Finally, by combining this with Claim 2.2 and Claim 2.4 (and some tedious calculation) we deduce

$$\begin{aligned} \mathbb{E}\left[\Phi(t) \mid C \subseteq I_{t-1}\right] &\leqslant \Phi(t-1) - \frac{1}{\Delta+1} - \frac{1}{10}\frac{\Delta-\bar{d}_{IP}}{\Delta+1} + \frac{1}{100}\frac{2\Delta+1-2\bar{d}_{IP}-\bar{d}_{IP}\bar{d}_{PI}/\Delta}{\Delta+1} \\ &\leqslant \Phi(t-1) - \frac{2}{25}\frac{\Delta-\bar{d}_{IP}}{\Delta+1} - \frac{1}{100}\frac{\bar{d}_{IP}\bar{d}_{PI}}{\Delta(\Delta+1)}. \end{aligned} \tag{5}$$

With all these preparations we are now in a position to bound $\mathbb{E}[\Phi(t)]$. As seen in (4) and (5), both conditioning on components of size at least three or on vertices in isolated edges lead to a non-positive contribution to the drift. In order to derive an upper bound on $\mathbb{E}[\Phi(t)]$ we may thus ignore one of the terms for convenience. If we assume $|I_{t-1}| \leqslant |M_{t-1}|/2$ one would expect that the larger contribution to the change of $\Phi(t-1)$ comes from components which are not isolated edges. Indeed, in that case we may ignore the term from (5) and use (4) only to get

$$\mathbb{E}[\Phi(t)] \overset{(4)}{\leqslant} \Phi(t-1) - \sum_{C,\,|V(C)|\geqslant 3} \frac{|V(C)|}{|V(M_{t-1})|}\frac{\bar{d}(C)}{25} = \Phi(t-1) - \frac{2|M_{t-1}\setminus I_{t-1}|}{25|V(M_{t-1})|}$$
$$\leqslant \Phi(t-1) - \frac{|M_{t-1}|}{25n} \leqslant \Phi(t-1)\Big(1-\frac{1}{50n}\Big),$$

where the last inequality follows from Claim 2.6.

On the other hand, suppose $|I_{t-1}| \geqslant |M_{t-1}|/2$ and observe that this implies $|V(I_{t-1})| \geqslant |V(M_{t-1})|/2$. This means that the probability of picking a vertex in $V(I_{t-1})$ to recolor is at least $1/2$ and one may hope that the larger contribution to the change of $\Phi(t-1)$ comes from the isolated edges. Indeed, similarly as above, we now ignore the contribution from components of size at least three to get:

$$\mathbb{E}[\Phi(t)] \overset{(5)}{\leqslant} \Phi(t-1) - \frac{1}{25}\frac{\Delta-\bar{d}_{IP}}{\Delta+1} - \frac{1}{200}\frac{\bar{d}_{IP}\bar{d}_{PI}}{\Delta(\Delta+1)} \leqslant \Phi(t-1) - \frac{1}{50}\frac{\Delta-\bar{d}_{IP}}{\Delta} - \frac{1}{400}\frac{\bar{d}_{IP}\bar{d}_{PI}}{\Delta^2}. \quad (6)$$

If $\bar{d}_{IP} \leqslant \Delta - \Delta\Phi(t-1)/(30n)$, then the claim follows just from the first term. Otherwise, by Claim 2.6

$$\Phi(t-1) \leqslant 2|M_{t-1}| \leqslant 4|I_{t-1}| \leqslant 2n,$$

which in turn implies $\bar{d}_{IP} \geqslant \Delta(1-\Phi(t-1)/(30n)) \geqslant 14\Delta/15$. Recall, $\bar{d}_{PI}|P_{t-1}| = \bar{d}_{IP}|V(I_{t-1})|$, and note that $|V(I_{t-1})|/|P_{t-1}| \geqslant 2|I_{t-1}|/n \geqslant \Phi(t-1)/(2n)$. Therefore,

$$\frac{1}{400}\frac{\bar{d}_{IP}\bar{d}_{PI}}{\Delta^2} = \frac{1}{400}\frac{|V(I_{t-1})|\cdot\bar{d}_{IP}\bar{d}_{IP}}{|P_{t-1}|\Delta^2} \geqslant \Phi(t-1)\frac{1}{800n}\cdot\Big(\frac{14}{15}\Big)^2$$

and the second term in (6) is enough to conclude the proof of Claim 2.7. ◁

As mentioned in the paragraph before Claim 2.7, in order to make use of the assertion of Claim 2.7, we need a slightly different drift theorem, one for multiplicative drift.

▶ **Theorem 2.8** (Multiplicative Drift Theorem [4]). *Let $(X_t)_{t\geqslant 0}$ be a sequence of non-negative random variables with a finite state space $\mathcal{S} \subset \mathbb{R}_0^+$ such that $0 \in \mathcal{S}$. Let $s_{\min} := \min\{\mathcal{S}\setminus\{0\}\}$, let $s_0 \in \mathcal{S}\setminus\{0\}$, and let $T := \inf\{t \geqslant 0 \mid X_t = 0\}$. If there exists $\delta > 0$ such that for all $s \in \mathcal{S}\setminus\{0\}$ and for all $t > 0$,the case of*

$$\mathbb{E}[X_t - X_{t-1} \mid X_{t-1} = s] \leqslant -\delta s,$$

then

$$\mathbb{E}[T \mid X_0 = s_0] \leqslant \frac{1+\ln(s_0/s_{\min})}{\delta}.$$

Now we are ready to put things together to prove Theorem 1.1.

Proof of Theorem 1.1. For every $t \geqslant 0$, we define

$$\Phi'(t) = \begin{cases} \Phi(t), & \text{if } \Phi(t) \geqslant n/\Delta, \\ 0, & \text{otherwise.} \end{cases}$$

Note that, as long as $\Phi(t-1) \geqslant n/\Delta$, we have $\Phi'(t-1) = \Phi(t-1)$ and $\Phi'(t) \leqslant \Phi(t)$, so the deduced bound on $\Phi(t)$ in Claim 2.7 is also a bound for $\Phi'(t)$. Using Theorem 2.8 with Claim 2.7 for $T' := \inf\{t \geqslant 0 \mid \Phi'(t) = 0\} = \inf\{t \geqslant 0 \mid \Phi(t) < n/\Delta\}$, we get for all $s_0 > 0$

$$\mathbb{E}[T' \mid \Phi'(0) = s_0] \leqslant \frac{1+\ln\left(\frac{s_0}{n/\Delta}\right)}{(1000n)^{-1}}.$$

By Claim 2.6 we have $\Phi'(0) \leqslant 2|M_0| \leqslant n\Delta$, and therefore

$$\mathbb{E}[T'] \leqslant 1000n\big(1 + 2\ln\Delta\big) = O(n \log \Delta).$$

Finally, as by Claim 2.6 we then have $|M_{T'}| = O(n/\Delta)$, we conclude from Proposition 2.3 that the expected number of steps after T' to reach a legal coloring is $O(n)$. Therefore, the total number of required steps to reach a legal coloring is $O(n \log \Delta)$, which finishes the proof of Theorem 1.1. ◀

3 Tail Bounds

In this section, we prove that the runtime of the decentralized coloring algorithm is of order $O(n \log \Delta)$ not only in expectation, but also with high probability. It turns out that this does not require much additional work, as the drift theorems are accompanied with suitable tail bounds. In many situations, concentration bounds require conditions beyond the drift, for example bounds on the step size. Notably, for multiplicative drift such additional conditions are not necessary, as the following theorem holds.

▶ **Theorem 3.1** (Multiplicative Drift Tail Bound [3]). *Let $(X_t)_{t\geqslant 0}$ be a sequence of non-negative random variables with a finite state space $\mathcal{S} \subset \mathbb{R}_0^+$ such that $0 \in \mathcal{S}$. Let $s_{\min} := \min\{\mathcal{S} \setminus \{0\}\}$, let $s_0 \in \mathcal{S} \setminus \{0\}$, and let $T := \inf\{t \geqslant 0 \mid X_t = 0\}$. Suppose that $X_0 = s_0$, and that there exists $\delta > 0$ such that for all $s \in \mathcal{S} \setminus \{0\}$ and for all $t > 0$,*

$$\mathbb{E}[X_t - X_{t-1} \mid X_{t-1} = s] \leqslant -\delta s.$$

Then, for all $r \geqslant 0$

$$\Pr\left[T > \left\lceil \tfrac{r+\ln(s_0/s_{\min})}{\delta} \right\rceil\right] < e^{-r}.$$

The following proposition is a straightforward application of this theorem.

▶ **Proposition 3.2.** *Suppose $\Delta = \Omega(n^c)$ for some constant $c > 0$. Then, the decentralized coloring algorithm terminates after $O(n \log \Delta)$ steps with high probability.*

Proof. By Claim 2.6 we know that $s_0 \leqslant n\Delta$. In the proof of Theorem 1.1 we analyzed the process with multiplicative drift until the potential Φ hits n/Δ. Here, we track this potential until the end of the algorithm. Note that the smallest nonzero value Φ can attain is at least 1. Thus, under the assumption $\Delta = \Omega(n^c)$, we also have $\ln(s_0/s_{\min}) \leqslant C \log \Delta$ for large enough n, even if we do not truncate Φ. Here, $C > 0$ is a suitable constant, for example $C = 2(1 + 1/c)$. Setting $r = \log \Delta$, we can apply Theorem 3.1 to get

$$\Pr\left[T > \lceil (1 + C)1000n \log \Delta \rceil\right] \leqslant e^{-\log \Delta} = O(n^{-c}) = o(1),$$

where we used $\delta = (1000n)^{-1}$ as before, due to Claim 2.7. ◀

The proof of Proposition 3.2 fails when $\log n = \omega(\log \Delta)$. In the proof of Theorem 1.1 we switched to additive drift to analyze the second phase of the process. We use this approach again. The following tail bound for additive drift will be useful. It is a rather straightforward consequence of Azuma's inequality. Note that there is an additional assumption, namely that we have bounded step size.

▶ **Theorem 3.3** (Additive Drift Tail Bound [7]). *Let $(X_t)_{t\geqslant 0}$ be a sequence of non-negative random variables with a finite state space $\mathcal{S}\subset\mathbb{R}_0^+$ such that $0\in\mathcal{S}$. Let $T:=\inf\{t\geqslant 0\mid X_t=0\}$. Suppose there are $c,\delta>0$ such that for all $s\in\mathcal{S}\setminus\{0\}$ and for all $t>0$, we have both $\mathbb{E}[X_t-X_{t-1}\mid X_t=s]\leqslant-\delta$ and $|X_{t+1}-X_t|<c$. Then, for all $r\geqslant 2X_0/\delta$,*

$$\Pr[T\geqslant r]\leqslant\exp\Big(-\frac{r\delta^2}{8c^2}\Big).$$

The smaller Δ is, the less the potential changes at each step. Using this fact, the theorem above allows us to prove the next proposition. It gives us that the runtime of the algorithm is $O(n\log\Delta)$ for smaller Δ.

▶ **Proposition 3.4.** *If $\Delta=O(n^{1/4})$, the decentralized coloring algorithm terminates after $O(n\log\Delta)$ steps with high probability*

Proof. We go back to splitting the process in two phases as in the proof of Theorem 1.1. Let T_1 and T_2 be the duration of Phase 1 and 2 respectively. We consider Phase 1 first. To be able to apply Theorem 3.3, we use the potential function $\Psi(t):=\max\{\log(\Delta\Phi(t)/n),0\}$. As we will see, the logarithm converts multiplicative drift into additive drift. Note that $T_1=\inf\{t\geqslant 0\mid\Psi(t)=0\}$. Using Jensen's inequality and Claim 2.7, we get for all $s\in S\setminus\{0\}$ and $t\geqslant 0$

$$\begin{aligned}
\mathbb{E}[\Psi(t+1)-\Psi(t)\mid\Psi(t)=s]&=\mathbb{E}\left[\log\left(\frac{\Delta\Phi(t+1)}{n}\right)-\log\left(\frac{\Delta\Phi(t)}{n}\right)\middle|\Psi(t)=s\right]\\
&=\mathbb{E}\left[\log\left(\frac{\Phi(t+1)}{\Phi(t)}\right)\middle|\Psi(t)=s\right]\\
&\leqslant\log\mathbb{E}\left[\frac{\Phi(t+1)}{\Phi(t)}\middle|\Psi(t)=s\right]\\
&\leqslant\log\left(1-\frac{1}{1000n}\right)\\
&\leqslant-\frac{1}{1000n}.
\end{aligned}$$

The last inequality follows as $\log x\leqslant x-1$ for all $x>0$. Now that we have determined the drift, we need to bound the step size. $|M_t|$ and $|I_t|$ can change by at most Δ at each step and $e(V(I_t,P_t)$ by at most Δ^2. Thus, the step size of Φ is bounded by 2Δ. As the logarithm is concave, the largest effect of such a change in Φ on the value of Ψ is when Φ is as small as possible. In particular, this is the case if Φ goes from $2\Delta+n/\Delta$ to n/Δ. Thus we have

$$|\Psi(t+1)-\Psi(t)|\leqslant\left|\log\left(\frac{2\Delta+\frac{n}{\Delta}}{\frac{n}{\Delta}}\right)\right|=\log\left(1+\frac{2\Delta^2}{n}\right)<\frac{2\Delta^2}{n}.$$

Therefore, $2\Delta^2/n$ is a bound on the step size of Ψ. As $\Phi(0)\leqslant n\Delta$ we have $\Psi(0)\leqslant 2\log\Delta$. Hence we can use Theorem 3.3 with $r=4000n(1+\log\Delta)$. We get

$$\Pr[T_1\geqslant r]\leqslant\exp\left(-\frac{4000n(1+\log\Delta)\cdot\left(\frac{1}{1000n}\right)^2}{8\left(\frac{2\Delta^2}{n}\right)^2}\right)=\exp\left(-\frac{(1+\log\Delta)n}{8000\Delta^4}\right)=o(1).$$

We turn our attention to Phase 2. Here, we already have additive drift for $|M_t|$, so we can use Theorem 3.3 immediately. Claim 2.2 gives us

$$\mathbb{E}\left[|M_t|-|M_{t-1}|\;\middle|\;|M_{t-1}|=s\right]\leqslant-\frac{1}{\Delta+1}\leqslant-\frac{1}{2\Delta},$$

for all $s, t > 0$. We also have $\big||M_t| - |M_{t-1}|\big| \leqslant \Delta$ for all $t > 0$. By Claim 2.6 we get $|M_t| \leqslant 2n/\Delta$ at the start of Phase 2. Hence we can apply Theorem 3.3 with $r = (4 + \log \Delta)n$. We get

$$\Pr[T_2 \geqslant r] \leqslant \exp\left(-\frac{(4+\log\Delta)n \cdot \left(\frac{1}{2\Delta}\right)^2}{8\Delta^2}\right) = \exp\left(-\frac{(4+\log\Delta)n}{32\Delta^4}\right) = o(1).$$

Using a union bound gives us that the algorithm terminates in $O(n \log \Delta)$ round with high probability. ◀

Proposition 3.2 and 3.4 cover all possible values of Δ. Therefore, the algorithm has runtime $O(n \log \Delta)$ with high probability for any Δ.

4 A simultaneous-recoloring variant of the algorithm

A natural question is whether the original algorithm can be parallelized. So what if instead of choosing one conflicted vertex at a time in Step 2 *all* conflicted vertices would simultaneously want to change their color? It turns out that this process does not even have polynomial runtime on the complete graph K_n.

▶ **Proposition 4.1.** *The Decentralized Graph Colouring algorithm in which all conflicted vertices choose a new color uniformly at random needs $e^{\Omega(n)}$ rounds in expectation to terminate on a complete graph on n vertices K_n.*

Proof. Fix a sufficiently small constant $\varepsilon > 0$, e.g. $\varepsilon = 0.1$. For a round t, let X_t be the number of conflicted vertices, i.e., the number of vertices whose color is not unique. Due to symmetry, X_t is a Markov process. Let T_ε be the first round in which $X_t \leqslant \varepsilon n$. We show that T_ε has exponentially large expectation. Consider any round t with $X_t = x > \varepsilon n$. Then we show that

$$\Pr[X_{t+1} \leqslant \varepsilon n \mid X_t = x] = e^{-\Omega(n)}, \tag{7}$$

where the hidden constant is independent of x. We remark that the same argument also shows that with high probability $X_1 > \varepsilon n$, since the initial round is formally equivalent to the hypothetical case $X_0 = n$. So the proposition follows if we can show (7).

To show (7), we uncover the new colors in two batches. In the first batch, we uncover the colors of all but εn vertices. If there are more than εn vertices in conflicts from the first batch, then there is nothing to show. So in the following we may assume (and implicitly condition) on the opposite event that uncovering the first batch creates at most εn conflicted vertices. This implies that the set C_1 of colors appearing among the $(1-\varepsilon)n$ uncovered vertices, has size at least $|C_1| \geqslant (1-2\varepsilon)n$. Let $C_2 \subseteq C_1$ be the set of colors in C_1 that also appear in the second batch, i.e., for which a conflict is created by the second batch. The probability that a fixed color in C_1 does *not* occur in C_2 is $(1-1/n)^{\varepsilon n} = e^{-\varepsilon + O(1/n)} \leqslant 1 - 7\varepsilon/8$ for sufficiently large n, where we use that $e^{-\varepsilon} < 1 - 7\varepsilon/8$ for $\varepsilon < 0.2$. Hence, $\mathbb{E}[|C_2|] \geqslant 7\varepsilon/8 \cdot (1-2\varepsilon)n \geqslant 5\varepsilon/8 \cdot n$ for $\varepsilon \leqslant 1/7$.

The size of C_2 is given by the number of non-empty bins in a *Balls-and-Bins* problem, and this number is known to be concentrated around its expectation since the number of empty bins is negatively associated, and thus the Chernoff bounds are applicable. Since this is a well-known argument, we refrain from spelling out the details and refer the reader to the standard exposition [5, Proposition 29 and Section 3.3]. The result is that $\Pr[|C_2| \leqslant \varepsilon/2 \cdot n] = e^{-\Omega(n)}$.

It remains to observe that $X_{t+1} > 2|C_2|$, since every color in C_2 causes at least two conflicted vertices (one from the second batch and one from the rest). Hence, $\Pr[X_{t+1} \leqslant \varepsilon n] \leqslant \Pr[|C_2| \leqslant \varepsilon/2 \cdot n] = e^{-\Omega(n)}$, as required. ◀

Abstract

The k-means++ algorithm due to Arthur and Vassilvitskii [4] has become the most popular seeding method for Lloyd's algorithm. It samples the first center uniformly at random from the data set and the other $k-1$ centers iteratively according to D^2-sampling, i.e., the probability that a data point becomes the next center is proportional to its squared distance to the closest center chosen so far. k-means++ is known to achieve an approximation factor of $\mathcal{O}(\log k)$ in expectation.

Already in the original paper on k-means++, Arthur and Vassilvitskii suggested a variation called *greedy k-means++ algorithm* in which in each iteration multiple possible centers are sampled according to D^2-sampling and only the one that decreases the objective the most is chosen as a center for that iteration. It is stated as an open question whether this also leads to an $\mathcal{O}(\log k)$-approximation (or even better). We show that this is not the case by presenting a family of instances on which greedy k-means++ yields only an $\Omega(\ell \cdot \log k)$-approximation in expectation where ℓ is the number of possible centers that are sampled in each iteration.

Inspired by the negative results, we study a variation of greedy k-means++ which we call *noisy k-means++ algorithm*. In this variation only one center is sampled in every iteration but not exactly by D^2-sampling. Instead in each iteration an adversary is allowed to change the probabilities arising from D^2-sampling individually for each point by a factor between $1-\epsilon_1$ and $1+\epsilon_2$ for parameters $\epsilon_1 \in [0,1)$ and $\epsilon_2 \geq 0$. We prove that noisy k-means++ computes an $\mathcal{O}(\log^2 k)$-approximation in expectation. We use the analysis of noisy k-means++ to design a moderately greedy k-means++ algorithm.

1 Introduction

Clustering is a very important tool in many machine learning applications. The task is to find structure that is hidden in input data in the form of clusters, and to do this in an unsupervised way. Since clusters come with very different properties depending on the application, a variety of clustering algorithms and measures to judge clusterings have arisen in the last decades. Among those, a hugely popular method is Lloyd's algorithm [19] (also called the k-means algorithm), which for example was voted to be one of the ten most influential data mining algorithms in machine learning at the IEEE International Conference on Data Mining (ICDM) in 2006 [24].

Lloyd's algorithm is an iterative local search heuristic operating on points from Euclidean space $\mathbb{R}^d$. The measure that it implicitly strives to optimize is the k-means cost function: For a point set $X \subset \mathbb{R}^d$ and a center set $C \subset \mathbb{R}^d$, the k-means cost function is defined as

$$\Phi(X, C) = \sum_{x \in X} \min_{c \in C} ||x - c||^2,$$

the sum of the squared distances of all points to their respective center. The k-means problem asks to minimize the k-means cost over all choices of C with $|C| = k$. In an optimal solution of the k-means problem, the centers are means of their clusters, and Lloyd's algorithm iterates between computing the means of all clusters as the new center set and reassigning all points to their closest centers to form new clusters. The k-means cost function is also called *sum of squared errors* because when the means are viewed as representatives of the clusters, then the k-means cost is the squared error of this representation.

The k-means problem is NP-hard [3, 20], and it is also hard to approximate to arbitrary precision [5, 18]. On the positive side, constant-factor approximations are possible, and the best known factor is 6.357 due to a break-through result by Ahmadian et al. [2, 18]. However, the constant-factor approximation algorithms for k-means are not very practical. On the other hand, Lloyd's method is hugely popular in practice, but can produce solutions that are arbitrarily bad in the worst case.

A major result in clustering thus was the k-means++ algorithm due to Arthur and Vassilvitskii [4] in 2007, which enhances Lloyd's method with a fast and elegant initialization method that provides an $\mathcal{O}(\log k)$-approximation in expectation. The k-means++ algorithm samples k initial centers by adaptive sampling, where in each step, a point's probability of being sampled is proportional to its cost in the current solution (we will refer to this kind of sampling as D^2-sampling in the following). After sampling k centers, the solution is refined by using Lloyd's algorithm. Algorithm 1 contains pseudo code for the k-means++ algorithm.

The beauty of the algorithm is that it has a bounded approximation ratio of $\mathcal{O}(\log k)$ in expectation, and at the same time computes solutions that are good (much better than $\Theta(\log k)$) on practical tests. By feeding the computed centers into Lloyd's method, the solutions are refined to even better quality. Nevertheless, Arthur and Vassilvitskii show that the approximation ratio of k-means++ is tight in the worst case: They give an (albeit artificial) example where the expected approximation ratio is $\Omega(\log k)$, and this has been extended by now to examples where k-means++ outputs a $\Omega(\log k)$-approximate solution with high probability [8], and even in the plane [7].

Due to its beneficial theoretical and practical properties, k-means++ has by now become the de-facto standard for solving the k-means problem in practice. What is less known is that the original paper [4] and the associated PhD thesis [22] actually propose a possible

Algorithm 1 The k-means++ algorithm [4].

1: Sample a point c_1 independently and uniformly at random from X.
2: Let $C = \{c_1\}$.
3: **for** $i = 2$ to k **do**
4: **for** $x \in X$ **do**
5: $p(x) := \frac{\min_{c \in C} ||x-c||^2}{\sum_{y \in X} \min_{c \in C} ||y-c||^2}$
6: **end for**
7: Sample a point c_i from X, where every $x \in X$ has probability $p(x)$.
8: Update $C = C \cup \{c_i\}$.
9: **end for**
10: Run Lloyd's algorithm initialized with center set C and output the result.

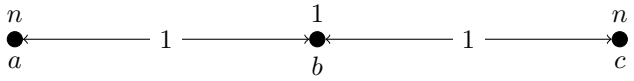

Figure 1 A bad example for the deterministic heuristic that always chooses the current cost minimizer as the next center. An optimal 2-clustering costs less than 1, while a clustering where b is a center costs $\Omega(n)$.

improvement to the k-means++ algorithm: the *greedy k-means++ algorithm*. Here in each of the adaptive sampling steps, not only one center but ℓ possible centers are chosen (independently according to the same probability distribution), and then among these l centers, the one that decreases the k-means cost the most is chosen. This is greedy because a center that reduces the cost in the current step might be a bad center later on (for example if we choose a center that lies between two optimum clusters, thus preventing us from choosing good centers for both on the long run). The original paper [4] says:

> *Also, experiments showed that k-means++ generally performed better if it selected several new centers during each iteration, and then greedily chose the one that decreased Φ (the cost function) as much as possible. Unfortunately, our proofs do not carry over to this scenario. It would be interesting to see a comparable (or better) asymptotic result proven here.*

The intuition is that k-means++ tries to find clusters in the dataset, and with each sample, it tries to find a new cluster that has not been hit by a previously sampled center. This has a failure probability, and the super-constant approximation ratio stems from the probability that some clusters are missed. In this failure event, the algorithm chooses two centers that are close to each other compared to the optimum cost. Greedy k-means++ tries to make this failure event less likely by boosting the probability to find a center from a new cluster that has not been hit previously and greedily choosing the center.

For $\ell = 1$, the greedy k-means++ becomes the k-means++ algorithm, and for very large ℓ it becomes nearly deterministic, a heuristic that always chooses the current minimizer among the whole dataset. It is easy to observe that the latter is not a good algorithm: Consider Figure 1. In the first step, the center that minimizes the overall k-means cost in the next step is b. But if we choose b, then the second greedy center is either a or c, and we end up with a clustering of cost $\Omega(n)$, while the solution $\{a, c\}$ has a cost of 1 (and the optimum solution is even slightly better).

So the crucial question is how to set ℓ, and whether there is an ℓ for which greedy k-means++ outperforms k-means++. It has been shown in [1] that for any optimal clustering of an input data set, k-means++ has in each iteration a constant probability to sample a point from a 'new' optimal cluster, where new means that no point from that cluster has previously been chosen as a center. This leads to a bicriteria approximation, since after $\mathcal{O}(k)$ centers, the algorithm has discovered all optimal clusters in expectation. Following the intuition that stems from this analysis, a natural idea would be to set $\ell = \mathcal{O}(\log k)$: This reduces the probability to pick no point from a new cluster to $\Omega(1/k)$, and by union bound, the failure probability that this event happens in one of the k samples decreases to a constant. This choice is also advertized by Celebi et al. [9], who feature greedy k-means++ in a study of initialization strategies for Lloyd's method. They report that it performs better than k-means++, for a suggested value of $\ell = \log k$. The PhD thesis [22] reports experiments with $\ell = 2$ that outperformed k-means++. It also states that the approximation guarantee of greedy k-means++ is unknown (pp. 62+63).

We initiate the analysis of the greedy k-means++ algorithm. Firstly, we prove that greedy k-means++ is *not* asymptotically better than k-means++. More precisely, we show the following statement.

▶ **Theorem 1.** *For any $k \geq 4$ and any ℓ, there exists a point set $X_{k,\ell}$ such that the expected approximation guarantee of greedy k-means++ is $\Omega(\min\{\ell, k/\log k\} \cdot \log k)$.*

Theorem 1 implies that the worst-case approximation guarantee of greedy k-means++ cannot get better by choosing $\ell > 1$. In particular for $\ell = \log k$, the approximation guarantee worsens to $\Omega(\log^2 k)$.

As indicated in the quote from [4] above, the original proof of k-means++ does not carry over to greedy k-means++, not even if we aim for a higher approximation guarantee like $\mathcal{O}(\ell \log k)$. Roughly speaking, the main problem in the analysis is that while the probability to choose a point as a center can only be increased by a factor of ℓ by the greedy procedure, there is no multiplicative lower bound on how much individual probabilities can be *de*creased. Indeed, if a point $x \in P$ is the worst greedy choice, then its probability to be chosen decreases from some $p(x)$ in the original k-means++ algorithm to $(p(x))^\ell$, which is much smaller than $p(x)$. If this happened to good centers, it could hurt the approximation factor badly.

We proceed to study a different variation of k-means++ which we call the *noisy k-means++* algorithm. This algorithm performs k-means++, but does not sample with exact probabilities. Instead of sampling a point x with probability $p(x)$ as suggested by D^2-sampling, it uses an arbitrary probability $p'(x)$ with $(1-\epsilon_1)p(x) \leq p'(x) \leq (1+\epsilon_2)p(x)$, where $\epsilon_1 \in [0, 1)$ and $\epsilon_2 \geq 0$. If we cast greedy k-means++ as a noisy k-means++ algorithm, we observe that we get a trivial upper bound of $\epsilon_2 = \ell - 1$, however, no trivial *lower* bound on how much the probabilities are skewed.

Noisy k-means++ is also interesting in its own right, since in practice, the probabilities actually computed are prone to rounding errors. Due to the iterative nature of k-means++, it is not at all clear how large the effect of a small rounding can be. We show that the following theorem holds.

▶ **Theorem 2.** *Let T_k denote the set of centers sampled by noisy k-means++ on dataset X and assume that $\frac{k}{\ln k} \geq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\}$. Then,*

$$\mathbb{E}[\Phi(X, T_k)] \leq \mathcal{O}\left(\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right)^3 \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right),$$

where $\mathrm{OPT}_k(X)$ denotes the k-means costs of an optimal k-clustering of X. If $\frac{k}{\ln k} \leq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\}$, then $\mathbb{E}[\Phi(X, T_k)] \leq \mathcal{O}\left(\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right)^4 \cdot \log^2\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right) \cdot \mathrm{OPT}_k(X)\right)$.

We use Theorem 2 to analyze a *moderately greedy* variant of k-means++, where the simple idea is that with probability p, we do a normal k-means++ step, and with probability $1-p$, we do a greedy k-means++ step. The idea is that in this variant, a point is never completely disregarded, so we do get a lower bound on the probabilities, yet in many steps, we do still profit from the additional power of greedy k-means++ seen in experiments. For constant p and ℓ, this variant gives an $\mathcal{O}(\log^2 k)$-approximation by Theorem 2.

Techniques

Our lower bound example for greedy k-means++ is close to the original $\Omega(\log k)$ lower bound example in [4] (we contract each cluster to a single location except for one cluster where one point is moved away from the location into the center of the instance, see Section 2).

However, the proof of the lower bound proceeds very differently. Morally, instead of missing clusters (which becomes less likely due to the multiple samples), the failure event is to choose a bad point as a center. This alone is responsible for the $\Omega(\ell \log k)$ lower bound, while the original $\Omega(\log k)$ bound stems from missing clusters.

To analyze noisy k-means++, we build upon an analysis of k-means++ by Dasgupta [12]. Analyzing k-means++ is about 'hitting' clusters. For some fixed optimal solution we call a cluster *covered* if a point is sampled that provides a good enough center for it. An iteration of k-means++ is *wasted* if a point is sampled from an already covered cluster. Dasgupta uses a potential function which accumulates costs over the wasted iterations. To make the connection between k-means++ and this potential function, it is crucial that the expected average cost of the uncovered clusters does not increase over time (in k-means++). For noisy k-means++, this is not true: The cost can increase. We show that the increase can be bounded, roughly by a factor of $\log k$. Then the key difficulty is to analyze the resulting random process which is highly dependent. We analyze an abstract version first and then show how to apply it to the setting of noisy k-means++.

Additional related work

In his master's thesis, Pago [21] shows that for $\ell = \log k$, the example in Figure 1 can be extended such that greedy k-means++ gives an $\Omega(\log k)$-approximation in expectation.

Bachem et al. [6] suggest to speed up k-means++ by replacing the exact sampling according to the probabilities $p(x)$ by a fast approximation based on Markov Chain Monte Carlo sampling. They prove that under certain assumptions on the dataset their algorithm yields the same approximation guarantee in expectation as k-means++, namely $\mathcal{O}(\log k)$. Their algorithm can be viewed as a special case of noisy k-means++. However, their analysis of the approximation factor is based on making the total variation distance between the probability distributions p and p' (in every step) so small that with high probability their algorithm behaves identically to k-means++. In contrast to this, Theorem 2 also applies to choices of ϵ_1 and ϵ_2 for which noisy k-means++ behaves differently from k-means++ with high probability.

Lattanzi and Sohler [17] propose an intermediate improvement step to be executed between the D^2-sampling and Lloyd's algorithm in order to improve the solution quality to a constant factor approximation in expectation. Their algorithm starts with a k-means++ solution and then performs $\mathcal{O}(k \log \log k)$ improvement steps: In each such step, a new center is sampled with D^2-sampling, and if swapping it with an existing center improves the solution, then this swap is performed. While this is a greedy improvement step and thus a bit related to greedy k-means++, their algorithm is closer in spirit to a known local search algorithm by Kanungo et al. [16] which uses center swaps (starting on an arbitrary solution) to obtain a constant-factor approximation, but needs a lot more rounds and is impractical. Very recently, Choo et. al. [10] improved the result by Lattanzi and Sohler and showed that $\mathcal{O}(k)$ swaps are sufficient to achieve a constant factor approximation.

The bicriteria analysis by Aggarwal et al. [1] mentioned above was improved by Wei [23] who showed that for any $\beta > 1$, sampling βk centers with D^2-sampling yields an $\mathcal{O}(1)$-approximation in expectation (with βk centers). Hsu and Telgarsky [15] show that greedy k-means++ for $\ell = \Theta(k)$ leads to a bicriteria O(1)-approximation if $\Theta(k)$ centers are chosen. All above cited works assume that k and d are input parameters; if one of them is a constant, then there exists a PTAS for the problem [11, 13, 14].

In bicriteria results (which, in a sense, also applies to [17] and [10]), the key is to show that a cluster that has not been covered by a good center is found with high probability. For the analysis of greedy k-means++ and noisy k-means++, the main challenge is to bound the expected cost after only k steps.

2 Lower Bound for Greedy k-means++

In this section we construct an instance on which greedy k-means++ yields only an $\Omega(\ell \log k)$-approximation in expectation. More precisely, we analyze Algorithm 2.

Algorithm 2 Greedy k-means++ algorithm [4].

Sample[1] a point c_1 independently and uniformly at random from X.
Let $C = \{c_1\}$.
for $i = 2$ to k **do**
  for $x \in X$ **do**
    $p(x) := \frac{\min_{c \in C} ||x-c||^2}{\sum_{y \in X} \min_{c \in C} ||y-c||^2}$.
  end for
  Sample[1] a set S of ℓ points independently according to this probability distribution.
  Let $c_i = \arg\min_{u \in S} \Phi(X, C \cup \{u\})$.
  Update $C = C \cup \{c_i\}$.
end for
Run Lloyd's algorithm initialized with center set C and output the result.

Note that we only draw one sample in the first step. This is due to the fact that in the first step, k-means++ is guaranteed to discover a new cluster, so there is no reason to draw multiple samples.

The instance is based on a regular $(k-1)$-simplex with side length $\sqrt{2}$. Let the vertices of this simplex be denoted by $v_1, \ldots, v_k$. There are k points each at vertices $v_1, \ldots, v_{k-1}$, $(k-1)$ points at vertex v_k, and there is one point at the center o of the simplex. Let X denote the set of all these points. The simplex can be constructed explicitly in $\mathbb{R}^k$ by letting v_i be the ith canonical unit vector for each i and $o = (1/k, \ldots, 1/k)$. Then it follows that the distance between the center o and any vertex v_i is $\sqrt{(k-1)/k}$.

An optimal clustering $(C_1^\star, \ldots, C_k^\star)$ of this instance is obtained as follows: The clusters $C_1^\star, \ldots, C_{k-1}^\star$ consist of the k points at vertices $v_1, \ldots, v_{k-1}$, respectively, and the cluster $C_k^\star$ consists of the $(k-1)$ points at vertex v_k and the point at the center o. The cost of this clustering is bounded from above by $||o - v_k||^2 = \frac{k-1}{k} = O(1)$.

Consider a k-clustering C obtained by greedy k-means++ that contains the point at o as one of the k centers. The cost of this clustering is at least $(k-1)^2/k = \Omega(k)$ because there exists at least one i such that C has no center at v_i. In the best case this is v_k, which generates the aforementioned cost because the $(k-1)$ points at v_k will be assigned to the center at o. The approximation guarantee of this clustering is $\Omega(k)$. We prove that with sufficiently large probability, greedy k-means++ places one of the centers at o.

Morally, we proceed as follows. We define a failure event F which captures the case that one of the points at v_k is chosen as a center during the execution of greedy k-means++. If this event happens, we cannot show a high lower bound on the approximation guarantee. So we show that F happens at most with constant probability, so with sufficient probability, F does not occur. Then we analyze the probablity that under the condition that F does not occur, o is chosen as a center during the execution of k-means++. This probability increases with every iteration (when the kth center is chosen, there are only o, the points at v_k and the points at one other location v_i left as possible choices). We analyze a simplified random experiment to lower bound the probablity that o is chosen as a center during the iterations $i = 2, \ldots, k$.

[1] In all our algorithms we do sampling with replacement.

▶ **Theorem 1.** *For any $k \geq 4$ and any ℓ, there exists a point set $X_{k,\ell}$ such that the expected approximation guarantee of greedy k-means++ is $\Omega(\min\{\ell, k/\log k\} \cdot \log k)$.*

Proof. Notice that for $\ell = 1$ there is nothing to show since a lower bound of $\Omega(\log k)$ is known for this case. So in the following, we assume that $\ell \geq 2$. Furthermore we consider first only the case that $\ell \leq \frac{k}{20\ln(k-1)}$ and defer the discussion of larger ℓ to the end of the proof.

We consider the point set X constructed above. Consider a k-clustering C obtained by greedy k-means++ that contains the point at o as one of the k centers. The cost of this clustering is at least $(k-1)^2/k = \Omega(k)$ because there exists at least one i such that C has no center at v_i. In the best case this is v_k, which generates the aforementioned cost because the $(k-1)$ points at v_k will be assigned to the center at o. The approximation guarantee of this clustering is $\Omega(k)$. We will prove that with sufficiently large probability, greedy k-means++ places one of the centers at o.

We start the analysis by defining the following events for all $i \in [k]$:

F_i = the center chosen in the ith iteration lies at v_k,

G_i = the center chosen in the ith iteration lies at o,

$H_i = F_i \cup G_i$.

We denote by Φ_i the potential after $i-1$ iterations if in these iterations no point from $C_k^\star$ has been chosen as a center. Since the probability to choose the same v_i more than once is zero, this means that $i-1$ centers from different clusters from $C_1^\star, \ldots, C_{k-1}^\star$ have been chosen. In the remaining $k-i+1$ clusters, k points pay a cost of 2, except for the one point at o which pays $1-1/k$. Thus,

$$\Phi_i = 2((k-i+1)k-1) + 1 - \frac{1}{k}$$

and

$$2((k-i+1)k-1) \leq \Phi_i \leq 2k(k-i+1).$$

We define

$$F = F_1 \cup (F_2 \cap \overline{H_1}) \cup \ldots \cup (F_{k-1} \cap \overline{H_1} \cap \ldots \cap \overline{H_{k-2}})$$

as the event that in one of the first $k-1$ iterations a point at v_k is chosen as a center and that this is the first center chosen from $C_k^\star$. We exclude the last iteration because $\mathbf{Pr}(F_k)$ is significantly higher than $\mathbf{Pr}(F_i)$ for $i \leq k-1$.

We will prove a lower bound for the probability of the event $\overline{F} \cap (G_2 \cup \ldots \cup G_{k-1})$ because if this event happens then the point at o is one of the centers computed by greedy k-means++, i.e., the approximation factor is at least $\Omega(k)$.

If the event F occurs then we cannot prove a lower bound on the approximation guarantee of greedy k-means++. Hence, we will prove an upper bound for the probability of F. Observe that

$$\mathbf{Pr}[F] \leq \sum_{i=1}^{k-1} \mathbf{Pr}[F_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \cdot \mathbf{Pr}[\overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \leq \sum_{i=1}^{k-1} \mathbf{Pr}[F_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}]$$

and

$$\mathbf{Pr}[F_1] = \frac{k-1}{k^2} \leq \frac{1}{k}.$$

Consider the situation that $1 \leq i-1 \leq k-2$ iterations have already been performed and that in these iterations cluster $C_k^\star$ has not been covered. Then each point from an uncovered cluster $C_j^\star$ with $j < k$ reduces the potential by $2k$. Each point at v_k reduces the potential by $2(k-1)$ and the point at o reduces the potential by

$$(\underbrace{(k-i+1)}_{\geq 2}k-1)(1+1/k)+1-1/k \geq (2k-1)(1+1/k)+1-1/k = 2(k+1-1/k) > 2k.$$

Hence, the points at v_k have the least potential reduction and thus a point at v_k is only selected as new center in iteration i if all ℓ sampled candidates are at v_k. Hence, we obtain

$$\mathbf{Pr}[F_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] = \left(\frac{2(k-1)}{\Phi_i}\right)^\ell.$$

Altogether this implies

$$\mathbf{Pr}[F] \leq \mathbf{Pr}[F_1] + \sum_{i=2}^{k-1} \mathbf{Pr}[F_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \leq \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{2(k-1)}{\Phi_i}\right)^\ell.$$

Together with $\Phi_i \geq 2((k-i+1)k-1)$ this implies

$$\begin{aligned}
\mathbf{Pr}[F] &\leq \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{2(k-1)}{2((k-i+1)k-1)}\right)^\ell \\
&= \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{k-1}{(k-i+1)k-1}\right)^\ell \\
&\leq \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{k}{(k-i+1)k}\right)^\ell \\
&= \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{1}{i}\right)^\ell,
\end{aligned}$$

where the inequality in the penultimate line of the calculation follows from $\frac{a}{b} < \frac{a+1}{b+1}$ for $0 < a < b$. Using $\ell \geq 2$ and $k \geq 4$, it follows

$$\mathbf{Pr}[F] \leq \frac{1}{k} + \sum_{i=2}^{k-1} \left(\frac{1}{i}\right)^2 \leq \frac{1}{k} + \sum_{i=2}^{\infty} \left(\frac{1}{i}\right)^2 = \frac{1}{k} + \left(\frac{\pi^2}{6} - 1\right) \leq 0.9.$$

This shows that with constant probability, the failure event F does not occur, i.e., with constant probability none of the points from v_k is chosen as a center in the first $k-1$ iterations.

Now let us consider the probability that the point at o is selected as a center. We have argued above that the potential reduction of the point at o in iteration $2 \leq i \leq k-1$ is larger than $2k$ if cluster $C_k^\star$ has not been covered in the first $i-1$ iterations. We have also seen that any other point reduces the potential by at most $2k$. Hence, in order to select the point at o as center it suffices already if it belongs to the ℓ candidates chosen in iteration i. Denote the event that the jth sample in iteration i is o by G_{ij}. Then for $i \in \{2, \ldots, k-1\}$,

$$\begin{aligned}\mathbf{Pr}[G_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] &= \mathbf{Pr}[\cup_{j=1}^{\ell} G_{ij} \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \\ &\geq \sum_{j=1}^{\ell} \mathbf{Pr}[G_{ij} \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] - \sum_{1 \leq j_1 < j_2 \leq j} \mathbf{Pr}[G_{ij_1} \cap G_{ij_2} \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \\ &= \frac{\ell(1-1/k)}{\Phi_i} - \frac{\binom{\ell}{2}(1-1/k)^2}{\Phi_i^2} \\ &\geq \frac{\ell(1-1/k)}{\Phi_i} - \frac{\ell^2(1-1/k)^2}{\Phi_i^2},\end{aligned}$$

where the first inequality follows from Bonferroni inequalities.

Since $\ell \leq k/(20\ln(k-1)) \leq k/2$, we obtain

$$\frac{\ell(1-1/k)}{\Phi_i} \leq \frac{\ell}{\Phi_i} \leq \frac{\ell}{2((k-i+1)k-1)} \leq \frac{\ell}{k} \leq \frac{1}{2}.$$

This is helpful, because for any $a \in \mathbb{R}$ with $0 \leq a \leq 1/2$, it holds that $a - a^2 \geq a/2$. Thus, the previous two inequalities imply

$$\mathbf{Pr}[G_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}] \geq \frac{\ell(1-1/k)}{\Phi_i} - \left(\frac{\ell(1-1/k)}{\Phi_i}\right)^2 \geq \frac{\ell(1-1/k)}{2\Phi_i}. \tag{1}$$

Let us now condition on the event $\overline{F}$, which happens with constant probability. Then we can write the probability of the event we care about as

$$\begin{aligned}\mathbf{Pr}[\overline{F} \cap (G_2 \cup \ldots \cup G_{k-1})] &= \mathbf{Pr}[\overline{F}] \cdot \mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}] = \mathbf{Pr}[\overline{F}] \cdot \sum_{i=2}^{k-1} \mathbf{Pr}[G_i \mid \overline{F}] \\ &\geq \mathbf{Pr}[\overline{F}] \cdot \sum_{i=2}^{k-1} \mathbf{Pr}[G_i \mid \overline{F_1} \cap \ldots \cap \overline{F_{i-1}}],\end{aligned}$$

where we used in the penultimate step that the events G_i are mutually exclusive and in the last step that $\overline{F} \subseteq \overline{F_1} \cap \ldots \cap \overline{F_{i-1}}$. We cannot use (1) directly to bound $\mathbf{Pr}[G_i \mid \overline{F_1} \cap \ldots \cap \overline{F_{i-1}}]$ because the condition is different (in (1) we condition on the event that no point from $C_k^\star$ has been chosen as center in the first $i-1$ iterations while conditioning on $\overline{F_1} \cap \ldots \cap \overline{F_{i-1}}$ only implies that no point at v_k has been chosen as a center).

To prove a lower bound on $\mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}]$, we consider a different random experiment E. This random experiment consists of $k-2$ iterations numbered from 2 to $k-1$ and each iteration i is successful with probability $\mathbf{Pr}[G_i \mid \overline{H_1} \cap \ldots \cap \overline{H_{i-1}}]$ independent of the other iterations. Then $\mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}]$ equals the probability that at least one of the iterations of E is successful. Let E' denote the same random experiment as E only with modified success probabilities. In E' iteration i is successful with probability $\frac{\ell(1-1/k)}{2\Phi_i}$. Due to (1) and Bonferroni inequalities and using $k \geq 4$, we obtain

$$\begin{aligned}\mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}] &= \mathbf{Pr}[\text{at least one success in } E] \\ &\geq \mathbf{Pr}[\text{at least one success in } E'] \\ &\geq \sum_{i=2}^{k-1} \frac{\ell(1-1/k)}{2\Phi_i} - \sum_{2 \leq i < j \leq k-1} \frac{\ell(1-1/k)}{2\Phi_i} \cdot \frac{\ell(1-1/k)}{2\Phi_j} \\ &\geq \sum_{i=2}^{k-1} \frac{\ell(1-1/k)}{4k(k-i+1)} - \sum_{2 \leq i < j \leq k-1} \frac{\ell}{4((k-i+1)k-1)} \cdot \frac{\ell}{4((k-j+1)k-1)}\end{aligned}$$

$$\geq \sum_{i=2}^{k-1} \frac{\ell(1-1/k)}{4k(k-i+1)} - \sum_{2\leq i<j\leq k-1} \frac{\ell}{3k(k-i+1)} \cdot \frac{\ell}{3k(k-j+1)}$$
$$= \frac{\ell(1-1/k)}{4k} \sum_{i=2}^{k-1} \frac{1}{i} - \frac{\ell^2}{9k^2} \sum_{2\leq i<j\leq k-1} \frac{1}{(k-i+1)(k-j+1)}$$
$$\geq \frac{3\ell}{16k} \sum_{i=2}^{k-1} \frac{1}{i} - \frac{\ell^2}{9k^2} \left(\sum_{i=2}^{k-1} \frac{1}{i} \right)^2$$
$$\geq \frac{3\ell}{16k} (\ln(k-1) - 1) - \frac{\ell^2}{9k^2} \ln^2(k-1).$$

For $k \geq 4$, we have $\ln(k-1) - 1 \geq 0.089 \ln(k-1)$. Together with the previous calculation we get

$$\mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}] \geq 0.0166 \cdot \frac{\ell \cdot \ln(k-1)}{k} - \left(\frac{\ell \cdot \ln(k-1)}{3k} \right)^2$$
$$= \frac{\ell \cdot \ln(k-1)}{k} \cdot \left(0.0166 - \frac{\ell \cdot \ln(k-1)}{9k} \right)$$
$$\geq 0.01 \cdot \frac{\ell \cdot \ln(k-1)}{k},$$

where we used $\ell \leq \frac{0.05 \cdot k}{\ln(k-1)}$ for the last inequality.

Overall we obtain

$$\mathbf{Pr}[\overline{F} \cap (G_2 \cup \ldots \cup G_{k-1})] = \mathbf{Pr}[\overline{F}] \cdot \mathbf{Pr}[G_2 \cup \ldots \cup G_{k-1} \mid \overline{F}]$$
$$\geq 0.1 \cdot 0.01 \cdot \frac{\ell \cdot \ln(k-1)}{k} = \Omega\left(\frac{\ell \cdot \log(k)}{k} \right).$$

If this event happens, then the costs of the clustering are $\Omega(k)$. Hence the expected costs of the clustering computed by greedy k-means++ are $\Omega(\ell \cdot \log(k))$.

Finally let us consider the case $\ell > \frac{k}{20 \ln(k-1)}$. We argue that in this case the approximation guarantee cannot be better than for $\ell = \frac{k}{20 \ln(k-1)}$. To see that this is true, one has to have a closer look at where the upper bound on ℓ has been used in the argument above. It is used twice: once for proving an upper bound on the conditional probability of G_i and once for proving an upper bound on the conditional probability of $G_2 \cup \ldots \cup G_{k-1}$. Both these probabilities increase with ℓ so if ℓ is larger one could simply replace it by $\frac{k}{20 \ln(k-1)}$, leading to a lower bound of $\Omega(k/\log(k) \cdot k) = \Omega(k)$ for the approximation guarantee. ◀

3 Analysis of Noisy k-means++ Seeding

In this section we analyze a noisy seeding procedure, which we call *noisy k-means++* in the following. This procedure iteratively selects k centers from the data set in a similar fashion as k-means++. The only difference is that the probability of sampling a point as the next center is no longer exactly proportional to its squared distance to the closest center chosen so far. The probabilities are only approximately correct. To be more precise, consider an iteration of noisy k-means++. For any point $x \in X$, we denote by p_x the probability that x is chosen by k-means++ as the next center (i.e., p is the uniform distribution in the first iteration and the distribution that results from D^2-sampling in the following iterations). In noisy k-means++ an adversary can choose an arbitrary probability distribution q on X

with $q_x \in [(1-\epsilon_1)p_x, (1+\epsilon_2)p_x]$ for all $x \in X$ where $\epsilon_1 \in [0,1)$ and $\epsilon_2 \geq 0$ are parameters[2]. Then the next center is sampled according to q. This is repeated in every iteration of noisy k-means++ and in every iteration the adversary can decide arbitrarily how to choose q based on the current distribution p that results from D^2-sampling. We analyze the worst-case approximation guarantee provided by noisy k-means++.

The difficulty with noisy k-means++ is that a) it has a high probability to differ from k-means++, and b) the steps are highly dependent on each other, so once the algorithm has deviated, this propagates in the subsequent steps. It may be surprising that such a little change to the algorithm has such a huge effect. After some considerations it is even unclear if noisy k-means++ has any approximation guarantee at all. While we achieve worse guarantees compared to k-means++, we do at least answer this question affirmatively, showing that noisy k-means++ achieves an expected approximation guarantee of $\mathcal{O}(\log^2 k)$. Achieving this requires an intricate analysis of the highly dependent algorithm. We could not make it work with the original proof, so we use an alternative proof by Dasgupta [12] as a starting point. Also in this proof, a crucial step breaks down (the expected average cost of uncovered clusters can now increase, which is not the case for k-means++). This makes the process difficult to analyze and solving this challenge is the main technical contribution of this paper.

Let us first introduce some notation. We denote by $\Phi(X, C)$ the k-means costs of data set X with respect to center set C, i.e.,

$$\Phi(X, C) = \sum_{x \in X} \min_{c \in C} ||x - c||^2.$$

For $c \in \mathbb{R}^d$ we also write $\Phi(X, c)$ instead of $\Phi(X, \{c\})$ and similarly for $x \in \mathbb{R}^d$ we write $\Phi(x, C)$ instead of $\Phi(\{x\}, C)$. Let $\mathrm{OPT}_k(X)$ denote the optimal k-means costs of dataset X. In the following we assume that a data set X is given and we denote by $(C_1^\star, \dots, C_k^\star)$ an optimal k-clustering of X. For a finite set $X \subset \mathbb{R}^d$, we denote by $\mu(X) = \frac{1}{|X|} \sum_{x \in X} x$ its mean. The following lemma is well-known.

▶ **Lemma 3.** *For any finite $X \subset \mathbb{R}^d$ and any $z \in \mathbb{R}^d$,*

$$\Phi(C, z) = \Phi(C, \mu(C)) + |C| \cdot ||z - \mu(C)||^2 = \mathrm{OPT}_1(C) + |C| \cdot ||z - \mu(C)||^2.$$

We call an optimal cluster $C_i^\star$ *covered* by (noisy) k-means++ if at least one point from $C_i^\star$ is selected as a center. Arthur and Vassilvitskii [4] observe that covered clusters are well approximated by k-means++ in expectation. In particular, they show that the expected costs of an optimal cluster $C_i^\star$ with respect to the center set computed by k-means++ are at most $2 \cdot \mathrm{OPT}_1(C_i^\star)$ and $8 \cdot \mathrm{OPT}_1(C_i^\star)$ if the cluster is covered in the first or any of the following iterations, respectively. First of all, we carry these observations over to noisy k-means++. The following two lemmata are straightforward adaptations of Lemma 3.2 and Lemma 3.3 in [4].

▶ **Lemma 4.** *Let c_1 denote the first center chosen by noisy k-means++. For each optimal cluster $C_i^\star$,*

$$\mathbb{E}[\Phi(C_i^\star, c_1) \mid c_1 \in C_i^\star] \leq \frac{2(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_1(C_i^\star).$$

[2] For better readability, whenever we write $q(x) \leq (1+\epsilon_2)p_x$, we implicitly require $q(x) \leq \min\{1, (1+\epsilon_2)p_x\}$

Proof. In k-means++ the first center is chosen uniformly at random, i.e., each point from X has a probability of $1/|X|$ of being chosen. In noisy k-means++, all points have a probability in $[(1-\epsilon_1)/|X|, (1+\epsilon_2)/|X|]$ of being chosen. Hence, the probability of choosing a point $x \in C_i^\star$ as the first center conditioned on the first center being chosen from $C_i^\star$ is at most $\frac{1+\epsilon_2}{(1-\epsilon_1)|C_i^\star|}$. This implies

$$\begin{aligned}
\mathbb{E}[\Phi(C_i^\star, \{c_1\})] &\leq \sum_{c \in C_i^\star} \frac{1+\epsilon_2}{(1-\epsilon_1)|C_i^\star|}\, \Phi(C_i^\star, c) \\
&= \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \frac{1}{|C_i^\star|} \sum_{c \in C_i^\star} \Phi(C_i^\star, c) \\
&= \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \frac{1}{|C_i^\star|} \sum_{c \in C_i^\star} (\mathrm{OPT}_1(C_i^\star) + |C_i^\star| \cdot ||c - \mu(C_1^\star)||^2) \qquad \text{(Lemma 3)} \\
&= \frac{2(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_1(C_i^\star)
\end{aligned}$$

◀

▶ **Lemma 5.** *Consider an iteration of noisy k-means++ after the first one and let $C \neq \emptyset$ denote the current set of centers. We denote by z the center sampled in the considered iteration. Then for any $C \neq \emptyset$ and any optimal cluster $C_i^\star$,*

$$\mathbb{E}[\Phi(C_i^\star, C \cup \{z\}) \mid C, z \in C_i^\star] \leq \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_1(C_i^\star).$$

Proof. Conditioned on sampling a point from $C_i^\star$, the probability of choosing point $x \in C_i^\star$ as the next center is at most $\frac{1+\epsilon_2}{1-\epsilon_1} \cdot \frac{\Phi(x,C)}{\Phi(C_i^\star, C)}$. If x is chosen as the next center, the costs of any point $p \in C_i^\star$ become $\min\{\Phi(p,C), ||p-x||^2\}$. This implies

$$\begin{aligned}
\mathbb{E}[\Phi(C_i^\star, C \cup \{z\}) \mid C, z \in C_i^\star] &= \sum_{x \in C_i^\star} \mathbf{Pr}[z = x \mid C] \cdot \Phi(C_i^\star, C \cup \{x\}) \\
&\leq \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{x \in C_i^\star} \frac{\Phi(x,C)}{\Phi(C_i^\star, C)} \sum_{p \in C_i^\star} \min\{\Phi(p,C), ||p-x||^2\}.
\end{aligned} \tag{2}$$

For any two points $x, p \in C_i^\star$, we can write

$$\Phi(x,C) = \Big(\min_{c \in C} ||x-c||\Big)^2 \leq \Big(\min_{c \in C}(||x-p|| + ||p-c||)\Big)^2 \leq 2\Phi(p,C) + 2||x-p||^2.$$

By summing over all p in $C_i^\star$, we get

$$\Phi(x,C) \leq \frac{2}{|C_i^\star|} \sum_{p \in C_i^\star} \Phi(p,C) + \frac{2}{|C_i^\star|} \sum_{p \in C_i^\star} ||x-p||^2.$$

With (2), this implies that $\mathbb{E}[\Phi(C_i^\star, C \cup \{z\}) \mid C, z \in C_i^\star]$ is bounded from above by

$$\begin{aligned}
&\frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{x \in C_i^\star} \frac{\frac{2}{|C_i^\star|}\sum_{p \in C_i^\star} \Phi(p,C) + \frac{2}{|C_i^\star|}\sum_{p \in C_i^\star} ||x-p||^2}{\Phi(C_i^\star, C)} \sum_{p \in C_i^\star} \min\{\Phi(p,C), ||p-x||^2\} \\
&= \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{\frac{2}{|C_i^\star|}\sum_{p \in C_i^\star} \Phi(p,C)}{\sum_{p \in C_i^\star} \Phi(p,C)} \sum_{p \in C_i^\star} \min\{\Phi(p,C), ||p-z||^2\}
\end{aligned}$$

$$
\begin{aligned}
&+ \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{\frac{2}{|C_i^\star|} \sum_{p \in C_i^\star} ||p-z||^2}{\sum_{p \in C_i^\star} \Phi(p,C)} \sum_{p \in C_i^\star} \min\{\Phi(p,C), ||p-z||^2\} \\
&\leq \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{2}{|C_i^\star|} \sum_{p \in C_i^\star} ||p-z||^2 + \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{2}{|C_i^\star|} \sum_{p \in C_i^\star} ||p-z||^2 \\
&= \frac{4(1+\epsilon_2)}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{1}{|C_i^\star|} \sum_{p \in C_i^\star} ||p-z||^2 \\
&= \frac{4(1+\epsilon_2)}{1-\epsilon_1} \cdot \sum_{z \in C_i^\star} \frac{1}{|C_i^\star|} (\mathrm{OPT}_1(C_i^\star) + |C_i^\star| \cdot ||z - \mu(C_i^\star)||^2) \qquad \text{(Lemma 3)} \\
&= \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_1(C_i^\star)
\end{aligned}
$$

◀

Consider a run of noisy k-means++. For $t \in [k]$, let H_t and U_t denote the set of all points from X that belong after iteration i to covered and uncovered optimal clusters, respectively. Let u_t denote the number of uncovered clusters after iteration t. Furthermore let T_t denote the set of centers chosen by noisy k-means++ in the first t iterations. We say that iteration t is *wasted* if the center chosen in iteration t comes from H_{t-1}, i.e., if in iteration t no uncovered cluster becomes covered.

▶ **Corollary 6.** *For any $t \in [k]$,*

$$\mathbf{E}\left[\Phi(H_t, T_t)\right] \leq \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_k(X)$$

Proof. Using Lemma 4 and Lemma 5 we obtain

$$
\begin{aligned}
\mathbf{E}\left[\Phi(H_t, T_t)\right] &= \sum_{i=1}^{k} \mathbf{Pr}[C_i^\star \subseteq H_t] \cdot \mathbf{E}\left[\Phi(C_i^\star, T_t) \mid C_i^\star \subseteq H_t\right] \\
&\leq \sum_{i=1}^{k} \mathbf{Pr}[C_i^\star \subseteq H_t] \cdot \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_1(C_i^\star) \\
&\leq \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \sum_{i=1}^{k} \mathrm{OPT}_1(C_i^\star) \\
&= \frac{8(1+\epsilon_2)}{1-\epsilon_1} \cdot \mathrm{OPT}_k(X).
\end{aligned}
$$

◀

Corollary 6 implies that the covered clusters contribute in expectation at most $O(\mathrm{OPT}_k(X))$ to the costs of the solution computed by noisy k-means++ (assuming ϵ_1 and ϵ_2 to be constants). The not straightforward part is to prove an upper bound for the costs of the clusters that are not covered by noisy k-means++. For this, we adapt the analysis of k-means++ due to Dasgupta [12]. This analysis is based on a potential function that accumulates costs in every wasted iteration. The potential function has the property that the expected value of the potential function in the end can be bounded and that the total costs accumulated are in expectation at least the costs of the uncovered clusters in the end.

Dasgupta crucially uses that the expected average costs of the uncovered clusters do not increase in k-means++. For noisy k-means++ this is not true anymore in general. Hence, we have to adapt the potential function and the analysis. We define $W_i = 1$ if iteration i is wasted and $W_i = 0$ otherwise. We define the potential function as

$$\Psi_k = \sum_{i=2}^{k} W_i \cdot \frac{\Phi(U_i, T_i)}{u_i}.$$

The easier part is to show that the potential can be bounded from above.

▶ **Lemma 7.** *It holds*

$$\mathbf{E}[\Psi_k] \leq \frac{8(1+\epsilon_2)^2}{(1-\epsilon_1)^2} \cdot (\ln(k)+1) \cdot \mathrm{OPT}_k(X).$$

Proof. Let $i \in \{2,\dots,t\}$. In the following calculation we sum over all realizations $\mathcal{F}_{i-1}$ of the first $i-1$ iterations of noisy k-means++. Any realization $\mathcal{F}_{i-1}$ determines the value of $\Phi(U_{i-1},T_{i-1})$ and u_{i-1}. We use the notation $[\dots]_{\mathcal{F}_{i-1}}$ to express that all terms inside the brackets take the values determined by $\mathcal{F}_{i-1}$. Then

$$\begin{aligned}\mathbf{E}\left[W_i \cdot \frac{\Phi(U_i,T_i)}{u_i}\right] &= \sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \mathbf{E}\left[W_i \cdot \frac{\Phi(U_i,T_i)}{u_i} \;\middle|\; \mathcal{F}_{i-1}\right] \\ &= \sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \mathbf{Pr}[W_i = 1 \mid \mathcal{F}_{i-1}] \cdot \mathbf{E}\left[\frac{\Phi(U_i,T_i)}{u_i} \;\middle|\; \mathcal{F}_{i-1} \cap (W_i = 1)\right]\end{aligned}$$

Since under the condition that iteration i is wasted the average costs of the uncovered clusters cannot increase, we can upper bound the term above by

$$\begin{aligned}&\sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \mathbf{Pr}[W_i = 1 \mid \mathcal{F}_{i-1}] \cdot \left[\frac{\Phi(U_{i-1},T_{i-1})}{u_{i-1}}\right]_{\mathcal{F}_{i-1}} \\ &\leq \sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \left[\frac{(1+\epsilon_2)\Phi(H_{i-1},T_{i-1})}{(1-\epsilon_1)\Phi(U_{i-1},T_{i-1})} \cdot \frac{\Phi(U_{i-1},T_{i-1})}{u_{i-1}}\right]_{\mathcal{F}_{i-1}} \\ &= \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \left[\frac{\Phi(H_{i-1},T_{i-1})}{u_{i-1}}\right]_{\mathcal{F}_{i-1}} \\ &\leq \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{\mathcal{F}_{i-1}} \mathbf{Pr}[\mathcal{F}_{i-1}] \cdot \left[\frac{\Phi(H_{i-1},T_{i-1})}{k-i+1}\right]_{\mathcal{F}_{i-1}} \\ &= \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \frac{\mathbf{E}[\Phi(H_{i-1},T_{i-1})]}{k-i+1}.\end{aligned}$$

This implies

$$\begin{aligned}\mathbf{E}[\Psi_k] &= \sum_{i=2}^{k} \mathbf{E}\left[W_i \cdot \frac{\Phi(U_i,T_i)}{u_i}\right] \\ &\leq \frac{1+\epsilon_2}{1-\epsilon_1} \cdot \sum_{i=2}^{k} \frac{\mathbf{E}[\Phi(H_{i-1},T_{i-1})]}{k-i+1}.\end{aligned}$$

With Corollary 6 this yields

$$\mathbf{E}[\Psi_k] \leq \frac{8(1+\epsilon_2)^2}{(1-\epsilon_1)^2} \cdot \mathrm{OPT}_k(X) \sum_{i=2}^{k} \frac{1}{k-i+1} \leq \frac{8(1+\epsilon_2)^2}{(1-\epsilon_1)^2} \cdot (\ln(k)+1) \cdot \mathrm{OPT}_k(X). \quad \blacktriangleleft$$

Now our goal is to prove a lower bound on the potential, namely, we want to prove the following lemma, where we use $D(\epsilon_1,\epsilon_2,\ln k) = \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\} \cdot \ln k$.

▶ **Lemma 8.** *If $k \geq D(\epsilon_1,\epsilon_2,\ln k)$, then set $B(\epsilon_1,\epsilon_2,\ln k) = \frac{4(1+\epsilon_2)}{1-\epsilon_1} \cdot \ln(k) + 2$, and otherwise, set $B(\epsilon_1,\epsilon_2,\ln k) = D(\epsilon_1,\epsilon_2,\ln k)$. Then*

$$\mathbf{E}[\Psi_k] \geq \frac{\mathbf{E}[\Phi(U_k,T_k)]}{B(\epsilon_1,\epsilon_2,\ln k)}.$$

The main technical challenge is to bound the increase in the expected average cost of uncovered clusters, namely, the proof of Lemma 8 heavily depends on the following lemma. We state the lemma below and prove it later. We use the notation $[\ldots]_{\mathcal{F}_i}$ to express that all terms inside the brackets take the values determined by $\mathcal{F}_i$.

▶ **Lemma 9.** *Set* $D(\epsilon_1, \epsilon_2, \ln k) = \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\} \cdot \ln k$. *If* $k \geq D(\epsilon_1, \epsilon_2, \ln k)$, *then set* $B(\epsilon_1, \epsilon_2, \ln k) = \frac{4(1+\epsilon_2)}{1-\epsilon_1} \cdot \ln(k) + 2$, *and otherwise, set* $B(\epsilon_1, \epsilon_2, \ln k) = D(\epsilon_1, \epsilon_2, \ln k)$. *Then for any* $i \in [k]$ *and any realization* $\mathcal{F}_i$ *of the first* i *iterations*

$$\mathbf{E}\left[\frac{\Phi(U_k, T_k)}{u_k} \,\middle|\, \mathcal{F}_i\right] \leq B(\epsilon_1, \epsilon_2, \ln k) \cdot \left[\frac{\Phi(U_i, T_i)}{u_i}\right]_{\mathcal{F}_i}.$$

We assume Lemma 9 to prove Lemma 8 as follows. Later, we give the proof of Lemma 9.

Proof. For any $i \in \{2, \ldots, k\}$, we obtain using Lemma 9

$$\begin{aligned}
\mathbf{E}\left[W_i \cdot \frac{\Phi(U_i, T_i)}{u_i}\right] &= \sum_{\mathcal{F}_i, [W_i]_{\mathcal{F}_i}=1} \mathbf{Pr}[\mathcal{F}_i] \cdot \left[\frac{\Phi(U_i, T_i)}{u_i}\right]_{\mathcal{F}_i} \\
&\geq \sum_{\mathcal{F}_i, [W_i]_{\mathcal{F}_i}=1} \mathbf{Pr}[\mathcal{F}_i] \cdot \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \mathbf{E}\left[\frac{\Phi(U_k, T_k)}{u_k} \,\middle|\, \mathcal{F}_i\right] \\
&= \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \sum_{\mathcal{F}_i} \mathbf{Pr}[\mathcal{F}_i] \cdot \mathbf{E}\left[W_i \cdot \frac{\Phi(U_k, T_k)}{u_k} \,\middle|\, \mathcal{F}_i\right] \\
&= \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \mathbf{E}\left[W_i \cdot \frac{\Phi(U_k, T_k)}{u_k}\right].
\end{aligned}$$

Hence,

$$\begin{aligned}
\mathbf{E}[\Psi_k] &= \sum_{i=2}^{k} \mathbf{E}\left[W_i \cdot \frac{\Phi(U_i, T_i)}{u_i}\right] \\
&\geq \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \sum_{i=2}^{k} \mathbf{E}\left[W_i \cdot \frac{\Phi(U_k, T_k)}{u_k}\right] \\
&= \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \mathbf{E}\left[\left(\sum_{i=2}^{k} W_i\right) \cdot \frac{\Phi(U_k, T_k)}{u_k}\right] \\
&= \frac{1}{B(\epsilon_1, \epsilon_2, \ln k)} \cdot \mathbf{E}\left[u_k \cdot \frac{\Phi(U_k, T_k)}{u_k}\right] \\
&= \frac{\mathbf{E}[\Phi(U_k, T_k)]}{B(\epsilon_1, \epsilon_2, \ln k)}
\end{aligned}$$

◀

With Lemma 7, Lemma 8 and Corollary 6, we prove the main theorem.

▶ **Theorem 2.** *Let* T_k *denote the set of centers sampled by noisy* k*-means++ on dataset* X *and assume that* $\frac{k}{\ln k} \geq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\}$. *Then,*

$$\mathbb{E}[\Phi(X, T_k)] \leq \mathcal{O}\left(\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right)^3 \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right),$$

where $\mathrm{OPT}_k(X)$ *denotes the* k*-means costs of an optimal* k*-clustering of* X. *If* $\frac{k}{\ln k} \leq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\}$, *then* $\mathbb{E}[\Phi(X, T_k)] \leq \mathcal{O}\left(\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right)^4 \cdot \log^2\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right) \cdot \mathrm{OPT}_k(X)\right)$.

Proof. For $k \geq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\} \cdot \ln k$, Lemma 7 and Lemma 8 imply

$$\begin{aligned}\mathbf{E}\left[\Phi(U_k, T_k)\right] &\leq B(\epsilon_1, \epsilon_2, \ln k) \cdot \mathbf{E}\left[\Psi_k\right] \\ &\leq B(\epsilon_1, \epsilon_2, \ln k) \cdot \frac{8(1+\epsilon_2)^2}{(1-\epsilon_1)^2} \cdot (\ln(k)+1) \cdot \mathrm{OPT}_k(X) \\ &= O\left(\frac{(1+\epsilon_2)^3}{(1-\epsilon_1)^3} \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right).\end{aligned}$$

With Corollary 6 this implies

$$\begin{aligned}\mathbf{E}\left[\Phi(H_k, T_k) + \Phi(U_k, T_k)\right] &\leq O\left(\frac{1+\epsilon_2}{1-\epsilon_1} \cdot \mathrm{OPT}_k(X)\right) + O\left(\frac{(1+\epsilon_2)^3}{(1-\epsilon_1)^3} \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right) \\ &\leq O\left(\frac{(1+\epsilon_2)^3}{(1-\epsilon_1)^3} \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right)\end{aligned}$$

For $k \leq \max\{18, \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\} \cdot \ln k$, we get

$$\begin{aligned}&B(\epsilon_1, \epsilon_2, \ln k) \cdot \frac{8(1+\epsilon_2)^2}{(1-\epsilon_1)^2} \cdot (\ln(k)+1) \cdot \mathrm{OPT}_k(X) \\ &= O\left(\frac{(1+\epsilon_2)^4}{(1-\epsilon_1)^4} \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right),\end{aligned}$$

where we use that $\epsilon_1 < 1$, so $\epsilon_1 + \epsilon_2 \leq 1 + \epsilon_2$. This implies

$$\begin{aligned}\mathbf{E}\left[\Phi(H_k, T_k) + \Phi(U_k, T_k)\right] &\leq O\left(\frac{(1+\epsilon_2)^4}{(1-\epsilon_1)^4} \cdot \log^2(k) \cdot \mathrm{OPT}_k(X)\right) \\ &\leq O\left(\frac{(1+\epsilon_2)^4}{(1-\epsilon_1)^4} \cdot \log^2\left(\frac{(1+\epsilon_2)^2}{(1-\epsilon_1)^2}\right) \cdot \mathrm{OPT}_k(X)\right) \\ &= O\left(\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right)^4 \cdot \log^2\left(\frac{1+\epsilon_2}{1-\epsilon_1}\right) \cdot \mathrm{OPT}_k(X)\right),\end{aligned}$$

where we use for the second inequality that either $\sqrt{k} \leq \frac{k}{\ln k} \leq 18$ and then $\ln k \leq O(1)$, or

$$\begin{aligned}\sqrt{k} \leq \frac{k}{\ln k} \leq \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2} &\Rightarrow \ln\sqrt{k} \leq \ln\left(\frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}\right) \\ &\Rightarrow \log k \leq O\left(\log\left(\frac{(1+\epsilon_2)^2}{(1-\epsilon_1)^2}\right)\right).\end{aligned}$$

◀

We conclude this section by discussing Lemma 9. It says that the average potential of uncovered clusters increases by at most a logarithmic multiplicative factor. We first consider the following abstract random experiment whose connection to noisy k-means++ we discuss in the actual proof of Lemma 9 below. Let $a_1, \ldots, a_z \in \mathbb{R}_{\geq 0}$ denote numbers with average value 1. Since there are z numbers with the average equal to one, their sum equals z. We assume that in each step of our experiment with probability $\epsilon \in [0, 1)$ an adversary chooses one of the numbers to be removed and with probability $1 - \epsilon$ a number is removed by proportional sampling (i.e., if number a_i still exists then it is removed with probability a_i/S, where S denotes the sum of the remaining numbers). Note that in this process the number a_i is sampled with probability at least $(1-\epsilon)\frac{a_i}{S}$. Additionally after each step an adversary can arbitrarily lower the value of some numbers. This process is run for ℓ steps and we are interested in an upper bound for the expected average of the numbers remaining after these ℓ steps. We denote this average by A_ℓ.

▶ **Lemma 10.** *Let $\epsilon \in (0,1)$, assume that $\frac{z}{\ln z} \geq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\}$, and $\ell \geq z/2$. Then $\mathbf{E}[A_\ell] \leq \frac{4}{1-\epsilon} \cdot \ln(z) + 2$. For $z \leq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\} \cdot \ln z$, we observe that $\mathbf{E}[A_\ell] \leq z \leq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\} \cdot \ln z$.*

Proof. Let Z denote the number of adversarial steps among the first ℓ steps. Then $\mathbf{E}[Z] = \epsilon\ell$. We denote by $\mathcal{F}_1$ the event that $Z \geq \frac{1+\epsilon}{2} \cdot \ell$. Note that $(1+\epsilon)/2 = \epsilon + (1-\epsilon)/2$ always lies between ϵ and 1.

By Chernoff bound we get

$$\begin{aligned}\mathbf{Pr}[\mathcal{F}_1] = \mathbf{Pr}\left[Z \geq \frac{1+\epsilon}{2}\ell\right] &= \mathbf{Pr}\left[Z \geq \frac{1+\epsilon}{2\epsilon}\epsilon\ell\right] \\ &= \mathbf{Pr}\left[Z \geq \left(1 + \frac{1-\epsilon}{2\epsilon}\right) \cdot \mathbf{E}[Z]\right] \leq \exp\left(-\frac{\min\{\delta, \delta^2\} \cdot \mathbf{E}[Z]}{3}\right)\end{aligned}$$

for $\delta = \frac{1-\epsilon}{2\epsilon}$. We make a case analysis. For $\frac{1-\epsilon}{2\epsilon} \geq 1 \Leftrightarrow \epsilon \leq \frac{1}{3}$, $\min\{\delta, \delta^2\} = \delta$, so we have

$$\mathbf{Pr}[\mathcal{F}_1] \leq \exp\left(-\frac{\delta \cdot \mathbf{E}[Z]}{3}\right) = \exp\left(-\frac{\frac{1-\epsilon}{2\epsilon} \cdot \epsilon\ell}{3}\right) = \exp\left(-\frac{(1-\epsilon)}{6}\ell\right) \leq \exp\left(-\frac{(1-\epsilon)}{12}z\right),$$

where the last inequality follows from $\ell \geq z/2$. We observe that

$$\exp\left(-\frac{(1-\epsilon)}{12}z\right) \leq \frac{1}{z} \Leftrightarrow \frac{z}{\ln z} \geq \frac{12}{1-\epsilon},$$

and by $\epsilon \leq 1/3$ and by our lower bound on $z/\ln z$, we have $\frac{z}{\ln z} \geq 18 \geq \frac{12}{1-\varepsilon}$.

If $\epsilon > 1/3$, we compute similarly that

$$\mathbf{Pr}[\mathcal{F}_1] \leq \exp\left(-\frac{\frac{(1-\epsilon)^2}{(2\epsilon)^2} \cdot \epsilon\ell}{3}\right) \leq \exp\left(-\frac{(1-\epsilon)^2}{12\epsilon}\ell\right) \leq \exp\left(-\frac{(1-\epsilon)^2}{24\epsilon}z\right) \leq \frac{1}{z},$$

where the last inequality follows from $z/(\ln z) \geq \frac{24\epsilon}{(1-\epsilon)^2}$.

If the event $\mathcal{F}_1$ does not happen then in at least $(1 - \frac{1+\epsilon}{2})\ell = \frac{1-\epsilon}{2}\ell \geq \frac{1-\epsilon}{4}z =: z/c'$ steps proportional sampling is used to remove one of the numbers (we set $c' = 4/(1-\epsilon)$). We will show that with high probability after these steps all remaining numbers are at most $2c' \ln z$. Let $\mathcal{F}_2$ denote the event that after z/c' steps of proportional sampling at least one number with final value at least $2c' \ln z$ is remaining. Furthermore, let $\mathcal{E}_i$ denote the event that the ith number a_i remains after z/c' steps of proportional sampling and its final value $\tilde{a}_i$ is at least $2c' \ln z$ (remember that the adversary can decrease numbers during the process but not increase and hence $\tilde{a}_i \leq a_i$). Then $\mathcal{F}_2 = \mathcal{E}_1 \cup \ldots \cup \mathcal{E}_z$. If $\mathcal{E}_i$ occurs then the ith number is in every step at least $\tilde{a}_i \geq 2c' \ln z$. Since the numbers $a_1, \ldots a_z$ have average 1, their sum is z. The sum of the remaining numbers cannot increase during the process. Hence, in every step the probability of taking the ith number is at least $(2c' \ln z)/z$. This implies

$$\mathbf{Pr}[\mathcal{E}_i] \leq \left(1 - \frac{2c' \ln z}{z}\right)^{z/c'} \leq \exp(-2 \ln z) = \frac{1}{z^2}.$$

We use a union bound to obtain

$$\mathbf{Pr}[\mathcal{F}_2] = \mathbf{Pr}[\exists i \in [z] : \mathcal{E}_i] \leq \frac{1}{z}.$$

If neither $\mathcal{F}_1$ nor $\mathcal{F}_2$ occurs then the final value of each remaining number is at most $2c' \ln z$. Hence, in this case, also the average is bounded from above by $2c' \ln z$. Otherwise we only use the trivial upper bound of z for the average of the remaining numbers (observe that initially each a_i is at most z because the average is 1). Altogether we obtain

$$\begin{aligned}\mathbf{E}[A_\ell] &\leq \mathbf{Pr}[\neg\mathcal{F}_1 \wedge \neg\mathcal{F}_2] \cdot 2c' \ln z + \mathbf{Pr}[\mathcal{F}_1 \vee \mathcal{F}_2] \cdot z \\ &\leq 2c' \ln z + (\mathbf{Pr}[\mathcal{F}_1] + \mathbf{Pr}[\mathcal{F}_2]) \cdot z \\ &\leq 2c' \ln z + \left(\frac{1}{z} + \frac{1}{z}\right) \cdot z \\ &= 2c' \ln(z) + 2 = 4/(1-\epsilon) \ln z + 2.\end{aligned}$$

For the second inequality stated in the lemma, we only observe that even if we draw all but one number, the average cannot increase beyond z since the sum of the numbers is z. Thus $\mathbf{E}[A_\ell] \leq z$ is true for any $1 \leq \ell \leq z$. ◀

We prove below that if $\ell < z/2$ then $\mathbf{E}[A_\ell] \leq 2$.

▶ **Lemma 11.** *Let $\ell < z/2$. Then $\mathbf{E}[A_\ell] \leq 2$.*

Proof. In the worst case all steps are adversarial and the ℓ smallest numbers are removed. Then the average of the remaining numbers is at most

$$\frac{z}{z-\ell} < \frac{z}{z-z/2} = 2.$$ ◀

Using Lemma 11, we obtain the following corollary.

▶ **Corollary 12.** *Let $\epsilon \in (0,1)$ and $1 \leq \ell \leq z-1$. Then for $z \geq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\} \cdot \ln z$, we get*

$$\mathbf{E}[A_\ell] \leq \frac{4}{1-\epsilon} \cdot \ln z + 2,$$

and for $z \leq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\} \cdot \ln z$, we have $\mathbf{E}[A_\ell] \leq \max\{18, \frac{24\epsilon}{(1-\epsilon)^2}\} \cdot \ln z$.

Proof. Follows from Lemma 10 and Lemma 11. ◀

Now we are ready to prove Lemma 9.

Proof of Lemma 9. Given realization F_i, after the first i iterations there are $z = u_i \leq k$ uncovered clusters. Each of them has certain costs with respect to the center set after the first i iterations. The costs of each cluster do not increase in the following iterations anymore because only new centers are added. In any iteration the costs of these clusters may decrease and one uncovered cluster may become covered. If the latter happens, the average costs of the uncovered clusters can increase (if the costs of the uncovered cluster that becomes covered are less than the average costs of the uncovered clusters). Hence, only the non-wasted iterations are of interest.

The costs of the uncovered clusters after the first i iterations correspond to the numbers $a_1, \ldots, a_z$ in the random experiment above. We scaled the instance such that the sum of the a_i is equal to z. This is without loss of generality. In each iteration of noisy k-means++ either a covered cluster is hit again, which can only reduce the numbers a_i, or an uncovered cluster becomes covered, in which case the corresponding number is removed. Conditioned on covering an uncovered cluster, the probability p_i that a_i is removed is at least $\frac{1-\epsilon_1}{1+\epsilon_2} \cdot \frac{a_i}{S}$, where S denotes the sum of the costs of the uncovered clusters (i.e., the sum of the remaining a_i). We can simulate the probability distribution induced by the probabilities p_i

by mixing two distributions: with probability $\frac{1-\epsilon_1}{1+\epsilon_2}$ we do proportional sampling, i.e., we choose a_i with probability $\frac{a_i}{S}$, and with probability $1-\frac{1-\epsilon_1}{1+\epsilon_2}$ we sample according to some other distribution to obtain the right probabilities p_i. In the abstract random experiment analyzed above this second distribution is selected by an adversary. For $\epsilon = \frac{\epsilon_1+\epsilon_2}{1+\epsilon_2} \in (0,1)$ we have

$$1-\epsilon = 1-\frac{\epsilon_1+\epsilon_2}{1+\epsilon_2} = \frac{1+\epsilon_2-(\epsilon_1+\epsilon_2)}{1+\epsilon_2} = \frac{1-\epsilon_1}{1+\epsilon_2}.$$

Hence, Corollary 12 applies to noisy k-means++ with $\epsilon = \frac{\epsilon_1+\epsilon_2}{1+\epsilon_2}$. Observe that then

$$\frac{24\epsilon}{(1-\epsilon)^2} = \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)^2}{(1+\epsilon_2)(1-\epsilon_1)^2} = \frac{24(\epsilon_1+\epsilon_2)(1+\epsilon_2)}{(1-\epsilon_1)^2}.$$ ◀

Bicriteria Approximation

We remark that noisy k-means++ still gives a bicriteria approximation because the probability that an uncovered cluster is hit can only be decreased by a constant factor, and the probability to pick a good center is also still comparably high. The theorem mentioned below follows from [1]. We omit the proof of this theorem in this paper as it easily follows from [1].

▶ **Theorem 13.** *Let S denote a set of $16(\frac{1+\epsilon_2}{1-\epsilon_1})^2(k+\sqrt{k})$ centers sampled using noisy k-means++, then $\Phi(X,S) \leq 20\ \mathrm{OPT}_k(X)$ with probability at least $1-\exp\left(-0.0157\cdot\frac{1-\epsilon_1}{1+\epsilon_2}\right)$.*

Not so greedy k-means++

Consider the following variant of the greedy k-means++ algorithm (Algorithm 3).

Algorithm 3 Moderately greedy k-means++.

Input: Set $X \subseteq \mathbb{R}^d$, integers k, l
Output: $C \subseteq X, |C| = k$
$C = \emptyset$
Sample a point c_1 independently and uniformly at random from X.
Let $C = \{c_1\}$.
for $i = 2$ to k **do**
    With probability p, sample one point c_i with D^2-sampling and set $C = C \cup \{c_i\}$.
    With the remaining probability:
        Sample a set S of ℓ points independently with D^2-sampling from X wrt C.
        Let $c_i = \arg\min_{u\in S} \Phi(X, C\cup\{u\})$.
        Update $C = C \cup \{c_i\}$.
end for
Return C

Let $x \in P$ be any point. Say that $p_i(x)$ is the probability to draw x with one D^2-sample from X based on the center set $c_1,\ldots,c_{i-1}$. Then the probability $q_i(x)$ to sample x in iteration i of the above algorithm satisfies

$$p\cdot p_i(x) \leq q_i(x) \leq [(1-p)\cdot\ell + p]\cdot p_i(x),$$

since with probability p, we do exactly the same as k-means++, and with probability $(1-p)$, we sample ℓ times, which can at most boost the probability by a factor of $(1-p)\cdot\ell$. Assume that p is a constant. Then by Theorem 2, moderately greedy k-means++ has an expected approximation guarantee of $\mathcal{O}(\ell^3\cdot\log^2 k)$ (for large k).

Abstract

Map labeling is a classical problem in cartography and geographic information systems (GIS) that asks to place labels for area, line, and point features, with the goal to select and place the maximum number of independent, i.e., overlap-free, labels. A practically interesting case is point labeling with axis-parallel rectangular labels of common size. In a fully dynamic setting, at each time step, either a new label appears or an existing label disappears. Then, the challenge is to maintain a maximum cardinality subset of pairwise independent labels with sub-linear update time. Motivated by this, we study the maximal independent set (MIS) and maximum independent set (Max-IS) problems on fully dynamic (insertion/deletion model) sets of axis-parallel rectangles of two types – (i) uniform height and width and (ii) uniform height and arbitrary width; both settings can be modeled as rectangle intersection graphs.

We present the first deterministic algorithm for maintaining a MIS (and thus a 4-approximate Max-IS) of a dynamic set of uniform rectangles with amortized sub-logarithmic update time. This breaks the natural barrier of $\Omega(\Delta)$ update time (where Δ is the maximum degree in the graph) for *vertex updates* presented by Assadi et al. (STOC 2018). We continue by investigating Max-IS and provide a series of deterministic dynamic approximation schemes. For uniform rectangles, we first give an algorithm that maintains a 4-approximate Max-IS with $O(1)$ update time. In a subsequent algorithm, we establish the trade-off between approximation quality $2(1 + \frac{1}{k})$ and update time $O(k^2 \log n)$, for $k \in \mathbb{N}$. We conclude with an algorithm that maintains a 2-approximate Max-IS for dynamic sets of unit-height and arbitrary-width rectangles with $O(\omega \log n)$ update time, where ω is the maximum size of an independent set of rectangles stabbed by any horizontal line. We have implemented our algorithms and report the results of an experimental comparison exploring the trade-off between solution quality and update time for synthetic and real-world map labeling instances.

1 Introduction

Map Labeling is a classical problem in cartography and geographic information systems (GIS), that has received significant attention in the past few decades and is concerned with selecting and positioning labels on a map for area, line, and point features. The focus in the computational geometry community has been on labeling point features [3, 20, 39, 40]. The labels are typically modeled as the bounding boxes of short names, which correspond precisely to unit height, but arbitrary width rectangles; alternatively, labels can be standardized icons or symbols, which correspond to rectangles of uniform size. In map labeling, a key task is in fact to select an independent (i.e., overlap-free) set of labels from a given set of candidate labels. Commonly the optimization goal is related to maximizing the number of labels. Given a set $\mathcal{R}$ of rectangular labels, Map Labeling is essentially equivalent to the problem of finding a maximum independent set in the intersection graph induced by $\mathcal{R}$.

The independent set problem is a fundamental graph problem with a wide range of applications. Given a graph $G = (V, E)$, a set of vertices $M \subset V$ is *independent* if no two vertices in M are adjacent in G. A *maximal independent set* (MIS) is an independent set that is not a proper subset of any other independent set. A *maximum independent set* (Max-IS) is a maximum cardinality independent set. While Max-IS is one of Karp's 21 classic NP-complete problems [31], computing a MIS can easily be done by a simple greedy algorithm in $O(|E|)$ time. The MIS problem has been studied in the context of several other prominent problems, e.g., graph coloring [33], maximum matching [30], and vertex cover [36]. On the other hand, Max-IS serves as a natural model for many real-life optimization problems, including map labeling [3], computer vision [6], information retrieval [37], and scheduling [38].

Stronger results for independent set problems in geometric intersection graphs are known in comparison to general graphs. For instance, it is known that Max-IS on general graphs cannot be approximated better than $|V|^{1-\epsilon}$ in polynomial time for any $\epsilon > 0$ unless NP=ZPP [27]. In contrast, a randomized polynomial-time algorithm exists that computes for rectangle intersection graphs an $O(\log \log n)$-approximate solution to Max-IS with high probability [12], as well as QPTASs [2,16]. The Max-IS problem is already NP-Hard on unit square intersection graphs [21], however, it admits a polynomial-time approximation scheme (PTAS) for unit square intersection graphs [19] and more generally for pseudo disks [13]. Moreover, for rectangles with either uniform size or at least uniform height and bounded aspect ratio, the size of an MIS is not arbitrarily worse than the size of a Max-IS. For instance, any MIS of a set of uniform rectangles is a 4-approximate solution to the Max-IS problem, since each rectangle can have at most four independent neighbors.

Past research has mostly considered static label sets in static maps [3, 20, 39, 40] and in dynamic maps allowing zooming [7] or rotations [25], but not fully dynamic label sets with insertions and deletions of labels. Recently, Klute et al. [32] proposed a framework for semi-automatic label placement, where domain experts can interactively insert and delete labels. In their setting an initially computed large independent set of labels can be interactively modified by a cartographer, who can easily take context information and soft criteria such as interactions with the background map or surrounding labels into account. Standard map labeling algorithms typically do not handle such aspects well. Based on these modifications (such as deletion, forced selection, translation, or resizing), the solution is updated by a dynamic algorithm while adhering to the new constraints. Another scenario for dynamic labels are maps, in which features and labels (dis-)appear over time, e.g., based on a stream of geotagged, uniform-size photos posted on social media or, more generally, maps with labels of dynamic spatio-temporal point sets [22]. For instance, a geo-located event

that happens at time t triggers the availability of a new label for a certain period of time, after which it vanishes again. Examples beyond social media are reports of earth quakes, forest fires, or disease incidences. Motivated by this, we study the independent set problem for dynamic rectangles of two types – (i) uniform height and width and (ii) uniform height and arbitrary width. We consider fully dynamic algorithms for maintaining independent sets under insertions and deletions of rectangles, i.e., vertex insertions and deletions in the corresponding dynamic rectangle intersection graph.

Dynamic graphs are subject to discrete changes over time, i.e., insertions or deletions of vertices or edges [18]. A dynamic graph algorithm solves a computational problem, such as the independent set problem, on a dynamic graph by updating efficiently the previous solution as the graph changes over time, rather than recomputing it from scratch. A dynamic graph algorithm is called *fully dynamic* if it allows both insertions and deletions, and *partially dynamic* if only insertions or only deletions are allowed. While general dynamic independent set algorithms can obviously also be applied to rectangle intersection graphs, our goal is to exploit their geometric properties to obtain more efficient algorithms.

Related Work. There has been a lot of work on dynamic graph algorithms in the last decade and dynamic algorithms still receive considerable attention in theoretical computer science. We point out some of these works, e.g., on spanners [9], vertex cover [10], set cover [1], graph coloring [11], and maximal matching [23]. In particular, the maximal independent set problem on dynamic graphs with edge updates has attracted significant attention in the last two years [4, 5, 8, 15, 17]. Recently, Henzinger et al. [28] studied the Max-IS problem for intervals, hypercubes and hyperrectangles in d dimensions, with special assumptions. They assumed that the objects are axis-parallel and contained in the space $[0, N]^d$; the value of N is given in advance, and each edge of an input object has length at least 1 and at most N. Moreover, they have designed dynamic approximation algorithms and lower bounds, where the update time depends on N and is of high complexity. Gavruskin et al. [24] studied the Max-IS problem for dynamic proper intervals (intervals cannot contain one another), and showed how to maintain a Max-IS with polylogarithmic update time.

Results and Organization. We study MIS and Max-IS problems for dynamic sets of $O(n)$ axis-parallel rectangles of two types: (i) congruent rectangles of uniform height and width and (ii) rectangles of uniform height and arbitrary width. For both classes of rectangles a MIS can be maintained in $\Omega(\Delta)$ update time by using the recent algorithm of Assadi et al. [4], where Δ is the maximum degree of the intersection graph. A $(1+\epsilon)$-approximate Max-IS can be maintained for unit squares in $O(n^{1/\epsilon^2})$ time [19], and a $(1+\frac{1}{k})$-approximate Max-IS can be maintained for unit height and arbitrary width rectangles in $O(n^{2k-1})$ update time [3] for any integer $k \geq 1$. In this paper we design and implement algorithms for dynamic MIS and Max-IS that demonstrate the trade-off between update time and approximation factor, both from a theoretical perspective and in an experimental evaluation. In contrast to the recent dynamic MIS algorithms, which are randomized [4, 5, 8, 15], our algorithms are deterministic.

In Section 3 we present an algorithm that maintains a MIS of a dynamic set of unit squares in amortized $O(\log^{2/3+o(1)} n)$ update time, improving the best known update time $\Omega(\Delta)$ [4]. A major, but generally unavoidable bottleneck of that algorithm is that the entire graph is stored explicitly, and thus insertions/deletions of vertices take $\Omega(\Delta)$ time. We use structural geometric properties of the unit squares along with a dynamic orthogonal range searching data structure to bypass the explicit intersection graph and break this bottleneck.

In Section 4, we study the Max-IS problem. For dynamic unit squares, we give an algorithm that maintains a 4-approximate Max-IS with $O(1)$ update time. We generalize this algorithm and improve the approximation factor to $2(1+\frac{1}{k})$, which increases the update time to $O(k^2 \log n)$. We conclude with an algorithm that maintains a 2-approximate Max-IS for a dynamic set of unit-height and arbitrary-width rectangles (in fact, for a dynamic interval graph, which is of independent interest) with $O(\omega \log n)$ output-sensitive update time, where ω is the maximum size of an independent set of rectangles stabbed by any horizontal line.

Finally, Section 5 provides an experimental evaluation of the proposed Max-IS approximation algorithms on synthetic and real-world map labeling data sets using unit squares. The experiments explore the trade-off between solution size and update time, as well as the speed-up of the dynamic algorithms over their static counterparts. See the supplemental material for source code and benchmark data.

2 Model and Notation

Let $\mathcal{R} = \{r_1, \ldots, r_\nu\}$ be a set of ν axis-parallel, unit-height rectangles in the plane. If the rectangles are of uniform height and width, we can use an affine transformation to map $\mathcal{R}$ to a set of unit squares $\mathcal{S} = \{s_1, \ldots, s_\nu\}$ instead. We use the shorthand notation $[n] = \{1, 2, \ldots, n\}$. In our setting we assume that $\mathcal{R}$ is dynamically updated by a sequence of $N \in \mathbb{N}$ insertions and deletions. We denote the set of rectangles at step $i \in [N]$ as $\mathcal{R}_i$. For a set of unit squares $\mathcal{S}_i = \{s_1, \ldots, s_\nu\}$ at step $i \in [N]$ we further define the set $\mathcal{C}_i = \{c_1, \ldots, c_\nu\}$ of the corresponding square centers. Let $n = \max\{|\mathcal{R}_i| \mid i \in [N]\}$ be the maximum number of rectangles over all steps. The rectangle intersection graph defined by $\mathcal{R}_i$ at time step i is denoted as $G_i = (\mathcal{R}_i, E_i)$, where two rectangles $r, r' \in \mathcal{R}_i$ are connected by an edge $\{r, r'\} \in E_i$ if and only if $r \cap r' \neq \emptyset$. We use M_i to denote a maximal independent set in G_i, and OPT_i to denote a maximum independent set in G_i. For a graph $G = (V, E)$ and a vertex $v \in V$, let $N(v)$ denote the set of neighbors of v in G. This notation also extends to any subset $U \subseteq V$ by defining $N(U) = \bigcup_{v \in U} N(v)$. We use $\deg(v)$ to denote the degree of a vertex $v \in V$. For any vertex $v \in V$, let $N^r(v)$ be the r-neighborhood of v, i.e., the set of vertices that are within distance at most r from v (excluding v).

3 Dynamic MIS with Sub-Logarithmic Update Time

In this section, we study the MIS problem for dynamic uniform rectangles. As stated before we can assume w.l.o.g. that the rectangles are unit squares. We design an algorithm that maintains a MIS for a dynamic set of $O(n)$ unit squares in sub-logarithmic update time. Assadi et al. [4] presented an algorithm for maintaining a MIS on general dynamic graphs with $\Omega(\Delta)$ update time, where Δ is the maximum degree in the graph. In the worst case, however, that algorithm takes $O(n)$ update time. In fact, it seems unavoidable for an algorithm that explicitly maintains the (intersection) graph to perform a MIS update in less than $\Omega(\deg(v))$ time for an insertion/deletion of a vertex v. In contrast, our proposed algorithm in this section does not explicitly maintain the intersection graph $G_i = (\mathcal{S}_i, E_i)$ (for any $i \in [N]$), but rather only the set of squares $\mathcal{S}_i$ in a suitable dynamic geometric data structure. For the ease of explanation, however, we do use graph terms at times.

Let $i \in [N]$ be any time point in the sequence of updates. For each square $s_v \in \mathcal{S}_i$, let s_v^a be a square of side length a concentric with s_v. Further, let M_i denote the MIS that we compute for $G_i = (\mathcal{S}_i, E_i)$, and let $\mathcal{C}(M_i) \subseteq \mathcal{C}_i$ be their corresponding square centers. We

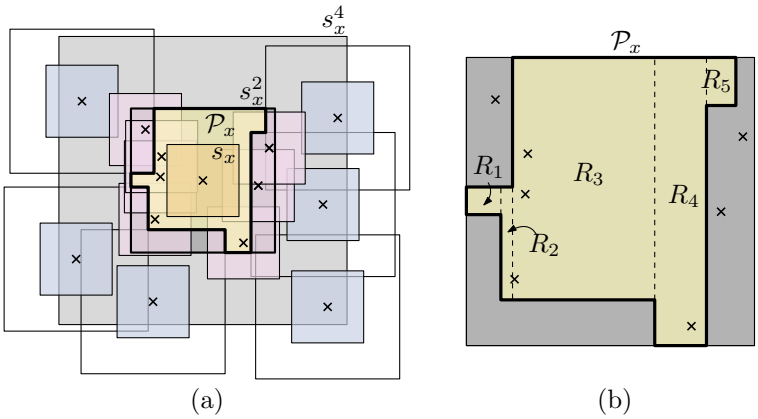

Figure 1 Example for the deletion of a square s_x. (a) Square s_x, its neighborhood with centers in s_x^2, its 2-neighborhood with centers in s_x^4, and the polygon $\mathcal{P}_x$. (b) Vertical slab partition of $\mathcal{P}_x$.

maintain two fully dynamic orthogonal range searching data structures throughout: (i) a dynamic range tree $T(\mathcal{C}_i)$ for the entire point set $\mathcal{C}_i$ and (ii) a dynamic range tree $T(\mathcal{C}(M_i))$ for the point set $\mathcal{C}(M_i)$ corresponding to the centers of M_i. They can be implemented with dynamic fractional cascading [34], which yields $O(\log n \log\log n)$ update time and $O(k + \log n \log\log n)$ query time for reporting k points. The currently best fully dynamic data structure for orthogonal range reporting requires $O(\log^{2/3+o(1)} n)$ amortized update time and $O(k + \frac{\log n}{\log\log n})$ amortized query time [14].

We compute the initial MIS M_1 for $G_1 = (\mathcal{S}_1, E_1)$ by using a simple linear-time greedy algorithm. First we initialize the range tree $T(\mathcal{C}_i)$. Then we iterate through the set $\mathcal{S}_1$ as long as it is not empty, select a square s_v for M_1 and insert its center into $T(\mathcal{C}(M_i))$, find its neighbors $N(s_v)$ by a range query in $T(\mathcal{C}_i)$ with the concentric square s_v^2, and delete $N(s_v)$ from $\mathcal{S}_1$. It is clear that once this process terminates, M_1 is a MIS.

When we move in the next step from $G_i = (\mathcal{S}_i, E_i)$ to $G_{i+1} = (\mathcal{S}_{i+1}, E_{i+1})$, either a square is inserted into $\mathcal{S}_i$ or deleted from $\mathcal{S}_i$. Let s_x be the square that is inserted or deleted.
Insertion: When we insert a square s_x into $\mathcal{S}_i$ to obtain $\mathcal{S}_{i+1}$, we do the following operations. First, we obtain $T(\mathcal{C}_{i+1})$ by inserting the center of s_x into $T(\mathcal{C}_i)$. Next, we have to detect whether s_x can be included in M_{i+1}. If there exists a square s_u from M_i intersecting s_x, we should not include s_x; otherwise we will add it to the MIS. To check this, we search with the range s_x^2 in $T(\mathcal{C}(M_i))$. By a simple packing argument, we know that no more than four points (the centers of four independent squares) of $\mathcal{C}(M_i)$ can be in the range s_x^2. If the query returns such a point, then s_x would intersect with another square in M_i and we set $M_{i+1} = M_i$. Otherwise, we insert s_x into $T(\mathcal{C}(M_i))$ to get $T(\mathcal{C}(M_{i+1}))$.
Deletion: When we delete a square s_x from $\mathcal{S}_i$, it is possible that $s_x \in M_i$. In this case we may have to add squares from $N(s_x)$ into M_{i+1} to keep it maximal. Since any square can have at most four independent neighbors, we can add in this step up to four squares to M_{i+1}.

First, we check if $s_x \in M_i$. If not, then we simply delete s_x from $T(\mathcal{C}_i)$ to get $T(\mathcal{C}_{i+1})$ and set $M_{i+1} = M_i$. Otherwise, we delete again s_x from $T(\mathcal{C}_i)$ and also from $T(\mathcal{C}(M_i))$. In order to detect which neighbors of s_x can be added to M_i, we use suitable queries in the data structures $T(\mathcal{C}(M_i))$ and $T(\mathcal{C}_i)$. Figure 1a illustrates the next observations. The centers of all neighbors in $N(s_x)$ must be contained in the square s_x^2. But some of these neighbors may intersect other squares in M_i. In fact, these squares would by definition belong to the 2-neighborhood, i.e., be in the set $Q_x = N^2(s_x) \cap M_i$. We can obtain Q_x by querying

$T(\mathcal{C}(M_i))$ with the range s_x^4. Since $s_x \in M_i$, we know that $Q_x \cap s_x^2 = \emptyset$ and hence the center points of the squares in Q_x lie in the annulus $s_x^4 - s_x^2$. A simple packing argument implies that $|Q_x| \leq 12$ and therefore querying $T(\mathcal{C}(M_i))$ will return at most 12 points.

Next we define the rectilinear polygon $\mathcal{P}_x = s_x^2 - \bigcup_{s_y \in Q_x} s_y^2$, which contains all possible center points of squares that are neighbors of s_x but do not intersect any square $s_y \in M_i \setminus \{s_x\}$.

▶ **Observation 1** (⋆). *The polygon $\mathcal{P}_x$ has at most 28 corners.*

Next we want to query $T(\mathcal{C}_i)$ with the range $\mathcal{P}_x$, which we do by vertically partitioning $\mathcal{P}_x$ into rectangular slabs $R_1, \ldots, R_c$ for some $c \leq 28$ (see Figure 1b). For each slab R_j, where $1 \leq j \leq c$, we perform a range query in $T(\mathcal{C}_i)$. If a center p is returned, we can add the corresponding square s_p into M_{i+1}, and p into $T(\mathcal{C}(M_i))$ to obtain $T(\mathcal{C}(M_{i+1}))$. Moreover, we have to update $\mathcal{P}_x \leftarrow \mathcal{P}_x - s_p$, refine the slab partition and continue querying $T(\mathcal{C}_i)$ with the slabs of $\mathcal{P}_x$. We know that the deleted square s_x can have at most four independent neighbors. So after adding at most four new squares to M_{i+1} we know that $\mathcal{P}_x = \emptyset$ and we can stop searching.

▶ **Lemma 2** (⋆). *The set M_i is a maximal independent set of $G_i = (\mathcal{S}_i, E_i)$ for each step $i \in [N]$.*

Both the Insertion and the Deletion operations consist of (i) a constant number of insertions or deletions in the two fully dynamic orthogonal range searching data structures and (ii) of a constant number of orthogonal range reporting queries. These queries return at most 12 points in $T(\mathcal{C}(M_{i-1}))$. While the query range $\mathcal{P}_x$ for $T(\mathcal{C}_{i-1})$ in the Deletion operation may contain many points, an arbitrary point in $\mathcal{P}_x$ is sufficient for adding a new square to the independent set. Thus we do not need to enumerate all contained points, but just a single witness. In the orthogonal range searching data structure of Chan and Tsakalidis [14], the amortized update time for an insertion/deletion is $O(\log^{2/3+o(1)} n)$; this dominates the query time and together with Lemma 2 yields:

▶ **Theorem 3.** *We can maintain a maximal independent set of a dynamic set of unit squares, deterministically, in amortized $O(\log^{2/3+o(1)} n)$ update time.*

Proof. The correctness follows from Lemma 2. It remains to show the running time for the fully dynamic updates. At each step i we perform either an Insertion or a Deletion operation. Let us first discuss the update time for the insertion of a square. As described above, an insertion performs one or two insertions of the center of the square into the range trees and one range query in $T(\mathcal{C}(M_{i-1}))$, which will return at most four points. Using dynamic fractional cascading [34], this requires $O(\log n \log\log n)$ time; with the data structure of Chan and Tsakalidis [14], the amortized update time for inserting a square is $O(\log^{2/3+o(1)} n)$, the time for inserting a new point into their range searching data structure; this dominates the query time. The deletion of a square triggers either just a single deletion from the range tree $T(\mathcal{C}_{i-1})$ or, if it was contained in the MIS M_{i-1}, two deletions, up to four insertions, and a sequence of range queries: one query in $T(\mathcal{C}(M_{i-1}))$, which can return at most 12 points and a constant number of queries in $T(\mathcal{C}_{i-1})$ with the constant-complexity slab partition of $\mathcal{P}_x$. Note that while the number of points in $\mathcal{P}_x$ can be large, for our purpose it is sufficient to return a single point in each query range if it is not empty. Therefore, the update time for a deletion is again $O(\log n \log\log n)$ with dynamic fractional cascading [34] or amortized $O(\log^{2/3+o(1)} n)$ [14], depending on the selected data structure. ◀

For unit square intersection graphs, recall that any square in a MIS can have at most four mutually independent neighbors. Therefore, maintaining a dynamic MIS immediately implies maintaining a dynamic 4-approximate Max-IS.

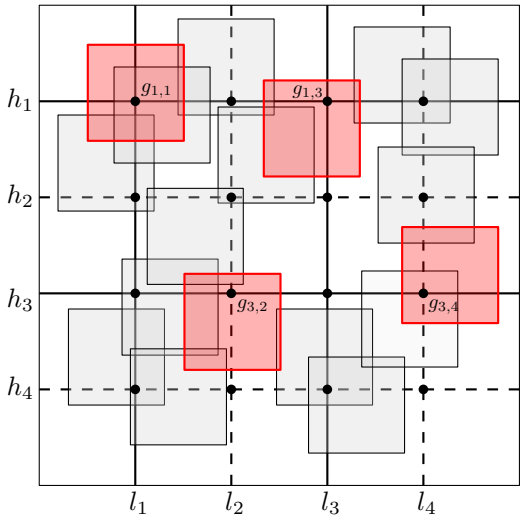

Figure 2 Example instance with bounding square $\mathcal{B}$ partitioned into a 5×5 grid. Red squares represent the computed 4-approximate solution, which here is $M(O(H))$.

▶ **Corollary 4.** *We can maintain a 4-approximate maximum independent set of a dynamic set of unit squares, deterministically, in amortized* $O(\log^{2/3+o(1)} n)$ *update time.*

4 Approximation Algorithms for Dynamic Maximum Independent Set

In this section, we study the Max-IS problem for dynamic unit squares as well as for unit-height and arbitrary-width rectangles. In a series of dynamic schemes proposed in this section, we establish the trade-off between the update time and the solution size, i.e., the approximation factors. First, we design a 4-approximation algorithm with $O(1)$ update time for Max-IS on dynamic unit squares (Section 4.1). We improve this to an algorithm that maintains a $2(1+\frac{1}{k})$-approximate Max-IS with $O(k^2 \log n)$ update time (Section 4.2). Finally, we conclude with an algorithm that deterministically maintains a 2-approximate Max-IS with output-sensitive $O(\omega \log n)$ update time, where ω is the maximum size of an independent set of the unit-height rectangles stabbed by any horizontal line (Section 4.3).

Let $\mathcal{B}$ be a bounding square of the dynamic set of 1×1-unit squares $\bigcup_{i\in[N]} \mathcal{S}_i$ of side length $\kappa \times \kappa$; we can assume that $\kappa = O(n)$; otherwise we could contract empty horizontal/vertical strips of $\mathcal{B}$. Let $H = \{h_1, \ldots, h_\kappa\}$ and $L = \{l_1, \ldots, l_\kappa\}$ be a set of top-to-bottom and left-to-right ordered equidistant horizontal and vertical lines partitioning $\mathcal{B}$ into a square grid of side-length-1 cells, see Figure 2. Let $E_H = \{h_i \in H \mid i = 0 \pmod 2\}$ and $O_H = \{h_i \in H \mid i = 1 \pmod 2\}$ be the set of even and odd horizontal lines, respectively.

4.1 4-Approximation Algorithm with Constant Update Time

We design a 4-approximation algorithm for the Max-IS problem on dynamic unit square intersection graphs with constant update time. Our algorithm is based on a grid partitioning approach. Consider the square grid on $\mathcal{B}$ induced by the sets H and L of horizontal and vertical lines. We denote the grid points as $g_{p,q}$ for $p, q \in [\kappa]$, where $g_{p,q}$ is the intersection point of lines h_p and l_q. Under a general position assumption (otherwise we slightly perturb the grid position to handle degenerate cases), each unit square in any set $\mathcal{S}_i$, for $i \in [N]$ contains exactly one grid point. For each $g_{p,q}$, we store a Boolean *activity value* 1 or 0 based

on its intersection with $\mathcal{S}_i$ (for any step $i \in [N]$). If $g_{p,q}$ intersects at least one square of S_i, we say that it is *active* and set the value to 1; otherwise, we set the value to 0. Observe that for each grid point $g_{p,q}$ and each time step i at most one square of $\mathcal{S}_i$ intersecting $g_{p,q}$ can be chosen in any MAX-IS. This holds because all squares that intersect the same grid point form a clique in G_i, and at most one square from a clique can be chosen in any independent set.

We first initialize an independent set M_1 for $G_1 = (\mathcal{S}_1, E_1)$ with $|M_1| \geq |OPT_1|/4$. For each horizontal line $h_j \in H$, we compute two independent sets $M^1_{h_j}$ and $M^2_{h_j}$, where $M^1_{h_j}$ (resp. $M^2_{h_j}$) contains an arbitrary square intersecting each odd (resp. even) grid point on h_j. Since every other grid point is omitted in these sets, any two selected squares are independent. Let $M(h_j) = \arg\max\{|M^1_{h_j}|, |M^2_{h_j}|\}$ be the larger of the two independent sets. We define $p(h_j) = |M^1_{h_j}|$ and $q(h_j) = |M^2_{h_j}|$, as well as $c(h_j) = |M(h_j)| = \max\{p(h_j), q(h_j)\}$.

We construct the independent sets $M(E_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor}(M(h_{2j}))$ for E_H and $M(O_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor}(M(h_{2j-1})$ for O_H. We return $M_1 = \arg\max\{|M(E_H)|, |M(O_H)|\}$ as the independent set for G_1. See Figure 2 for an illustration. The initialization of all $O(\kappa^2)$ variables and the computation of the first set M_1 take $O(\kappa^2)$ time. (Alternatively, a hash table would be more space efficient, but could not provide the $O(1)$-update time guarantee.)

▶ **Lemma 5 (⋆).** *The set M_1 is an independent set of $G_1 = (\mathcal{S}_1, E_1)$ with $|M_1| \geq |OPT_1|/4$ and can be computed in $O(\kappa^2)$ time.*

In the following step, when we move from G_i to G_{i+1}, for any $i \in [N]$, a square s_x is inserted into $\mathcal{S}_i$ or deleted from $\mathcal{S}_i$. Intuitively, we check the activity value of the grid point that s_x intersects. If the update has no effect on its activity value, we keep $M_{i+1} = M_i$. Otherwise, we update the activity value, the corresponding cardinality counters, and report the solution accordingly. All of these operations can be performed in $O(1)$-time. For a more detailed description see the full version of this paper.

▶ **Lemma 6 (⋆).** *The set M_i is an independent set of $G_i = (\mathcal{S}_i, E_i)$ for each $i \in [N]$ and $|M_i| \geq |OPT_i|/4$.*

Lemmas 5 and 6 together with the $O(1)$ update time yield:

▶ **Theorem 7 (⋆).** *We can maintain a 4-approximate maximum independent set in a dynamic unit square intersection graph, deterministically, in $O(1)$ update time.*

4.2 $2(1 + \frac{1}{k})$-Approximation Algorithm with $O(k)$ Update Time

Next, we improve the approximation factor from 4 to $2(1 + \frac{1}{k})$, for any $k \geq 1$, by combining the shifting technique [29] with the insights gained from Section 4.1. This comes at the cost of an increase of the update time to $O(k^2 \log n)$, which illustrates the trade-off between solution quality and update time. We reuse the grid partition and some notations from Section 4.1. We first describe how to obtain a solution M_1 for the initial graph G_1 that is of size at least $|OPT_1|/2(1 + \frac{1}{k})$ and then discuss how to maintain this under dynamic updates.

Let $h_j \in H$ be a horizontal stabbing line and let $\mathcal{S}(h_j) \subseteq \mathcal{S}$ be the set of squares stabbed by h_j. Since they are all stabbed by h_j, the intersection graph of $\mathcal{S}(h_j)$ is equivalent to the unit interval intersection graph obtained by projecting each unit square $s_x \in \mathcal{S}(h_j)$ to a unit interval i_x on the line h_j; we denote this set of unit intervals as $I(h_j)$. First, we sort the intervals in $I(h_j)$ from left to right. Next we define $k+1$ *groups* with respect to h_j that are formed by deleting those squares and their corresponding intervals from $S(h_j)$ and $I(h_j)$, respectively, that intersect every $k+1$-th grid point on h_j, starting from some $g_{j,\alpha}$ with $\alpha \in [k+1]$. Now consider the k consecutive grid points on h_j between two deleted grid points

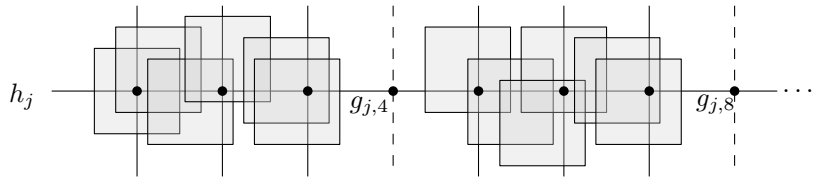

Figure 3 Illustration of a group on line h_j for $k = 3$ with the two subgroups $I_1^3(h_j)$ and $I_5^3(h_j)$.

in one such group, say, $\{g_{j,\ell}, \ldots, g_{j,\ell+k-1}\}$ for some $\ell \in [\kappa]$. Let $I_\ell^k(h_j) \subseteq I(h_j)$ be the set of unit intervals intersecting the k grid points $g_{j,\ell}$ to $g_{j,\ell+k-1}$. We refer to them as *subgroups*. See Figure 3 for an illustration. Observe that the maximum size of an independent set of each subgroup is at most k, since the width of each subgroup is strictly less than $k+1$ and each interval has unit length.

We compute M_1 for G_1 as follows. For each stabbing line $h_j \in H$, we form the $k+1$ different groups of $I(h_j)$. For each group, a MAX-IS is computed optimally and separately inside each subgroup. Since any two subgroups are horizontally separated and thus independent, we can then take the union of the independent sets of the subgroups to get an independent set for the entire group. This is done with the linear-time greedy algorithm to compute maximum independent sets for interval graphs [26]. Let $\{M_{h_j}^1, \ldots, M_{h_j}^{k+1}\}$ be $k+1$ maximum independent sets for the $k+1$ different groups and let $M(h_j) = \arg\max\{|M_{h_j}^1|, |M_{h_j}^2|, \ldots, |M_{h_j}^{k+1}|\}$ be one with maximum size. We store its cardinality as $c(h_j) = \max\{|M_{h_j}^i| \mid i \in [k+1]\}$. Next, we compute an independent set for E_H, denoted by $M(E_H)$, by composing it from the best solutions $M(h_j)$ from the even stabbing lines, i.e., $M(E_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor} M(h_{2j})$ and its cardinality $|M(E_H)| = \sum_{j=1}^{\lfloor \kappa/2 \rfloor} c(h_{2j})$. Similarly, we compute an independent set for O_H as $M(O_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor} M(h_{2j-1})$ and its cardinality $|M(O_H)| = \sum_{j=1}^{\lfloor \kappa/2 \rfloor} c(h_{2j-1})$. Finally, we return $M_1 = \arg\max\{|M(E_H)|, |M(O_H)|\}$ as the solution for G_1.

▶ **Lemma 8** (⋆). *The independent set M_1 of $G_1 = (\mathcal{S}_1, E_1)$ can be computed in $O(n \log n + kn)$ time and $|M_1| \geq |OPT_1|/2(1 + \frac{1}{k})$.*

Next, we describe a pre-processing step, which is required for the dynamic updates.
PRE-PROCESSING: For each horizontal line $h_j \in H$, consider a group. For each subgroup $I_\ell^k(h_j)$ (for some $\ell \in [k+1]$), we construct a balanced binary tree $T(I_\ell^k(h_j))$ storing the intervals of $I_\ell^k(h_j)$ in left-to-right order (indexed by their left endpoints) in the leaves. This process is done for each group of every horizontal line $h_j \in H$. We mark those leaves in $T(I_\ell^k(h_j))$ as *selected* that correspond to an independent interval in the solution and maintain a list of pointers to those independent intervals. This tree also lets us quickly identify the location of an interval that is inserted or deleted. In fact, while we run the greedy algorithm on $I_\ell^k(h_j)$, we can already mark precisely the selected intervals for the independent set.

When we perform the update step from $G_i = (\mathcal{S}_i, E_i)$ to $G_{i+1} = (\mathcal{S}_{i+1}, E_{i+1})$, either a square is inserted into $\mathcal{S}_i$ or deleted from $\mathcal{S}_i$. Let s_x and i_x be this square and its corresponding interval. Let $g_{u,v}$ (for some $u, v \in [\kappa]$) be the grid point that intersects s_x. We describe here the INSERTION and refer to the full version of this paper for the DELETION.
INSERTION: The insertion of i_x affects all but one of the groups on line h_u. We describe the procedure for one such group on h_u; it is then repeated for the other groups. In each group, i_x appears in exactly one subgroup and the other subgroups remain unaffected. This subgroup, say $I_\ell^k(h_u)$, is determined by the index v of the grid point $g_{u,v}$ intersecting i_x. First, we locate i_x in the sorted list of intervals of $I_\ell^k(h_u)$, which can be done in $O(\log n)$ time by searching in the associated tree $T(I_\ell^k(h_u))$. If i_x is immediately left of a selected interval

i_y, but does not intersect the previous selected interval, then i_x becomes a new selected interval that replaces i_y and triggers a sequence of updates of the later selected intervals. Let us first consider the case that i_x is not selected as a new independent interval. Then we simply insert i_x into $T(I_\ell^k(h_u))$ in $O(\log n)$ time. Otherwise, we mark i_x as selected, remove the selection mark from its successor interval i_y, and replace i_y by i_x in the maintained subsolution. Since the right endpoint of i_x is left of the right endpoint of i_y, this change possibly triggers a sequence of updates to the subsequent selected intervals.

We thus identify in $T(I_\ell^k(h_u))$ the leftmost interval i_z that starts to the right of the right endpoint of i_x. This takes $O(\log n)$ time. If this interval i_z is not yet marked as selected, we replace the previous successor of i_x in the current list of selected intervals by i_z and repeat the update process for i_z. Otherwise, if i_z is already selected, we can stop the update of the subsolution as there would be no further changes.

Since a maximum independent set in each subgroup contains at most k intervals, the update time is $O(k \log n)$ per group and $O(k^2 \log n)$ for all k affected groups.

While doing the updates, we collect the new selected intervals as the MAX-IS for the subgroup $I_\ell^k(h_u)$. For all groups affected by the insertion of i_x we update the corresponding independent sets $M_{h_u}^p$ for $p \in [k+1]$, whenever some updates of selected intervals were necessary. Then we select the largest independent set of all $k+1$ groups as $M(h_j)$ and update its new cardinality in $c(h_j)$. Finally, we update the independent sets $M(E_H)$ and $M(O_H)$ and their cardinalities and return $M_{i+1} = \arg\max\{|M(E_H)|, |M(O_H)|\}$ as the solution for G_{i+1}.

▶ **Lemma 9** (⋆). *The set M_i is an independent set of $G_i = (\mathcal{S}_i, E_i)$ for each $i \in [N]$ and $|M_i| \geq |OPT_i|/2(1 + \frac{1}{k})$.*

With Lemma 9 and the update time discussion in the full version of the paper we obtain:

▶ **Theorem 10** (⋆). *We can maintain a $2(1 + \frac{1}{k})$-approximate maximum independent set in a dynamic unit square intersection graph, deterministically, in $O(k^2 \log n)$ update time.*

4.3 2-Approximation Algorithm with $O(\omega \log n)$ Update Time

We finally design a 2-approximation algorithm for the MAX-IS problem on dynamic axis-aligned unit height, but arbitrary width rectangles. Let $\mathcal{B}$ be the bounding box of the dynamic set of rectangles $\widetilde{\mathcal{R}} = \bigcup_{i \in [N]} \mathcal{R}_i$. We begin by dividing $\mathcal{B}$ into horizontal strips of height 1 defined by the set $H = \{h_1, \ldots, h_\kappa\}$ of $\kappa = O(n)$ horizontal lines. We assume, w.l.o.g., that every rectangle in $\widetilde{\mathcal{R}}$ is stabbed by exactly one line in H. For a set of rectangles $\mathcal{R}$, we denote the subset stabbed by a line h_j as $\mathcal{R}(h_j) \subseteq \mathcal{R}$.

We first describe how to obtain an independent set M_1 for the initial graph $G_1 = (\mathcal{R}_1, E_1)$ such that $|M_1| \geq |OPT_1|/2$ by using the following algorithm of Agarwal et al. [3]. For each horizontal line $h_j \in H$, we compute a maximum independent set for $\mathcal{R}_1(h_j)$. The set $\mathcal{R}_i(h_j)$ (for any $i \in [N]$ and $j \in [\kappa]$) can again be seen as an interval graph. For a set of n intervals, a MAX-IS can be computed by a left-to-right greedy algorithm visiting the intervals in the order of their right endpoints in $O(n \log n)$ time. So for each horizontal line $h_j \in H$, let $M(h_j)$ be a MAX-IS of $\mathcal{R}_1(h_j)$, and let $c(h_j) = |M(h_j)|$. Then we construct the independent set $M(E_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor}(M(h_{2j}))$ for E_H. Similarly, we construct the independent set $M(O_H) = \bigcup_{j=1}^{\lfloor \kappa/2 \rfloor}(M(h_{2j-1})$ for O_H. We return $M_1 = \arg\max\{|M(E_H)|, |M(O_H)|\}$ as the independent set for $G_1 = (\mathcal{R}_1, E_1)$. See Figure 4 for an illustration.

▶ **Lemma 11** (Theorem 2, [3]). *The set M_1 is an independent set of $G_1 = (\mathcal{R}_1, E_1)$ with $|M_1| \geq |OPT_1|/2$ and can be computed in $O(n \log n)$ time.*

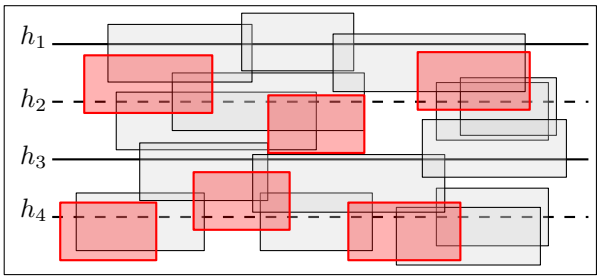

Figure 4 Example instance with four horizontal lines. Red rectangles represent the computed 2-approximate solution, which here is $M(E(H))$.

We describe the following pre-processing step to initialize in $O(n \log n)$ time the data structures that are required for the subsequent dynamic updates.
Pre-Processing: Consider a stabbing line h_j and the stabbed set of rectangles $\mathcal{R}_i(h_j)$ for some $i \in [N]$. We denote the corresponding set of intervals as $I(h_j)$. We build a balanced binary search tree $T_l(I(h_j))$, storing the intervals in $I(h_j)$ in left-to-right order based on their left endpoints. This is called the *left tree* of $I(h_j)$. We augment the left tree such that each tree node additionally stores a pointer to the interval with leftmost right endpoint in its subtree. This pointer structure can easily be computed by a bottom-up pass through $T_l(I(h_j))$. Note that a leaf update in $T_l(I(h_j))$ takes $O(\log n)$ time as for standard binary search trees, but we can in the same $O(\log n)$ time propagate the change that potentially affects the leftmost right endpoints of the tree nodes along the path to the root. Additionally, we store the set of selected independent intervals for the Max-IS of $I(h_j)$ in left-to-right order in another balanced binary search tree $T_s(I(h_j))$ (the so-called *solution tree*). Let ω_j be the cardinality of the maximum independent of $I(h_j)$ for $j \in [\kappa]$, and let $\omega = \max_j \omega_j$ be the maximum of these cardinalities over all stabbing lines h_j.

When we move from G_i to G_{i+1} (for some $1 \leq i < N$), either we insert a new rectangle into $\mathcal{R}_i$ or delete one rectangle from $\mathcal{R}_i$. Let r_x be the rectangle that is inserted or deleted, let i_x be its corresponding interval, and let h_j (for some $j \in [\kappa]$) be the horizontal line that intersects r_x. In what follows, we describe how to maintain a 2-approximate Max-IS with $O(\omega_j \log n) = O(\omega \log n)$ update time. We distinguish Insertion and Deletion.
Insertion: We first determine whether i_x should be a new selected interval or not. Because the greedy algorithm for constructing the Max-IS visits the intervals in left-to-right order based on the right endpoints, we need to reconstruct the state of the algorithm when it would visit i_x. We query the solution tree $T_s(I(h_j))$ with both endpoints of i_x in $O(\log \omega_j)$ time. If and only if both search paths end up between the same two leaves belonging to two consecutive selected intervals i_y and i_z (considering their right endpoints), then i_x would have been chosen as the next selected interval after i_y and before i_z in the greedy algorithm. This implies that i_y and i_x are independent, but i_x and i_z may or may not intersect.

If the two search paths in the solution tree are different, then i_x does not become a new selected interval, and we simply insert it into $T_l(I(h_j))$ in $O(\log n)$ time. Else we also insert i_x into $T_l(I(h_j))$, but we also have to perform a sequence of selection update operations, which are more involved for intervals of arbitrary length compared to the updates in Section 4.2. Figure 5 shows an example. First we mark i_x as selected and insert it into $T_s(I(h_j))$. Now we need to identify the next selected interval right of i_x that would have been found by the greedy algorithm. We use the left tree $T_l(I(h_j))$ to search in $O(\log n)$ time for the interval i'_z with leftmost right endpoint, whose left endpoint is right of the right endpoint p of i_x.

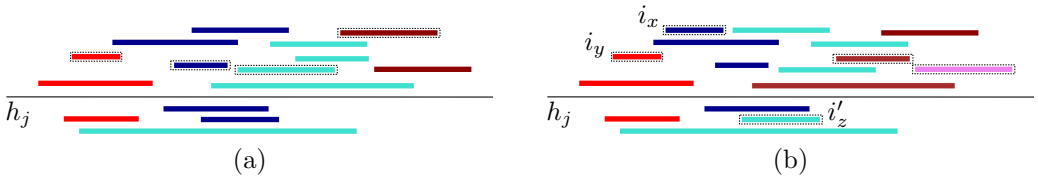

Figure 5 Illustration of the updates triggered by the insertion of an interval; selected independent intervals are marked by a dotted bounding box and intervals intersected by a selected interval have the same color as the rightmost such interval. (a) Before insertion of i_x, (b) after insertion of i_x.

More precisely, we search for p in $T_l(I(h_j))$ and whenever the search path branches into the left subtree, we compare whether the leftmost right endpoint stored in the root of the right subtree is left of the right endpoint of the current candidate interval. Once a leaf is reached, the leftmost found candidate interval is the desired interval i'_z. This interval i'_z is precisely the first interval after i_x in the order considered by the greedy algorithm that is independent of i_x and thus must be the next selected interval. If $i_z \neq i'_z$, we repeat the update process for i'_z as if it would have been the newly inserted interval until we reach the end of $I(h_j)$; otherwise we keep i_z as the successor of i_x and stop the update process.

For each update of a selected interval, we perform one search in $T_l(I(h_j))$ in $O(\log n)$ time. There are at most ω_j updates, so the update time is $O(\omega_j \log n)$. Finally, we need to delete $O(\omega_j)$ old selected intervals from and insert $O(\omega_j)$ new selected intervals into the solution tree $T_s(I(h_j))$, which takes $O(\log \omega_j)$ time for each insertion and deletion. We now re-evaluate the new Max-IS $M(h_j)$ and its cardinality $c(h_j)$, which possibly affects $M(E_H)$ or $M(O_H)$. We obtain the new independent set $M_{i+1} = \arg\max\{|M(E_H)|, |M(O_H)|\}$ for $G_{i+1} = (\mathcal{R}_{i+1}, E_{i+1})$.

Deletion: If the interval i_x to be deleted is not a selected interval, it is sufficient to delete it from the left tree $T_l(I(h_j))$ in $O(\log n)$ time. Otherwise, if i_x is a selected interval, let i_y be the selected interval preceding i_x in the solution tree $T_s(I(h_j))$. We first delete i_x from $T_l(I(h_j))$ and $T_s(I(h_j))$. Then we need to select a new interval to replace i_x according to the greedy Max-IS algorithm, which is the interval i_z whose right endpoint is leftmost among all intervals that are completely to the right of i_y. We find this interval i_z again by a search in the left tree $T_l(I(h_j))$ with the right endpoint of i_y as the query point. We make i_z a new selected interval and use the right endpoint of i_z as the query point for finding the next selected interval in $T_l(I(h_j))$. We repeat this process until we have reached the last interval of $I(h_j)$.

As for the Insertion step, each update of a selected interval requires $O(\log n)$ time due to the query for the next selected interval in $T_l(I(h_j))$. There are $O(\omega_j)$ such updates. Further, we need to update the solution tree $T_s(I(h_j))$ by performing $O(\omega_j)$ insertions and deletions of seeds, each in $O(\log \omega_j)$ time. Once all updates to the selected intervals and the data structures for $I(h_j)$ are done, we re-evaluate the new Max-IS $M(h_j)$ and its cardinality $c(h_j)$, which possibly affects $M(E_H)$ or $M(O_H)$. This yields the new independent set $M_{i+1} = \arg\max\{|M(E_H)|, |M(O_H)|\}$ for $G_{i+1} = (\mathcal{R}_{i+1}, E_{i+1})$.

▶ **Lemma 12.** *The set M_i is an independent set of $G_i = (\mathcal{R}_i, E_i)$ for each $i \in [N]$ and $|M_i| \geq |OPT_i|/2$.*

Proof. We prove the lemma by induction. From Lemma 11 we know that M_1 satisfies the claim, and in particular each set $M(h)$ for $h \in H$ is a Max-IS of the interval set $I(h)$. So let us consider the set M_i for $i \geq 2$ and assume that M_{i-1} satisfies the claim by the induction hypothesis. Let r_x and i_x be the updated rectangle and its interval, and assume that it

belongs to the stabbing line h_j. Then we know that for each $h_k \in H$ with $k \neq j$ the set $M(h_k)$ is not affected by the update to r_x and thus is a MAX-IS by the induction hypothesis. It remains to show that the update operations described above restore a MAX-IS $M(h_j)$ for the set $I(h_j)$. But in fact the updates are designed in such a way that the resulting set of selected intervals is identical to the set of intervals that would be found by the greedy MAX-IS algorithm for $I(h_j)$. Therefore $M(h_j)$ is a MAX-IS for $I(h_j)$ and by the pigeonhole principle $|M_i| \geq |OPT_i|/2$. ◀

Each update of a rectangle r_x (and its interval i_x) triggers either an INSERTION or a DELETION operation on the unique stabbing line of r_x. As we have argued in the description of these two update operations, the insertion or deletion of i_x requires one $O(\log n)$-time update in the left tree data structure. If i_x is a selected independent interval, the update further triggers a sequence of at most ω_j selection updates, each of which requires $O(\log n)$ time. Hence the update time is bounded by $O(\omega_j \log n) = O(\omega \log n)$. Recall that ω_j and ω are output-sensitive parameters describing the maximum size of an independent set of $I(h)$ for a specific stabbing line $h = h_j$ or any stabbing line h.

▶ **Theorem 13.** *We can maintain a 2-approximate maximum independent set in a dynamic unit-height arbitrary-width rectangle intersection graph, deterministically, in $O(\omega \log n)$ time, where ω is the cardinality of a maximum independent set of the rectangles stabbed by the horizontal stabbing line affected by the dynamic update.*

▶ Remark 14. We note that Gavruskin et al. [24] gave a dynamic algorithm for maintaining a MAX-IS on *proper* interval graphs. Their algorithm runs in amortized time $O(\log^2 n)$ for insertion and deletion, and $O(\log n)$ for element-wise decision queries. The complexity to report a MAX-IS J is $\Theta(|J|)$. Whether the same result holds for general interval graphs was posed as an open problem [24]. Our algorithm in fact solves the MAX-IS problem on arbitrary dynamic interval graphs, which is of independent interest. Moreover, it explicitly maintains a MAX-IS at every step.

5 Experiments

We implemented all our MAX-IS approximation algorithms presented in Sections 3 and 4 in order to empirically evaluate their trade-offs in terms of *solution quality*, i.e., the cardinality of the computed independent sets, and *update time* measured on a set of suitable synthetic and real-world map-labeling benchmark instances with unit squares. The goal is to identify those algorithms that best balance the two performance criteria. Moreover, for smaller benchmark instances with up to 2 000 squares, we compute exact MAX-IS solutions using a MaxSAT model by Klute et al. [32] that we solve with MaxHS 3.0 (see `www.maxhs.org`). These exact solutions allow us to evaluate the optimality gaps of the different algorithms in light of their worst-case approximation guarantees. Finally, we investigate the speed-ups gained by using our dynamic update algorithms compared to the baseline of recomputing new solutions from scratch with their respective static algorithm after each update.

5.1 Experimental Setup

We have implemented the five algorithms (and their greedy augmentation variants) listed below in C++. The experiments were run on a server equipped with two Intel Xeon E5-2640 v4 processors (2.4 GHz 10-core) and 160GB RAM. The machine ran the 64-bit version of Ubuntu Bionic (18.04.2 LTS). The code was compiled with g++ 7.4.0.

MIS-graph A naive graph-based dynamic MIS algorithm, explicitly maintaining the square intersection graph and a MIS [4, Sec. 3]. In order to evaluate and compare the performance of our algorithm *MIS-ORS* (Section 3) for the MIS problem, we have implemented this alternative dynamic algorithm. This algorithm, instead of maintaining the current instance in a dynamic geometric data structure, maintains the rectangle intersection graph explicitly as a baseline approach. We use standard adjacency lists to represent the intersection graph, implemented as unordered sets in C++. Now, to obtain a MIS at the first step, we add an arbitrary (unmarked) vertex v to the solution and mark $N(v)$ in the corresponding intersection graph. This process is repeated iteratively until there is no unmarked vertex left in the intersection graph. Clearly, by following this greedy method, we obtain a MIS. Moreover, for each vertex v, we maintain an augmenting *counter* that stores the number of vertices from its neighborhood $N(v)$ that are contained in the current MIS.

This approach handles the updates in a straightforward manner. When a new vertex is inserted, its corresponding rectangle introduces new intersections in the current intersection graph. Therefore, when adding this vertex, we also determine the edges that are required to be added to the intersection graph. Notice that, unlike the canonical vertex update operation defined in the literature, where the adjacencies of the new vertex are part of the dynamic update, here, we actually need to figure out the neighborhood of a vertex. This is done by iterating over each vertex and checking whether its corresponding rectangle is overlapping with the newly inserted rectangle. Thus, it takes $O(n)$ time to obtain the neighborhood of this vertex. If the newly inserted rectangle has no intersection with any rectangle from the current solution, then we simply add its vertex to the solution; otherwise, we ignore it. Finally, we update the counters. If a vertex is deleted, we update the intersection graph by deleting its corresponding rectangle. If the deleted vertex was in the solution, then we decrease the counters of its neighbors by 1. Once the counter of a vertex is updated to 0, we add this vertex into the solution. Both the insertion (after computing $N(v)$) and deletion operation for a vertex v take $O(\deg(v))$ time each to update the intersection graph and the MIS solution.

MIS-ORS The dynamic MIS algorithm based on orthogonal range searching (Section 3); this algorithm provides a 4-approximation. In the implementation we used the dynamic orthogonal range searching data structure implemented in CGAL (version 4.11.2), which is based on a dynamic Delaunay triangulation [35, Chapter 10.6]. Hence, this implementation does not provide the sub-logarithmic worst-case update time of Theorem 3.

grid The grid-based 4-approximation algorithm (Section 4.1).

grid-k The shifting-based $2(1+\frac{1}{k})$-approximation algorithm (Section 4.2). In the experiments we use $k = 2$ (i.e., a 3-approximation) and $k = 4$ (i.e., a 2.5-approximation).

line The stabbing-line based 2-approximation algorithm (Section 4.3).

Since the algorithms *grid*, *grid-k*, and *line* are based on partitioning the set of squares and considering only sufficiently segregated subsets, they produce a lot of white space in practice. For instance, they ignore the squares stabbed by either all the even or all the odd stabbing lines completely in order to create isolated subinstances. In practice, it is therefore interesting to augment the computed approximate MAX-IS by greedily adding independent, but initially discarded squares. We have also implemented the greedy variants of these algorithms, which are denoted as *g-grid*, *g-grid-k*, and *g-line*.

We created three types of benchmark instances. The synthetic data sets consist of n 30×30-pixel squares placed inside a bounding rectangle $\mathcal{B}$ of size $1\,080 \times 720$ pixels, which also creates different densities. The real-world instances use the same square size, but geographic feature distributions. For the updates we consider three models: *insertion-only*, *deletion-only*, and *mixed*, where the latter selects insertion or deletion uniformly at random.

Table 1 Specification of the six OSM instances.

	post-CH	peaks-AT	hotels-CH	hotels-AT	peaks-CH	hamlets-CH
features (n)	646	652	1 788	2 209	4 320	4 326
overlaps (m)	5 376	5 418	28 124	68 985	107 372	159 270
density (m/n)	8.32	8.31	15.73	31.23	24.85	36.92

Gaussian In the Gaussian model, we generate n squares randomly in $\mathcal{B}$ according to an overlay of three Gaussian distributions, where 70% of the squares are from the first distribution, 20% from the second one, and 10% from the third one. The means are sampled uniformly at random in $\mathcal{B}$ and the standard deviation is 100 in both dimensions.

Uniform In the uniform model, we generate n squares in $\mathcal{B}$ uniformly at random.

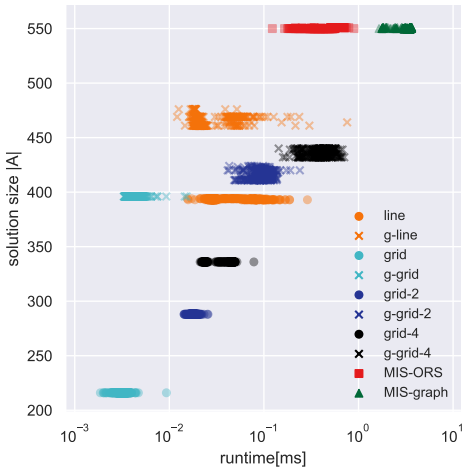
Real-world We created six real-world data sets by extracting point features from OpenStreetMap (OSM), see Table 1 for their detailed properties.

5.2 Experimental Results

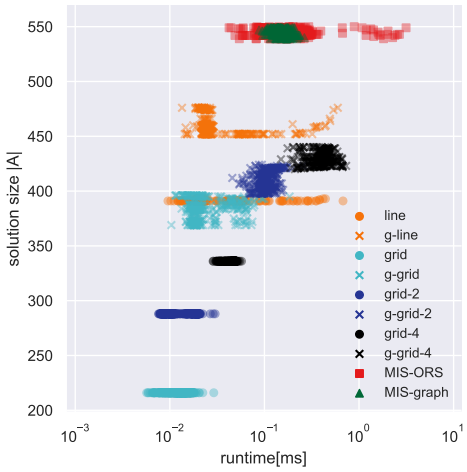
Time-quality trade-offs. For our first set of experiments we compare the five implemented algorithms, including their greedy variants, in terms of update time and size of the computed independent sets. Figure 6 shows scatter plots of runtime vs. solution size on uniform and Gaussian benchmarks, where algorithms with dots in the top-left corner perform well in both measures.

We first consider the results for the uniform instances with $n = 10\,000$ squares in the top row of Figure 6. Each algorithm performed $N = 400$ updates, either insertions (Figure 6a) or deletions (Figure 6b) and each update is shown as one point in the respective color. Both plots show that the two MIS algorithms compute the best solutions with almost the same size and well ahead of the rest. While *MIS-ORS* is clearly faster than *MIS-graph* on insertions, they are comparably fast for deletions, with some slower outliers of *MIS-ORS*. The approximation algorithms *grid*, *grid*-2, *grid*-4, and *line* (without the greedy optimizations) show their predicted relative behavior: The better the solution quality, the worse the update times. Algorithms *line* and *g-line* show a wide range of update times, spanning almost two orders of magnitude. Adding the greedy optimization drastically improves the solution quality in all cases, but typically at the cost of higher runtimes. For *g-grid-k* the algorithms get slower by an order of magnitude and increase the solution size by 30–50%. For *g-grid*, the additional runtime is not as significant (but deletions are slower than insertions), and the solution size almost doubles. Finally, *g-line* is nearly as fast as *line*, and reaches the best quality among the approximation algorithms with about 80% of the MIS solutions, but faster by one or two orders of magnitude.

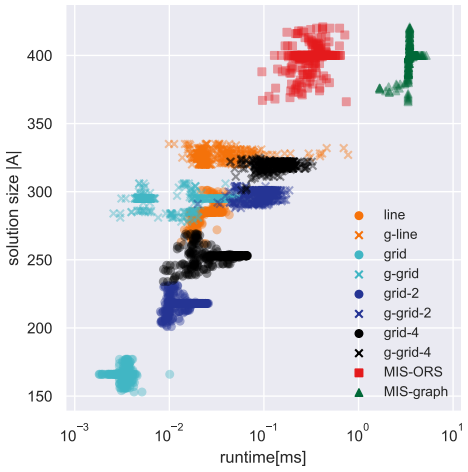
For the results of the Gaussian instances with $n = 10\,000$ squares and $N = 400$ updates plotted in Figures 6c (insertions) and 6d (deletions) we observe the same ranking between the different algorithms. However, due to the non-uniform distribution of squares, the solution sizes are more varying, especially for the insertions. For the deletions it is interesting to see that *grid* and *MIS-graph* have more strongly varying runtimes, which is in contrast to the deletions in the uniform instance, possibly due to the dependence on the vertex degree. The best solutions are computed by *MIS-ORS* and *MIS-graph*, which show similar deletion times, but the insertion times of *MIS-ORS* are one order of magnitude faster than *MIS-graph*. Algorithm *g-line* again reaches more than 80% of the quality of the MIS algorithms, with a speed-up between one and two orders of magnitude.



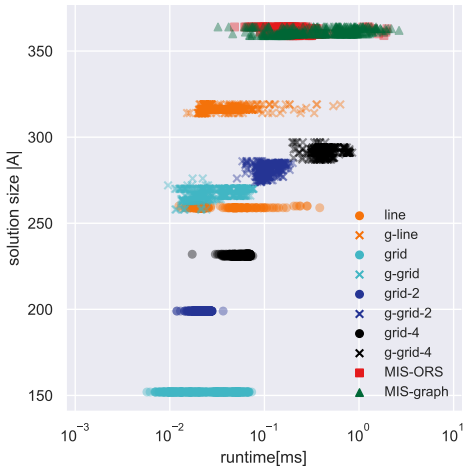
(a) Uniform, $n = 10\,000$, 400 insertions.



(b) Uniform, $n = 10\,000$, 400 deletions.



(c) Gaussian, $n = 10\,000$, 400 insertions.



(d) Gaussian, $n = 10\,000$, 400 deletions.

Figure 6 Time-quality scatter plots for synthetic benchmark instances. The x-axis (log-scale) shows runtime, the y-axis shows the solution size.

Optimality gaps. Next, let us look at the results of the real-world instances in Figure 7. The first four instances in Figure 7a–d, were small enough so that we could compute each Max-IS exactly with MaxHS and compare the solutions of the approximation algorithms with the optimum on the y-axis. The largest two instances in Figure 7e and 7f plot the solution size on the y-axis. First, let us consider Figure 7c as a representative, which is based on a data set of 1 788 hotels and hostels in Switzerland with mixed updates of 10% of the squares ($N = 179$). Generally speaking, the results of the different algorithms are much more overlapping in terms of quality than for the synthetic instances. The plot shows that the MIS algorithms reach consistently between 80% and 85% of the optimum, but are sometimes outperformed by *g-grid*-4 and *g-line*. Regarding the runtime, *MIS-ORS* has more homogeneous update times ranging between the extrema of *MIS-graph*, which suffers from the rather slow insertions. The original approximations are well above their respective worst-case ratios, but stay between 45% and 65% of the optimum. The greedy extensions

push this towards larger solutions, at the cost of higher runtimes. However, *g-line* seems to provide a very good balance between quality and speed. We point out that because the updates comprise insertions and deletions, the marks for algorithms that are sensitive to the update type, such as *g-grid* and *MIS-graph* form two separate runtime clusters. The same relative observations of the algorithms' performance can be made in Figures 7a–d, yet they show different absolute quality offsets and variance.

Let us next consider the largest OSM instance in Figure 7f. It again reflects the same findings as obtained from the smaller instances. The instance consists of $n = 4\,326$ hamlets in Switzerland with 10% mixed updates ($N = 433$) and is denser by a factor of about 2.3 than hotels-CH (see Table 1). There is quite some overlap of the different algorithms in terms of the solution size, yet the algorithms form the same general ranking pattern as observed before. Interestingly, while the MIS algorithms contribute some of the best solutions, they also show a variance of ± 50 squares. In contrast, *g-line*, the best of the approximation algorithms, is competing well and is more stable in terms of solution size and again about an order of magnitude faster than the MIS algorithms. The update-type dependent behavior of *MIS-graph* with its significantly slower insertions is observed once more, making *MIS-ORS* the better choice for a mixed update model.

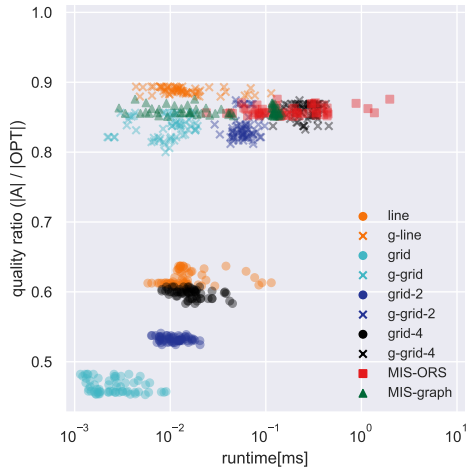
Finally, Figure 8 shows the optimality ratios of the algorithms for small uniform and Gaussian instances with $n = 1\,000$ squares. They confirm our earlier observations, but also show that for these small instances, *MIS-graph* is about as fast as *MIS-ORS* for insertions and faster than *MIS-ORS* for deletions. This is because the graph size and vertex degrees do not yet influence the running time of *MIS-graph* strongly. Yet, as the next experiment shows, this changes drastically, as the instance size grows.

Runtimes. In our last experiment, we explore in more detail the scalability of the algorithms for larger instances, both relative to each other and in comparison to the re-computation times of their corresponding static algorithms. We generated one random instance with $n = 1\,000k$ squares for each $k \in \{1, 2, 4, 8, 16, 32\}$ and measured the average update times over $n/10$ insertions or deletions. The results for the Gaussian and uniform model are plotted in Figure 9. Considering the update times for insertions, we confirm the observations from the scatter plots in terms of the performance ranking. Most algorithms grow only very slowly in terms of their running time, with the notable exception of *MIS-graph*, but that was to be expected. For deletions, *MIS-graph* is initially faster than *MIS-ORS*, but again shows the steepest increase in runtime. Deletions in the Gaussian model also affect the runtime of *grid* and *g-grid* quite noticeably, yet one order of magnitude below *MIS-graph*.

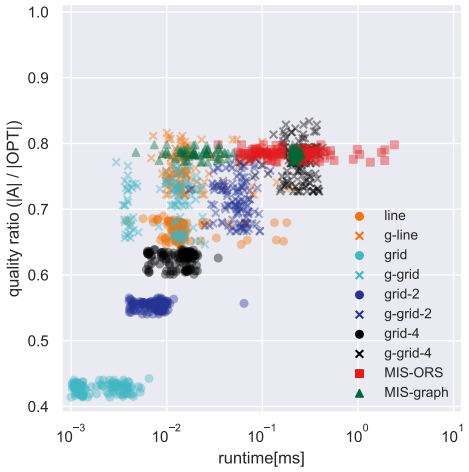
In the comparison with their non-dynamic versions, i.e., re-computing solutions after each update, the dynamic algorithms indeed show a significant speed-up in practice, already for small instance sizes of $n = 1\,000$, and even more so as n grows (notice the different y-offsets). For some algorithms, including *MIS-ORS* and *g-line*, this can be as high as 3–4 orders of magnitude for $n = 32\,000$. It clearly confirms that the investigation of algorithms for dynamic MIS and Max-IS problems for rectangles is well justified also from a practical point of view.

5.3 Discussion

Our experimental evaluation provides several interesting insights into the practical performance of the different algorithms. First of all, both MIS-based algorithms generally showed the best solution quality in the field, reaching 85% of the exact Max-IS size, where we could compare against optimal solutions. This is in strong contrast to their factor-4 worst-case approximation guarantee of only 25%.



(a) post-CH, 10% mixed updates.



(b) peaks-AT, 10% mixed updates.

Our algorithm *MIS-ORS* avoids storing the intersection graph explicitly. Instead, we only store the relevant geometric information in a dynamic data structure and derive edges on demand. Therefore it breaks the natural barrier of $\Omega(\Delta)$ (amortized) vertex update in a dynamic graph, where Δ is the maximum degree in the graph. However, it has to find the intersections using the complex range query, which takes $O(\log n)$ time. We did not involve any geometric data structure in the baseline MIS approach *MIS-graph*. Recall that, the update of the intersection graph when adding a new rectangle includes the time to figure out the neighborhood of the newly added vertex. Therefore, the graph-based algorithm showed a slow insertion update and was quite sensitive to the size of instances in insertion updates. However, the deletion update only depends on the degree of the involved vertex, not the size of instances directly. And as expected, the graph-based algorithm was indeed much faster for small instances, but *MIS-ORS* was more scalable in our experiment. However, the intersection graph update for *MIS-graph* can be improved by using additionally a geometric

data structure to store the rectangle set and detect intersections. We expect that it would show improvements for insertion updates, but may slow down deletions, since the state-of-the art data structure provides only an amortized update time guarantee. Therefore, it is an open question whether the performance of *MIS-graph* can indeed be improved by using a suitable dynamic geometric data structure. Note, *MIS-ORS* too, can sometimes show slower deletions, due to the necessary complex orthogonal range search in some cases. Recall that, in our implementation, we used a dynamic range searching data structure from CGAL, which does not provide the theoretical sub-logarithmic worst-case update time of Chan et al. [14] used in Theorem 3. Exploring how *MIS-ORS* can benefit from such a state-of-the-art dynamic data structure in practice remains to be investigated in future work. Notwithstanding, it remains to state that even with the suboptimal data structure, *MIS-ORS* was able to compute its solutions for up to 32 000 squares in less than 1ms. So if solution quality is the priority, then the *MIS-ORS* algorithm is the method of choice. It provides the best solutions (together with *MIS-graph*), but is significantly more scalable.

An expected observation is that while consistently exceeding their theoretical guarantees, the approximation algorithms do not perform too well in practice due to their pigeonhole choice of too strictly separated subinstances. However, a simple greedy augmentation of the approximate solutions can boost the solution size significantly, and for some algorithms even to almost that of the MIS algorithms. Of course, at the same time this increases the runtime of the algorithms. We want to point out *g-line*, the greedy-augmented version of the 2-approximation algorithm *line*, as it computes very good solutions, even comparable or better than *MIS-ORS* and *MIS-graph* for the real-world instances, and at 80% of the MIS solutions for the synthetic instances. At the same time, *g-line* is still significantly faster than *MIS-ORS* and *MIS-graph* and thus turns out to be a well-balanced compromise between time and quality. It would be our recommended method if *MIS-ORS* or *MIS-graph* are too slow for an application.

6 Conclusions

We investigated the MIS and Max-IS problems on dynamic sets of uniform rectangles and uniform-height rectangles from an algorithm engineering perspective, providing both theoretical results for maintaining a MIS or an approximate Max-IS and reporting insights from an experimental study. Open problems for future work include (i) finding Max-IS sublinear-update-time approximation algorithms for dynamic unit squares with approximation ratio better than 2, (ii) studying similar questions for dynamic disk graphs, and (iii) implementing improvements such as a sub-logarithmic dynamic range searching data structure to speed-up our algorithm *MIS-ORS*. Moreover, it would be interesting to design dynamic approximation schemes for Max-IS that maintain stability in a solution.

Abstract

Contraction hierarchies (CH) is a prominent preprocessing-based technique that accelerates the computation of shortest paths in road networks by reducing the search space size of a bidirectional Dijkstra run. To explain the practical success of CH, several theoretical upper bounds for the maximum search space size were derived in previous work. For example, it was shown that in minor-closed graph families search space sizes in $\mathcal{O}(\sqrt{n})$ can be achieved (with n denoting the number of nodes in the graph), and search space sizes in $\mathcal{O}(h \log D)$ in graphs of highway dimension h and diameter D. In this paper, we primarily focus on lower bounds. We prove that the average search space size in a so called weak CH is in $\Omega(b_\alpha)$ for $\alpha \geq 2/3$ where b_α is the size of a smallest α-balanced node separator. This discovery allows us to describe the first approximation algorithm for the average search space size. Our new lower bound also shows that the $\mathcal{O}(\sqrt{n})$ bound for minor-closed graph families is tight. Furthermore, we deeper investigate the relationship of CH and the highway dimension and skeleton dimension of the graph, and prove new lower bound and incomparability results. Finally, we discuss how lower bounds for strong CH can be obtained from solving a HittingSet problem defined on a set of carefully chosen subgraphs of the input network.

1 Introduction

The concept of contraction hierarchies (CH) was introduced by Geisberger et al. [15] to accelerate shortest path planning in road networks. The basic idea is to precompute an overlay graph in which the search space size of a bidirectional Dijkstra run can be drastically reduced. For example, on the road network of Western Europe with 18 million nodes, a bidirectional Dijkstra run in the original graph scans almost 5 million nodes on average, while in the CH overlay graph only 280 nodes are scanned. This decreases the query time from over two seconds to about one millisecond [5].

There exist two CH variants, referred to as strong and weak contraction hierarchies. In a strong CH, the overlay graph construction takes the edge weights directly into account. In a weak CH, the preprocessing phase is split into a metric-independent overlay graph construction phase, and a subsequent customization phase in which the edges are augmented with weights. Weak CH is used in practice to deal with dynamically changing edge weights, as changes in the metric only require to repeat the customization phase but not the overlay graph construction [12]. In [7], the first theoretical upper bounds for search space sizes in weak CH were described, which are valid for strong CH as well. Other lines of research focus on strong CH directly. Graph parameters such as the highway dimension [1] or the skeleton dimension [17] were explictly introduced with the purpose of analyzing search space sizes

of preprocessing-based route planning techniques. However, most existing work focuses on upper bounding the maximum search space. In this paper, we are particularily interested in constructing tight bounds for the average search space size, as those are more expressive for judging whether the CH technique is useful for a given graph (family). We provide a multitude of novel results, including several lower bounding techniques as well as the first approximation algorithm for the average search space size in a weak CH.

1.1 Related Work

In [2, 1], the *highway dimension* h was introduced as a novel graph parameter to capture the shortest path structure of road networks. It was proven that in a strong CH maximum search space sizes in $\mathcal{O}(h \log D)$ can be achieved where D denotes the diameter of the graph. At the same time, the size of the overlay graph is bounded by $\mathcal{O}(n \cdot h \log D)$ where n is the number of nodes in the graph. In [7], the first upper bounds for weak CH were proven. There, *nested dissection* was used to guide the overlay graph construction; a technique that relies on recursive decomposition of the graph into smaller subgraphs by removing balanced node separators. It was shown that in graphs of *treewidth* tw an upper bound of $\mathcal{O}(tw \log n)$ for the maximum search space size S_{max} can be achieved with an overlay graph size of $\mathcal{O}(n \cdot tw \log n)$. For minor-closed graph families that exhibit $\mathcal{O}(\sqrt{n})$ balanced separators, $S_{max} \in \mathcal{O}(\sqrt{n})$ and an overlay graph size in $\mathcal{O}(n \log n)$ was proven. In [14, 8], the *bounded growth model* was proposed as a theoretical framework for studying road networks. There, CH search space sizes in $\mathcal{O}(\sqrt{n} \log n)$ and overlay graph sizes in $\mathcal{O}(n \log D)$ were shown for graphs with unit edge costs that adhere to the model.

Concerning lower bounds, White [22] proved that for any h, D and n, there exists a graph with at least n nodes that has a highway dimension h, a diameter of $\Theta(D)$, and in which the average search space size in a strong CH is in $\Omega(h \log D)$. Therefore, the upper bound by Abraham et al. [1] for strong CH search space sizes parametrized by h is tight. An analogue result was proven for the related route planning technique *hub labeling*. In [20], it was shown on the example of a carefully weighted grid graph that there exists graphs for which the average search space is in $\Omega(\sqrt{n})$ for any strong CH (and for hub labeling as well). In addition, a greedy algorithm was proposed to compute lower bounds for the average search space size of any strong CH in a given weighted graph. In [7], it was observed that the maximum search space size in a weak CH coincides with the so called elimination tree height. As proven by Bodlaender et al. [9], the minimum elimination tree height of a graph equals the *treedepth* td, and the following relations to other graph parameters hold

$$b - 1 \leq tw \leq pw \leq td$$

where b is the *balanced separator number* of the graph, tw is the *treewidth*, and pw the *pathwidth*. Accordingly, the balanced separator number, the treewidth, the pathwidth, and the treedepth are all valid lower bounds for S_{max}. In [6], it was proven by reduction from VertexCover that it is NP-hard to find a contraction order for a strong CH that minimizes the average search space size while adding at most K shortcuts to the graph. Furthermore it was observed that in a complete graph $S_{avg} \in \Omega(n)$ holds, and in path graphs $S_{avg} \in \Omega(\log n)$. For the special case of trees, a linear-time optimal preprocessing algorithm is known that minimizes S_{max} [21]. Complementarily, it was shown in [7] that a CH-graph constructed with a nested dissection contraction order provides a 2-approximation for S_{avg} in trees.

1.2 Contribution

We significantly extend the set of known results on (average) search space sizes in weak and strong contraction hierarchies. Our main findings are listed in the following.

- Although the balanced separator number, the treewidth, the pathwidth and the treedepth are all lower bounds for the maximum search space size S_{max} in a weak CH, we prove that in general none of them is a valid lower bound for S_{avg}. However, we prove that the average search space size S_{avg} in a weak CH is in $\Omega(b_\alpha)$ for $\alpha \geq 2/3$ where b_α is the size of a smallest α-balanced node separator in G.
- We establish the first approximation result for S_{avg} in weak CHs which applies to general graphs. In particular, we prove that a nested dissection CH construction scheme leads to an average search space size within a factor of $1 + 1.5 \log_{1.5} n$ of the optimum. This answers an open question from [7]. We also discuss how to turn the nested dissection approach into an efficient CH construction algorithm on general graphs.
- We furthermore show that for every unweighted graph, one can choose metric edge weights such that the highway dimension h of the graph equals 1, and hence constitutes a trivial lower bound for the average search space size in a strong CH. On such graphs, the algorithms described in [2, 1] with an upper bound on the search space size of $\mathcal{O}(h \log D)$ are close-to-optimal. However, we also show that in case the metric is given, there can be a gap of size $\Omega(n)$ between the highway dimension and the maximum search space size.
- For a given weighted graph, we prove that lower bounds on the average search space size in the respective strong CH can be obtained by solving a (hierarchical) HittingSet problem defined on a set of specific subgraphs of G.

2 Preliminaries

In this section, we describe the concepts of strong and weak CH more formally and provide the definitions of some separator-related graph parameters that will be relevant in our analysis.

2.1 Strong and Weak Contraction Hierarchies

Given an undirected[1], connected graph $G(V, E)$ with edge costs $c : E \to \mathbb{R}^+$, the preprocessing phase for *strong CH* works as follows: First a node permutation is fixed which constitutes the so called contraction order of the nodes. Note that any contraction order is feasible but that the overlay graph size as well as the search space sizes crucially depend on that order. Let $r : V \to \{1, \dots, n\}$ with $n = |V|$ be the respective ranks of the nodes in the contraction order. Then an overlay graph is constructed with the following property: A shortcut edge $\{v, w\}$ is introduced between v and w if and only if there exists a shortest path π between them that except for v and w only contains nodes u with $r(u) < \min\{r(v), r(w)\}$. The cost of that shortcut edge is set to $c(\pi)$. When constructing a *weak CH* instead, shortcuts are introduced between nodes v and w iff there exists any path between them that except for v and w only contains nodes u with $r(u) < \min\{r(v), r(w)\}$. In either case, the set of shortcuts E^+ is then added to the original graph G to obtain the CH-graph $G^+(V, E \cup E^+)$. For strong CH, this completes the preprocessing phase. For weak CH, a so called customization phase follows in which edge weights are first assigned to the original edges, and are then propagated to the shortcuts. For further details, we refer to [12].

[1] With slight modifications, CH also works on directed graphs. To simplify the presentation, we only consider undirected graphs throughout the paper.

In practical implementations, the node contraction order is not always fixed a priori but might be determined in a process which interleaves the overlay graph construction and the node rank assignments. The insertion of shortcut edges is then based on the so called node contraction operation: Here, a node v and its incident edges are removed from the graph and new edges are inserted between certain pairs of its former neighbors. In a strong CH, a shortcut between the neighbors u, w of v is only inserted if the path u, v, w is a shortest path. In a weak CH, shortcuts are inserted between all pairs of neighbors (as without knowledge about the metric, any of those paths could become a shortest path later). The preprocessing then consists of contracting all nodes in the graph one after the other, using e.g. the current degree of the nodes as guidance which of them to contract next (or more complicated criteria, see [15]). But independently of the chosen implementation, the formal characterization of the resulting overlay CH-graph given above always applies.

To compute a shortest path between nodes $s, t \in V$ in the CH-graph G^+, a bidirectional Dijkstra run is started from s and t in G^+ with the restriction that from any node v incident edges $\{v, w\}$ are only relaxed if $r(w) > r(v)$. The set of nodes that can be reached from a node $v \in V$ via paths which go strictly upwards with respect to the contraction order is called the search space $SS(v)$. By construction of G^+ one can show that there always exists a node $p \in SS(s) \cap SS(t)$ which lies on a shortest path between s and t in G, and the shortest path distance from s to p as well as the shortest path distance from p to t are correctly computed in G^+. Accordingly, the computed shortest path distance in G^+ equals the shortest path distance in G.

Note that in general there is a difference between the search space size and the query time. The search space size $|SS(v)|$ of a node v is the number of nodes settled in the Dijkstra run from v in the CH-graph while the query time also accounts for edge relaxation and priority queue operations. However, an upper bound U on the search space size also yields an upper bound of U^2 on the query time as there can be at most a quadratic number of edges between U nodes. The other way around, a lower bound on the search space size is automatically also a lower bound for the query time. Therefore, we stick to the notion of search space sizes throughout the paper. We distinguish between the maximum CH search space size $S_{max} = \max_{v \in V} |SS(v)|$ and the average CH search space size $S_{avg} = \frac{1}{n} \sum_{v \in V} |SS(v)| \leq S_{max}$.

2.2 Balanced Separators

Existing upper bounds for search space sizes in weak CH were obtained by using nested dissection based overlay graph construction, which involves the recursive computation of balanced node separators. We will investigate which separator-related graph parameters can be used to lower bound the average search space size. The *balanced separator number* is defined as the smallest integer b such that for every $V' \subseteq V$, the induced subgraph $G[V']$ admits a balanced separator of size at most b, i.e. after the removal of at most b nodes every remaining connected component of $G[V']$ contains at most $\lceil (|V'| - b)/2 \rceil$ nodes. While $b - 1$ is known to lower bound the maximum CH search space size in any given graph, we will show that the same is not true for S_{avg}. However, we will prove a lower bound of $\alpha \cdot b_\alpha$ for $\alpha \geq 2/3$ which later will be used to get an approximation guarantee for S_{avg} when constructing the CH with a variant of nested dissection. The parameter b_α, for an $\alpha \in [0, 1]$, is the size of a minimum α-balanced node separator of $G(V, E)$, i.e., the smallest number of nodes that have to be removed from the input graph $G(V, E)$ such that all remaining connected components have size at most $\alpha \cdot |V|$. Note that the value of b_α is solely determined by considering the input graph as a whole, while for b all induced subgraphs are relevant as well. By definition,

the following hierarchy holds: $b_{2/3} \leq b_{1/2} \leq b$.

3 Bounds and Algorithms for Search Space Sizes in Weak CH

In this section, we discuss at the beginning how S_{avg}, S_{max}, and the balanced separator number relate to each other in a weak CH. Subsequently, we describe new lower bounding techniques and present the first approximation algorithm for S_{avg}.

3.1 Maximum versus Average Search Space Size

As discussed above, the smallest possible maximum search space size of a weak CH is equal to the treedepth of the input graph. However, there can be a large gap between treedepth and average search space size. In fact, not even the balanced separator number b yields a lower bound for S_{avg} as the following lemma shows.

▶ **Lemma 1.** *There exist graphs $G(V, E)$ with $S_{avg} \in o(b)$.*

Proof. Take a star graph with k leaves and replace one leaf with a clique C of size $\sqrt{k}$. Every balanced separator of the subgraph induced by C contains $\Omega(\sqrt{k})$ vertices, which implies that $b \in \Omega(\sqrt{k})$. Consider a contraction order where the central node obtains rank $n = |V|$. Then the search space size of the central node is 1, the search space size of every leaf is 2 and the search space size of a node in the clique is at most $\sqrt{k} + 1$. It follows that the average search space size is

$$S_{avg} \leq \frac{1 + (k-1) \cdot 2 + \sqrt{k} \cdot (\sqrt{k} + 1)}{n} = \frac{3k + \sqrt{k} - 1}{n} = \frac{3k + \sqrt{k} - 1}{k + \sqrt{k}} < 3 \in o(\sqrt{k}). \quad \blacktriangleleft$$

With $b - 1 \leq tw \leq pw \leq td$, the lemma implies that none of those parameters is a valid lower bound for S_{avg}; and that there can be an exponential gap between the average and the maximum search space size.

3.2 Balanced Separators and Average Search Space Size

In a weak CH, a node $w \in V$ of rank R is in the search space $SS(v)$ of another node $v \in V$ with rank $r < R$ if there exists a path from v to w which – except for w – exclusively contains nodes of rank $< R$. This fact leads to the following central observation.

▶ **Observation 2.** *Let $G(V, E)$ be a connected graph. In a weak CH on G, for a node $w \in V$ of rank R to* not *be in the search space $SS(v)$ of a node $v \in V$ of rank $r < R$, there needs to be a set of nodes of rank higher than R that separates w from v.*

We will now present our first main theorem, which exploits this observation to show a general relationship between the average serach space size S_{avg} in a weak CH and balanced node separators in G.

▶ **Theorem 3.** *For any weak CH and any $\alpha \geq \frac{2}{3}$, at least αn nodes in G have a search space of size at least b_α.*

Proof. Consider some contraction order of the nodes. We identify the smallest integer k such that the k nodes with highest rank in the given order form an α-balanced node separator S in G. Hence, if we remove the $k - 1$ nodes of highest rank, there is still a connected component C of size $> \alpha n$. If we now remove the node v_k with kth highest rank, we can

split C into two subgraphs of size at most αn each, which are not connected to each other. We observe that the larger of the two subgraphs C^* (which is not necessarily connected) has to contain at least $\frac{\alpha}{2}n$ nodes. Therefore, there are at most $n - \frac{\alpha}{2}n$ nodes that are not contained in C^*, which for any $\alpha \geq \frac{2}{3}$ is at most αn. It follows that the separator nodes $S^* \subseteq S$ that are adjacent to C^* form an α-balanced separator already. By definition of b_α, we have $|S^*| \geq b_\alpha$. It remains to be shown that between any node v in $C \setminus v_k$ (which has rank $r(v) < n-k$) and any separator node $s \in S^*$ (which has rank $r(s) \geq n-k$) there exists a path in G on which all nodes have rank at most $r(s)$. For $s = v_k$ this is true, because C is connected and v_k has maximum rank among all nodes of C. If we have $s \neq v_k$, the node s has a neighbor w contained in C. As C is connected, there is a path from v to w in C and hence, the maximum rank on this path is at most $n - k < r(s)$. It follows that G contains a path from v to s of maximum rank $r(s)$. This means that there are αn nodes (recall that C has size $> \alpha n$), which have a search space size of at least $|S^*| \geq b_\alpha$. ◀

It follows that for any $\alpha \geq \frac{2}{3}$ the sum of the search space sizes of all nodes in G is at least $\alpha n \cdot b_\alpha$ and hence the average search space size is lower bounded by $\alpha \cdot b_\alpha$.

▶ **Corollary 4.** *In any weak CH graph, $S_{avg} \geq \alpha \cdot b_\alpha$ for $\alpha \in \left[\frac{2}{3}, 1\right)$.*

The theorem implies that weak CH performs poorly on graph families with no small balanced separators. For the class of planar graphs, and $\alpha = \frac{2}{3}$, there exist graphs with a smallest α-balanced separator of size at least $1.55\sqrt{n}$ [13]. Hence, according to Corollary 4, their induced average CH search spaces are in $\frac{2}{3}1.55\sqrt{n} = 1.0\overline{3}\sqrt{n} \in \Omega(\sqrt{n})$. This matches the known upper bounds for S_{max} in minor-closed graph families with $\mathcal{O}(\sqrt{n})$ sized balanced separators, proving them to be tight.

We prove next that $S_{avg} \in \Omega(b_{1/2})$ holds as well which will later be important for establishing our approximation guarantee. Note that if we just consider balanced separators in G directly, there could be an arbitrary large gap between $b_{1/2}$ and $b_{2/3}$. Hence, we will consider separators in G and in a selected subgraph of G simultaneously to get a meaningful bound. We first show a helping lemma which might also be of independent interest.

▶ **Lemma 5.** *Let G' be a connected subgraph of G with n' nodes and let b'_α be the size of a smallest α-balanced separator in G' for an $\alpha \geq \frac{2}{3}$, then it follows that $S_{avg} \geq \frac{n'}{n}\alpha b'_\alpha$.*

Proof. The proof is the same as the proof of Theorem 3 with the only modification that we consider the k nodes with highest rank in G' that form an α-balanced separator in G' instead of considering G as a whole. ◀

The lemma improves the lower bound on S_{avg} shown in Theorem 6 in case a subgraph of G has a larger balanced separator than G as a whole and this subgraph G' is not too small compared to the total size of G. And it also allows us to prove a general relationship between S_{avg} and $b_{1/2}$ as manifested in the following theorem.

▶ **Theorem 6.** *The average search space size in a weak CH is lower bounded by $\frac{2}{9}b_{1/2}$.*

Proof. Let $b_{1/2}$ and $b_{2/3}$ be minimum balanced separator sizes in G for the respective α-values. Obviously, $b_{2/3} \leq b_{1/2}$ holds. Let G^* be the larger of the two parts that results from removing the $b_{2/3}$ nodes in the respective separator from G. The smaller part has to contain less then $\frac{1}{2}n$ nodes; but G^* may contain between $\frac{1}{3}n$ and $\frac{2}{3}n$ nodes. Now let $b'_{2/3}$ be the minimum size of a $2/3$-balanced separator in G^*. The largest part of G^* after the removal of such a separator has size at most $\frac{2}{3} \cdot \frac{2}{3}n = \frac{4}{9}n < \frac{1}{2}n$. Accordingly, the union of the nodes in the $2/3$-balanced separator in G and the $2/3$-balanced separator in G^* form a $1/2$-balanced separator in G. It

follows that $b_{1/2} \leq b_{2/3} + b'_{2/3} \leq 2\max(b_{2/3}, b'_{2/3})$. Using Lemma 5 together with the relation between the separators in G and G^* leads to the following set of inequalities that lower bound the average search space size: $S_{avg} \geq \max(\frac{2}{3}b_{2/3}, \frac{2}{3} \cdot \frac{2}{3}b'_{2/3}) \geq \frac{4}{9}\max(b_{2/3}, b'_{2/3}) \geq \frac{2}{9}b_{1/2}$ ◀

3.3 An Approximation Algorithm for the Average Search Space Size

The crucial part of CH construction is fixing the contraction order of the nodes. When using nested dissection, as proposed in [7], the input graph G is partitioned recursively into smaller subgraphs via a balanced separator decomposition, and for each obtained subgraph the nodes in the separator are contracted before the other nodes. It was proven that this contraction order allows to upper bound the resulting maximum search space size S^{ND}_{max}. More precisely, an (α, f_α)-balanced separator decomposition of $G(V, E)$ for $\alpha \in (0, 1)$ is a rooted tree T whose nodes are disjoint subsets of V and that is recursively defined as follows. If $n = 1$, then T consists of a single node $X = V$. If $n > 1$, then the root of T is a set $X \subseteq V$ of size at most $f_\alpha(n)$ whose removal separates G into $d \geq 2$ subgraphs $G_1, \ldots, G_d$ with at most αn vertices, each. Moreover, the children of X are the roots of (α, f_α)-balanced separator decompositions of $G_1, \ldots, G_d$. A nested dissection order can then be obtained via a post-order traversal of such a (α, f_α)-balanced decomposition (nodes within one separator X can be contracted in an arbitrary order). It follows that $S^{ND}_{max} \leq (1 + \log_{1/\alpha} n) \cdot B$ where B is an upper bound on the separator sizes f_α in all subgraphs. As every graph has a $(1/2, b)$-balanced separator decomposition where b is the balanced separator number of G, it follows that $S^{ND}_{max} \in \mathcal{O}(b \log n)$. Combined with $S^{ND}_{max} \geq S^*_{max} = td > b$, where S^*_{max} is the smallest possible value of S_{max}, this proves an $\mathcal{O}(\log n)$ approximation guarantee for the maximum search space size[2].

For trees, a $(1/2, 1)$-balanced separator decomposition exists. Accordingly, $S^{ND}_{max} \in \mathcal{O}(\log n)$ holds for trees. Furthermore, it was proven in [7] that the nested dissection contraction order for trees also is an approximation algorithm for S_{avg}. In particular, $S^{ND}_{avg} \leq 2 \cdot S^*_{avg}$ was shown where S^*_{avg} is the optimal average search space size. It was posed as one of the main open questions whether there are ways to approximate the average search space size in general graphs. Note that the approximation guarantee proof given for trees explicitly leverages the fact that trees are cycle free, and that balanced separators in trees always consist of a single node. Hence new proof concepts are required for generalizing the result.

Exploiting our novel lower bound shown in Corollary 4, we will now prove that for general graphs, the contraction order induced by a (α, b_α)-balanced decomposition indeed comes with an approximation guarantee for S_{avg}. Our proof consists of the following three steps:

1. *Upper bounding* $S^{ND}_{avg}(G)$. We show that $S^{ND}_{avg}(G) \leq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^{ND}_{avg}(G_i) + b_\alpha$ where b_α is the size of an α-balanced separator B in G, whose removal splits G into the connected subgraphs $G_1, \ldots, G_d$ of sizes $n_1, \ldots, n_d$ (cf. Lemma 7).
2. *Lower bounding* $S^*_{avg}(G)$. We prove that for the optimal average search space size S^*_{avg} it holds that $S^*_{avg}(G) \geq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^*_{avg}(G_i)$ (cf. Lemma 8).
3. *Combining upper and lower bounds.* Combining the outcomes of steps 1 and 2 as well as Corollary 4, we show that with every level of the separator decomposition, the ratio between S^{ND}_{avg} and S^*_{avg} increases at most by $\frac{1}{\alpha}$. This results in an overall approximation factor of $1 + \frac{1}{\alpha}\log_{1/\alpha}$ for $\alpha \in [\frac{2}{3}, 1)$ (cf. Theorem 9).

[2] This result does not hold in directed graphs as shown in [11].

▶ **Lemma 7.** *Given a graph G, it yields $S^{ND}_{avg}(G) \leq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^{ND}_{avg}(G_i) + b_\alpha$ where b_α is the size of a given α-balanced separator B in G, and $G_1, \ldots, G_d$ are the connected subgraphs of G that remain after removing B, with $n_1, \ldots, n_d$ being their respective node set sizes.*

Proof. The average search space size S_{avg} is defined as the sum of the individual search space sizes divided by n. For each node in the separator B, the search space size can be at most $|B| = b_\alpha$ as the nodes in B all have higher rank in the contraction order than the nodes in $V \setminus B$. For $i = 1, \ldots, d$, the n_i nodes of G_i have a total search space sizes of $n_i \cdot S^{ND}_{avg}(G_i)$ if we do not count the nodes from B. The search space size of each individual node increases by at most b_α when adding B to the graph. Hence in total we get $n \cdot S^{ND}_{avg} \leq \sum_{i=1}^{d} n_i \cdot S^{ND}_{avg}(G_i) + n \cdot b_\alpha$. Dividing both sides by n concludes the proof. ◀

▶ **Lemma 8.** *Given a graph G, the optimal average search space size in a weak CH is lower bounded by $S^*_{avg}(G) \geq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^*_{avg}(G_i)$ where G_i are disjoint subgraphs of G.*

Proof. Let r^* be the optimal contraction order for G, leading to an average search space size of $S^*_{avg}(G) = \frac{1}{n}\sum_{v \in V} |SS^*(v)|$. By r^*_i we denote the restriction of r^* to subgraph G_i, that is, the nodes in G_i are sorted by their r^* values and $r^*_i : V(G_i) \to \{1, \ldots, n_i\}$ then assigns each node $v \in V(G_i)$ the rank of v in the obtained order. Let $v \in V(G_i)$ and denote by $SS'(v)$ the search space of v in G_i when using contraction order r^*_i. We show that $|SS^*(v) \cap V(G_i)| \geq |SS'(v)|$, implying that the part of a search space of a node v that intersects a certain subgraph is as least as large as the search space of v in that subgraph when using the globally optimal contraction order restricted to that subgraph. For proving this property, consider a node $w \in SS'(v)$. As w is contained in this search space, there exists a path from v to w in G_i with all nodes on the path having a rank of at most $r^*_i(w)$. This path then also exists in G and as for nodes x, y with $r^*(x) > r^*(y)$, we have $r^*_i(x) > r^*_i(y)$ by construction, it follows that $w \in SS^*(v) \cap V(G_i)$ holds as well. Therefore, $SS^*(v) \cap V(G_i) \supseteq SS'(v)$ applies. Plugging the resulting size inequality into the definition of the average search space results in the following lower bound:

$$\begin{aligned} n \cdot S^*_{avg}(G) &= \sum_{v \in V} |SS^*(v)| \geq \sum_{i=1}^{d} \sum_{v \in V(G_i)} |SS^*(v)| \geq \sum_{i=1}^{d} \sum_{v \in V(G_i)} |SS^*(v) \cap V(G_i)| \\ &\geq \sum_{i=1}^{d} \sum_{v \in V(G_i)} |SS'(v)| \end{aligned}$$

As the application of any contraction order to G_i results in summed search space sizes that are at least as large as $n_i \cdot S^*_{avg}(G_i)$ where $S^*_{avg}(G_i)$ is the optimal average search space in G_i, we get $S^*_{avg}(G) \geq \frac{1}{n}\sum_{i=1}^{d}\sum_{v \in V(G_i)} |SS'(v)| \geq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^*_{avg}(G_i)$. ◀

▶ **Theorem 9.** *Given a graph G, nested dissection contraction results in search space sizes $S^{ND}_{avg} \leq (1 + \frac{1}{\alpha}\log_{1/\alpha} n) \cdot S^*_{avg}$ for any $\alpha \geq \frac{2}{3}$, if optimal separators are used.*

Proof. Consider the (α, b_α)-balanced separator decomposition which induces the nested dissection order. For every leaf X in the decomposition we have $S^{ND}_{avg}(X) = S^*_{avg}(X)$ as X contains only one vertex. Consider now some non-leaf node X from the decomposition. Let H be the subgraph of G induced by X and its descendants in the separator decomposition and denote the connected components of $H \setminus X$ by $H_1, \ldots, H_d$. Denote the size of H_i by n_i and assume that for the average search spaces of $H_1, \ldots, H_d$ we have an approximation

factor of γ, i.e. $S^{ND}_{avg}(H_i) \leq \gamma \cdot S^*_{avg}(H_i)$. Lemma 7 implies

$$S^{ND}_{avg}(H) \leq \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^{ND}_{avg}(H_i) + |X| \leq \gamma \cdot \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^*_{avg}(H_i) + |X|$$

Moreover, X is an optimal α-balanced separator, so Corollary 4 implies that $S^*_{avg}(H) \geq \alpha \cdot |X|$, which can be rearranged to $|X| \leq \frac{1}{\alpha} S^*_{avg}(H)$. In combination with Lemma 8 we obtain

$$\gamma \cdot \frac{1}{n}\sum_{i=1}^{d} n_i \cdot S^*_{avg}(H_i) + |X| \leq \gamma \cdot S^*_{avg}(H) + \frac{1}{\alpha} \cdot S^*_{avg}(H) \leq (\gamma + \frac{1}{\alpha}) \cdot S^*_{avg}(H)$$

As for every leaf X we have $S^{ND}_{avg}(X) = S^*_{avg}(X)$ and the height of the separator decomposition is $\log_{1/\alpha} n$, it follows by induction that $S^{ND}_{avg}(G) \leq (1 + \frac{1}{\alpha}\log_{1/\alpha} n) \cdot S^*_{avg}(G)$. ◀

▶ **Corollary 10.** *The average search space size in a weak CH using nested dissection based on recursive decomposition with $b_{2/3}$ is at most $1 + 1.5\log_{1.5} n$ times the optimal size.*

However, as computing optimal balanced separators is NP-hard in general, nested dissection does not directly yield a polynomial time approximation algorithm. But we can exploit the existence of a pseudo-approximation for balanced separators. In [18] it was proven that one can find a 3/4-balanced separator that has size at most $\mathcal{O}(\log n) \cdot b_{2/3}$ in polynomial time[3]. In general, if we have a γ-approximation for $b_{2/3}$, Lemma 7 can be modified to show that $S^{ND}_{avg} \leq \sum_{i=1}^{d} n_i \cdot S^{ND}_{avg}(G_i) + \gamma b_{2/3}$ which plugged into Theorem 9 results in an average search space size of $S^{ND}_{avg} \leq (1 + 1.5\gamma\log_{1.5} n) S^*_{avg}$. Using the pseudo-approximation result, we have $\gamma = \mathcal{O}(\log n)$, and additionally the depth of the recursion increases from $\log_{3/2} n$ to $\log_{4/3} n$. We call the nested dissection based contraction algorithm which leverages the pseudo-approximation algorithm to compute the node separators the pND-algorithm. Combining the aforementioned observations, we get the following theorem.

▶ **Theorem 11.** *Given a graph $G(V, E)$, then a weak CH obtained from the pND-algorithm in polynomial time leads to an average search space size of $S^{pND}_{avg}(G)$ with $S^{pND}_{avg}(G) \leq \mathcal{O}(\log^2 n) S^*_{avg}(G)$, where $S^*_{avg}(G)$ denotes the minimum average search space size.*

Note that for some graph classes better approximation algorithms for balanced node separators exist, which then can be plugged into our analysis to achieve tighter overall results. For example, for any graph class for which optimal balanced separators can be approximated by some constant factor $c > 0$ in polynomial time (as it is the case e.g., for planar graphs [4]), we achieve an overall approximation ratio of $\mathcal{O}(\log n)$ for S_{avg}. For the special case of $\sqrt{n} \times \sqrt{n}$ rectangular grids, the results from [7] imply that nested dissection leads to search space sizes of at most $3\sqrt{n}$. This matches our lower bound of $\alpha \cdot b_\alpha$ (translating for grids to $\frac{2}{3}\sqrt{n}$) up to a factor of 4.5. As the respective separators can be found efficiently in grids, this implies that nested dissection yields a constant factor approximation algorithm for this graph class.

Regarding space consumption, it was argued in [7] that a weak CH-graph constructed by nested dissection contains at most $n \cdot S_{avg}$ shortcut edges. However, this bound is rather loose on some graphs. For example, it is known for planar graphs that contraction orders exist such that the CH-graph size is in $\mathcal{O}(n \log n)$ while e.g., for grids we know by

[3] This is called a pseudo-approximation or bicriteria approximation as the approximation factor compares the output for a relaxed problem version to the optimum of the unrelaxed version.

Corollary 4 that $n \cdot S_{avg}$ amounts to $\Omega(n\sqrt{n})$. In [3], it was proven that nested dissection indeed approximates the number of shortcut edges within a factor of $\mathcal{O}(\sqrt{d}\log^4 n)$ where d is the maximum degree of the input graph. To achieve polynomial running time, the nested dissection variant described there relies on a pseudo-approximation for $1/2$-balanced separators. As proven in Theorem 6, the average search space size is also lower bounded by $2/9 \cdot b_{1/2}$. This can be plugged in our approximation algorithm analysis to also get an $\mathcal{O}(\log^2 n)$ overall approximation factor for S_{avg}. For road networks, where the maximum node degree is a small constant, it therefore yields that a polynomial time variant of nested dissection approximates the three important aspects of a CH-graph – space consumption (number of inserted shortcuts), maximum search space size, and average search space size – all by polylogarithmic factors.

4 Relation to Road Network Dimensions

So far, we considered search space sizes in weak CHs. Now we shift our focus to strong CH. In particular, we now study the relationship between the average search space size in a strong CH and the highway dimension h as well as the skeleton dimension k of the graph. Those two parameters were both previously used to show upper bounds on the search space size of preprocessing-based route planning techniques.

4.1 Highway Dimension Lower Bound

The highway dimension of a weighted graph $G(V, E)$ is defined as follows [1]: For $u \in V$ and $r > 0$, the ball $B_r(u)$ consists of all nodes at distance at most r from u. Consider now the set $\mathcal{P}$ of all shortest paths longer than r that are contained within the ball $B_{4r}(u)$ and let $H_r^u \subseteq V$ be a minimum hitting set for $\mathcal{P}$. The highway dimension of G is defined as $h = \max_{u,r} |H_r^u|$. For a graph with highway dimension h, $S_{max} \in \mathcal{O}(h \log D)$ was proven for strong CH [1]. Furthermore, it was shown in [7] that there exist graphs and edge weights such that $h \in \Omega(pw/\log n)$ holds. We now establish a complementary result where the aim is to find edge weights such that the value of h is as small as possible.

▶ **Lemma 12.** *For any unweighted graph G there are metric edge weights such that the highway dimension of G is 1.*

Proof. Let $V = \{1, \dots, n\}$ and choose the weight of an edge $\{u, v\}$ as $9^{\max\{u,v\}}$. To bound the highway dimension consider some ball $B_{4r}(v)$ and choose the largest j such that $9^j \leq 4r$. If $v > j$, any edge incident to v has length at least $9^v \geq 9^{j+1} > 4r$. This means that $B_{4r}(v) = \{v\}$ and the ball contains no shortest path that needs to be hit. Let now $v \leq j$. Consider some shortest path π that passes only through vertices $i < j$. The path π is simple and hence by the choice of the edge weights it contains no three edges of same length. This means that we can bound the length of π by $\sum_{i=j/2}^{j-1} 2 \cdot 9^i < 2 \cdot \sum_{i=0}^{j-1} 9^i = (9^j - 1)/4 \leq r$. Moreover, any $u > j$ has distance $9^u \geq 9^{j+1} > 4r$ from v and hence no shortest path passing through u is contained in $B_{4r}(v)$. This means that every relevant shortest path contains j and can be hit by the set $\{j\}$. ◀

The lemma shows that the known upper bound on the maximum search space size of $\mathcal{O}(h \log D)$ is almost tight when the metric is chosen appropriately. White [22] showed for a special family of graphs called $G_{t,k,q}$ graphs (introduced in [19]) that the average search space size is in $\Omega(h \log D)$, which matches the upper bound asymptotically. His proof strongly relies on the characteristics of that graph family, though, and especially on the graph topology.

Our lower bound, however, is independent of the graph structure but just considers the metric. Our result also generalizes to the hub labeling technique where a matching upper bound on the maximum number of hubs per node was proven in [1].

4.2 General Incomparability

While we showed above that we can always choose edge weights such that the highway dimension lower bounds the average search space size, this is not necessarily true if the edge weights are given. In fact, we will prove that in general, it is not possible to lower bound the maximum (or average) CH search space size in terms of the highway dimension or the skeleton dimension. For the skeleton dimension k, no upper bounds for CH are known so far, but for the related technique of hub labeling [17], upper bounds of $\mathcal{O}(k \log n)$ were shown.

Intuitively, the skeleton dimension measures how many "important" branches every shortest path tree contains. For a concise definition we refer to [17]. Our incomparability result just exploits the fact that the maximum degree is a lower bound for the skeleton dimension.

▶ **Lemma 13.** *There are graphs with skeleton dimension k and highway dimension h such that $S_{\max} \in o(k)$ and $S_{\max} \in o(h)$.*

Proof. Take a star graph, subdivide every edge by inserting one vertex and assume unit edge weights. The maximum degree Δ of the graph is linear in the number of nodes n and as Δ is a lower bound for the skeleton dimension k, it follows that $k \in \Omega(n)$. Moreover half of the edges are incident to a leaf node. All these edges are pairwise disjoint and every such edge forms a shortest path of length $1 =: 2r > r$, which intersects the ball of radius $4r = 2$ around the central vertex of the graph. This means that the highway dimension is in $\Omega(n)$.

Consider a contraction order where the highest rank is assigned to the central vertex of the graph and the lowest ranks are assigned to the leaves. Then the maximum search space size is $3 \in o(n)$, which is assumed in the leaves. ◀

Accordingly, search space sizes might be significantly smaller than the discussed road network dimensions. Therefore, the upper bounds derived in dependency of those parameters might be very loose on some graphs. This motivates further research into finding other graph parameters where the possible gap between the average/maximum search space size and the parameter value is in $o(n)$; and to investigate these gaps on real-world networks.

5 Lower Bounds for Strong CH

In this section, we present algorithms to obtain lower bounds for the average search space size of a strong CH in a given weighted graph, e.g., to judge how large the gaps to the road network dimensions are, or to investigate whether a contraction order used in practice produces search space sizes close to the optimum.

5.1 HittingSet Lower Bound

In a strong CH, a node w of rank R is in the search space of a node v with rank $r < R$, if on the shortest path between v and w there is no node with a rank higher than R. (Note that this is a sufficient but not necessary condition.) Accordingly, if we consider the node with maximum rank in the contraction order, we know that it has to be contained in the search space of each node in G. This leads us to the definition of the inverse search space of a node v as $ISS(v) := \{w \in V | v \in SS(w)\}$ which can be used as an alternative mean to determine the average search space $S_{avg} = \frac{1}{n} \sum_{v \in V} |SS(v)| = \frac{1}{n} \sum_{v \in V} |ISS(v)|$. For the node v_{max}

with the highest rank, we know that $|ISS(v_{max})| = n$. Now the goal is to show large inverse search spaces also for other nodes of sufficiently high rank. Note however, that the inverse search space sizes are not necessarily proportional to the rank, as nodes of even higher rank might block many shortest paths. Therefore, we have to take the topology of the graph as well as the shortest path structure into account.

▶ **Observation 14.** *Let G' be the subgraph of G induced by a node set $V' \subseteq V$ and let $v'_{max} \in V'$ be the node with the highest rank in the contraction order among all nodes in V'. Then the number of nodes in V' with their shortest path towards v'_{max} being completely contained in G' is a lower bound for $|ISS(v'_{max})|$.*

To get a lower bound which adheres to all possible contraction orders we need to deal with the fact that we do not know which node in V' will become v'_{max}. To make the bound more general, we can iterate through all nodes $v \in V'$ and compute the number of nodes in V' with the shortest path towards v being completely contained in G', keeping track of the minimum. We call this value the minimum shortest path tree size in G' or $misp(G')$.

▶ **Theorem 15.** *For any $\beta \in (0, 1]$, let $\mathcal{G}$ be a collection of subgraphs of G with $misp(G') \geq \beta n$ for all $G' \in \mathcal{G}$. Furthermore, let H be a minimum HittingSet for the set system $(V, \mathcal{G})$. Then it yields $S_{avg} \geq \beta |H|$.*

Proof. We want to count the inverse search space sizes induced by the nodes of highest rank within each subgraph. To that end, we interpret H as the set of nodes contracted last. We know by definition of $\mathcal{G}$ and minimality of H that for every node $h \in H$, we have $|ISS(h)| \geq \beta n$. Furthermore, by H being a minimum HittingSet, we conclude that there can't be fewer than $|H|$ nodes with that property. Accordingly, we get $S_{avg} = \frac{1}{n} \sum_{v \in V} |ISS(v)| \geq \frac{1}{n} \sum_{h \in H} |ISS(h)| \geq \frac{1}{n} \beta n |H| = \beta |H|$ which completes the proof. ◀

▶ **Example 16.** To illustrate the usefulness of the HittingSet lower bound, we consider a complete graph G with n nodes and metric edge weights, and we choose $\beta = \frac{1}{2}$. We observe that any induced subgraph G' of G of size $\geq \frac{n}{2}$ has $misp(G') \geq \frac{n}{2}$ as well. It follows that we need a HittingSet H of size $\frac{n}{2} + 1$ to hit all these subgraphs. According to Theorem 15, we hence get $S_{avg} \geq \frac{n}{4}$ which matches the upper bound on S_{max} of $n - 1$ asymptotically.

For practical exploitation in real networks, we remark that for every shortest path π of length βn in G, we automatically have $misp(\pi) = \beta n$ and that for any selected subgraph the misp-value can be computed in polytime.

5.2 Hierarchical Lower Bound

In general graphs, the question arises how to choose β in practice to get the best bound. For large β the size of H is expected to be small, while gains in the HittingSet size for small values β might be diminished by the multiplication with β itself. To get a useful lower bound nevertheless, we propose a hierarchical scheme based on the following observation.

▶ **Observation 17.** *Let $\beta_1, \beta_2 \in (0, 1]$ be two parameters with $\beta_1 > \beta_2$ and $\mathcal{G}_1$, H_1 as well as $\mathcal{G}_2, H_2$ the respective subgraph collections and minimum HittingSets. Then we have $S_{avg} \geq \beta_1 |H_1| + \beta_2 (|H_2| - |H_1|)$.*

This observation can be generalized to an arbitrarily fine-grained succession of β-values.

▶ **Corollary 18.** *Given a weighted graph $G(V, E)$, as well as $\beta_1 > \beta_2 > \cdots > \beta_k$ with $\beta_i \in (0, 1]$, let H_i be the respective HittingSet sizes for all subgraphs G' of G with $misp(G') \geq \beta_i n$. Then the average search space size S_{avg} is lower bounded by $\beta_1 |H_1| + \sum_{i=2}^{k} \beta_i (|H_i| - |H_{i-1}|)$.*

▶ **Example 19.** To illustrate that the hierarchical scheme can be beneficial, we consider a path graph with $n = 2^q$ nodes. For any choice of β, we know that a trivial HittingSet of size $\frac{1}{\beta}$ exists. Therefore the bound we get from Theorem 15 only amounts to $S_{avg} = \beta \cdot \frac{1}{\beta} = 1$. If we now use Corollary 18 with $\beta_i = 2^{-i}$ for $i = 0, \ldots, \log_2 n$, we get

$$S_{avg} \geq 1 + \sum_{i=1}^{q} 2^{-i}(2^i - 2^{i-1}) = 1 + \sum_{i=1}^{q} \tfrac{1}{2} = \tfrac{1}{2} \log_2 n$$

which matches the known upper bound up to constant factors.

6 Conclusions and Future Work

We described several novel lower bounding techniques for average and maximum search space sizes in contraction hierarchies. Lower bounds are an important mean to judge the quality of existing construction schemes and theoretical upper bounds. While for hub labeling (a preprocessing-based route planning technique closely related to contraction hierarchies), approximation algorithms for the average number of nodes that have to be scanned in a query were known for some time [10], we proved the first general approximation result for the average search space size in weak contraction hierarchies. As the construction of weak contraction hierarchies is closely related to graph triangulation and to solving systems of linear equations [3], there might be cross-implications to explore.

Future work could also consider weak contraction hierarchies on directed graphs. As the graph parameters used in our analysis are classically defined on undirected graphs only, the established relationships to CH search space sizes do not automatically transfer to directed graphs. One possibility would be to consider parameter variants, as the directed treewidth [16], which are explicitly defined on directed graphs and to check whether approximation results can be obtained in dependency of those parameters.

Another interesting open question is whether there are efficient approximation algorithms for the average or maximum search space size in strong CHs. While upper bounds for search space sizes in weak CHs are valid for strong CHs as well, it is the other way around for lower bounds. Therefore, strong CHs are not covered by our approximation results for weak CHs. Our lower bounds for average search space sizes in strong CHs rely on HittingSet computation, though, as do some strong CH construction schemes which come with provable upper bounds [1]. It hence might be possible to link those results.

Finally, it might be interesting to experimentally investigate the strength of our lower bounds and the efficiency of the proposed algorithms on real-world (road) networks.

Abstract

We investigate the maximum-entropy model $\mathcal{B}_{n,m,p}$ for random n-vertex, m-edge multi-hypergraphs with expected edge size pn. We show that the expected size of the minimization $\min(\mathcal{B}_{n,m,p})$, i.e., the number of inclusion-wise minimal edges of $\mathcal{B}_{n,m,p}$, undergoes a phase transition with respect to m. If m is at most $1/(1-p)^{(1-p)n}$, then $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|]$ is of order $\Theta(m)$, while for $m \geq 1/(1-p)^{(1-p+\varepsilon)n}$ for any $\varepsilon > 0$, it is $\Theta(2^{(\mathrm{H}(\alpha)+(1-\alpha)\log_2 p)\,n}/\sqrt{n})$. Here, H denotes the binary entropy function and $\alpha = -(\log_{1-p} m)/n$. The result implies that the maximum expected number of minimal edges over all m is $\Theta((1+p)^n/\sqrt{n})$. Our structural findings have algorithmic implications for minimizing an input hypergraph. This has applications in the profiling of relational databases as well as for the Orthogonal Vectors problem studied in fine-grained complexity. We make several technical contributions that are of independent interest in probability. First, we improve the Chernoff–Hoeffding theorem on the tail of the binomial distribution. In detail, we show that for a binomial variable $Y \sim \mathrm{Bin}(n,p)$ and any $0 < x < p$, it holds that $\mathrm{P}[Y \leq xn] = \Theta(2^{-\mathrm{D}(x\,\|\,p)\,n}/\sqrt{n})$, where D is the binary Kullback–Leibler divergence between Bernoulli distributions. We give explicit upper and lower bounds on the constants hidden in the big-O notation that hold for all n. Secondly, we establish the fact that the probability of a set of cardinality i being minimal after m i.i.d. maximum-entropy trials exhibits a sharp threshold behavior at $i^* = n + \log_{1-p} m$.

1 Introduction

A plethora of work has been dedicated to the analysis of random graphs. Random hypergraphs, however, received much less attention. For many types of data, hypergraphs provide a much more natural model. This is especially true if the data has a hierarchical structure or reflects interactions between groups of entities. In non-uniform hypergraphs, where edges can have different numbers of vertices, a phenomenon occurs that is unknown to graphs: an edge may be contained in another, with multiple edges even forming chains of inclusion. We are often only interested in the endpoints of those chains, namely, the collections of inclusion-wise minimal or maximal edges. This is the *minimization* or *maximization* of the hypergraph.

[1] Corresponding author: `martin.schirneck@hpi.de`.

We investigate the maximum-entropy model $\mathcal{B}_{n,m,p}$ for random multi-hypergraphs with n vertices and m edges and expected edge size pn for some constant sampling probability p. In other words, out of all probability distributions on hypergraphs with expected edge size pn, $\mathcal{B}_{n,m,p}$ is the one of maximum entropy.[2] This is equivalent to sampling m independent edges by adding any vertex $v \in [n]$ independently with probability p (see Section 2 for details). We are interested in the expected size of the minimization/maximization of $\mathcal{B}_{n,m,p}$, that is, the expected number of minimal/maximal edges. Most of our results are phrased in terms of the minimization, but replacing the probability p with $1-p$ immediately transfers them to the maximization. We show that the size of the minimization undergoes a phase transition with respect to m with the point of transition at $m = 1/(1-p)^{(1-p)n}$. While the number of edges is still small, a constant fraction of them is minimal and the minimization grows linearly in the total sample sizes. For m beyond the transition, we can instead characterize the size of the minimization in terms of the entropy function of $\log_{1-p} m$, see Theorem 1.2 for a precise statement. This characterization shows that the minimality ratio goes down dramatically when m increases. It also allows us to prove that the maximum expected number of minimal edges over all m is of order $\Theta((1+p)^n/\sqrt{n})$. These results draw from another, more hidden, threshold behavior. The probability of a set to be minimal in the hypergraph $\mathcal{B}_{n,m,p}$ depends only on its cardinality i and we show that this probability falls sharply from almost 1 to almost 0 at $i^* = n + \log_{1-p} m$.

The main tool in our analysis is the Chernoff–Hoeffding theorem bounding the tail of the binomial distribution via the Kullback–Leibler divergence from information theory. However, the existing inequalities are not sharp enough to derive tight statements on the expected size of the minimization. So far, there is a gap of order $\sqrt{n}$ between the best-known upper and lower estimates. In this work, we improve these bounds such that they match up to constant factors. We give an explicit interval for the constants involved that holds for all positive integers n making the result useful also in a non-asymptotic setting.

Our structural findings have algorithmic implications for the computation of the minimization $\min(\mathcal{H})$ from an input hypergraph $\mathcal{H}$. We discuss two examples in the context of fine-grained complexity as well as data profiling. There are reasons to believe that there exists no minimization algorithm running in time $m^{2-\varepsilon} \cdot \mathrm{poly}(n)$ for any $\varepsilon > 0$ on m-edge, n-vertex hypergraphs. The reason is as follows: The Sperner Family problem is to decide whether $\mathcal{H}$ comprises two edges such that one is contained in the other, i.e., whether $|\min(\mathcal{H})| < |\mathcal{H}|$. It is equivalent under subquadratic reductions to the more prominent Orthogonal Vectors problem [14, 25]. Hence, a truly subquadratic algorithm would falsify the Orthogonal Vectors Conjecture[3] and in turn the Strong Exponential Time Hypothesis [52]. Partitioning the edges by the number of vertices and processing them in order of increasing cardinality gives an algorithm running in $\mathrm{O}(mn\,|\min(\mathcal{H})| + mn)$, which is $\mathrm{O}(m^2 n)$ in the worst case. However, when looking at the average-case complexity for $\mathcal{B}_{n,m,p}$, we get a run time of $\mathrm{O}(mn\,\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] + mn)$. Our main result therefore shows that the algorithm is subquadratic for all m beyond the phase transition, and even linear for $m \geq 1/(1-p)^n$.

There is also a connection to the profiling of relational databases. Data scientists regularly need to compile and output a comprehensive list of metadata, like unique column combinations, functional dependencies, or, more general, denial constraints, cp. [1]. These multi-column dependencies can all be described as the minimal hitting sets of certain hypergraphs created from comparing pairs of rows in the database and recording the sets

[2] The notation $\mathcal{B}_{n,m,p}$ is mnemonic of the binomial distribution emerging in the sampling process.
[3] Precisely, we mean the Orthogonal Vectors Conjecture for moderate dimensions, see [25].

of attributes in which they differ [24, 11, 10, 40]. Computing these difference sets one by one generates an incoming stream of seemingly random subsets. Filtering the inclusion-wise minimal ones from this stream does not affect the solution, but reduces the number of sets to store and the complexity of the resulting hitting set instance. Minimizing the input is therefore a standard preprocessing technique in data profiling. It has been observed in practice that the minimal sets make up only a small fraction of the whole input [45]. Usually there are fewer minimal difference sets than rows in the database, let alone pairs thereof [11]. The upper bounds given in the Theorems 1 and 2 provide a way to explain this phenomenon. We show that only a few edges can be expected to be minimal, their number may even shrink as the database grows, provided that the number of rows is large enough compared to the number of columns. The respective lower bounds can further be seen as the smallest amount of data any dependency enumeration algorithm needs to hold in memory.

Related Work. Erdős–Rényi graphs $\mathcal{G}_{n,m}$ [23] and Gilbert graphs $\mathcal{G}_{n,p}$ [27] are arguably the most-discussed random graph models in the literature. We refer the reader to the monograph by Bollobás [12] for an overview. A majority of the work on these models concentrates on various phase transitions with respect to the number of edges m or the sample probability p, respectively. This intensive treatment is fueled by the appealing property that Erdős–Rényi graphs are "maximally random" in that they do not assume anything but the number of vertices and edges. More formally, among all probability distributions on graphs with n vertices and m edges, $\mathcal{G}_{n,m}$ is the unique distribution of maximum entropy. The same holds for $\mathcal{G}_{n,p}$ under the constraint that the expected number of edges is $p\binom{n}{2}$, see [2].

The intuition of being maximally random is captured by the Shannon entropy, which is the central concept in information theory [18, 50]. A discrete stochastic system that can be described by the probability distribution $(p_i)_i$ has a (binary) *entropy* of $H((p_i)_i) = -\sum_i p_i \log_2 p_i$. The *self-information* of a single state with probability p is $-\log_2 p$, the entropy is thus the expected information of the whole system. It is a measure of surprisal or how "spread out" the distribution is. Originally stemming from thermodynamics [39], the versatility of this definition is key to the successful application of information theory to fields as diverse as cryptography [15], machine learning [28], quantum computing [44], and of course network analysis [43], to name only a few topics close to computer science. The *principle of maximum entropy* states that out of an ensemble of probability distributions that all describe the observed phenomena equally well, the one of maximum entropy is to be preferred in order to minimize any outside bias. The principle is usually attributed to Jaynes [37, 32, 33]. In the context of random graphs, it is mainly used to define so-called *null models* [53]. One fixes certain graph statistics to mimic those of an observed network and then chooses the maximum-entropy distribution that meets these constraints. By comparing the original network with a "typical graph" drawn from the null model, one can infer whether other observed properties are correlated with the constraints. This method was made rigorous by Park and Newman [46] building on earlier work in general statistics. Prescribing the exact or expected number of edges leads to the $\mathcal{G}_{n,m}$ or $\mathcal{G}_{n,p}$ distributions, respectively. The configuration model fixes the whole degree sequence [13], and in the soft configuration model the degrees hold at least in expectation [8, 26].

Many early attempts to transfer the concept of null models to hypergraphs were only indirect in that they studied hypergraphs via their clique-expansion [42] or as bipartite graphs [48]. This is unsatisfactory since these projections alter relevant observables, like node degrees or the number of triangles. Only recently, Chodrow generalized the configuration model directly to multi-hypergraphs [16]. There also seems to be not much literature on

hypergraph models that can be cast into the maximum-entropy framework without being intentionally designed as such. A notable early exception is the work by Schmidt-Pruzan and Shamir [49]. They fixed the exact/expected edge sequence such that the largest edge has cardinality $\mathrm{O}(\log n)$ and showed a "double jump" phase transition in the size of the largest connected component. Most of the recent literature on random hypergraphs concentrates on the k-uniform model where every edge has exactly k vertices [34, 5, 6] or, equivalently, on random binary matrices with k 1s per column [17]. In our model, we do not prescribe the exact cardinalities of the edges and neither do we bound their maximum size, instead we only require that the *expected* edge size is pn.

Probably closest to our work is a string of articles by Demetrovics et al. [20] as well as Katona [35, 36]. They investigated random databases and connected the Rényi entropy of *order 2* of the logarithmic number of rows with the probability that certain unique column combinations or functional dependencies hold. In contrast, we connect the Shannon entropy of the logarithmic number of *pairs* of rows with the expected number of minimal difference sets. Unique column combinations and functional dependencies are dual to the difference sets of record pairs, one are the minimal hitting sets of the other [1, 9]. Also, the Shannon entropy is the same as the Rényi entropy of *order 1* [18]. In this sense, we complement the result by Demetrovics et al. by showing that the duality also pertains to the order of entropy.

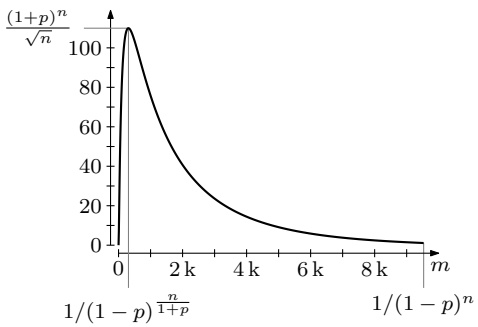
The analysis of random (hyper-)graphs naturally uses tools from combinatorics and probability theory. Conversely, it has always helped to advance the fields by sharpening those tools [7, 12, 31]. In this work, we improve the bounds of the Chernoff–Hoeffding theorem [30] on the tail of the binomial distribution. We use an observation by Klar [38] on the relation between the distribution function and the probability mass function. There were some refined inequalities known before. By Cramér's theorem [19], Chernoff–Hoeffding is asymptotically tight up to subexponential factors. The gap was subsequently reduced to order $\mathrm{O}(\sqrt{n})$, cp. [3], we close it down to a constant. There also exist some comparatively tight bounds based on the normal limit of the binomial distribution, contributions by Prokhorov [47] and Slud [51] founded major lines of research. However, we avoid this approach since the normal approximation cannot be expressed in terms of elementary functions. Also, it tends to place unnecessary restrictions on the success probability p when deriving non-asymptotic results.

Outline. Next, we introduce the hypergraph model and state our results in full detail. We review some notation in Section 3. Section 4 is dedicated to the Chernoff–Hoeffding theorem. Section 5 adds further technical contributions, including the sharp threshold of minimal sets at a certain cardinality. The main theorem is proven in Section 6. Section 7 discusses the phase transition and concludes the work.

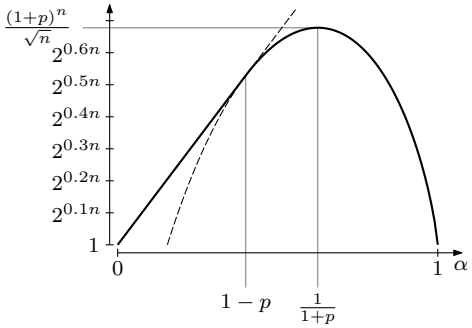
2 Model and Main Theorem

Fix a probability p and positive integers n and m. The random multi-hypergraph $\mathcal{B}_{n,m,p}$ is defined by independently sampling m (not necessarily distinct) subsets of $[n]$. Each set is generated by including a vertex $v \in [n]$ with probability p independently of all other choices.

We quickly argue that this is indeed the maximum-entropy model. Besides the size of the universe n and the number of edges m, the only other constraint is the expected edge size pn. The independence bound on the entropy reads as follows: Let X_1 to X_m be random variables with joint distribution $\mathrm{P}_{X_1,\dots,X_m}$ and marginal distributions P_{X_j}. Then, their entropies observe the inequality $H(\mathrm{P}_{X_1,\dots,X_m}) \leq \sum_{j=1}^{m} H(\mathrm{P}_{X_j})$, equality holds if and only if the X_j are independent, see [18]. This suggests that we should choose the edges independently if we



(a) Our bound as a function of m for $n = 10$ and $p = 0.6$ in the information-theoretic regime. The vertical line at $m = 1/(1-p)^{\frac{n}{1+p}}$ indicates the maximum (Theorem 2). For $m > 1/(1-p)^n$, the size goes to 1. The linear bound for $m \leq 1/(1-p)^{(1-p)n}$ is not shown as it is too close to 0.



(b) Our bound as a function of α for $p = 0.6$ (the plot is independent of n). The vertical line at $\alpha = 1/(1+p)$ indicates the maximum (Theorem 2). For $\alpha \leq 1-p$, the linear bound holds, for larger α, we get the information-theoretic bound. They are continued as dashed lines into the other regime.

Figure 1 Illustration of Theorem 1 showing the expected size of the minimization of a random hypergraph depending on the number of edges m (a) and on α (b). As α grows logarithmically in m, (b) shows the same plot as (a) but with both axes being logarithmic.

want to maximize the entropy and the same is true for the vertices inside an edge. Finally, the fact that setting the sampling probability to be equal for all vertices indeed maximizes the entropy under a given mean set size was proven by Harremoës [29].

We are interested in the expected number of inclusion-wise minimal sets in $\mathcal{B}_{n,m,p}$, denoted by $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|]$. We describe the asymptotic behavior of this expectation with respect to n. In more detail, we view $m = m(n)$ as a function of n assuming integer values and bound the univariate asymptotics of $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|]$ in n for different choices of m. The probability p is considered to be a constant throughout. We show that the size of the minimization can be described precisely in terms of p and the Shannon entropy of the logarithm of m.

We let $\mathrm{H}(x) = H((x, 1-x))$ denote the binary entropy function and define the quantity $\alpha = \log_{\frac{1}{(1-p)^n}} m = -(\log_{1-p} m)/n$. The quantity α is well-defined for all $0 < p < 1$ and $n, m \geq 1$. It is always non-negative and asymptotically of order $\Theta((\log m)/n)$. If p and n are fixed, choosing a value for α determines m since we can rewrite m as $1/(1-p)^{\alpha n}$.

▶ **Theorem 1.** *Let p be a probability, and n, m be two positive integers. If $p = 0$ or $p = 1$, then $|\min(\mathcal{B}_{n,m,p})| = 1$ holds deterministically. For $0 < p < 1$, the following statements hold.*

1. *If $m \leq 1/(1-p)^{(1-p)n}$, then $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \Theta(m)$.*
2. *For any two $\varepsilon, \varepsilon' > 0$ and all m such that $1/(1-p)^{(1-p+\varepsilon)n} \leq m \leq 1/(1-p)^{(1-\varepsilon')n}$, i.e., all α such that $1 - p + \varepsilon \leq \alpha \leq 1 - \varepsilon'$, we have*

$$\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \Theta\Big(2^{(\mathrm{H}(\alpha)+(1-\alpha)\log_2 p)\,n}\Big/\sqrt{n}\Big) = \Theta\bigg(\bigg(\frac{p^{1-\alpha}}{(1-\alpha)^{1-\alpha}\ \alpha^{\alpha}}\bigg)^n\Big/\sqrt{n}\bigg);$$

3. *If $m = 1/(1-p)^{n+\omega(\log n)}$, then $1 \leq \mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = 1 + \mathrm{o}(1)$.*

The bounds in the distinct cases are very different in nature. They are visualized in Figure 1 showing the expectation both as a function of the number of trials m and of α. To distinguish the behavior also in writing, we use the term *linear regime* if m is between 1 and $1/(1-p)^{(1-p)n}$, corresponding to $0 \leq \alpha \leq 1-p$, likewise, we refer to m being between $1/(1-p)^{(1-p)n}$ and $1/(1-p)^n$, i.e., $1-p \leq \alpha \leq 1$, as the *information-theoretic regime*.

All asymptotic estimates in Theorem 1 are at least tight up to constants, the third statement is even tight up to lower-order terms. The constants hidden in the big-O-notation are universal in the sense that they do not depend on m or n, and also not on α describing the relation between the former two. However, they may depend on the probability p and, in case of Statement 2, on the particular choices for ε and ε'. We note that the bounds for the information-theoretic regime have two gaps at $m = 1/(1-p)^{(1-p)n}$ and $m = 1/(1-p)^n$. These gaps can be made arbitrarily small: Let $c = 1/(1-p)$, then Statement 2 holds if $m \leq (c-\gamma)^n$ for any constant $\gamma > 0$ and Statement 3 takes over at $m \geq (c+\delta(n))^n$, where $\delta(n)$ is a function converging to 0 as n increases.

From the main theorem, we derive bounds on the maximum expectation over all m.

▶ **Theorem 2.** *If $p = 0$ or $p = 1$, then $\max_{m\geq 1} |\min(\mathcal{B}_{n,m,p})| = 1$. For $0 < p < 1$, we have $\max_{m\geq 1} \mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \Theta((1+p)^n/\sqrt{n})$, attained at $m = 1/(1-p)^{\frac{n}{1+p}}$.*

3 Preliminaries and Notation

Multi-Hypergraphs. A *hypergraph* on $[n] = \{1, \dots, n\}$ is a set of subsets $\mathcal{H} \subseteq \mathcal{P}([n])$, called the *(hyper-)edges*. If $\mathcal{H}$ is a multiset instead, we have a *multi-hypergraph*. We do not allow multiple copies of the same vertex in one edge. The *minimization* of a hypergraph $\mathcal{H}$ is the collection of its inclusion-wise minimal edges, $\min(\mathcal{H}) = \{E \in \mathcal{H} \mid \forall E' \in \mathcal{H} \colon E' \subseteq E \Rightarrow E' = E\}$. We extend this notion to multi-hypergraphs by requiring that whenever a minimal edge has multiple copies, only one of them is included in the minimization. This way $\min(\mathcal{H})$ is always a mere hypergraph (a set). For a multi-hypergraph $\mathcal{H}$, we use $|\mathcal{H}|$ to denote the total number of edges counting multiplicities, and $\|\mathcal{H}\|$ for the number of *distinct* edges, i.e., the cardinality of the support of $\mathcal{H}$. Evidently, we have $|\min(\mathcal{H})| \leq \|\mathcal{H}\| \leq |\mathcal{H}|$.

Information Theory. We intend the expressions $0 \cdot \log_a 0$ and $0 \cdot \log_a(\frac{0}{0})$ to all mean 0 for any positive real base $a > 0$. Note that this convention also implies $0^0 = a^{0 \log_a 0} = 1$ and $(\frac{0}{0})^0 = 1$. We use $\operatorname{ld} x$ for the binary (base-2) logarithm of x. The (binary) *entropy function* H is defined for all probabilities x as $\mathrm{H}(x) = -x \operatorname{ld} x - (1-x)\operatorname{ld}(1-x)$. It describes the Shannon entropy or, equivalently, the Rényi entropy of order 1, of the Bernoulli distribution with parameter x. In the notation of the previous sections, $\mathrm{H}(x) = H((x, 1-x))$. Evidently, the entropy function is symmetric around $1/2$ with $\mathrm{H}(x) = \mathrm{H}(1-x)$. On the open unit interval, H is positive and differentiable with derivative $\frac{\mathrm{d}}{\mathrm{d}x}\mathrm{H}(x) = \operatorname{ld}\left(\frac{1-x}{x}\right)$. This is the negative (binary) *logit function*, also dubbed *log-odds* in statistics. H is strictly concave and has its maximum at $1/2$ with value $\mathrm{H}(1/2) = 1$. The *perplexity* of x is $2^{\mathrm{H}(x)} = 1/(x^x(1-x)^{1-x})$. We utilize it to estimate binomial coefficients. The bounds are well-known in the literature [18].

▶ **Lemma 3.** *Let n be a positive integer and $0 < x < 1$ such that xn is an integer, then $2^{\mathrm{H}(x)n}/\sqrt{8nx(1-x)} \leq \binom{n}{xn} \leq 2^{\mathrm{H}(x)n}/\sqrt{\pi nx(1-x)}$.*

Let $(p_i)_i$ and $(q_i)_i$ be two distributions on the same state space such that $(p_i)_i$ is absolutely continuous with respect to $(q_i)_i$, i.e., $q_i = 0$ implies $p_i = 0$ for all i. The (binary) *Kullback–Leibler divergence*[4] from $(q_i)_i$ to $(p_i)_i$ is given by $D((p_i)_i \,\|\, (q_i)_i) = -\sum_i p_i \operatorname{ld}(\frac{q_i}{p_i})$. It is the expected information loss when assuming that the distribution is $(q_i)_i$ while the system actually follows $(p_i)_i$. The divergence is a premetric in that it is non-negative and 0 iff the distributions are the same. However, it is neither symmetric nor does it observe the triangle

[4] The divergence is sometimes also called *relative entropy*, we avoid this term due to ambiguities, cf. [18].

inequality. In this work, we only need the divergence between Bernoulli distributions. For any two probabilities x, y, the divergence between two Bernoulli distributions with respective parameters x and y is $\mathrm{D}(x \,\|\, y) = D((x,1-x) \,\|\, (y,1-y)) = -x \operatorname{ld}\left(\frac{y}{x}\right) - (1-x) \operatorname{ld}\left(\frac{1-y}{1-x}\right)$. The function $\mathrm{D}(x \,\|\, y)$ is convex in both x and y, attains its minimum 0 for $x = y$, and observes $\mathrm{D}(x \,\|\, y) = \mathrm{D}(1-x \,\|\, 1-y)$. We often use the derived quantity $2^{-\mathrm{D}(x \,\|\, y)} = \left(\frac{y}{x}\right)^x \left(\frac{1-y}{1-x}\right)^{1-x}$.

Polynomials of Probabilities.

▶ **Lemma 4.** *Let n be a non-negative integer and x a probability, then it holds that $e^{-nx}\left(1-nx^2\right) \leq (1-x)^n \leq e^{-nx}$.*

▶ **Lemma 5** (Lemma 10 in [4])**.** *Let n be a non-negative integer and x a probability, then $nx/(1+nx) \leq 1-(1-x)^n \leq nx$.*

▶ **Lemma 6.** *Consider a random experiment with outcomes A, B, and C, where $\mathrm{P}[B] > 0$. In a series of m i.i.d. trials, let A_j denote the event that the outcome of the j-th trial is A, same with B. Then, we have $\mathrm{P}[\forall j \leq m\colon \neg A_j \mid \exists k \leq m\colon B_k] \leq \mathrm{P}[\forall j \leq m\colon \neg A_j \mid B_m]$.*

4 The Chernoff–Hoeffding Theorem

In this section, we tighten the Chernoff–Hoeffding theorem bounding the tail of the binomial distribution. The result will later help us with the random hypergraphs, but more importantly it provides a powerful tool of general interest in probability theory. Fix a positive integer n and probabilities x and p. Recall that the Kullback–Leibler divergence between the respective Bernoulli distributions is $\mathrm{D}(x \,\|\, p) = -x \operatorname{ld}\left(\frac{p}{x}\right) - (1-x) \operatorname{ld}\left(\frac{1-p}{1-x}\right)$. The Chernoff–Hoeffding theorem [30, 22] employs the divergence to bound the probability that a binomially distributed random variable $Y \sim \mathrm{Bin}(n,p)$ deviates from its expected value $\mathrm{E}[Y] = pn$. If $x \leq p$, then $\mathrm{P}[Y \leq xn] \leq 2^{-\mathrm{D}(x \,\|\, p)\, n} = \left(\frac{p}{x}\right)^{xn} \left(\frac{1-p}{1-x}\right)^{(1-x)n}$. Similarly, if $p \leq x$, we have $\mathrm{P}[Y \geq xn] \leq 2^{-\mathrm{D}(x \,\|\, p)\, n}$. Several weaker but more practical inequalities have been inferred from this, summarized as *Chernoff bounds* [41, 21]. We sharpen these inequalities by a $\sqrt{n}$-factor for all but the extreme values of x. While the upper bound of Chernoff–Hoeffding holds for all probabilities x, there are some lower bounds known for $\mathrm{P}[Y \leq xn]$ if the product xn is an integer, c.f. the textbook by Ash [3, Lemma 4.7.2]. We use a proposition by Klar [38] to improve the upper bound such that it matches the lower one up to constants. We then extend both bounds to the general case of arbitrary products xn.

▶ **Theorem 7.** *Let n be a positive integer, x and p two probabilities with $0 < p < 1$, and $Y \sim \mathrm{Bin}(n,p)$ a binomial random variable.*

1. *If $1/n \leq x < p$, then $\frac{(1-p)\sqrt{x}}{2e\sqrt{2\,(1-x)}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}} \leq \mathrm{P}[Y \leq xn] \leq \frac{\sqrt{1-x}}{(p-x)\sqrt{\pi\, x}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}}$.*
2. *If $p < x \leq 1 - 1/n$, then $\frac{p\sqrt{1-x}}{2e\sqrt{2\,x}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}} \leq \mathrm{P}[Y \geq xn] \leq \frac{\sqrt{x}}{(x-p)\sqrt{\pi\,(1-x)}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}}$.*

Proof sketch. The second statement of the theorem is implied by the first one by applying it to the complementary variable $\overline{Y} \sim \mathrm{Bin}(n, 1-p)$. Let $x \leq p$ be a probability. We mainly confine ourselves here to the case that the product xn is integral and show that then we get $\frac{1}{\sqrt{8\,x(1-x)}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}} \leq \mathrm{P}[Y \leq xn] \leq \frac{p\sqrt{1-x}}{(p-x)\sqrt{\pi\, x}} \cdot \frac{2^{-\mathrm{D}(x \,\|\, p)\, n}}{\sqrt{n}}$.

Lemma 3 provides the following error bounds for the probability mass function of Y: $1/\sqrt{8nx(1-x)} \leq \mathrm{P}[Y = xn]/(2^{\mathrm{H}(x)n} \cdot p^{xn}(1-p)^{(1-x)n}) \leq 1/\sqrt{\pi nx(1-x)}$. We further have $2^{\mathrm{H}(x)n} \cdot p^{xn}(1-p)^{(1-x)n} = 2^{-\mathrm{D}(x\,\|\,p)\,n}$. This proves the first part that $\mathrm{P}[Y \leq xn] \geq \mathrm{P}[Y = xn] \geq 2^{-\mathrm{D}(x\,\|\,p)\,n}/\sqrt{8\,n\,x(1-x)}$ holds.

A result by Klar [38, Proposition 1(c)] states that the ratio $\mathrm{P}[Y \leq xn]/\mathrm{P}[Y = xn]$ is at most $f_{n,xn}(p) = p\,(1 - \frac{xn}{n+1})/(p - \frac{xn}{n+1})$. The partial discrete derivative of $f_{n,xn}$ with respect to n, that is, $\Delta_n(f_{n,xn})(p) = f_{n+1,x(n+1)}(p) - f_{n,xn}(p)$ can be shown to be positive whenever $x < p$. Thus $f_{n,xn}(p)$ converges from below to $p(1-x)/(p-x)$ as n increases. Combined with the error bounds this is $\mathrm{P}[Y \leq xn] \leq \frac{p\,(1-x)}{p-x} \cdot \frac{1}{\sqrt{\pi\,n\,x(1-x)}} \cdot 2^{-\mathrm{D}(x\,\|\,p)\,n} = \frac{p\sqrt{1-x}}{(p-x)\sqrt{\pi\,x}} \cdot \frac{2^{-\mathrm{D}(x\,\|\,p)\,n}}{\sqrt{n}}$.

Transferring the improvements also to non-integral products xn is not straightforward. A careful analysis of the monotonicity of the entropy function H as well as that of the divergence D reveals that this transition weakens the upper bound only by a additional factor of $1/p$ and the lower bound by $x\,(1-p)/e$, independently of n. ◀

We showed that for all values x strictly between 0 and p, the Chernoff–Hoeffding theorem can be asymptotically improved to $\mathrm{P}[Y \leq xn] = \Theta(2^{-\mathrm{D}(x\,\|\,p)\,n}/\sqrt{n})$. However, the constants hidden in the big-O notation diverge at the boundaries. This caveat cannot be healed, there is no way to extend the improvement also to $x = 0$ or p. Simply put, the original formulation of the theorem is tight. First, pn is not only the mean but also the median of the binomial distribution, whence $\mathrm{P}[Y \leq pn] \geq 1/2$ is constant and *not* of order $\mathrm{O}(2^{-\mathrm{D}(p\,\|\,p)\,n}/\sqrt{n}) = \mathrm{O}(1/\sqrt{n})$. Secondly, the initial bound $\mathrm{P}[Y \leq 0] = (1-p)^n = 2^{-\mathrm{D}(0\,\|\,p)\,n}$ even is exact.

5 Distinct Sets and Minimality

We now return to the main topic of this work, which is determining the expected size of the minimization $\min(\mathcal{B}_{n,m,p})$ of the maximum-entropy multi-hypergraph $\mathcal{B}_{n,m,p}$. The sampling probabilities $p = 0$ or $p = 1$ are trivial, we thus assume $0 < p < 1$ in this work unless explicitly stated otherwise. Every subset of $[n]$ then has a non-vanishing chance to be sampled. Such a set is minimal for $\mathcal{B}_{n,m,p}$ iff it is generated in one of the trials and no proper subset ever occurs. Both of these aspects influence the chance of minimality, but their impact varies depending on the cardinality of the set in question. The number of vertices per edge is heavily concentrated around pn and the more vertices there are in an edge, the less likely it is minimal. Intuitively, almost no sets with very low cardinalities are sampled, but if so, they are often included in $\min(\mathcal{B}_{n,m,p})$. There are plenty of edges with a medium number of vertices and there is a good chance they are minimal. Finally, sets of very high cardinality rarely occur and usually they are then dominated by smaller ones. This disparity is exacerbated by a large number of trials. Boosting m increases the probability that also sets of cardinality a bit further away from pn are sampled, at the same time the process generates more duplicates of sets that occurred before. More importantly though, the likelihood of a larger set being minimal is even smaller with many trials. Eventually, the last effect outweighs all others, creating a situation in which the only minimal edge is empty.

We start making this intuition rigorous by giving preliminary bounds on the number of minimal edges as a first step towards the proof of Theorem 1. The results are binomial sums of polynomials of probabilities, depending on which factors we choose, we get an upper or a lower bound. The estimates are already tight up to constants but are rather unwieldy. They will serve as the basis for our further analysis. Let $\mathcal{D}_{n,p}$ denote the maximum-entropy distribution on the power set $\mathcal{P}([n])$ provided that $\mathrm{E}_{X\sim\mathcal{D}_{n,p}}[|X|] = pn$, meaning each vertex is included independently with probability p.

▶ **Lemma 8.** *Let $0 < p < 1$ be a probability, n, m positive integers, and let $X_j \sim \mathcal{D}_{n,p}$ denote the outcome of the j-th independent trial. For any integer i with $0 \leq i \leq n$, define $s_{n,p}(i,m) = \mathrm{P}[\exists j \leq m \colon X_j = [i]]$ and $w_{n,p}(i,m) = \mathrm{P}[\forall j \leq m \colon \neg(X_j \subsetneq [i])]$ to be the respective probabilities[5] that some trial produces the set $[i]$ and no trial produces a proper subset of $[i]$. Then, we have $s_{n,p}(i,m) = 1 - (1 - p^i(1-p)^{n-i})^m$ and $w_{n,p}(i,m) = \left(1 - (1-p)^{n-i}(1-p^i)\right)^m$. Furthermore, the following statements hold.*

1. $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] \geq \sum_{i=0}^{n} \binom{n}{i} s_{n,p}(i,m) \cdot w_{n,p}(i,m)$.
2. $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] \leq \sum_{i=0}^{n} \binom{n}{i} s_{n,p}(i,m) \cdot w_{n,p}(i,m-1)$.
3. $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] \leq 1 + \frac{1}{p} \sum_{i=0}^{n} \binom{n}{i} s_{n,p}(i,m) \cdot w_{n,p}(i,m)$.

Proof sketch. The formula for $w_{n,p}(i,m) = \mathrm{P}[\forall j \leq m \colon \neg(X_j \subsetneq [i])]$ can be seen as follows. The random set $X_j \sim \mathcal{D}_{n,p}$ is a subset of $[i]$ iff it does not contain an element of $[n] \setminus [i]$, which happens with probability $(1-p)^{n-i}$. Conditioned on being any subset, X_j is a *proper* subset if it is missing at least one element of $[i]$, having conditional probability $1 - p^i$.

Regarding the main statements, a set $S \subseteq [n]$ is in $\min(\mathcal{B}_{n,m,p})$ iff it is sampled in one of the m trials and no proper subset is sampled. The probability for both events depends only on the cardinality $|S|$: $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \sum_{S \subseteq [n]} \mathrm{P}[\exists k \leq m \colon X_k = S \wedge \forall j \leq m \colon \neg(X_j \subsetneq S)] = \sum_{i=0}^{n} \binom{n}{i} \cdot \mathrm{P}[\exists k \leq m \colon X_k = [i]] \cdot \mathrm{P}[\forall j \leq m \colon \neg(X_j \subsetneq [i]) \mid \exists k \leq m \colon X_k = [i]]$. Generating any *other* set than $[i]$ in a single trial has probability $1 - p^i(1-p)^{n-i}$, over the independent trials we thus get $s_{n,p}(i,m) = \mathrm{P}[\exists j \leq m \colon X_j = [i]] = 1 - (1 - p^i(1-p)^{n-i})^m$

The last factor $\mathrm{P}[\forall j \leq m \colon \neg(X_j \subsetneq [i]) \mid \exists k \leq m \colon X_k = [i]]$ in each term describes the likelihood that the set $[i]$ is minimal, conditioned on it being sampled at all. Conditioning on at least one trial producing $[i]$ itself only increases the chances of never sampling a proper subset, which gives Statement 1. To prove Statement 2, we apply Lemma 6. Statement 3 follows from the ratio between $w_{n,p}(i,m)$ and $w_{n,p}(i,m-1)$ being the probability that a non-subset of $[i]$ is sampled in a single trial. ◀

The part that all three bounds of Lemma 8 have in common describes the expected number of *distinct* sets in $\mathcal{B}_{n,m,p}$. Recall that we use $\|\mathcal{H}\|$ to denote the number of distinct sets of some multi-hypergraph $\mathcal{H}$. That means, we have $\mathrm{E}[\|\mathcal{B}_{n,m,p}\|] = \sum_{i=0}^{n} \binom{n}{i} s_{n,p}(i,m)$. We weighted the terms of this sum by $w_{n,p}(i,m)$ or $w_{n,p}(i,m-1)$, respectively. In the following, we analyze the two parts separately, starting with the *weighting factors* $w_{n,p}$. They are of interest beyond their application to random multi-hypergraphs. Consider m trials according to the maximum-entropy distribution $\mathcal{D}_{n,p}$ on subsets of $[n]$ with expected set size pn. The quantity $w_{n,p}(i,m)$ is, by definition, the probability that any fixed subset of cardinality i survives as minimal after all trials. Equivalently, $1 - w_{n,p}(i,m)$ is the probability of any proper subset being sampled. We prove next that the weighting factors are in fact threshold functions falling abruptly from almost 1 to almost 0 as i increases from 0 to n, the position of the transition depends on n, m, and p. Recall that α abbreviates $-(\log_{1-p} m)/n$. Lemma 9 below establishes a sharp threshold at $i^* = n + \log_{1-p} m = (1-\alpha)n$. Note that i^* is always at most n since $\log_{1-p} m$ is non-positive. The definition ensures the equality $m = 1/(1-p)^{n-i^*} = 1/(1-p)^{\alpha n}$. For increasing m, the threshold gets smaller relative to n. Once m grows beyond $1/(1-p)^n$, i.e., $\alpha > 1$, the quantity i^* can no longer be interpreted as a cardinality as it becomes negative. Later, in Lemma 12, we will see that m being this large is in fact irrelevant for the minimization.

[5] The notation $s_{n,p}$ refers the set being *sampled*; these probabilities are then *weighted* by the factors $w_{n,p}$.

▶ **Lemma 9.** *Let $0 < p < 1$ be a probability, and n, m positive integers, then $w_{n,p}(0,m) = 1$, and $w_{n,p}(n,m) = p^{nm}$. Now let $i = i(n)$ with $0 < i < n$ be a function taking integer values.*

1. *We have $\exp(-m\,(1-p)^{n-i}) \cdot (1 - m\,(1-p)^{2(n-i)}) \leq w_{n,p}(i,m) \leq \exp(-m\,(1-p)^{n-i+1})$.*

In particular, the following statements hold.[6]

2. *If $i = n + \log_{1-p} m + \omega(1)$, then $\lim_{n\to\infty} w_{n,p}(i,m) = 0$.*
3. *If $i = n + \log_{1-p} m - \omega(1)$, then $\lim_{n\to\infty} w_{n,p}(i,m) = 1$.*
4. *If $i = n + \log_{1-p} m \pm \Theta(1)$, then $w_{n,p}(i,m) = \Theta(1)$.*

Proof. Suppose $0 < i < n$, we estimate $w_{n,p}(i,m)$ using mainly Lemma 4. This yields $w_{n,p}(i,m) = (1-(1-p)^{n-i}(1-p^i))^m \leq (1-(1-p)^{n-i}(1-p))^m \leq \exp\Big(-m\,(1-p)^{n-i}\cdot(1-p)\Big)$. Since $1-p$ is constant, the limit behavior is entirely determined by the product $m\,(1-p)^{n-i}$. If $i = n + \log_{1-p} m + \omega(1)$, then $m\,(1-p)^{n-i} = m\,(1-p)^{n-n-(\log_{1-p} m)-\omega(1)} = (1-p)^{-\omega(1)}$ diverges and thus the weighting factor $w_{n,p}(i,m)$ converges to 0. Conversely, from $1-p^i \leq 1$ we get that $w_{n,p}(i,m) \geq (1-(1-p)^{n-i})^m \geq \exp\Big(-m\,(1-p)^{n-i}\Big)\cdot(1-m\,(1-p)^{2(n-i)})$. If $i = n + \log_{1-p} m - \omega(1)$, both $m\,(1-p)^{n-i} = (1-p)^{\omega(1)}$ and $m\,(1-p)^{2(n-i)} = (1-p)^{\omega(1)}/m$ tend to 0, implying $\lim_{n\to\infty} w_{n,p}(i,m) = 1$.

Finally, if the cardinality i is around the threshold $i^* = n + \log_{1-p} m$, the limit may not exist. We show that $w_{n,p}(i,m)$ is still bounded away from 0. Suppose $i = n + \log_{1-p} m \pm \Theta(1)$; in particular, the difference $i^* - i$ is bounded for all n. If m is constant w.r.t. n, so is $w_{n,p}(i,m) \geq (1-(1-p)^{n-i})^m \geq p^m$. Here, we used the assumption $i < n$. Finally, if m diverges, then $n - i = \log_{1-p} m \mp \Theta(1) = \omega(1)$ diverges with it. Together with the fact that $m\,(1-p)^{n-i} = (1-p)^{i^*-i}$ holds by the definition of i^*, we get that $w_{n,p}(i,m)$ is bounded since $w_{n,p}(i,m) \geq \exp\Big(-(1-p)^{i^*-i}\Big)\cdot(1-(1-p)^{(i^*-i)+(n-i)}) = \Omega(1)$. ◀

After we have shown the existence of a sharp threshold for the weighting factors, we now treat the number of distinct sets $\|\mathcal{B}_{n,m,p}\|$ in the multi-hypergraph. This is a natural upper bound for the size of the minimization. In turn, a trivial cap for the number of distinct sets is the total number of sets $|\mathcal{B}_{n,m,p}| = m$. When starting the sampling, many different sets are generated and $\|\mathcal{B}_{n,m,p}\|$ is indeed close to m. As the number of trials increases though, duplicates occur in the sample and the two quantities grow apart.

To discuss this in more detail, we introduce some notation. For a pair of integers ℓ, u with $0 \leq \ell \leq u \leq n$, let $\|\mathcal{B}_{n,m,p}(\ell,u)\|$ denote the number of distinct sampled sets whose cardinality is between ℓ and u, including. This is also at most as large as the total number of samples in that range. It thus makes sense to expect an upper bound in terms of the binomial distribution. We confirm this below and further prove that there is also a lower bound of the same flavor.

▶ **Lemma 10.** *Let $0 < p < 1$ be a probability, n, m positive integers, and $Y \sim \mathrm{Bin}(n,p)$ a binomially distributed random variable with parameters n and p. Let ℓ, u be integers such that $0 \leq \ell \leq u \leq n$ and define $\mathbf{p} = \max_{\ell\leq i\leq u}\{p^i(1-p)^{n-i}\}$. Then, $\mathbf{p}$ is equal to $p^\ell(1-p)^{n-\ell}$ if $p \leq 1/2$; otherwise, we have $\mathbf{p} = p^u(1-p)^{n-u}$. Further, the expected number of distinct sets in $\mathcal{B}_{n,m,p}$ with cardinality between ℓ and u observes $\frac{m}{1+m\mathbf{p}} \cdot \mathrm{P}[\ell \leq Y \leq u] \leq \mathrm{E}[\,\|\mathcal{B}_{n,m,p}(\ell,u)\|\,] \leq m \cdot \mathrm{P}[\ell \leq Y \leq u]$.*

[6] We understand $\omega(1)$ as the class of all non-negative unbounded functions of n. In particular, the classes $n + \log_{1-p} m + \omega(1)$ and $n + \log_{1-p} m - \omega(1)$ are disjoint.

6 Proof of the Main Theorem

We prove the main results on the expected size of the minimization of the hypergraph $\mathcal{B}_{n,m,p}$ in this section with the help of the tools above. The key observation is that the minimization is dominated by the sets with cardinalities around the threshold $i^* = n + \log_{1-p} m$.

6.1 The Lower Bound

We prove the main results, Theorem 1, with the help of the tools above. The key observation is that the minimization is dominated by the sets with cardinalities around the threshold $i^* = n + \log_{1-p} m$ of the weighting factors. We will see that the distinct edges make up a constant fraction of $\mathcal{B}_{n,m,p}$ as long as m is at most $1/(1-p)^{(1-p)n}$. In turn, a constant fraction of those distinct edges are indeed minimal. However, the linear growth of $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|]$ cannot be maintained for a larger sample size. We prove that once m is so large that the threshold i^* is below pn, the ratio of minimal edges decreases significantly. The minimization then enters a regime governed by the entropy of $\alpha = -(\log_{1-p} m)/n$.

The next lemma shows both lower bounds of Theorem 1 together. The information-theoretic one is slightly more general than what was stated in Theorem 1.2 in that it pertains to all m between $1/(1-p)^{(1-p)n}$ and $1/(1-p)^{(1-\varepsilon')n}$. Let H denote the entropy function.

▶ **Lemma 11** (Theorem 1.1 and the lower bound of Theorem 1.2)**.** *Let $0 < p < 1$. If $m \leq 1/(1-p)^{(1-p)n}$, then $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \Theta(m)$. For any $\varepsilon' > 0$ and m such that $1/(1-p)^{(1-p)n} \leq m \leq 1/(1-p)^{(1-\varepsilon')n}$, corresponding to $1-p \leq \alpha \leq 1-\varepsilon'$, we have $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \Omega\big(2^{(\mathrm{H}(\alpha)+(1-\alpha)\operatorname{ld} p)\,n}/\sqrt{n}\big)$.*

Proof sketch. The sought expectation is at least as large as the number of distinct sets up to some cardinality i that are minimal after m trials for arbitrary values of i. As an ansatz, we choose this to be the threshold $i^* = n + \log_{1-p} m$. Lemmas 8 and 10 together then imply that $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] \geq (m/(1+m\mathbf{p})) \cdot \mathrm{P}[Y \leq i^*] \cdot w_{n,p}(i^*, m)$. It can be shown via Lemma 10 that the denominator $1 + m\mathbf{p}$ is at most 2 as long as $m \leq 1/(1-p)^n$. Lemma 9.1 shows that there exists a universal constant $\delta > 0$ (again for all $m \leq 1/(1-p)^n$) such that $w(i^*, m) \geq \delta$.

The bounds in the two regimes differ in the way the product $m \cdot \mathrm{P}[Y \leq i^*]$ is estimated. If $m \leq 1/(1-p)^{(1-p)n}$, then $i^* \geq pn$ is at least as large as the median of Y, whence $m \cdot \mathrm{P}[Y \leq i^*] \geq m/2$. This gives the lower bound in the linear regime. In the information-theoretic regime, we use the rewrite $m = 1/(1-p)^{\alpha n}$. Suppose first that there are constants $\varepsilon, \varepsilon' > 0$ such that $1 - p + \varepsilon \leq \alpha \leq 1 - \varepsilon'$ holds. These are exactly the prerequisites of Theorem 1.2. We apply the improved lower bound of the Chernoff–Hoeffding theorem, Theorem 7.1. Let D denote the Kullback–Leibler divergence. There exists a positive constant $C > 0$–independent of n and m but possibly dependent on p, ε, and ε'–such that

$$\begin{aligned} m \cdot \mathrm{P}[Y \leq i^*] &= m \cdot \mathrm{P}[Y \leq (1-\alpha)n] \geq m \cdot C\,\frac{2^{-\mathrm{D}(1-\alpha\,\|\,p)\,n}}{\sqrt{n}} \\ &= \frac{1}{(1-p)^{\alpha n}} \cdot \frac{C}{\sqrt{n}} \left(\frac{p}{1-\alpha}\right)^{(1-\alpha)n} \left(\frac{1-p}{\alpha}\right)^{\alpha n} = \frac{C}{\sqrt{n}} \cdot \left(\frac{p^{1-\alpha}}{(1-\alpha)^{1-\alpha}\,\alpha^{\alpha}}\right)^n. \end{aligned}$$

The latter expression equals $C \cdot 2^{(\mathrm{H}(\alpha)+(1-\alpha)\operatorname{ld} p)\,n}/\sqrt{n}$. Finally, if $m(1-p)^{(1-p)n}$ converges to 1 from above, i.e., $\alpha \searrow 1-p$, then the result follows from a direct application of Lemma 3. ◀

6.2 The Upper Bound

The upper bound draws from the same core observations as the lower one: the threshold position of the weighting factors $w_{n,p}$ and the proportion of distinct sets in the sample. First, we show that once m is more than a polynomial factor larger than $1/(1-p)^n$, the minimization essentially consists of a single edge, the empty set. Lemma 13 then proves our claim that the information-theoretic lower bound is tight beyond the phase transition.

▶ **Lemma 12** (Theorem 1.3). *If* $m = 1/(1-p)^{n+\omega(\log n)}$, *then* $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = 1 + \mathrm{o}(1)$.

▶ **Lemma 13** (Upper bound of Theorem 1.2). *Let* $0 < p < 1$ *be a probability,* $\varepsilon, \varepsilon' > 0$ *positive reals, and* n, m *positive integers such that* m *is between* $1/(1-p)^{(1-p+\varepsilon)n}$ *and* $1/(1-p)^{(1-\varepsilon')n}$, *i.e.,* $1 - p + \varepsilon \le \alpha \le 1 - \varepsilon'$. *Then, we have* $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] = \mathrm{O}\big(2^{(\mathrm{H}(\alpha)+(1-\alpha)\,\mathrm{ld}\,p)\,n}/\sqrt{n}\big)$.

Proof sketch. We get $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|] \le \sum_{i=0}^{n} \binom{n}{i}(1-(1-p^i(1-p)^{n-i})^m) \cdot w_{n,p}(i, m-1)$ from Lemma 8.2. The idea of this proof is to split the sum at the threshold $i^* = (1-\alpha)n$ and handle the two parts separately. Let $Y \sim \mathrm{Bin}(n,p)$ be a binomial variable. Lemma 10 shows for the first part that $\sum_{i=0}^{i^*} \binom{n}{i}(1-(1-p^i(1-p)^{n-i})^m) \cdot w_{n,p}(i, m-1) \le m \cdot \mathrm{P}[Y \le i^*]$. The new Chernoff–Hoeffding theorem (Theorem 7.1) gives a constant $C' = C'(p, \varepsilon, \varepsilon')$ with

$$m \cdot \mathrm{P}[Y \le i^*] = m \cdot \mathrm{P}[Y \le (1-\alpha)n] \le m \cdot C' \frac{2^{-\mathrm{D}(1-\alpha\,\|\,p)\,n}}{\sqrt{n}} = \mathrm{O}\left(\frac{2^{(\mathrm{H}(\alpha)+(1-\alpha)\,\mathrm{ld}\,p)\,n}}{\sqrt{n}}\right).$$

The lemma follows from the second part of the sum being at most a constant factor larger than the first one. This is shown using the assumption $\alpha \le 1 - \varepsilon'$ and the weighting factors $w_{n,p}(i,m)$ going doubly exponentially to 0 if i crosses the threshold i^*, see Lemma 9.1. ◀

7 Conclusion

We examined the expected number of minimal edges of the maximum-entropy multi-hypergraph model with expected edge size pn. We discovered a phase transition with respect to the total number of edges at $m = 1/(1-p)^{(1-p)n}$. Now that we have tight upper and lower bounds in place, we can discuss the transition in full detail. For small m, $\mathrm{E}[|\min(\mathcal{B}_{n,m,p})|]$ is linear in m. Beyond that point, the minimization instead follows $2^{(\mathrm{H}(\alpha)+(1-\alpha)\,\mathrm{ld}\,p)\,n}/\sqrt{n}$ with $\alpha = -(\log_{1-p} m)/n$. In the information-theoretic regime the size of the minimization is decoupled from the number of edges. It continues to grow initially, but now sublinearly in m and only until $m = 1/(1-p)^{\frac{n}{1+p}}$. From there on, the size of the minimization decays rapidly although the total number of trials increases. Once m exceeds $1/(1-p)^n$, the minimization collapses under the sheer likelihood of sampling the empty set.

We gain additional insights by contrasting the results in the two regimes (ignoring constant factors here). The ratio between the two bounds at $m = 1/(1-p)^{\alpha n}$ for any $0 \le \alpha \le 1$ is $((2^{(\mathrm{H}(\alpha)\,+\,(1-\alpha)\,\mathrm{ld}\,p)\,n})/\sqrt{n})/m = (2^{-\mathrm{D}(1-\alpha\,\|\,p)\,n})/\sqrt{n}$. This is exponentially small in n when α lies strictly between 0 and $1-p$. Therefore, the information-theoretic *lower* bound of Theorem 1.2 also pertains to the linear regime, but is unnecessarily loose there. If the number of trials m is close to $1/(1-p)^{(1-p)n}$, the two bounds coincide, up to a factor of $\sqrt{n}$, since the divergence vanishes at $1-\alpha = p$. This overlap is indicated in Figure 1b by dashed lines. Finally, for α beyond $1-p$ the relative share of minimal edges becomes exponentially small.

The Chernoff–Hoeffding theorem played an integral role in verifying these results. We tightened the tail bounds on the binomial distribution and provided explicit upper and lower bounds on the constants involved. We are convinced that this sharpened tool can help researchers in all of probability beyond the scope of this paper.

There is more work needed for the upper and lower bounds in the information-theoretic regime. Currently, α has to be bounded away from from $1-p$ and 1 for the bounds to be tight. For $\alpha \searrow 1-p$ the lower bound goes to $\Omega(2^{(\mathrm{H}(1-p)+p\operatorname{ld} p)\,n}/\sqrt{n}) = \Omega(m/\sqrt{n})$. Here, we profit from the hidden constant not depending on α. In actuality though, the minimization at $m = 1/(1-p)^{(1-p)n}$ has size $\Theta(m)$, so the share of minimal edges in the sample moves from order $1/\sqrt{n}$ to a constant. The speed of this shift depends on how fast $\alpha = 1-p+\mathrm{o}(1)$ converges. The situation for $\alpha \nearrow 1$ is different as in this parameter range there is a huge disparity between the number of minimal edges $|\min(\mathcal{B}_{n,m,p})|$ and the number of distinct edges $||\mathcal{B}_{n,m,p}||$. Thus, the expected size of the minimization is not completely captured by the binomial distribution and additional tools are needed for tight estimates. An immediate extension of our work would therefore be to pinpoint the exact behavior of the minimization at the two transitions points. Another interesting question in light of the original motivation of random databases is to allow different sample probabilities per vertex as well as dependencies between the elements. To fit the maximum-entropy setting, this would require the model to incorporate additional constraints.

Abstract

A k-colouring c of a graph G is a mapping $V(G) \to \{1, 2, \ldots\ k\}$ such that $c(u) \neq c(v)$ whenever u and v are adjacent. The corresponding decision problem is Colouring. A colouring is acyclic, star, or injective if any two colour classes induce a forest, star forest or disjoint union of vertices and edges, respectively. Hence, every injective colouring is a star colouring and every star colouring is an acyclic colouring. The corresponding decision problems are Acyclic Colouring, Star Colouring and Injective Colouring (the last problem is also known as $L(1,1)$-Labelling).

A classical complexity result on Colouring is a well-known dichotomy for H-free graphs, which was established twenty years ago (in this context, a graph is H-free if and only if it does not contain H as an *induced* subgraph). Moreover, this result has led to a large collection of results, which helped us to better understand the complexity of Colouring. In contrast, there is no systematic study into the computational complexity of Acyclic Colouring, Star Colouring and Injective Colouring despite numerous algorithmic and structural results that have appeared over the years.

We initiate such a systematic complexity study, and similar to the study of Colouring we use the class of H-free graphs as a testbed. We prove the following results:

1. We give almost complete classifications for the computational complexity of Acyclic Colouring, Star Colouring and Injective Colouring for H-free graphs.
2. If the number of colours k is fixed, that is, not part of the input, we give full complexity classifications for each of the three problems for H-free graphs.

From our study we conclude that for fixed k the three problems behave in the same way, but this is no longer true if k is part of the input. To obtain several of our results we prove stronger complexity results that in particular involve the girth of a graph and the class of line graphs.

1 Introduction

We study the complexity of three classical colouring problems. We do this by focusing on *hereditary* graph classes, i.e., classes closed under vertex deletion, or equivalently, classes characterized by a (possibly infinite) set $\mathcal{F}$ of forbidden induced subgraphs. As evidenced by numerous complexity studies in the literature, even the case where $|\mathcal{F}| = 1$ captures a rich family of graph classes suitably interesting to develop general methodology. Hence, we usually first set $\mathcal{F} = \{H\}$ and consider the class of *H-free* graphs, i.e., graphs that do not contain H as an induced subgraph. We then investigate how the complexity of a problem restricted to H-free graphs depends on the choice of H and try to obtain a *complexity dichotomy*.

To give a well-known and relevant example, the Colouring problem is to decide, given a graph G and integer $k \geq 1$, if G has a *k-colouring*, i.e., a mapping $c : V(G) \to \{1, \ldots, k\}$ such that $c(u) \neq c(v)$ for every two adjacent vertices u and v. Král' et al. [37] proved that Colouring on H-free graphs is polynomial-time solvable if H is an induced subgraph of P_4 or $P_1 + P_3$ and NP-complete otherwise. Here, P_n denotes the n-vertex path and $G_1 + G_2 = (V(G_1) \cup V(G_2), E(G_1) \cup E(G_2))$ the disjoint union of two vertex-disjoint graphs G_1 and G_2. If k is fixed (not part of the input), then we obtain the k-Colouring problem. No complexity dichotomy is known for k-Colouring if $k \geq 3$. In particular, the complexities of 3-Colouring for P_t-free graphs for $t \geq 8$ and k-Colouring for sP_4-free graphs for $s \geq 2$ and $k \geq 3$ are still open. Here, we write sG for the disjoint union of s copies of G. We refer to the survey of Golovach et al. [27] for further details and to [13, 36] for updated summaries.

For a colouring c of a graph G, a *colour class* consists of all vertices of G that are mapped by c to a specific colour i. We consider the following special graph colourings. A colouring of a graph G is *acyclic* if the union of any two colour classes induces a forest. The $(r+1)$-vertex *star* $K_{1,r}$ is the graph with vertices $u, v_1, \ldots, v_r$ and edges uv_i for every $i \in \{1, \ldots, r\}$. An acyclic colouring is a *star colouring* if the union of any two colour classes induces a *star forest*, that is, a forest in which each connected component is a star. A star colouring is *injective* (or an *$L(1,1)$-labelling*) if the union of any two colour classes induces an $sP_1 + tP_2$ for some integers $s \geq 0$ and $t \geq 0$. An alternative definition is to say that all the neighbours of every vertex of G are uniquely coloured. These definitions lead to the following three decision problems:

Acyclic Colouring	
Instance:	A graph G and an integer $k \geq 1$
Question:	Does G have an acyclic k-colouring?

Star Colouring	
Instance:	A graph G and an integer $k \geq 1$
Question:	Does G have a star k-colouring?

Injective Colouring	
Instance:	A graph G and an integer $k \geq 1$
Question:	Does G have an injective k-colouring?

If k is fixed, we write Acyclic k-Colouring, Star k-Colouring and Injective k-Colouring, respectively.

All three problems have been extensively studied. We note that in the literature on the Injective Colouring problem it is often assumed that two adjacent vertices may be coloured alike by an injective colouring (see, for example, [29, 30, 33]). However, in our

paper, we do **not** allow this; as reflected in their definitions we only consider colourings that are proper. This enables us to compare the results for the three different kinds of colourings with each other.

So far, systematic studies mainly focused on structural characterizations, exact values, lower and upper bounds on the minimum number of colours in an acyclic colouring or star colouring (i.e., the *acyclic* and *star chromatic number*); see, e.g., [2, 9, 19, 20, 21, 34, 35, 50, 51, 53], to name just a few papers, whereas injective colourings (and the *injective chromatic number*) were mainly considered in the context of the distance constrained labelling framework (see the survey [11] and Section 6 therein). The problems have also been studied from a complexity perspective, but apart from a study on Acyclic Colouring for graphs of bounded maximum degree [45], known results are scattered and relatively sparse. We perform a *systematic* and *comparative* complexity study by focusing on the following research question both for k part of the input and for fixed k:
What are the computational complexities of Acyclic Colouring, Star Colouring and Injective Colouring for H-free graphs?
Before discussing our new results and techniques, we first briefly discuss some known results.

Coleman and Cai [14] proved that for every $k \geq 3$, Acyclic k-Colouring is NP-complete for bipartite graphs. Afterwards, a number of hardness results appeared for other hereditary graph classes. Alon and Zaks [3] showed that Acyclic 3-Colouring is NP-complete for line graphs of maximum degree 4. Angelini and Frati [4] showed that Acyclic 3-Colouring is NP-complete for planar graphs of maximum degree 4. Mondal et al. [45] proved that Acyclic 4-Colouring is NP-complete for graphs of maximum degree 5 and for planar graphs of maximum degree 7. Albertson et al. [1] and recently, Lei et al. [38] proved that Star 3-Colouring is NP-complete for planar bipartite graphs and line graphs, respectively. Bodlaender et al. [7], Sen and Huson [48] and Lloyd and Ramanathan [41] proved that Injective Colouring is NP-complete for split graphs, unit disk graphs and planar graphs, respectively. Mahdian [44] proved that for every $k \geq 4$, Injective k-Colouring is NP-complete for line graphs, whereas Injective 4-Colouring is known to be NP-complete for cubic graphs (see [11]); observe that Injective 3-Colouring is trivial for general graphs.

On the positive side, Lyons [43] showed that every acyclic colouring of a P_4-free graph is, in fact, a star colouring. Lyons [43] also proved that Acyclic Colouring and Star Colouring are polynomial-time solvable for P_4-free graphs; we note that Injective Colouring is trivial for P_4-free graphs, as every injective colouring must assign each vertex of a connected P_4-free graph a unique colour. The results of Lyons have been extended to P_4-tidy graphs and $(q, q-4)$-graphs [40]. Cheng et al. [12] complemented the aforementioned result of Alon and Zaks [3] by proving that Acyclic Colouring is polynomial-time solvable for claw-free graphs of maximum degree at most 3. Calamoneri [11] observed that Injective Colouring is polynomial-time solvable for comparability and co-comparability graphs. Zhou et al. [52] proved that Injective Colouring is polynomial-time solvable for graphs of bounded treewidth (which is best possible due to the W[1]-hardness result of Fiala et al. [22]).

Our Complexity Results and Methodology

The *girth* of a graph G is the length of a shortest cycle of G (if G is a forest, then its girth is ∞). To answer our research question we focus on two important graph classes, namely the classes of graphs of high girth and line graphs, which are interesting classes on their own. If a problem is NP-complete for both classes, then it is NP-complete for H-free graphs whenever H has a cycle or a claw. It then remains to analyze the case when H is a *linear forest*, i.e., a disjoint union of paths; see [8, 10, 25, 37] for examples of this approach, which we discuss in detail below.

The construction of graph families of high girth and large chromatic number is well studied in graph theory (see, e.g. [18]). To prove their complexity dichotomy for Colouring on H-free graphs, Král' et al. [37] first showed that for every integer $g \geq 3$, 3-Colouring is NP-complete for the class of graphs of girth at least g. This approach can be readily extended to any integer $k \geq 3$ [17, 42]. The basic idea is to replace edges in a graph by graphs of high girth and large chromatic number, such that the resulting graph has sufficiently high girth and is k-colourable if and only if the original graph is so (see also [28, 32]).

By a more intricate use of the above technique we are able to prove that for every $g \geq 3$, Acyclic 3-Colouring is NP-complete for the class of graphs of girth at least g. This implies that Acyclic 3-Colouring is NP-complete for H-free graphs whenever H has a cycle. We prove the same result for every $k \geq 4$ by combining known results, just as we use known results to prove that Star k-Colouring ($k \geq 3$) and Injective k-Colouring ($k \geq 4$) are NP-complete for H-free graphs if H has a cycle.

A classical result of Holyer [31] is that 3-Colouring is NP-complete for line graphs (and Leven and Galil [39] proved the same for $k \geq 4$). As line graphs are claw-free, Král' et al. [37] used Holyer's result to show that 3-Colouring is NP-complete for H-free graphs whenever H has an induced claw. For Acyclic 3-Colouring, this follows from Alon and Zaks' result [3], which we extend to work for $k \geq 4$. For Injective k-Colouring ($k \geq 4$) we can use the aforementioned result on line graphs of Mahdian [44].

The above hardness results leave us to consider the case where H is a linear forest. In Section 2 we will use a result of Atminas et al. [5] to prove a general result from which it follows that for fixed k, all three problems are polynomial-time solvable for H-free graphs if H is a linear forest. Hence, we have full complexity dichotomies for the three problems when k is fixed. However, these positive results do not extend to the case where k is part of the input: we prove NP-completeness for graphs that are P_r-free for some small value of r or have a small independence number, i.e., that are sP_1-free for some small integer s.

Our complexity results for H-free graphs are summarized in the following three theorems, proven in Sections 3–5, respectively; see Table 1 for a comparison. For two graphs F and G, we write $F \subseteq_i G$ or $G \supseteq_i F$ to denote that F is an *induced* subgraph of G.

▶ **Theorem 1.** *Let H be a graph. For the class of H-free graphs it holds that:*

- **(i)** Acyclic Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ and NP-complete if H is not a forest or $H \supseteq_i 19P_1, 3P_3$ or $2P_5$;*
- **(ii)** *For every $k \geq 3$,* Acyclic k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

▶ **Theorem 2.** *Let H be a graph. For the class of H-free graphs it holds that:*

- **(i)** Star Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ and NP-complete for any $H \neq 2P_2$.*
- **(ii)** *For every $k \geq 3$,* Star k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

▶ **Theorem 3.** *Let H be a graph. For the class of H-free graphs it holds that:*

- **(i)** Injective Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ or $H \subseteq_i P_1 + P_3$ and NP-complete if H is not a forest or $2P_2 \subseteq_i H$ or $6P_1 \subseteq_i H$.*
- **(ii)** *For every $k \geq 4$,* Injective k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

In Section 6 we give a number of open problems that resulted from our systematic study; in particular we will discuss the distance constrained labelling framework in more detail.

Table 1 The state-of-the-art for the three problems in this paper and the original Colouring problem; both when k is fixed and when k is part of the input.

	polynomial time	NP-complete
Colouring [37]	$H \subseteq_i P_4$ or $P_1 + P_3$	else
Acyclic Colouring	$H \subseteq_i P_4$	else except for at most 1991 open cases
Star Colouring	$H \subseteq_i P_4$	else except for 1 open case
Injective Colouring	$H \subseteq_i P_4$ or $P_1 + P_3$	else except for 10 open cases
k-Colouring (see [13, 27, 36])	depends on k	infinitely many open cases for all $k \geq 3$
Acyclic k-Colouring ($k \geq 3$)	H is a linear forest	else
Star k-Colouring ($k \geq 3$)	H is a linear forest	else
Injective k-Colouring ($k \geq 4$)	H is a linear forest	else

2 A General Polynomial Result

A *biclique* or *complete bipartite graph* is a bipartite graph on vertex set $S \cup T$, such that S and T are independent sets and there is an edge between every vertex of S and every vertex of T; if $|S| = s$ and $|T| = t$, we denote this graph by $K_{s,t}$, and if $s = t$, the biclique is *balanced* and of *order* s. We say that a colouring c of a graph G satisfies the *balance biclique condition* (BB-condition) if c uses at least $k + 1$ colours to colour G, where k is the order of a largest biclique that is contained in G as a (not necessarily induced) subgraph.

Let π be some colouring property; e.g., π could mean being acyclic, star or injective. Then π *can be expressed in MSO*$_2$ (monadic second-order logic with edge sets) if for every $k \geq 1$, the graph property of having a k-colouring with property π can be expressed in MSO$_2$. The general problem Colouring(π) is to decide, on a graph G and integer $k \geq 1$, if G has a k-colouring with property π. If k is fixed, we write k-Colouring(π). We now prove the following result.

▶ **Theorem 4.** *Let H be a linear forest, and let π be a colouring property that can be expressed in MSO$_2$, such that every colouring with property π satisfies the BB-condition. Then, for every integer $k \geq 1$, k-Colouring(π) is linear-time solvable for H-free graphs.*

Proof. Atminas, Lozin and Razgon [5] proved that that for every pair of integers ℓ and k, there exists a constant $b(\ell, k)$ such that every graph of treewidth at least $b(\ell, k)$ contains an induced P_ℓ or a (not necessarily induced) biclique $K_{k,k}$. Let G be an H-free graph, and let ℓ be the smallest integer such that $H \subseteq_i P_\ell$; observe that ℓ is a constant. Hence, we can use Bodlaender's algorithm [6] to test in linear time if G has treewidth at most $b(\ell, k) - 1$.

First suppose that the treewidth of G is at most $b(\ell, k) - 1$. As π can be expressed in MSO$_2$, the result of Courcelle [15] allows us to test in linear time whether G has a k-colouring with property π. Now suppose that the treewidth of G is at least $b(\ell, k)$. As G is H-free, G is P_ℓ-free. Then, by the result of Atminas, Lozin and Razgon [5], we find that G contains $K_{k,k}$ as a subgraph. As π satisfies the BB-condition, G has no k-colouring with property π. ◀

We now apply Theorem 4 to obtain the polynomial cases for fixed k in Theorem 1–3.

▶ **Corollary 5.** *Let H be a linear forest. For every $k \geq 1$,* Acyclic k-Colouring, Star k-Colouring *and* Injective k-Colouring *are polynomial-time solvable for H-free graphs.*

Proof. All three kinds of colourings use at least s colours to colour $K_{s,s}$ (as the vertices from one bipartition class of $K_{s,s}$ must receive unique colours). Hence, every acyclic, star and injective colouring of every graph satisfies the BB-condition. Moreover, it is readily seen that the colouring properties of being acyclic, star or injective can all be expressed in MSO$_2$. Hence, we may apply Theorem 4. ◀

3 Acyclic Colouring

In this section, we prove Theorem 1. For a graph G and a colouring c, the pair (G, c) has a *bichromatic* cycle C if C is a cycle of G with $|c(V(C)| = 2$, i.e., the vertices of C are coloured by two alternating colours (so C is even). A path P in G is an *i-j-path* if the vertices of P have alternating colours i and j. We now prove the following result.

▶ **Lemma 6.** *For every $g \geq 3$,* Acyclic 3-Colouring *is NP-complete for graphs of girth at least g.*

Proof. We reduce from Acyclic 3-Colouring, which is known to be NP-complete [14]. We start by taking a graph F that has a 4-colouring but no 3-colouring and that is of girth at least g. By a seminal result of Erdős [18], such a graph F exists (and its size is constant, as it only depends on g which is a fixed integer). We now repeatedly remove edges from F until we obtain a graph F' that is acyclically 3-colourable. Let xy be the last edge that we removed. As F has no 3-colouring, the edge xy exists. Moreover, by our construction, the graph $F' + xy$ is not acyclically 3-colourable. As edge deletions do not decrease the girth, $F' + xy$ and F' have girth at least g.

The basic idea (Case 1) is as follows. Let G be an instance of Acyclic 3-Colouring. We pick an edge $uv \in E(G)$. In $G - uv$ we "glue" F' by identifying u with x and y with v; see also Figure 1. We then prove that G has an acyclic 3-colouring if and only if G' has an acyclic 3-colouring. Then, by performing the same operation for each other edge of G as well, we obtain a graph G'', such that G has an acyclic 3-colouring if and only if G'' has so. As the size of G'' is polynomial in the size of G and the girth of G'' is at least g, we have proven the theorem. The challenge in this technique is that we do not know how the graph F' looks. We can only prove its existence and therefore have to consider several possibilities for the properties of the acyclic 3-colourings of F'. Hence, we distinguish between Cases 1–3, 4a, and 4b.

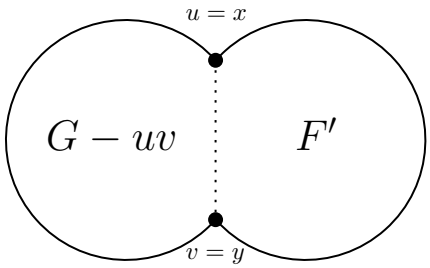

Figure 1 The graph G' from Case 1.

Case 1: *Every acyclic 3-colouring of F' assigns different colours to x and y.*
We construct the graph G' as described above and in Figure 1. We claim that G is a yes-instance of Acyclic 3-Colouring if and only if G' is a yes-instance of Acyclic 3-Colouring.

First suppose that G has an acyclic 3-colouring c. Let c^* be an acyclic 3-colouring of F'. We may assume without loss of generality that $c(u) = c^*(x)$ and $c(v) = c^*(y)$. Hence, we can define a vertex colouring c' of G' with $c'(w) = c(w)$ if $w \in V(G)$ and $c'(w) = c^*(w)$ if $w \in V(F')$. As c and c^* are 3-colourings of G and F', respectively, c' is a 3-colouring of G'. We claim that c' is acyclic. For contradiction, assume that (G', c') has a bichromatic cycle C. If all edges of C are in G or all edges of C are in F', then (G, c) or (F', c^*) has a bichromatic

cycle, which is not possible as c and c^* are acyclic. Hence, at least one edge of C belongs to G and at least one edge of C belongs to F'. This means that C contains both $u = x$ and $v = y$. Recall that G contains the edge uv. Consequently, (G, c) has a bichromatic cycle, namely the cycle induced by $V(C) \cap V(G)$, a contradiction.

Now suppose that G' has an acyclic 3-colouring c'. Let c and c^* be the restrictions of c' to $V(G)$ and $V(F')$, respectively. Then c and c^* are acyclic 3-colourings of $G - uv$ and F', respectively. By our assumption and because c^* is an acyclic 3-colouring of F', we find that $c^*(x) \neq c^*(y)$, or equivalently, $c(u) \neq c(v)$. This means that c is also a 3-colouring of G and c^* is also a 3-colouring of $F' + xy$. We claim that c is acyclic on G. For contradiction, assume that (G, c) has a bichromatic cycle C. As c is an acyclic 3-colouring of $G - uv$, we deduce that C must contain the edge $uv = xy$. As $F' + xy$ has no acyclic 3-colouring by construction and c^* is a 3-colouring of $F' + xy$, we find that $(F' + xy, c^*)$ has a bichromatic cycle D. As c^* is an acyclic 3-colouring of F', this means that D contains the edge $xy = uv$. However, then (G', c') has a bichromatic cycle, namely the cycle induced by $V(C) \cup V(D)$, a contradiction.

Let F^* be the graph obtained from F' by adding a new vertex x' and edges xx' and $x'y$. As $F' + xy$ has girth at least g, we find that F^* and $F^* - x'y$ have girth at least g. As x' has degree 1 in $F^* - x'y$ and F' has an acyclic 3-colouring, $F^* - x'y$ has an acyclic 3-colouring.

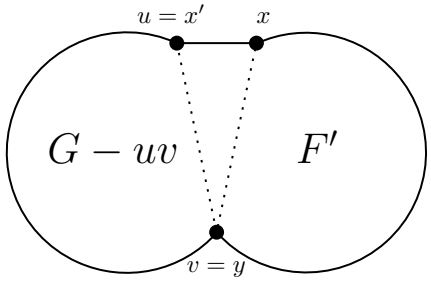

Figure 2 The graph G' from Case 2.

Case 2: *All acyclic 3-colourings of F' assign the same colour to x and y and F^* has no acyclic 3-colouring.*

In this case we let G' be the graph obtained from $G - uv$ and $F^* - x'y$ by identifying u with x' and v with y; see also Figure 2. We claim that G is a yes-instance of Acyclic 3-Colouring if and only if G' is a yes-instance of Acyclic 3-Colouring.

First suppose that G has an acyclic 3-colouring c. Let c^* be an acyclic 3-colouring of $F^* - x'y$. Then the restriction of c^* to F' is an acyclic 3-colouring of F'. By our assumption, it holds therefore that $c^*(x) = c^*(y)$ and thus $c^*(x') \neq c^*(y)$. We may assume without loss of generality that $c(u) = c^*(x')$ and $c(v) = c^*(y)$. Hence, we can define a vertex labelling c' of G' with $c'(w) = c(w)$ if $w \in V(G)$ and $c'(w) = c^*(w)$ if $w \in V(F^*)$. As c and c^* are 3-colourings of G and $F^* - x'y$, respectively, c' is a 3-colouring of G'. We claim that c' is acyclic. For contradiction, assume that (G', c') has a bichromatic cycle C. If the edges of C are all in G or all in $F^* - x'y$, then (G, c) or $(F^* - x'y, c^*)$ has a bichromatic cycle, which is not possible as c and c^* are acyclic. Hence, at least one edge of C belongs to G and at least one edge of C belongs to F'. This means that C contains both $u = x'$ and $v = y$. Recall that G contains the edge uv. Consequently, (G, c) has a bichromatic cycle, namely the cycle induced by $V(C) \cap V(G)$, a contradiction.

Now suppose that G' has an acyclic 3-colouring c'. Let c and c^* be the restrictions of c' to $V(G-uv)$ and $V(F^*-x'y)$, respectively. Then c and c^* are acyclic 3-colourings of $G-uv$ and $F^*-x'y$, respectively. Moreover, the restriction of c' to $V(F')$ is an acyclic 3-colouring of F'. By our assumption, this means that $c'(x)=c'(y)$ and thus $c^*(x')\neq c^*(y)$, or equivalently, $c(u)\neq c(v)$. Consequently, c is also a 3-colouring of G and c^* is also a 3-colouring of F^*. We claim that c is acyclic. For contradiction, assume that (G,c) has a bichromatic cycle C. As c is an acyclic 3-colouring of $G-uv$, we deduce that C must contain the edge $uv=x'y$. As F^* does not have an acyclic 3-colouring by our assumption and c^* is a 3-colouring of F^*, we find that (F^*,c^*) has a bichromatic cycle D. As c^* is an acyclic 3-colouring of $F^*-x'y$, this means that D must contain the edge $x'y=uv$. However, then (G',c') has a bichromatic cycle, namely the cycle induced by $V(C)\cup V(D)$, a contradiction.

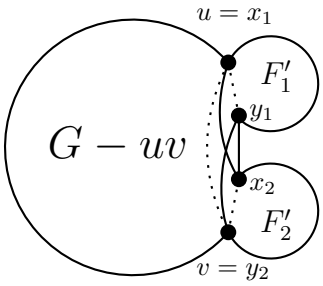

Figure 3 The graph G' with the graph F^+ from Case 3 (before we recursively repeat g times the operation of placing the graph F^+ on the y_1x_2-edge).

Case 3: *All acyclic* 3*-colourings of* F' *assign the same colour to* x *and* y *and* F^* *has an acyclic* 3*-colouring.*

We first construct a new graph F^+ as follows. We take the disjoint union of two copies F_1' and F_2' of F', where we denote the vertices x and y as x_1 and y_1 in F_1' and as x_2 and y_2 in F_2'. We add edges x_1x_2, x_2y_1, and y_1y_2 to $F_1'+F_2'$; see also Figure 3.

We claim that F^+ has an acyclic 3-colouring. First, observe that F^+ is the union of two copies of F^* sharing exactly one edge, namely y_1x_2. That is, $F_1'+x_1x_2,y_1x_2$ and $F_2'+y_1y_2,y_1x_2$ are both isomorphic to F^*. By our assumption on F^*, graphs $F_1'+x_1x_2,x_2y_1$ and $F_2'+y_1y_2,y_1x_2$ have acyclic 3-colourings c_1 and c_2, respectively. By our assumption on F', the restriction of c_1 to F_1' gives x_1,y_1 the same colour and the restriction of c_2 to F_2' gives x_2 and y_2 the same colour. We may assume without loss of generality that c_1 assigns colour 1 to x_1 and y_1 and colour 2 to x_2, and that c_2 assigns colour 2 to x_2 and y_2 and colour 1 to y_1. This yields a 3-colouring c^+ of F^+. We claim that c^+ is acyclic. For contradiction, suppose (F^+,c^+) has a bichromatic cycle C. As the restrictions of c^+ to $F_1'+x_1x_2,y_1x_2$ and $F_2'+y_1y_2,y_1x_2$ (the 3-colourings c_1 and c_2) are acyclic, C must contain the edges x_1x_2 and y_1y_2, so C has the chord y_1x_2. Hence, $(F_1'+x_1x_2,y_1x_2,c_1)$ has a bichromatic cycle on vertex set $(V(C)\setminus V(F_2))\cup\{x_2\}$, a contradiction.

We now essentially reduce to Case 1. Set $x=x_1$, $y=y_2$ and take the graph F^+. We proved above that F^+ has an acyclic 3-colouring. As every acyclic 3-colouring c of F^+ colours x_1 and y_1 alike, c colours $x=x_1$ and $y=y_2$ differently (as y_1x_2 is an edge). Finally, the graph $F^++xy=F^++x_1y_2$ has no acyclic 3-colouring, as for every 3-colouring c of $F^++x_1y_2$, the 4-vertex cycle $x_1x_2y_1y_2x_1$ is bichromatic for $(F^++x_1y_2,c)$. The only difference with Case 1 is that the graph $F^++x_1y_2$ has girth 4 due to the cycle $x_1x_2y_1y_2x_1$ whereas we need the girth to be at least g just as the graph $F'+xy$ in Case 1 has girth g. Hence, before reducing to Case 1, we first recursively repeat g times the operation of placing the graph F^+ on the y_1x_2-edge; note that the size of the resulting graph G' is still polynomial in the size of G.

Case 4: *There exist acyclic* 3*-colourings* c_1 *and* c_2 *of* F' *with* $c_1(x) = c_1(y)$ *and* $c_2(x) \neq c_2(y)$. We first construct a new graph J. We take two disjoint copies F'_1 and F'_2 of F' and identify the two x-vertices with each other and also the two y-vertices with each other. We write $x = x_1 = x_2$ and $y = y_1 = y_2$; see also Figure 4 (left).

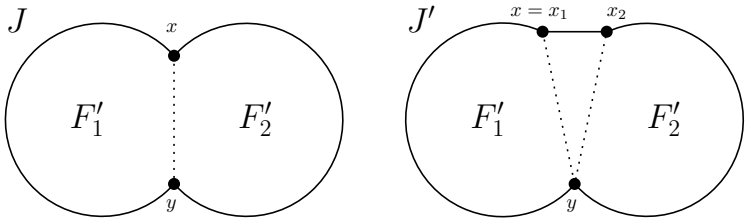

Figure 4 The graph J from Case 4 (left) and the graph J' from Case 4b (right).

We distinguish between two sub-cases.

Case 4a: *J has an acyclic* 3*-colouring.*
Our goal is to reduce either to Case 2 or 3 by using J instead of F'. We first observe that J and $J + xy$ have girth at least g. We also note that $J + xy$ has no acyclic 3-colouring, as otherwise $F' + xy$, being an induced subgraph of $J + xy$, has an acyclic 3-colouring. Hence, in order to reduce to Case 2 or 3 it remains to show that every acyclic 3-colouring of J assigns the same colour to x and y. For contradiction, suppose that J has an acyclic 3-colouring c such that $c(x) \neq c(y)$, say $c(x) = 1$ and $c(y) = 2$. Then in at least one of the two subgraphs F'_1 and F'_2 of J, say F'_1, there exists no 1-2 path from x to y; otherwise (J, c) has a bichromatic cycle formed by the union of the two 1-2-paths, which is not possible as c is acyclic. Let c' be the restriction of c to $V(F'_1)$. Then, as $c(x) = 1$ and $c(y) = 2$, we find that c' is a 3-colouring of $F'_1 + xy$. As there is no 1-2 path from x to y in F'_1, we find that c' is even an acyclic 3-colouring of $F'_1 + xy$, a contradiction (recall that $F' + xy$ has no acyclic 3-colouring by construction).

Case 4b: *J has no acyclic* 3*-colouring.*
By assumption, F' has an acyclic 3-colouring that gives x and y different colours. We first prove a claim.[1]

▷ Claim 1. For every triple (h, i, j) with $\{h, i, j\} = \{1, 2, 3\}$, every acyclic 3-colouring c of F' with $c(x) = c(y) = h$ yields an h-i path and h-j path from x to y.

We prove Claim 1 as follows. For contradiction, suppose that F' has an acyclic 3-colouring c that colours x and y alike, say $c(x) = c(y) = 1$, such that F' contains no 1-2-path or no 1-3-path, say F' contains no 1-2-path from x to y. Then by swapping colours 2 and 3, we obtain another acyclic 3-colouring c' of F' such that F' contains no 1-3-path from x to y. In J we now colour the vertices of F'_1 by c and the vertices of F'_2 by c'. As $c(x) = c(x') = 1$ and $c(y) = c(y') = 1$, this yields a 3-colouring c_J. By assumption, c_J is not acyclic. Hence, (J, c_J) contains a bichromatic cycle C with colours 1 and i for some $i \in \{2, 3\}$. As the restrictions of c_J to F'_1 and F'_2 are acyclic, C must contain at least one vertex of $V(F'_1) \setminus \{x, y\}$ and at least one vertex of $V(F'_2) \setminus \{x, y\}$. Thus C consists of 1-i-paths from x to y in both F'_1 and F'_2. As at least one of these paths is missing in F'_1 or F'_2, this yields a contradiction.

[1] Claim 1 only holds for $k = 3$ and is the reason we cannot generalize Lemma 6 to $k \geq 3$.

We now construct a new graph J' as follows. We take two disjoint copies F_1' and F_2' of F' and still identify y_1 and y_2 as y, but instead of identifying x_1 and x_2 we add an edge between x_1 and x_2; see also Figure 4 (right).
We now prove some more claims that will enable us to reduce to Case 1.

(i) The graphs J' and $J' + x_1y$ have girth at least g.
This follows directly from the fact that respectively, F' and $F' + xy$ have girth at least g.

(ii) The graph $J' + x_1y$ has no acyclic 3-colouring.
This follows directly from the fact that $F' + xy$ is an induced subgraph of $J' + x_1y$ and has no acyclic 3-colouring by construction.

(iii) The graph J' has an acyclic 3-colouring.
This can be seen as follows. By assumption, F' has an acyclic 3-colouring c that gives x and y different colours, say $c(x) = 1$ and $c(y) = 3$. By swapping colours 1 and 2 we obtain an acyclic 3-colouring c' of F' with $c'(x) = 2$ and $c'(y) = 3$. As $c(y) = c'(y) = 3$, this yields a 3-colouring $c_{J'}$ of J'. As the restrictions of $c_{J'}$ to F_1' and F_2' are acyclic, any bichromatic cycle of $(J', c_{J'})$ must pass through x_1, x_2 and y. However, x_1, x_2 and y have colours 1, 2, 3, respectively. Hence, this is not possible.

(iv) Every acyclic 3-colouring of J' gives x_1 and y different colours.
For contradiction, assume J' has an acyclic 3-colouring c that colours x_1 and y alike, say $c(x_1) = c(y) = 1$ and $c(x_2) = 2$. The restriction of c to $V(F_1')$ is an acyclic 3-colouring of F_1' that gives x_1 and y colour 1. Hence, by Claim 1, F_1' contains a 1-2 path from x_1 to y. The restriction of c' to $V(F_2')$ is an acyclic 3-colouring of F_2' that gives x_2 colour 2 and y colour 1. Then F_2' must contain a 1-2 path from x_2 to y; otherwise we found an acyclic 3-colouring of $F_2' + x_2y$, which is not possible by construction. The two 1-2 paths now form, with the edge x_1x_2, a bichromatic cycle of (J', c). As c is acyclic, this is not possible.

By (i)-(iv) we may take J' with x_1 and y instead of F' with x and y and reduce to Case 1. ◀

The *line graph* of a graph G has vertex set $E(G)$ and an edge between two vertices e and f if and only if e and f share an end-vertex of G. In Lemma 7 we modify the construction of [3] for line graphs from $k = 3$ to $k \geq 3$. In Lemma 8 we give a new construction for proving hardness when k is part of the input.

▶ **Lemma 7.** *For every $k \geq 3$,* Acyclic k-Colouring *is NP-complete for line graphs.*

Proof. For an integer $k \geq 1$, a *k-edge colouring* of a graph $G = (V, E)$ is a mapping $c : E \to \{1, \ldots, k\}$ such that $c(e) \neq c(f)$ whenever the edges e and f share an end-vertex. A *colour class* consists of all edges of G that are mapped by c to a specific colour i. The pair (G, c) has a *bichromatic* cycle C if C is a cycle of G with its edges coloured by two alternating colours. The notion of a *bichromatic* path is defined in a similar manner. We say that c is *acyclic* if (G, c) has no bichromatic cycle. For a fixed integer $k \geq 1$, the Acyclic k-Edge Colouring problem is to decide if a given graph has an acyclic k-edge colouring. Alon and Zaks proved that Acyclic 3-Edge Colouring is NP-complete for multigraphs. We note that a graph has an acyclic k-edge colouring if and only if its line graph has an acyclic k-colouring. Hence, it remains to generalize the construction of Alon and Zaks [3] from $k = 3$ to $k \geq 3$. Our main tool is the gadget graph F_k, depicted in Figure 5, about which we prove the following two claims.

- **(i)** *The edges of F_k can be coloured acyclically using k colours, with no bichromatic path between v_1 and v_{14}.*
- **(ii)** *Every acyclic k-edge colouring of F_k using k colours assigns e_1 and e_2 the same colour.*

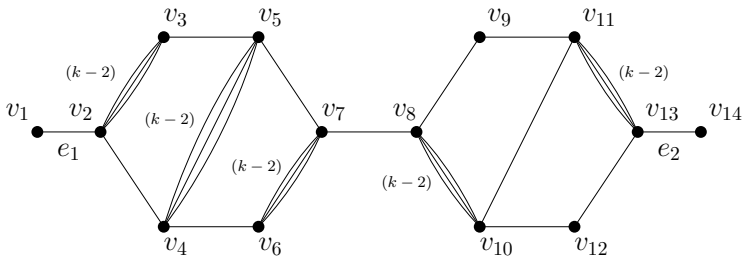

Figure 5 The gadget multigraph F_k. The labels on edges are multiplicities.

We first prove (ii). We assume, without loss of generality, that v_1v_2 is coloured by 1, v_2v_4 by 2 and the edges between v_2 and v_3 by colours $3, \ldots, k$. The edge v_3v_5 has to be coloured by 1, otherwise we have a bichromatic cycle on $v_2v_3v_5v_4$. This necessarily implies that

- the edges between v_4 and v_5 are coloured by $3, \ldots, k$,
- the edge v_5v_7 is coloured by 2,
- the edge v_4v_6 is coloured by 1,
- the edges between v_6 and v_7 are coloured by $3, \ldots, k$, and
- the edge v_7v_8 is coloured by 1.

Now assume that the edge v_8v_9 is coloured by $a \in \{2, \ldots, k\}$ and the edges between v_8 and v_{10} by colours from the set A, where $A = \{2, \ldots, k\} \setminus a$. The edge $v_{10}v_{11}$ is either coloured a or 1. However, if it is coloured 1, v_9v_{11} is assigned a colour $b \in A$ and necessarily we have either a bichromatic cycle on $v_8v_9v_{11}v_{13}v_{12}v_{10}$, coloured by b and a, or a bichromatic cycle on $v_{10}v_{11}v_{13}v_{12}$, coloured by a and 1. Thus $v_{10}v_{11}$ is coloured by a. To prevent a bichromatic cycle on $v_8v_9v_{11}v_{10}$, the edge v_9v_{11} is assigned colour 1. The rest of the colouring is now determined as $v_{10}v_{12}$ has to be coloured by 1, the edges between v_{11} and v_{13} by A, $v_{12}v_{13}$ by a, and $v_{13}v_{14}$ by 1. We then have a k-colouring with no bichromatic cycles of size at least 3 in F_k for every possible choice of a. This proves that v_1v_2 and $v_{13}v_{14}$ are coloured alike under every acyclic k-edge colouring.

We prove (i) by choosing a different from 2. Then there is no bichromatic path between v_1 and v_{14}.

We now reduce from k-Edge-Colouring to Acyclic k-Edge Colouring as follows. Given an instance G of k-edge Colouring we construct an instance G' of Acyclic k-Edge Colouring by replacing each edge uv in G by a copy of F_k where u is identified with v_1 and v is identified with v_{14}.

If G' has an acyclic k-edge colouring c' then we obtain a k-edge colouring c of G by setting $c(uv) = c'(e_1)$ where e_1 belongs to the gadget F_k corresponding to the edge uv. If G has a k-edge colouring c then we obtain an acyclic k-edge colouring c' of G' by setting $c'(e_1) = c(uv)$ where e_1 belongs to the gadget corresponding to the edge uv. The remainder of each gadget F_k can then be coloured as described above. ◀

In our next result, k is part of the input.

▶ **Lemma 8.** Acyclic Colouring *is NP-complete for* $(19P_1, 3P_3, 2P_5)$*-free graphs.*

Proof. We reduce from 3-Colouring with maximum degree 4 which is known to be NP-complete [26]. Let G be an instance of 3-Colouring with $|V(G)| = n$ vertices and maximum degree 4. We will construct an instance G' of Acyclic Colouring where $k = 4n$. Our vertex gadget is built from two k-cliques, J_0 and J_1, with a matching between them. We number the vertices of each of the cliques 0 to $k-1$. The matching we insert into the graph

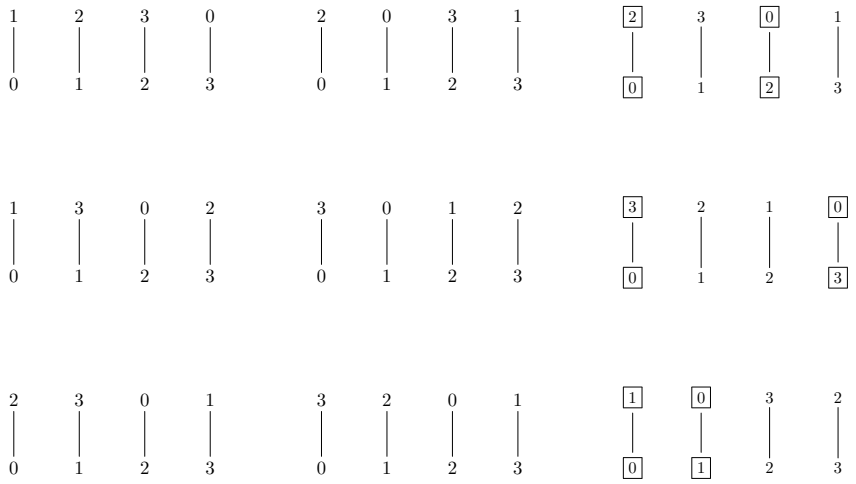

Figure 6 Acyclic colourings in the proof of Lemma 8 for a vertex representing one of the three colours (left and middle). Sample failures for an acyclic colouring from other permutations of $(0, 1, 2, 3)$ together with a failure cycle (right). Note that each row of quadruples is joined in a clique.

is $(0, 0), \ldots, (k-1, k-1)$. In addition, we place an edge from i in J_0 to j in J_1 if and only if $\lfloor i/4 \rfloor < \lfloor j/4 \rfloor$. Suppose that some assignment of colours is given to J_0. By recolouring, we assume it is the identity colouring of i to i on J_0. Then the possible acyclic k-colourings of vertices $(\lfloor i/4 \rfloor + 0, \lfloor i/4 \rfloor + 1, \lfloor i/4 \rfloor + 2, \lfloor i/4 \rfloor + 3)$ in J_1 are

$$
\begin{aligned}
&(\lfloor i/4 \rfloor + 1, \lfloor i/4 \rfloor + 2, \lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 0),\\
&(\lfloor i/4 \rfloor + 1, \lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 0, \lfloor i/4 \rfloor + 2),\\
&(\lfloor i/4 \rfloor + 2, \lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 1, \lfloor i/4 \rfloor + 0),\\
&(\lfloor i/4 \rfloor + 2, \lfloor i/4 \rfloor + 0, \lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 1),\\
&(\lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 0, \lfloor i/4 \rfloor + 1, \lfloor i/4 \rfloor + 2),\\
&(\lfloor i/4 \rfloor + 3, \lfloor i/4 \rfloor + 2, \lfloor i/4 \rfloor + 0, \lfloor i/4 \rfloor + 1).
\end{aligned}
$$

They are built from the permutations of $(0, 1, 2, 3)$ that do not contain a transposition. We draw all of them, to demonstrate it is not an acyclic colouring, in Figure 6 (keep in mind that vertices in a row are joined in a clique).

In our reduction, the first two acyclic k-colourings will represent colour 1, the second two colour 2 and the third two colour 3 of the sought 3-colouring of G. To force similarly coloured copies of J_0 we add a new k-clique J_2 with edges from i in J_0 to j in J_2 if and only if $i < j$. To prevent the existence of bichromatic cycles in our later construction, we add a k-clique J_3 with edges from i in J_2 to j in J_3 if and only if $i < j$. This enforces that in any acyclic k-colouring of G', the i-th vertices (where $i \in \{0, \ldots, k-1\}$) in cliques J_0, J_2, J_3 would have the same colour. Therefore, by the way we placed the edges between different cliques from $\{J_0, J_2, J_3\}$, there is no bichromatic path with vertices from more than one clique in $\{J_0, J_2, J_3\}$.

We now construct edge gadgets. We take another two k-cliques to join J_2, say J_4 and J_5. We will want them coloured exactly like J_0, so for i in J_2 and j in J_4 or J_5, where $i < j$, we will add an edge ij. Suppose we have an edge in G between p and q for some $p, q \in \{0, \ldots, n-1\}$. Then we place an edge from the vertex $4p$ in J_1 to $4q+1$ in J_3 and from $4q$ in J_1 to $4p+1$ in J_3 (recall that $p, q \in \{0, \ldots, n-1\}$ and cliques J_1 and J_3 are of size $4n$, so these edges are well defined). See Figure 7. Now we place an edge from $4p$ in J_1 to $4q+2$ in J_4 and of $4q$ in J_1 to $4p+2$ in J_4. Finally, we place an edge from $4p$ in J_1 to $4q+3$ in J_5 and from $4q$ in J_1 to $4p+3$ in J_5. This concludes the construction for the edge pq in $E(G)$.

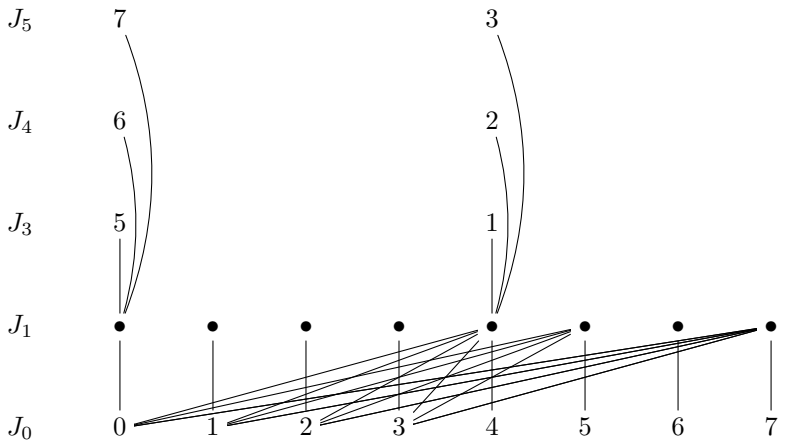

Figure 7 Edge construction in the proof of Lemma 8 between vertices 0 and 1 of G. Everything in a row is joined in a clique. Edges are omitted between J_0 and J_3, J_4, J_5, though they enforce the colouring.

Suppose we have an edge $rs \in E(G)$ so that $\{p,q\} \cap \{r,s\} = \emptyset$. Then we build a gadget for rs using the same additional three cliques that we used for the edge pq. However, if we have edges with a common endpoint, e.g. $pq, ps \in E(G)$, then by adding the edges from $4p$ in J_1 to $4q+1$ in J_3, from $4q$ in J_1 to $4p+1$ in J_3, from $4p$ in J_1 to $4s+1$ in J_3, and from $4s$ in J_1 to $4p+1$ in J_3 we introduce new 4-cycles, one of them induced by the vertices $4q$ and $4p$ in J_1 and $4p+1$ and $4s+1$ in J_3. To avoid this, we add three additional k-cliques to build the gadget for ps. By Vizing's Theorem [49], we obtain in polynomial time a 5-edge colouring of G (as G has maximum degree 4). Using this 5-edge colouring, we build gadgets for all the edges with at most $5 \times 3 = 15$ additional k-cliques (we use 3 additional cliques for each colour class).

The clique structure of G' is drawn in Figure 8. As G' consists of at most 18 cliques, G' is $19P_1$-free. Furthermore, any induced linear forest where each connected component has size at least 3 contains vertices in at most five cliques. Hence G' is $(3P_3, 2P_5)$-free. It remains to prove that G has a 3-colouring if and only if G' has an acyclic k-colouring.

First, suppose that G' has an acyclic k-colouring c'. Then each k-clique of G' has to use each colour exactly once. We can permute colours so that vertex i in J_0 (where $0 \leq i \leq 4n-1$) has colour i. It follows from the connections between cliques that the i-th vertices in cliques $J_2, \ldots, J_{17}$ also have colour i and the vertices $4j, 4j+1, 4j+2, 4j+3$, $(0 \leq j \leq n-1)$ in J_1 have colours from the set $\{4j, 4j+1, 4j+2, 4j+3\}$. For each vertex i in G, set $c(i) = 1$ if the colours of $(4i, 4i+1, 4i+2, 4i+3)$ in J_1 under c' correspond to one of the first two possible colourings (listed above); set $c(i) = 2$ if it corresponds to one of the second two possible colourings; set $c(i) = 3$ if it corresponds to one of the last two colourings. We claim that c is a 3-colouring of G. Suppose that pq is an edge in G with edge gadget using cliques J_3, J_4, J_5. Since c' is acyclic and c' is identity on J_3, we have $c'(4p) \neq 4p+1$ in J_1 or $c'(4q) \neq 4q+1$ in J_1. Both $4p$ and $4q$ are the first vertices of the respective quadruples, so p and q are not both coloured 1. Similarly, the edges going between cliques J_1 and J_4 ensure that they are not both coloured 2 and the edges going between cliques J_1 and J_5 ensure that they are not both coloured 3. Hence, $c(p) \neq c(q)$ and c is a 3-colouring of G.

Now suppose G has a 3-colouring c. We construct a labelling c' of G' where we colour each quadruple in J_1 corresponding to a vertex of G by the first of each pair of colourings listed in the table for each of the three colours, respectively. The labelling c' in other cliques of G' is the identity. By the construction of G' and particularly by the properties of edge gadgets in G', we find that c' is a k-colouring of G'.

Finally, we need to verify that c' is acyclic. We will begin with bichromatic cycles between two cliques. No bichromatic cycle can appear in J_0 and J_1 forming the vertex gadget. This is due to the edges from the former to the latter always pointing to a higher number (or the same but here we chose a 3-colouring to avoid such situation). A similar explanation works for all the clique pairs $(0,2),(2,3),\ldots,(2,17)$ in Figure 8. The last possibility is a bichromatic cycle formed through J_1 from one of the cliques J_3 to J_{17}. However, such a cycle would have to pass through an actual edge gadget (where it is forbidden by the 3-colouring) or through vertices in different edge gadgets, where it must form a cycle with four colours. Now we need to consider bichromatic cycles passing through three or more cliques, but they would have to involve a bichromatic path through J_0, J_2, J_3 which is not possible. This completes the proof. ◀

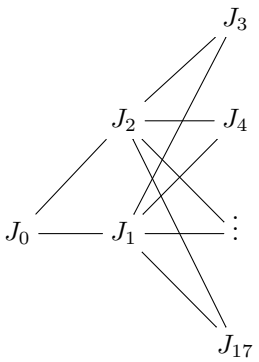

Figure 8 Connections between cliques in the construction from the proof of Lemma 8.

We combine the above results with results of Coleman and Cai [14] and Lyons [43] to prove Theorem 1.

▶ **Theorem 1 (restated).** *Let H be a graph. For the class of H-free graphs it holds that:*

(i) Acyclic Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ and NP-complete if H is not a forest or $H \supseteq_i 19P_1, 3P_3, 2P_5$ or P_{11};*

(ii) *For every $k \geq 3$,* Acyclic k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

Proof. We first prove (ii). First suppose that H contains an induced cycle C_p. If $p = 3$, then we use the result of Coleman and Cai [14], who proved that for every $k \geq 3$, Acyclic k-Colouring is NP-complete for bipartite graphs. Suppose that $p \geq 3$. If $k = 3$, then we let $g = p + 1$ and use Lemma 6. If $k \geq 4$, we reduce from Acyclic 3-Colouring for graphs of girth $p + 1$ by adding a dominating clique of size $k - 3$. Now assume H has no cycle so H is a forest. If H has a vertex of degree at least 3, then H has an induced $K_{1,3}$. As every line graph is $K_{1,3}$-free, we can use Lemma 7. Otherwise H is a linear forest and we use Corollary 5.

We now prove (i). Due to (ii), we may assume that H is a linear forest. If $H \subseteq_i P_4$, then we use the result of Lyons [43] that states that Acyclic Colouring is polynomial-time solvable for P_4-free graphs. If $H \supseteq_i 19P_1, 3P_3, 2P_5$ or P_{11}, then we use Lemma 8. ◀

Figure 9 The gadget replacing edges uv (on the left) and its natural star 3-colouring (on the right) in the proof of Lemma 9.

4 Star Colouring

In this section we prove Theorem 2. We first prove the following lemma.

▶ **Lemma 9.** *Let H be a graph with an* even *cycle. Then, for every $k \geq 3$,* Star k-Colouring *is NP-complete for H-free graphs.*

Proof. We reduce from 3-Colouring for graphs of girth at least $p+1$. Given an instance G of this problem, we construct an instance G' of Star 3-Colouring as follows. Take three vertex disjoint copies of P_3 and form a triangle using one endpoint of each; see Figure 9. Replace each edge uv in G by this gadget with u and v identified with the non-adjacent endpoints of two paths. Then G' is C_p-free since, aside from triangles, the construction cannot introduce any cycle shorter than those present in G.

We first show that any star 3-colouring of G' colours u and v differently. Assume not, their neighbours must be coloured differently since otherwise any 3-colouring of the remainder of the gadget will result in a bichromatic P_4. Without loss of generality, assume that u and v are coloured 1, the neighbour u' of u is coloured 2 and the neighbour v' of v is coloured 3. Let x be the neighbour of u' in the triangle and y the neighbour of v' in the triangle. Neither x or y can be coloured 1 since this will result in a bichromatic P_4. Therefore x is coloured 3, y is coloured 2 and the third vertex z of the triangle is coloured 1. This is a contradiction since we have a bichromatic P_4 on the vertices u', x, y, v'. Therefore, we obtain a 3-colouring c of G by setting $c(v) = c'(v)$ for some star 3-colouring c' of G'.

We extend a given 3-colouring of G to a star 3-colouring of G', by locally star 3-colouring as in the right hand side of Figure 9 (or automorphically). Hence, G is 3-colourable if and only if G' is star 3-colourable.

We obtain NP-completeness for $k \geq 4$ by a reduction from Star 3-Colouring for C_p-free graphs by adding a dominating clique of size $k-3$. ◀

In Lemma 10 we extend the recent result of Lei et al. [38] from $k = 3$ to $k \geq 3$. In Lemma 11 we show a result where k is part of the input. A graph is *co-bipartite* if it is the complement of a bipartite graph.

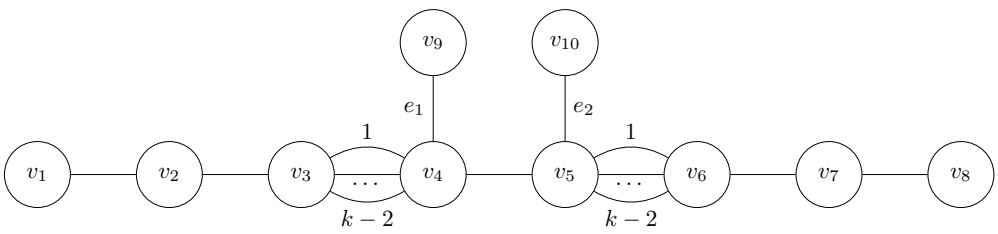

Figure 10 The gadget F_k in the proof of Lemma 10.

▶ **Lemma 10.** *For every $k \geq 3$,* Star k-Colouring *is NP-complete for line graphs.*

Proof. Recall that for an integer $k \geq 1$, a *k-edge colouring* of a graph $G = (V, E)$ is a mapping $c : E \to \{1, \ldots, k\}$ such that $c(e) \neq c(f)$ whenever the edges e and f share an end-vertex. Recall also that the notions of a colour class and bichromatic subgraph for colourings has its natural analogue for edge colourings. An edge k-colouring c is a *star* k-edge colouring if the union of any two colour classes induces a star forest. For a fixed integer $k \geq 1$, the Star k-Edge Colouring problem is to decide if a given graph has an star k-edge colouring. Lei et al. [38] proved that Star 3-Edge Colouring is NP-complete. Dvořák et al. [16] observed that a graph has a star k-edge colouring if and only if its line graph has a star k-colouring. Hence, it suffices to follow the proof of Lei et al.[38] in order to generalize the case $k = 3$ to $k \geq 3$. As such, we give a reduction from k-Edge Colouring to Star k-Edge Colouring which makes use of the gadget F_k in Figure 10. First we consider separately the case where the edges $e_1 = v_4v_9$ and $e_2 = v_5v_{10}$ are coloured alike and the case where they are coloured differently to show that in any star k-edge colouring of the gadget F_k shown in Figure 10, v_1v_2 and v_7v_8 are assigned the same colour.

Assume $c(e_1) = c(e_2) = 1$. We may then assume that the edge v_4v_5 is assigned colour 2 and the remaining $k - 2$ colours are used for the multiple edges v_3v_4 and v_5v_6. The edge v_2v_3, and similarly v_6v_7, must then be assigned colour 1 to avoid a bichromatic P_5 on the vertices $\{v_2, v_3, v_4, v_5, v_6\}$ using any two of the multiple edges in a single colour. The edge v_1v_2, and similarly v_7v_8 must then be assigned colour 2 to avoid a bichromatic P_5 on the vertices $\{v_1, v_2, v_3, v_4, v_9\}$.

Next assume e_1 and e_2 are coloured differently. Without loss of generality, let $c(e_1) = 1$, $c(e_2) = 2$ and $c(v_4v_5) = 3$. The multiple edges v_3v_4 must then be assigned colours 2 and $4 \ldots k$ and v_5v_6 colour 1 and colours $4 \ldots k$. To avoid a bichromatic P_5 on the vertices $\{v_2, v_3, v_4, v_5, v_6\}$, v_2v_3 must be coloured 1. Similarly, v_6v_7 must be assigned colour 2. Finally, to avoid a bichromatic P_5 on the vertices $\{v_1, v_2, v_3, v_4, v_9\}$, v_1v_2 must be coloured 3. By a similar argument, v_7v_8 must also be coloured 3, hence v_1v_2 and v_7v_8 must be coloured alike.

We can then replace every edge e in some instance G of k-Edge-Colouring by a copy of F_k, identifying its endpoints with v_1 and v_8, to obtain an instance G' of Star k-Edge-Colouring. If G is k-edge-colourable we can star k-edge-colour G' by setting $c'(v_1v_2) = c'(v_7v_8) = c(e)$. If G' is star k-edge-colourable, we obtain a k-edge-colouring of G by setting $c(e) = c'(v_1v_2)$. ◀

We now let k be part of the input. The *complement* of a graph G is the graph $\overline{G}$ with vertex set $V(G)$ and an edge between two vertices u and v if and only if $uv \notin E(G)$. A k-colouring of G can be seen as a partition of $V(G)$ into k independent sets. Hence, a k-colouring of G corresponds to a *clique-covering* of $\overline{G}$, which is a partition of $V(\overline{G}) = V(G)$ into k cliques. A graph is *co-bipartite* if it is the complement of a bipartite graph.

▶ **Lemma 11.** *Star Colouring is NP-complete for co-bipartite graphs.*

Proof. We show that finding an optimal star colouring of a co-bipartite graph G is equivalent to finding a maximum balanced biclique in its complement $\overline{G}$. An optimal star colouring of G corresponds to an optimal clique-covering of $\overline{G}$ such that the graph induced by the vertices of any two cliques in the covering partition is $\overline{P_4} = P_4$-free and $\overline{C_4} = 2P_2$-free. Since $\overline{G}$ is triangle-free, the clique-covering number of $\overline{G}$ is $n - M$ where n is the number of vertices of G and M is the number of edges in a maximum matching such that no two edges induce either $2P_2$ or P_4. Since $\overline{G}$ is bipartite, a maximum matching of this form is a maximum balanced biclique. It is NP-complete to find the maximum size of a balanced biclique in a bipartite graph [26]. Therefore Star Colouring is NP-complete for co-bipartite graphs. ◀

We combine the above results with results of Albertson et al. [1] and Lyons [43] to prove Theorem 2.

▶ **Theorem 2** (restated). *Let H be a graph. For the class of H-free graphs it holds that:*

(i) Star Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ and NP-complete for any $H \neq 2P_2$.*

(ii) *For every $k \geq 3$,* Star k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

Proof. We first prove (ii). First suppose that H contains an induced odd cycle. Then the class of bipartite graphs is contained in the class of H-free graphs. Lemma 7.1 in Albertson et al. [1] implies, together with the fact that for every $k \geq 3$, k-Colouring is NP-complete, that for every $k \geq 3$, Star k-Colouring is NP-complete for bipartite graphs. If H contains an induced even cycle, then we use Lemma 9. Now assume H has no cycle, so H is a forest. If H contains a vertex of degree at least 3, then H contains an induced $K_{1,3}$. As every line graph is $K_{1,3}$-free, we can use Lemma 10. Otherwise H is a linear forest, in which case we use Corollary 5.

We now prove (i). Due to (ii), we may assume that H is a linear forest. If $H \subseteq_i P_4$, then we use the result of Lyons [43] that states that Star Colouring is polynomial-time solvable for P_4-free graphs. If $3P_1 \subseteq_i H$, then we use Lemma 11 after observing that co-bipartite graphs are $3P_1$-free. Otherwise $H = 2P_2$, but this case was excluded from the statement of the theorem. ◀

5 Injective Colouring

In this section we prove Theorem 3. We first show three lemmas.

▶ **Lemma 12.** *For every $k \geq 4$,* Injective k-Colouring *is NP-complete for C_3-free graphs.*

Proof. We reduce from Injective k-Colouring. Given an instance G of Injective k-Colouring, construct an instance G' of Injective k-Colouring for triangle-free graphs as follows. For each edge uv of G, remove the edge uv and add two vertices u'_v adjacent to u and v'_u adjacent to v. Next, place an independent set of $k-2$ vertices adjacent to both u'_v and v'_u. Then G' is triangle-free since the edge gadget described is triangle-free, any two vertices of G are now at distance at least 4 and no vertex not belonging to an edge gadget has two adjacent neighbours belonging to edge gadgets. We claim that G' has an injective k-colouring if and only if G has an injective k-colouring.

First assume that G has an injective k-colouring c. Colour the vertices of G' corresponding to vertices of G as they are coloured by c. We can extend this to an injective k-colouring c' of G' by considering the gadget corresponding to each edge uv of G. Set $c'(u'_v) = c'(v)$ and $c'(v'_u) = c'(u)$. We can now assign the remaining $k-2$ colours to the vertices of the independent sets. Clearly c' creates no bichromatic P_3 involving vertices in at most one edge gadget. Assume there exists a bichromatic P_3 involving vertices in more than one edge gadget, then this path must consist of a vertex u of G together with two gadget vertices u'_v and u'_w which are coloured alike. This is a contradiction since it implies the existence of a bichromatic path v, u, w in G.

Now assume that G' has an injective k-colouring c'. Let c be the restriction of c' to those vertices of G' which correspond to vertices of G. To see that c is an injective colouring of G, note that we must have $c'(u'_v) = c'(v)$ and $c'(v'_u) = c'(u)$ for any edge uv. Therefore, if c induces a bichromatic P_3 on u, v, w, then c' induces a bichromatic P_3 on v'_u, v, v'_w. We conclude that c is injective. ◀

In our next two results, k is part of the input.

▶ **Lemma 13.** Injective Colouring *is polynomial-time solvable for P_4-free graphs and $(P_1 + P_3)$-free graphs.*

Proof. Since connected P_4-free graphs have diameter at most 2, no two vertices can be coloured alike in an injective colouring. Hence the injective chromatic number of a P_4-free graph is equal to the number of its vertices.

We now consider $(P_1 + P_3)$-free graphs. First, note that an injective colouring of G is equivalent to a clique-covering of its complement $\overline{G}$ such that the graph induced by the vertices of the union of any two clique classes is $(P_1 + P_2)$-free (as $\overline{P_3} = P_1 + P_2$). Since G is $(P_1 + P_3)$-free, $\overline{G}$ is $\overline{P_1 + P_3}$-free. By a result of Olariu [46], each connected component of $\overline{G}$ is either triangle-free or complete multi-partite. Let $D_1, \ldots, D_p$ be the vertex sets of the connected components of $\overline{G}$ for some $p \geq 1$. Then in G, every D_i is complete to every D_j. Hence, the injective chromatic number of G is the sum of the injective chromatic numbers of the subgraphs G_i induced by D_i ($i \in \{1, \ldots, p\}$). As such, it remains to determine the injective chromatic number of each G_i, which we do below.

Let $1 \leq i \leq p$. If $\overline{G_i}$ is complete multi-partite, then G_i is a disjoint union of cliques and its injective chromatic number is equal to the size of its largest connected component. In the other case, $\overline{G_i}$ is triangle-free. Then each clique class in a clique-covering has size at most 2, and any clique class of size 2 must dominate the remaining vertices of $\overline{G_i}$ to avoid a bichromatic $P_1 + P_2$. Thus, the clique-covering is a matching, each edge of which dominates $\overline{G_i}$, together with the remaining vertices which each form clique classes of size 1. Therefore, we find an optimal $(P_1 + P_2)$-free clique-covering of $\overline{G}$ by finding a maximum matching in the graph consisting of dominating edges of $\overline{G_i}$. The injective chromatic number of G_i is then the number of vertices of G_i minus the number of edges in such a matching. ◀

▶ **Lemma 14.** Injective Colouring *is NP-complete for $6P_1$-free graphs.*

Proof. We first show that Colouring remains NP-complete given a partition of the instance G into four cliques. The Clique Covering problem is NP-complete for planar graphs [37]. A 4-colouring of a planar graph G can be found in quadratic time [47] and gives a partition of $\overline{G}$ into four cliques. Hence, given a planar instance G of clique-covering, we construct an instance $(\overline{G}, c)$ of Colouring where c is a 4-colouring of G such that the chromatic number of $\overline{G}$ is equal to the clique-covering number of G.

We now give a reduction from this problem to Injective Colouring for $6P_1$-free graphs. Given a graph G and a partition c into four cliques $C^1 \ldots C^4$, let G' be the graph obtained from G by deleting those vertices with no neighbours outside of their own clique C^i. Then G can be coloured with k colours if and only if G' can be coloured with k colours and the maximum size of a clique in the partition c of G is at most k. To see this, note that the vertices of $G \setminus G'$ then have degree at most $k-1$, hence we can greedily colour these vertices given a k-colouring of G'.

This instance (G', c) of Colouring given a partition of G' into four cliques can then be transformed in polynomial time to an instance G'' of Injective Colouring as follows. Add a fifth clique C^0 with one vertex v_e for each edge $e = xy$ in G' which has endpoints in two different cliques of c. For each such edge, replace e by two edges xv_e and yv_e. G' has a colouring with k colours if and only if G'' has an injective colouring with $k + m$ colours where m is the number of edges in G with endpoints in different cliques. To see this, note that in any injective colouring of G'', the set of colours used in C^0 is disjoint from the set of those used in the cliques $C^1 \ldots C^4$. Therefore if G'' can be injective coloured with $m + k$ colours then G' can be coloured with k colours. On the other hand, colour the vertices of

$C^1 \dots C^4$ as they are coloured in some k colouring of G' and C^0 with m further colours. This is an injective colouring of G'' since any induced P_3 contains either two vertices of C^1 or one vertex of C^0 and two vertices adjacent in G'. In either case the path must be coloured with three distinct colours. This implies that G'' has an injective colouring with $k+m$ colours if and only if G' has a colouring with k colours. ◀

We combine the above results with results of Bodlaender et al. [7] and Mahdian [44] to prove Theorem 3.

▶ **Theorem 3** (restated). *Let H be a graph. For the class of H-free graphs it holds that:*

(i) Injective Colouring *is polynomial-time solvable if $H \subseteq_i P_4$ or $H \subseteq_i P_1 + P_3$ and NP-complete if H is not a forest or $2P_2 \subseteq_i H$ or $6P_1 \subseteq_i H$.*

(ii) *For every $k \geq 4$,* Injective k-Colouring *is polynomial-time solvable if H is a linear forest and NP-complete otherwise.*

Proof. We first prove (ii). If $C_3 \subseteq_i H$, then we use Lemma 12. Now suppose $C_p \subseteq_i H$ for some $p \geq 4$. Mahdian [44] proved that for every $g \geq 4$ and $k \geq 4$, Injective k-Colouring is NP-complete for line graphs of bipartite graphs of girth at least g. These graphs may not be C_3-free but for $g \geq p+1$ they are C_p-free. Now assume H has no cycle, so H is a forest. If H contains a vertex of degree at least 3, then H contains an induced $K_{1,3}$. As every line graph is $K_{1,3}$-free, we can use the aforementioned result of Mahdian [44] again. Otherwise H is a linear forest, in which case we use Corollary 5.

We now prove (i). Due to (ii), we may assume that H is a linear forest. If $H \subseteq_i P_4$ or $H \subseteq_i P_1 + P_3$, then we use Lemma 13. Now suppose that $2P_2 \subseteq_i H$. Then the class of $(2P_2, C_4, C_5)$-free graphs (split graphs) are contained in the class of H-free graphs. Recall that Bodlaender et al. [7] proved that Injective Colouring is NP-complete for split graphs. If $6P_1 \subseteq_i H$, then we use Lemma 14. ◀

6 Conclusions

Our complexity study led to three complete and three almost complete complexity classifications (Theorems 1–3). Due to our systematic approach we were able to identify some interesting open questions for future research, which we collect below.

▶ **Open Problem 1.** *For $k \geq 4$ and $g \geq 4$, determine the complexity of* Acyclic k-Colouring *for graphs of girth at least g.*

For solving Open Problem 1 it would be helpful to have a better understanding of the structure of the critical graphs used in the proof of Lemma 6. We also aim to prove analogous results for the other two problems.

▶ **Open Problem 2.** *For every $g \geq 4$, determine the complexities of* Star Colouring *and* Injective Colouring *for graphs of girth at least g.*

Naturally we also aim to settle the remaining open cases for our three problems in Table 1. In particular, there is one case left for Star Colouring.

▶ **Open Problem 3.** *Determine the complexity of* Star Colouring *for $2P_2$-free graphs.*

Recall that the other two problems and also Colouring are all NP-complete for $2P_2$-free graphs. However, none of the hardness constructions carry over to Star Colouring. In this context, the next open problem for split graphs ($(2P_2, C_4, C_5)$-free graphs) is also interesting.

▶ **Open Problem 4.** *Determine the complexity of* Star Colouring *for split graphs.*

We proved that Injective Colouring is NP-complete for triangle-free graphs, but the following problem is still open.

▶ **Open Problem 5.** *Determine the complexity of* Injective Colouring *for bipartite graphs.*

Jin et al. [33] proved that the variant of Injective Colouring where adjacent vertices may be coloured alike is NP-complete for bipartite graphs. However, their hardness construction does not carry over to Injective Colouring.

Finally, we recall that Injective Colouring is also known as $L(1,1)$-labelling. The general distance constrained labelling problem $L(a_1,\ldots,a_p)$-Labelling is to decide if a graph G has a labelling $c : V(G) \to \{1,\ldots,k\}$ for some integer $k \geq 1$ such that for every $i \in \{1,\ldots,p\}$, $|c(u) - c(v)| \geq a_i$ whenever u and v are two vertices of distance i in G. If k is fixed, we write $L(a_1,\ldots,a_p)$-k-Labelling instead. By applying Theorem 4 we obtain the following result.

▶ **Theorem 15.** *For all $k \geq 1, a_1 \geq 1,\ldots,a_k \geq 1$, the $L(a_1,\ldots,a_p)$-k-*Labelling *problem is polynomial-time solvable for H-free graphs if H is a linear forest.*

We leave a more detailed and systematic complexity study of problems in this framework for future work (see, for example, [11, 23, 24] for some complexity results for both general graphs and special graph classes).

Abstract

We study the approximability of the Maximum Independent Set (MIS) problem in H-free graphs (that is, graphs which do not admit H as an induced subgraph). As one motivation we investigate the following conjecture: for every fixed graph H, there exists a constant $\delta > 0$ such that MIS can be $n^{1-\delta}$-approximated in H-free graphs, where n denotes the number of vertices of the input graph. We first prove that a constructive version of the celebrated Erdős-Hajnal conjecture implies ours. We then prove that the set of graphs H satisfying our conjecture is closed under the so-called graph substitution. This, together with the known polynomial-time algorithms for MIS in H-free graphs (e.g. P_6-free and fork-free graphs), implies that our conjecture holds for many graphs H for which the Erdős-Hajnal conjecture is still open. We then focus on improving the constant δ for some graph classes: we prove that the classical Local Search algorithm provides an $OPT^{1-\frac{1}{t}}$-approximation in $K_{t,t}$-free graphs (hence a $\sqrt{OPT}$-approximation in C_4-free graphs), and, while there is a simple $\sqrt{n}$-approximation in triangle-free graphs, it cannot be improved to $n^{\frac{1}{4}-\varepsilon}$ for any $\varepsilon > 0$ unless $NP \subseteq BPP$. More generally, we show that there is a constant c such that MIS in graphs of girth γ cannot be $n^{\frac{c}{\gamma}}$-approximated. Up to a constant factor in the exponent, this matches the ratio of a known approximation algorithm by Monien and Speckenmeyer, and by Murphy. To the best of our knowledge, this is the first strong (i.e., $\Omega(n^\delta)$ for some $\delta > 0$) inapproximability result for Maximum Independent Set in a proper hereditary class.

1 Introduction

An *independent set* of a (simple, undirected) graph is a set of pairwise non-adjacent vertices. Independent sets have been central in various research topics, both in algorithmic and structural graph theory. In structural graph theory, independent sets (and their complements, cliques) are at the core of several celebrated results, such as Kőnig's theorem, Ramsey's theorem, or Turan's theorem [8], to name only a few. Finding an independent set of maximum cardinality (called the Maximum Independent Set problem, or MIS for short) is a fundamental intractable optimization problem. Indeed, it is NP-hard to solve [21], but

also to approximate within ratio $n^{1-\varepsilon}$ for any $\varepsilon > 0$ [27, 35], where n denotes the number of vertices of the input graph (definitions related to approximation algorithms are given at the end of the section). On the positive side, MIS becomes tractable when restricted to some specific graph classes: It is polynomial-time solvable in bipartite graphs and more generally in perfect graphs [22], admits a PTAS in planar graphs [6] and in more general geometric graph classes such as pseudo-disk graphs [10], bounded genus or H-minor-free graphs [14]. Notice that all the aforementioned graph classes are closed under taking induced subgraphs. We call *hereditary* such a class, and add the qualificative *proper* if it is not the class of all graphs. A hereditary class can be defined by a (possibly infinite) set of forbidden induced subgraphs. A potentially unifying framework is to consider the complexity of MIS in H-free graphs (i.e., graphs without induced copy of H) and $\mathcal{H}$-free graphs (i.e., graphs without induced copy of any $H \in \mathcal{H}$). However, a classical reduction [2, 3] consisting of subdividing every edge of a given graph G a fixed even number of times $2c$ leads to a graph G' such that $\alpha(G') = \alpha(G) + c|E(G)|$ (where $\alpha(.)$ denotes the size of a maximum independent set of a graph). This reduction, together with the fact that MIS remains APX-hard in graphs of maximum degree at most 3 [5] (which means in particular that we may assume that $\alpha(G) = \Omega(|E(G)|)$ in the reduction) implies the following:

▶ **Theorem 1** ([2, 3] and [5]). *For any fixed connected graph H which is neither a path nor a subdivision of the claw $K_{1,3}$, MIS is APX-hard in H-free graphs.*

On the positive side, polynomial algorithms are known for P_6-free graphs [24] and fork-free graphs [4]. For paths on at least seven vertices and subdivided claws not contained in the fork, the computational complexity of MIS remains unsettled.

In this work, we start a systematic investigation of the approximability of MIS in H-free graphs. The intuition is that forbidding a fixed graph H as an induced subgraph should imply a drastic change in the structure of independent sets and cliques. This idea is at the core of the Erdős-Hajnal conjecture: while in random graphs of $\mathcal{G}(n, 1/2)$ the expected maximum of the clique number and the independence number is $O(\log n)$ [19], this value should be significantly larger for an H-free graph. More formally:

▶ **Definition 2.** *A graph H satisfies the* Erdős-Hajnal property *if there exists a constant $\delta > 0$ such that every H-free graph G with n vertices contains either a clique or an independent set of size at least n^δ.*

▶ **Conjecture 3** ([16]). *Every graph H satisfies the Erdős-Hajnal property.*

So far, the Erdős-Hajnal conjecture has been verified for only a small number of graphs, namely: all graphs on at most four vertices, the bull[1], the cliques, and every graph that can be constructed from them using the so-called *substitution* operation [12] (we describe this operation in Section 2). Interestingly, for many graphs H satisfying the Erdős-Hajnal property, MIS is known to be either polynomial or at least to admit an $n^{1-\varepsilon}$-approximation algorithm for some $\varepsilon > 0$. A typical example of this situation is when H is the clique of size $t > 1$. In that case, Ramsey's theorem can be invoked to get a $n^{\frac{t-2}{t-1}}$-approximation algorithm. Indeed a K_t-free graph always contains an independent set of size at least $n^{\frac{1}{t-1}}$, and the classical proof readily yields a polytime algorithm finding such an independent set. This leads us to define an approximation weaker version of the Erdős-Hajnal property and its companion conjecture:

[1] The bull is the graph obtained by adding a pending vertex to two different vertices of a triangle.

▶ **Definition 4.** *A graph H satisfies the* improved approximation property *if there exists a constant $\varepsilon > 0$ such that MIS admits a randomized $n^{1-\varepsilon}$-approximation polynomial algorithm on every H-free n-vertex graph G.*

Here, a *randomized* ρ-approximation algorithm is an algorithm which, given an input graph on n vertices, outputs a ρ-approximation of the problem *with high probability* (*w.h.p.* for short), that is with probability at least a function of n tending to 1 when n goes to infinity.

▶ **Conjecture 5.** *Every graph H satisfies the improved approximation property.*

We refer to Conjecture 5 as the *improved approximation conjecture*. Informally, it states that the inapproximability of MIS in general graphs can be beaten in any proper hereditary class.

Results and organization of the paper

On the one hand, there exist graphs H satisfying the improved approximation property for which the Erdős-Hajnal conjecture is still open. Indeed, as mentioned previously, MIS is polynomial-time solvable in P_6-free graphs, whereas it is still open whether P_5 satisfies the Erdős-Hajnal property. On the other hand, one may wonder if the satisfiability of the Erdős-Hajnal property for a graph H can help designing an approximation algorithm in H-free graphs, and more concretely if Conjecture 3 implies Conjecture 5. In Section 2, we prove that this is almost the case. More precisely, we prove that every graph H satisfying a *constructive* version of the Erdős-Hajnal property also satisfies the improved approximation property. We also show that the improved approximation property is preserved through the substitution operation, which is the one graph operation known to preserve the Erdős-Hajnal property.

We then try and obtain better approximation ratios for the improved approximation property: for a given H, what is the largest $\varepsilon > 0$ such that MIS admits an $O(n^{1-\varepsilon})$-approximation algorithm in H-free graphs? We investigate this question in Sections 3 and 4. More precisely, in Section 3 we describe some particular properties of graphs H as well as graph operations preserving the improved approximation property in a better way than the substitution. We also prove that the classical local search algorithm provides a $\sqrt{OPT}$ approximation ratio in C_4-free graphs and, more generally, an $O(OPT^{1-1/t})$-approximation algorithm in $K_{t,t}$-free graphs. Finally, we present in Section 4 some negative results concerning the improved approximation property: while MIS can be easily $n^{1/2}$-approximated in triangle-free graphs, we show that this ratio cannot be improved to $n^{1/4-\varepsilon}$ for any $\varepsilon > 0$, unless $NP \subseteq BPP$. We also provide a generalization of this result when we forbid all cycles of length $3, \ldots, t$ for a fixed $t \geqslant 3$.

Notations and definitions

For two positive integers $i < j$, we denote the set of integers at least i and at most j by $[i, j]$, while $[i]$ is a short-hand for $[1, i]$. All the graphs we consider are simple; they have no multiple edges nor loops. For a vertex v in a simple graph G, $N_G(v)$, or simply $N(v)$ if the graph is unambiguous, denotes the set of neighbors of v. The *closed neighborhood* of v is defined as $N[v] := N(v) \cup \{v\}$. A *universal vertex* is a vertex whose closed neighborhood is the entire set of vertices. The size of a maximum independent set of G is denoted by $\alpha(G)$. The *girth* (resp. *odd girth*) of a graph is the smallest size of an induced cycle (resp. odd cycle) in the graph. K_s, P_s, C_s respectively denotes the clique, the path, and the cycle on s

vertices, and $K_{s,t}$ is the complete bipartite graph with s vertices on one side and t on the other side (it is also called a *biclique*). The graph $K_3 = C_3$ is also called the *triangle*. The *claw* is the biclique $K_{1,3}$. The *fork* is the 5-vertex graph obtained by subdividing one edge of the claw. For a triple of integers $0 \leqslant i \leqslant j \leqslant k$, the graph $S_{i,j,k}$ is obtained by subdividing one edge of a claw $i-1$ times, a second edge, $j-1$ times, and a third edge $k-1$ times (with the convention that subdividing -1 times means removing the edge and its degree-one endpoint). Observe that with that definition, the family $\{S_{i,j,k}\}_{0 \leqslant i \leqslant j \leqslant k}$ contains the paths.

Given a non-decreasing function $\rho : \mathbb{N} \to \mathbb{N}$, a $\rho(n)$-approximation algorithm for MIS is a polynomial-time algorithm which takes as input a graph G on n vertices, and output an independent set S such that $\alpha(G) \leqslant \rho(n)|S|$. In this case, we also say that the problem can be $\rho(n)$-approximated, or that the output solution is a $\rho(n)$-approximated solution.

2 Constructive Erdős-Hajnal and the substitution operation

A graph H is said to satisfy the *constructive Erdős-Hajnal* property if there is a constant $\delta > 0$ and a polynomial-time algorithm which takes as input an H-free graph G, and outputs a clique or an independent set of size at least $|V(G)|^\delta$. We prove that the constructive Erdős-Hajnal conjecture implies Conjecture 5. To our knowledge, all the graphs H shown to satisfy the Erdős-Hajnal property so far, also satisfy its constructive version.

▶ **Theorem 6.** *Let H be a graph which satisfies the constructive Erdős-Hajnal property with constant*[2] *$0 < \delta \leqslant 1/2$. Then H satisfies the improved approximation property with constant $\delta - \delta^2 - \varepsilon$ for any fixed $\varepsilon > 0$.*

Proof. Let G be an H-free graph with $n := |V(G)|$. We assume $n \geqslant 2^{\frac{1}{1-(\delta-\delta^2)}}$, since otherwise the problem can be solved optimally in constant time. We prove that Algorithm 1 provides a $n^{1-(\delta-\delta^2)}$-approximation. In this algorithm, `Constructive-Erdős-Hajnal`(J) represents the polynomial-time algorithm which takes a graph J and outputs a set of at least $|V(J)|^\delta$ vertices of J which is either an independent set or a clique.

Algorithm 1 Approximation algorithm for MIS in H-free graphs satisfying the constructive Erdős-Hajnal property.

Input: a graph G
Output: an independent set of G

1: $V' \leftarrow V(G)$
2: **while** $|V'| \geqslant n^{1-\delta}$ **do**
3: $\quad X \leftarrow$ `Constructive-Erdős-Hajnal`$(G[V'])$
4: $\quad$ **if** X is an independent set of G **then**
5: $\quad\quad$ **return** X
6: $\quad$ **else**
7: $\quad\quad V' \leftarrow V' \setminus X$
8: **return** $\{v\}$, for an arbitrary chosen $v \in V(G)$

Let X be the independent set returned by the algorithm. If X is returned through line 5, then by the definition of the `Constructive-Erdős-Hajnal` algorithm and because of line 2, we have $|X| \geqslant n^{(1-\delta)\delta}$ which is obviously an $n^{1-(\delta-\delta^2)}$-approximate solution, since any optimal solution has size at most n.

[2] Notice that MIS in H-free graphs is trivial if H has at most 2 vertices, whereas any graph with at least three vertices cannot satisfy the Erdős-Hajnal property with a constant $\delta > 1/2$. This is the reason why we assume $0 < \delta \leqslant 1/2$.

Otherwise, X is returned through line 8 and is thus of size 1. However, in this case, observe that $V(G)$ is partitioned into cliques $C_1, \ldots, C_q$, and the last set V'. Observe that $|V'| < n^{1-\delta}$, and that $|C_i| \geqslant n^{\delta-\delta^2}$ for every $i \in \{1, \ldots, q\}$. We thus have $q \leqslant n^{1-(\delta-\delta^2)}$. But also observe that in that case:

$$\begin{aligned}
\alpha(G) &\leqslant q + |V'| \\
&\leqslant n^{1-(\delta-\delta^2)} + n^{1-\delta} \\
&\leqslant 2n^{1-(\delta-\delta^2)} \\
&\leqslant n^{1-(\delta-\delta^2)+\varepsilon} \text{ as we may assume } n \geqslant 2^{1/\varepsilon} \text{ for any fixed } \varepsilon > 0.
\end{aligned}$$

◀

It is natural to ask which kind of graph operations preserves the satisfiability of the improved approximation property. Given the previous result, natural candidates are graph operations preserving the Erdős-Hajnal property. In the following we prove that this is indeed the case concerning the substitution operation.

▶ **Definition 7.** *Let H_1, H_2 be two vertex-disjoint graphs and $v_0 \in V(H_1)$. We say that a graph H is* obtained from H_1 by substituting H_2 at v_0 *if:*

- $V(H) = (V(H_1) \setminus \{v_0\}) \cup V(H_2)$
- *For $v, v' \in V(H_1) \setminus \{v_0\}$, vv' is an edge in H if and only if it is an edge in H_1.*
- *For $v, v' \in V(H_2)$, vv' is an edge in H if and only if it is an edge in H_2.*
- *For $v \in V(H_1) \setminus \{v_0\}$, $v' \in V(H_2)$, vv' is an edge in H if and only if vv_0 is an edge in H_1.*

More generally, we say that a graph H is obtained from H_1 and H_2 by substitution *if there exists $v_0 \in V(H_1)$ such that H is obtained from H_1 by substituting H_2 at v_0.*

▶ **Theorem 8.** *Let H_1, H_2 be two fixed graphs satisfying the improved approximation property. Then every graph H obtained from H_1 and H_2 by substitution satisfies the improved approximation property.*

Let us start by sketching the idea of our algorithm. We first check whether the number of copies of H_1 in G is small. If so, then a randomly chosen subset of vertices of appropriate size will be H_1-free *w.h.p.*, and we will be able to run our approximation algorithm for H_1-free graphs. If the number of copies of H_1 is large, then we claim that we can find a large subset of vertices inducing an H_2-free graph, and we thus run our approximation algorithm for H_2-free graphs. Each time we run one of our approximation algorithms in an induced subgraph $G[X]$ which is either H_1-free or H_2-free, either it outputs a solution of size at least n^δ for some constant δ, in which case we are done, or it means that $\alpha(G[X])$ is small, in which case we keep X apart and continue the algorithm on $G[V \setminus X]$ as long as enough vertices survive. If too many vertices were kept apart along the process, it means that $\alpha(G)$ was very small at the beginning, so that any singleton $\{v\}$ is actually an approximated solution. We now prove formally the result.

Proof. Let $approx_{H_1}(G)$ (resp. $approx_{H_2}(G)$) be a polynomial-time algorithm which takes as input an H_1-free graph (resp. H_2-free graph) G on n vertices and outputs an $n^{1-\varepsilon_1}$ (resp. $n^{1-\varepsilon_2}$)-approximated solution for the MIS problem in G, for some $\varepsilon_1 > 0$ (resp. $\varepsilon_2 > 0$). For the sake of readability, we set $\varepsilon = min\{\varepsilon_1, \varepsilon_2, 0.99\}$, so that $approx_{H_1}$ and $approx_{H_2}$ are $n^{1-\varepsilon}$-approximation algorithms in H_1-free graphs and H_2-free graphs, respectively[3].

[3] Our result also holds if $approx_{H_1}$ and $approx_{H_2}$ are exact algorithms (hence with $\varepsilon_1 = \varepsilon_2 = 1$), but, for technical reasons, we view them as $n^{0.01}$-approximation algorithms.

Let H be the graph obtained by substituting H_2 at some vertex $v_0 \in V(H_1)$, and let us consider an H-free graph G. We denote by n, n_1 and n_2 the number of vertices of G, H_1 and H_2, respectively. We say that $X \subseteq V(G)$ is a set of H_1-*candidates* if there exists a set $K \subseteq V(G)$ of $n_1 - 1$ vertices such that $G[K]$ is isomorphic to $H_1 - \{v_0\}$ and, for every $x \in X$, $G[K \cup \{x\}]$ is isomorphic to H_1. Since G is H-free, $G[X]$ is H_2-free.

Let $\gamma = \frac{\varepsilon}{2n_1}$, $\eta = \min(1-\varepsilon, \gamma)$, and $\delta = \frac{\varepsilon\eta}{2+\varepsilon\eta}$. We prove that Algorithm 2 is an $O(n^{1-\delta})$-approximation algorithm for MIS in H-free graphs.

Algorithm 2 Approximation algorithm for MIS in H-free graphs, where H is the substitution of H_1 and H_2.

Input: an H-free graph G with n vertices
Output: an independent set of G

1: $i = 1$, $V_1 \leftarrow V(G)$
2: **while** $|V_i| \geqslant n^{1-\delta}$ **do**
3: **if** $G[V_i]$ contains less than $|V_i|^{n_1-\varepsilon}$ copies of H_1 **then**
4: pick a set $X_i \subseteq V_i$ of size $\lceil |V_i|^{\gamma} \rceil$ uniformly at random
5: **if** $G[X_i]$ is H_1-free **then** ▷ This condition is true *w.h.p.*
6: $W_i \leftarrow approx_{H_1}(G[X_i])$
7: **if** $|W_i| \geqslant n^{\delta}$ **then return** W_i
8: **else return** FAIL
9: **else**
10: find a set of H_1-candidates $X_i \subseteq V_i$ with $|X_i| \geqslant |V_i|^{1-\varepsilon}$
11: $W_i \leftarrow approx_{H_2}(G[X_i])$ ▷ $G[X_i]$ is H_2-free
12: **if** $|W_i| \geqslant n^{\delta}$ **then return** W_i
13: $V_{i+1} \leftarrow V_i \setminus X_i$
14: $i \leftarrow i + 1$
15: **return** $\{v\}$ for an arbitrary vertex $v \in V$

▶ **Lemma 9.** *Algorithm 2 runs in polynomial time.*

Proof. An important remark is that at every step i, the graph $G[V_i]$ is an induced subgraph of G, hence is H-free. In line 3 (resp. 5), the algorithm runs through all subsets of n_1 vertices of V_i (resp. X_i), which can be done in $O(n^{n_1})$ time.

Finally, the existence of a set of H_1-candidates in line 10 is ensured by the fact that in that case, $G[V_i]$ contains at least $|V_i|^{n_1-\varepsilon}$ copies of H_1. Hence, by the pigeonhole principle, there must exist a set V_H of $n_1 - 1$ vertices with $V_H \subseteq V_i$ such that $G[V_H]$ induces $H_1 \setminus v_0$ together with a set $X_i \subseteq V_i \setminus V_H$ of size at least $|V_i|^{1-\varepsilon}$ such that for every $x \in X_i$, $G[V_H \cup \{x\}]$ induces H_1. Finding the set V_H can be done in $O(|V_i|^{n_1-1})$ time, while finding the set X_i can be done in $O(|V_i|)$ time, since it is sufficient to find the vertices in $V_i \setminus V_H$ with the right neighborhood with respect to V_H. By the definition of H_1-candidates, $G[X_i]$ is H_2-free, which allows to run $approx_{H_2}$ on $G[X]$ in the next line of the algorithm. ◀

We now prove that, *w.h.p.*, the solution S returned by our algorithm is an $O(n^{1-\delta})$-approximation. To this end, we first prove that *w.h.p.* it does not return FAIL.

▶ **Lemma 10.** *If the number of copies of H_1 in a graph G on n vertices is less than $n^{n_1-\varepsilon}$, then any subset of vertices of size $\lceil n^{\gamma} \rceil$ picked uniformly at random induces an H_1-free graph, with high probability.*

Proof. Let n be the number of vertices of G, and P be a subset of $\lceil n^\gamma \rceil$ vertices picked uniformly at random. For any set $V_H \subseteq V$ inducing H_1, the probability that V_H is contained in P is $\frac{\binom{n-n_1}{|P|-n_1}}{\binom{n}{|P|}} < \left(\frac{|P|}{n}\right)^{n_1}$. Hence the probability that P is H_1-free is at least

$$\left(1-\left(\frac{|P|}{n}\right)^{n_1}\right)^{n^{n_1-\varepsilon}} = \left(1-\frac{1}{n^{n_1-\frac{\varepsilon}{2}}}\right)^{n^{n_1-\varepsilon}}$$

which tends to 1 when $n \to +\infty$. ◀

Next, if it returns a solution through lines 7 or 12, then this solution is an independent set of size at least n^δ, by definition. We now deal with the case in which it returns a singleton, through line 15. The aim is to prove that $\alpha(G)$ is at most $O(n^{1-\delta})$. Let $q+1$ be the largest value of i in the execution of the algorithm (i.e., $|V_{q+1}| < n^{1-\delta}$). The vertex-set V is thus partitioned into $X_1, \ldots, X_q$, and V_{q+1}. Hence we have $\alpha(G) \leqslant |V_{q+1}| + \sum_{i=1}^{q} \alpha(G[X_i])$. Since $|V_{q+1}| < n^{1-\delta}$, we only need to upper bound the second part.

▶ **Lemma 11.** *With the above definitions,* $\sum_{i=1}^{q} \alpha(G[X_i]) \leqslant n^{1-\delta}$.

Proof. Recall that we have $X_i \subseteq V_i$, where $V_i = V \setminus \bigcup_{j=1}^{i-1} X_j$, and, for each $i \in [q]$, we have constructed an independent set $W_i \subseteq X_i$. All these sets have the following properties:

1. $|V_{q+1}| < n^{1-\delta}$, by definition of q.
2. $|X_i| \geqslant |V_i|^\eta \geqslant n^{\eta(1-\delta)}$. Indeed, if X_i is defined in line 4, then it is of size at least $|V_i|^\gamma$, whereas if it is defined in line 10, it is of size at least $|V_i|^{1-\varepsilon}$, and $\eta = \min(1-\varepsilon, \gamma)$.
3. $|W_i| < n^\delta$, otherwise we would have returned it.
4. $\alpha(G[X_i]) \leqslant |W_i| \cdot |X_i|^{1-\varepsilon}$, since W_i is returned by $approx_{H_1}$ or $approx_{H_2}$, which are approximation algorithms applied to $G[X_i]$.

Now, we have the following:

$$\begin{aligned}\sum_{i=1}^{q} \alpha(G[X_i]) &\leqslant \sum_{i=1}^{q} |W_i| \cdot |X_i|^{1-\varepsilon} \\ &\leqslant n^\delta \sum_{i=1}^{q} |X_i|^{1-\varepsilon}.\end{aligned}$$

We then need the following technical lemma.

▶ **Lemma 11.1.** *Let* $(a_i)_{i=1\ldots q}$ *be some positive numbers (with* $q \in \mathbb{N}$*) such that* $\sum_{i=1}^{q} a_i = N$ *and* $a_i \geqslant k > 0$ *for all* $i \in \{1, \ldots, q\}$*. Then* $\sum_{i=1}^{q} a_i^\zeta \leqslant N k^{\zeta-1}$ *for any* $0 < \zeta < 1$.

Proof. We have:

$$\sum_{i=1}^{q} a_i^\zeta \leqslant \left(\frac{N}{q}\right)^\zeta \cdot q = N \cdot \left(\frac{N}{q}\right)^{\zeta-1} \leqslant N k^{\zeta-1}.$$ ◀

Using the above lemma together with item 2 of the previous properties in order to lower bound each $|X_i|$, we obtain:

$$\begin{aligned}\sum_{i=1}^{q}\alpha(G[X_i]) &\leqslant n^{\delta}\left(\sum_{i=1}^{q}|X_i|\right)n^{\eta(1-\delta)(1-\varepsilon-1)}\\ &\leqslant n^{1-\varepsilon\eta(1-\delta)+\delta} \quad \text{since } \sum_{i=1}^{q}|X_i|\leqslant n\\ &\leqslant n^{1-\delta} \quad \text{because } \delta=\frac{\varepsilon\eta}{2+\varepsilon\eta}\text{, hence } \varepsilon\eta(1-\delta)=2\delta\end{aligned}$$

◀

Hence, any solution of size 1 is an $O(n^{1-\delta})$-approximation in this case, which concludes the proof. ◀

3 Better approximation ratios

In this section we improve over the ratio given by Theorem 8 for some graphs H that can be built by a sequence of substitutions from graphs H' such that MIS is polynomial-time solvable in H'-free graphs. Furthermore, we present deterministic algorithms.

3.1 Adding a universal vertex

Let H^{+u} be the graph H augmented by a universal vertex, i.e., we add one vertex adjacent to all the vertices of H.

▶ **Lemma 12.** *Let $0 \leqslant \gamma < 1$ be a real number and H be a graph such that MIS admits an OPT^{γ}-approximation $\mathcal{A}$ in H-free graphs. Then it also admits an $OPT^{\frac{1}{2-\gamma}}$-approximation $\mathcal{A}^{+u}$ in H^{+u}-free graphs.*

Proof. Let G be the input graph, thus OPT $:= \alpha(G)$. The base case of the algorithm is when G does not contain any vertex, and we correctly report the empty set as optimum solution. Otherwise G has at least one vertex, say v_1. We run the approximation $\mathcal{A}$ on $G[N(v_1)]$. G being H^{+u}-free, the subgraph induced by the open neighborhood of any vertex is indeed H-free. Let S_1 be the returned solution. By assumption, $|S_1| \geqslant \alpha(G[N(v_1)])^{1-\gamma}$. For what follows, the knowledge of the value OPT would help. Unfortunately we will make some recursive calls to $\mathcal{A}^{+u}$, so exhaustively guessing this value would result in an exponential running time. Instead we will branch but the branching tree will only have at most $n := |V(G)|$ leaves. More precisely the tree will be a so-called *comb*, i.e., a path where all the vertices except one end has an additional private neighbor. We eventually output the best solution found among all the leaves.

We inductively run $\mathcal{A}^{+u}$ on $G - N[v_1]$, which produces a tree T with at most $n-1$ leaves. And we output the best solution among S and all the solutions at the leaves of T augmented by the vertex v_1. This algorithm returns an independent set since v_1 is by definition non-adjacent to any vertex of $G - N[v_1]$. The running time of our algorithm satisfies $f_{\mathcal{A}^{+u}}(n) = f_{\mathcal{A}}(n_1 - 1) + f_{\mathcal{A}^{+u}}(n - n_1) + O(1)$ (with $n_1 = |N(v_1)|$). Hence $f_{\mathcal{A}^{+u}}(n) = O(\max\{f_{\mathcal{A}}(n), n\})$, and in the likely event that $\mathcal{A}$ is *not* sublinear, $\mathcal{A}^{+u}$ has the same running time as $\mathcal{A}$ up to a multiplicative constant factor.

We shall now show that $\mathcal{A}^{+u}$ is indeed a OPT$^{\frac{1}{2-\gamma}}$-approximation. We denote by $v_1, \ldots, v_p$ with $p \leqslant n$, the vertices added along the path to the deepest leaf of T. We denote by $S_1, \ldots, S_p$ the sets returned by $\mathcal{A}$ such that S_i is computed in the graph $G'_i := G[N(v_i) \setminus \bigcup_{j<i} N[v_j]]$.

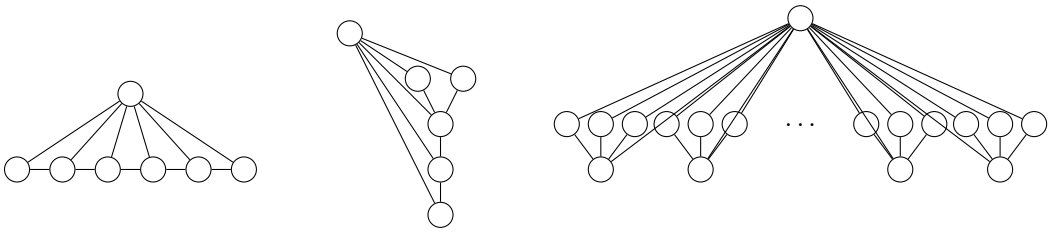

Figure 1 The three maximal locally easy graphs H constructed from P_6, the fork, and $tK_{1,3}$, respectively.

We also define $G_i := G[N[v_i] \setminus \bigcup_{j<i} N[v_j]]$, and $R_i := G - \bigcup_{j<i} N[v_j]$. Observe that $\{V(G_1), \dots, V(G_p)\}$ is a partition of $V(G)$, as well as, $\{V(G_1), \dots, V(G_i), V(R_{i+1})\}$ for every $i \in [p-1]$.

Let, if it exists, S_h be the first solution returned by $\mathcal{A}$ when called on G'_h such that $|S_h| \geqslant \alpha(R_h)^{1-\frac{1}{2-\gamma}}$. We claim that the solution output at this leaf, namely $S'_h := S_h \cup \{v_1, \dots, v_{h-1}\}$ is an $\mathrm{OPT}^{\frac{1}{2-\gamma}}$-approximation. If such an S_h does not exist, we show the same statement where $S_h = \emptyset$ and $h - 1 = p$.

We upperbound $\alpha(G_i)$ for every $i \in [h-1]$. By definition of S_h, it holds that $|S_i| < \alpha(R_i)^{1-\frac{1}{2-\gamma}}$ for any $i \in [h-1]$. Due to the approximation ratio of $\mathcal{A}$, it holds that:

$$\alpha(G_i)^{1-\gamma} \leqslant |S_i| < \alpha(R_i)^{1-\frac{1}{2-\gamma}} = \alpha(R_i)^{\frac{1-\gamma}{2-\gamma}},$$

hence $\alpha(G_i) < \alpha(R_i)^{\frac{1}{2-\gamma}} \leqslant \alpha(G)^{\frac{1}{2-\gamma}}$. Thus,

$$\mathrm{OPT} = \alpha(G) \leqslant \alpha(R_h) + \sum_{i\in[h-1]} \alpha(G_i) \leqslant |S_h|\alpha(R_h)^{\frac{1}{2-\gamma}} + \sum_{i\in[h-1]} \alpha(G)^{\frac{1}{2-\gamma}}$$

$$\leqslant |S_h|\alpha(G)^{\frac{1}{2-\gamma}} + (h-1)\alpha(G)^{\frac{1}{2-\gamma}} = (|S_h| + h - 1)\alpha(G)^{\frac{1}{2-\gamma}} = |S'_h|\alpha(G)^{\frac{1}{2-\gamma}} = |S'_h|\mathrm{OPT}^{\frac{1}{2-\gamma}}.$$

Therefore $\mathcal{A}^{+u}$ is an $\mathrm{OPT}^{\frac{1}{2-\gamma}}$-approximation for MIS in H^{+u}-free graphs. ◀

3.2 Locally easy graphs

We say that a graph H is *locally easy* if it has a universal vertex v such that there is a polynomial-time algorithm for MIS in $H - \{v\}$-free graphs. Up to now, the three maximal graphs H for which we know that MIS is polynomial-time solvable on H-free graphs are P_6 [23], the fork [4, 30], and $tK_{1,3}$ (or $t$claw) [9] (see Figure 1 for the corresponding maximal locally easy graphs).

The following is an immediate consequence of Lemma 12. Therein we recall that the constant γ may take value 0.

▶ **Theorem 13.** *For any locally easy H, MIS can be $\sqrt{OPT}$-approximated on H-free graphs.*

And in particular, there is a $\sqrt{n}$-approximation for triangle-free graphs. Lemma 12 also yields the following approximation ratio in K_{t+1}-free graphs.

▶ **Theorem 14.** *For any $t \geqslant 1$, MIS can be $OPT^{1-\frac{1}{t}}$-approximated on K_{t+1}-free graphs.*

Proof. We show this statement by induction. The base case says that we can exactly solve in polynomial time MIS in edgeless graphs, which is obviously true. We assume that the statement is true for a fixed t. As $K_{t+2} = (K_{t+1})^{+u}$, Lemma 12 implies that MIS can be $\mathrm{OPT}^{\frac{1}{2-(1-\frac{1}{t})}}$-approximated on K_{t+2}-free graphs. Furthermore, $\frac{1}{2-(1-\frac{1}{t})} = \frac{1}{1+\frac{1}{t}} = \frac{t}{t+1} = 1 - \frac{1}{t+1}$. Therefore we do obtain an $\mathrm{OPT}^{1-\frac{1}{t+1}}$-approximation on K_{t+2}-free graphs. ◀

We say that a graph H is *t-locally easy* if it has a set U of t universal vertices such that a polynomial algorithm is known for MIS in $H-U$-free graphs. Informally, these graphs are obtained by replacing universal vertices of Figure 1 by a k-clique. The previous result readily generalizes from K_{t+1}-free to H-free graphs with H $(t+1)$-locally easy, with the same proof.

▶ **Corollary 15.** *Let t be a non-negative integer. For any t-locally easy H, MIS can be $OPT^{1-\frac{1}{t+1}}$-approximated on H-free graphs.*

As we will see in Section 4.3 for forbidden graphs H containing a triangle, it is unlikely to improve the approximation ratio below $n^{1/4}$. However if H is a star, constant-approximations are achievable. It is known that MIS is polynomial-time solvable on claw-free graphs [31] (i.e., $K_{1,3}$-free graphs) while it is APX-hard on $K_{1,4}$-free graphs (see for instance [3]). The greedy algorithm (or actually any sensible algorithm) gives an s-approximation in $K_{1,s}$-free graphs. The ratio was improved to arbitrarily close to $\frac{s-1}{2}$ by Halldórsson.

▶ **Theorem 16** ([25])**.** *For every $s \geqslant 4$ and $\varepsilon > 0$, MIS is $\frac{s-1}{2}+\varepsilon$-approximable on $K_{1,s}$-free graphs.*

3.3 Local Search for $K_{t,t}$-free graphs

Here we analyze the performance of the t-Local Search algorithm in $K_{t,t}$-free graphs. Usually for the particular case of the biclique, "$K_{t,t}$-free" is intended as "no $K_{t,t}$ as a subgraph". Here we still mean "no $K_{t,t}$ as an *induced* subgraph", since our algorithm works even in this more general setting. For a fixed integer $t > 2$, t-Local Search takes as input a graph G, and construct an independent set S from a single vertex. Then, it tries to improve S in the following way: whenever there exist two sets $X \subseteq S$ (note that X can possibly be empty) and $Y \subseteq V \setminus S$ such that $0 \leqslant |X| < |Y| \leqslant t$ and $(S \setminus X) \cup Y$ is an independent set, it replaces S by $(S \setminus X) \cup Y$ (if there are several choices, it chooses an arbitrary one). When S can no longer be improved, it outputs it. Each improvement takes $O(n^{2t})$ time, and the number of such improvements is at most n, since the size of S increases by at least one at each step. Hence, the algorithm takes polynomial time. In the following theorem, we prove that this simple algorithm provides an $O(OPT^{1-1/t})$-approximation whenever the input graph is $K_{t,t}$-free. In particular, 2-Local Search is an $O(\sqrt{OPT})$-approximation in C_4-free graphs. It came to our knowledge that the same result was obtained independently by Dvořák, Feldmann, Rai, and Rzążewski [15].

▶ **Theorem 17.** *For any fixed $t \geqslant 2$, t-Local Search is an $O(OPT^{1-1/t})$-approximation in $K_{t,t}$-free graphs.*

Proof. Let S be the solution returned by the algorithm, and O be a fixed optimal solution. The objective is to bound $|O'|$ in terms of $|S'|$, where $O' := O \setminus S$ and $S' := S \setminus O$. To this end, let us consider $\mathcal{B} := G[S' \cup O']$ the bipartite graph induced by $S' \cup O'$. Let $k := |S'|$. We partition O' into D^- and D^+, where D^- are the vertices of O' whose degree within S' is at most $t-1$, and thus D^+ are the vertices of O' whose degree within S' is at least t. We now bound the sizes of D^- and D^+ separately.

- Let us partition D^- into classes $D_1^-, \ldots, D_q^-$ with respect to the equivalence relation $u \sim v$ if and only if $N_{S'}(u) = N_{S'}(v)$. By definition of D^- we have $q \leqslant \sum_{i=1}^{t-1} \binom{k}{i}$. Then, we claim that for every $i \in \{1, \ldots, q\}$, we have $|D_i^-| \leqslant t-1$. Indeed, we must have $|D_i^-| \leqslant |N_{S'}(D_i^-)|$, since otherwise the algorithm would have replaced S by $(S \setminus N_{S'}(D_i^-)) \cup D_i^-$. This proves $|D^-| \leqslant (t-1)\sum_{i=1}^{t-1} \binom{k}{i}$.

- For a set $X \subseteq S'$, let $I_X := \bigcap_{x \in X} N_{O'}(x)$. Observe that if $|X| = t$, then necessarily $I_X \subseteq D^+$, and moreover $|I_X| \leqslant t-1$, since otherwise the graph would have an induced $K_{t,t}$. Finally, we have $D^+ = \bigcup_{X \subseteq S', |X|=t} I_X$, which proves that $|D^+| \leqslant \binom{k}{t}(t-1)$.

Hence we have $|O'| \leqslant |D^-| + |D^+| \leqslant (t-1)\sum_{i=1}^{t-1}\binom{k}{i} + \binom{k}{t}(t-1) = O(k^t)$. ◀

4 Graphs without short cycles

In this section we show that the strong inapproximability of MIS in general graphs survives, albeit in a less severe form, on graphs without small cycles. More quantitatively, we show that for any positive integer γ, there is a constant $\beta = \Theta(1/\gamma)$ depending only on γ, such that an n^β-approximation of MIS in graphs with girth γ is unlikely.

4.1 Triangle-free graphs

While Lemma 12 implies an $n^{1/2}$-approximation of MIS in triangle-free graphs, a natural question is how much the ratio's exponent can be decreased. In this section we provide a lower bound for it.

The following result will be made obsolete twice. Indeed we will then generalize its statement from triangle-free, that is girth 4, to graphs with any constant girth. Then in Section 4.3 we will present a stronger inapproximability result of $\Omega(n^{1/4-\varepsilon})$. Nevertheless we choose to keep its proof as it is simpler, easier to follow, and self-contained. Furthermore, it contains all the ideas necessary to achieve the subsequent results.

▶ **Theorem 18.** *For any $\varepsilon > 0$, it is NP-hard to distinguish between triangle-free graphs G on n vertices satisfying*

- $\alpha(G) \leqslant n^{5/6-\varepsilon}$, *and*
- $\alpha(G) \geqslant n^{1-\varepsilon}$.

So for any $\varepsilon > 0$, MIS cannot be approximated within ratio $n^{1/6-\varepsilon}$ in triangle-free graphs unless NP $\subseteq$ BPP.

Proof. Let $\varepsilon > 0$ be an arbitrarily small real value, and $\varepsilon := 3\varepsilon$. We perform a randomized reduction from an infinite set of graphs H admitting the following gap: Positive instances have stable sets of size at least $|V(H)|^{1-\varepsilon}$ whereas negative instances have no stable set of size $|V(H)|^{\varepsilon}$. It is known that distinguishing between these two cases is NP-hard for randomized reductions [27], and even for deterministic ones [35].

Reduction. Given an N-vertex graph H, we construct a triangle-free graph G in the following way. We transform every vertex v of H into an independent set $I(v)$ of size $s := N^5$. For every edge $uv \in E(H)$, we put a random bipartite graph between $I(u)$ and $I(v)$: for each pair of vertices $x \in I(u)$, $y \in I(v)$, we independently add an edge xy to $E(G)$ with probability $p := N^{-4-\eta}$ with $\eta := 2\varepsilon/3$. We denote by $G_\triangle$ the graph thus obtained. A key property is that $G_\triangle$ contains only *few* triangles. For each triangle in $G_\triangle$, we remove all three vertices of it. We call that phase the *triangle removal*, and we denote by G the triangle-free graph that arises when that phase comes to an end. We further assume that N is larger than the smallest integral constant N_0 for which for every $N \geqslant N_0$, $N^{3\eta} > N^{2.5\eta} + 10N^{2\eta}\ln N$, $N^{-\varepsilon} > 6N^{-2\eta}$, $2^{17/6}N^{\eta/3} < N^{\varepsilon}$, and $N^{-\eta} < 10^{-100}$. In particular the second and third inequalities hold for sufficiently large N since $\eta < \varepsilon = 3\varepsilon < 2\eta$. The hardness of approximation [27, 35] still holds since instances with less than a constant number of vertices can be solved optimally in constant time.

▶ **Lemma 19.** *For every edge $uv \in E(H)$, the probability that there exist two sets $A \subset I(u), B \subset I(v)$ both of size $N^{4+2\eta}$ without any edge between A and B is at most $e^{-N^{4+2.5\eta}}$. Thus, with high probability, this event does not happen.*

Proof. The probability that there is no edge between two fixed sets A and B of size $N^{4+2\eta}$ is:

$$(1-p)^{|A|\cdot|B|} = (1-\frac{1}{N^{4+\eta}})^{N^{2(4+2\eta)}} \leqslant e^{-N^{4+3\eta}}.$$

By the union bound, the probability that there is at least one such pair of sets is at most:

$$\binom{N^5}{N^{4+2\eta}}^2 e^{-N^{4+3\eta}} \leqslant N^{10N^{4+2\eta}} e^{-N^{4+3\eta}} = e^{-N^{4+3\eta}+10N^{4+2\eta}\ln N} \leqslant e^{-N^{4+2.5\eta}}. \quad \blacktriangleleft$$

▶ **Lemma 20.** *The expected number of triangles in $G_\triangle$ is at most $N^{6-3\eta}$. Furthermore $|V(G_\triangle)| - |V(G)|$ is at most $3N^{6-2\eta}$ with probability at least $1 - N^{-\eta}$.*

Proof. The expected number of triangles in $G_\triangle$ is:

$$\mathbb{E}(\#(\triangle, G_\triangle)) \leqslant (sN)^3 p^3 = (N^6)^3 N^{-12-3\eta} = N^{6-3\eta}.$$

By Markov's inequality, $\mathbb{P}(\#(\triangle, G_\triangle) \geqslant N^{6-2\eta}) \leqslant N^{6-3\eta}/N^{6-2\eta} = N^{-\eta}$. $\blacktriangleleft$

Let n be the number of vertices of G (after the triangle removal). By the previous lemma $n := |V(G)| > N^6/2$, with high probability.

If H is a YES-instance, there is a stable set of size $\mathbf{n^{1-\varepsilon}}$ in G. We assume that H is a YES-instance, so there is a stable set S in H such that $|S| \geqslant N^{1-\varepsilon}$. By construction, $S_{G_\triangle} := \bigcup_{u\in S} I(u)$ is a stable set in $G_\triangle$ of size $s|S| \geqslant N^{6-\varepsilon}$. By Lemma 20, $S_{G_\triangle} \cap V(G)$ is an independent set in G of size, w.h.p., at least $N^{6-\varepsilon} - 3N^{6-2\eta} > N^{6-\varepsilon}/2 > n^{1-\varepsilon/6}/2 = n^{1-\varepsilon/2}/2 > n^{1-\varepsilon}$.

If H is a NO-instance, there is no stable set of size $\mathbf{n^{5/6+\varepsilon}}$ in G. Let S_G be an independent set of G and let $S := \{v \in V(H) \text{ such that } |I(v) \cap S_G| \geqslant N^{4+2\eta}\}$. If H is a NO-instance, then there is no stable set in H of size more than N^ε. By a union bound of applications of Lemma 19 to all pairs of vertices of S, w.h.p. S is an independent set of H, which implies that $|S| < N^\varepsilon$. Thus $|S_G| < sN^\varepsilon + N^{4+2\eta}(N - N^\varepsilon) < N^{5+\varepsilon} + N^{5+2\eta} < 2N^{5+2\eta} = 2N^{5(1+2\eta/5)} < 2^{11/6} n^{5/6+\eta/3} < n^{5/6+\varepsilon}$. $\blacktriangleleft$

4.2 Graphs with higher girth

Monien, Speckenmeyer and Murphy independently found improved approximations when the girth, actually even the odd girth, is any constant γ.

▶ **Theorem 21** ([32, 33])**.** *MIS admits a polynomial-time $n^{\frac{2}{\gamma-1}}$-approximation on graphs with odd girth γ.*

In particular, the result implies an $n^{1/2}$-approximation for triangle-free graphs, an $n^{1/3}$-approximation for $\{C_3, C_5\}$-free graphs, an $n^{1/4}$-approximation for $\{C_3, C_5, C_7\}$-free graphs, etc. On the complexity side, the construction of Theorem 18 where the probability p of having an edge between $I(u)$ and $I(v)$ with $uv \in E(H)$ is now set to $N^{-2(\gamma-1)-\eta}$ and the size s of each $I(u)$ is set to $N^{2\gamma-1}$ yields a polynomial gap on C_γ-free graphs, and even on graphs with girth $\gamma + 1$.

▶ **Theorem 22.** *For any $\varepsilon > 0$, it is NP-hard to distinguish between graphs G with n vertices and girth $\gamma + 1$ satisfying*

- $\alpha(G) \leqslant n^{\frac{2\gamma-1}{2\gamma}-\varepsilon}$, *and*
- $\alpha(G) \geqslant n^{1-\varepsilon}$.

Hence, for any $\varepsilon > 0$, MIS cannot be approximated within ratio $n^{\frac{1}{2\gamma}-\varepsilon}$ in graphs with girth $\gamma + 1$ unless NP $\subseteq$ BPP.

Proof. We do the same reduction as in Theorem 18 with the following modifications. We now set $\varepsilon := \gamma\varepsilon$, $s := N^{2\gamma-1}$, $p := N^{2(\gamma-1)-\eta}$, and $\eta := \frac{\gamma-1}{\gamma}\varepsilon$. We denote by $G_\circ$ the graph obtained before the removal step. For every cycle of length at most γ, we remove all the vertices of the cycle from the graph. When this short cycle removal ends, the graph has girth at least $\gamma + 1$. We call G the obtained graph.

▶ **Lemma 22.1.** *For every edge $uv \in E(H)$, the probability that there exist two sets $A \subset I(u), B \subset I(v)$ both of size $N^{2(\gamma-1)+2\eta}$ without any edge between A and B is at most $e^{-N^{2(\gamma-1)+2.5\eta}}$. Thus, with high probability, this event does not happen.*

Proof. The probability that there is no edge between two fixed sets A and B of size $N^{2(\gamma-1)+2\eta}$ is:

$$(1-p)^{|A|\cdot|B|} = (1 - \frac{1}{N^{2(\gamma-1)+\eta}})^{N^{2(2(\gamma-1)+2\eta)}} \leqslant e^{-N^{2(\gamma-1)+3\eta}}.$$

By the union bound, the probability that there is at least one such pair of sets is at most:

$$\binom{N^{2\gamma-1}}{N^{2(\gamma-1)+2\eta}}^2 e^{-N^{2(\gamma-1)+3\eta}} \leqslant N^{10N^{2(\gamma-1)+2\eta}} e^{-N^{2(\gamma-1)+3\eta}}$$

$$= e^{-N^{2(\gamma-1)+3\eta}+10N^{2(\gamma-1)+2\eta}\ln N} \leqslant e^{-N^{2(\gamma-1)+2.5\eta}}.$$ ◀

▶ **Lemma 22.2.** *The expected number of cycles of length at most γ in $G_\circ$ is at most $N^{(2-\eta)\gamma}$. Furthermore $|V(G_\circ)| - |V(G)|$ is at most $\gamma N^{2\gamma-\eta(\gamma-1)}$ with probability at least $1 - N^{-\eta}$.*

Proof. The expected number of cycles of length at most γ in $G_\circ$ is:

$$\mathbb{E}(\#(C_{3\to\gamma}, G_\circ)) \leqslant \gamma(sN)^\gamma p^\gamma = \gamma N^{2\gamma^2} N^{(-2(\gamma-1)-\eta)\gamma} = \gamma N^{(2-\eta)\gamma}.$$

By Markov's inequality, $\mathbb{P}(\#(C_{3\to\gamma}, G_\circ) \geqslant \gamma N^{2\gamma-\eta(\gamma-1)}) \leqslant N^{(2-\eta)\gamma}/N^{2\gamma-\eta(\gamma-1)} = N^{-\eta}$. ◀

Let n be the number of vertices of G (after the short cycle removal). By the previous lemma $n := |V(G)| > N^{2\gamma}/2$, with high probability.

If H is a YES-instance, there is a stable set of size $n^{1-\varepsilon}$ in G. We assume that H is a YES-instance, so there is a stable set S in H such that $|S| \geqslant N^{1-\varepsilon}$. By construction, $S_{G_\circ} := \bigcup_{u\in S} I(u)$ is a stable set in $G_\circ$ of size $s|S| \geqslant N^{2\gamma-\varepsilon}$. By Lemma 22.2, $S_{G_\circ} \cap V(G)$ is an independent set in G of size, w.h.p., at least $N^{2\gamma-\varepsilon} - \gamma N^{2\gamma-\eta(\gamma-1)} > N^{2\gamma-\varepsilon}/2 > n^{1-\varepsilon/2\gamma)}/2 = n^{1-\varepsilon/2}/2 > n^{1-\varepsilon}$.

If H is a NO-instance, there is no stable set of size $n^{(2\gamma-1)/(2\gamma)+\varepsilon}$ in G. Let S_G be an independent set of G and let $S := \{v \in V(H) \text{ such that } |I(v) \cap S_G| \geqslant N^{2(\gamma-1)+2\eta}\}$. If H is a NO-instance, then there is no stable set in H of size more than N^ε. By a union bound of applications of Lemma 22.1 to all pairs of vertices of S, w.h.p. S is an independent set of H, which implies that $|S| < N^\varepsilon$. Thus $|S_G| < sN^\varepsilon + N^{2(\gamma-1)+2\eta}(N - N^\varepsilon) < N^{2\gamma-1+\varepsilon} + N^{2\gamma-1+2\eta} < 2N^{2\gamma-1+2\eta} = 2N^{(2\gamma-1)(1+2\eta/(2\gamma-1))} < 2^{(4\gamma-1)/(2\gamma)} n^{(2\gamma-1)/(2\gamma)+\eta/\gamma} < n^{(2\gamma-1)/(2\gamma)+\varepsilon}$. ◀

Let us note that there is still a 4-fold multiplicative factor in the exponent between the approximation ratios of Theorem 21, namely $n^{2/\gamma}$, and the hardness ratios of $n^{1/(2\gamma)-o(1)}$ in Theorem 22. It is an interesting open question to bridge this gap.

An even hole is an induced cycle of even length at least 4. Even-hole-free graphs are $\{C_4, C_6, C_8, \ldots\}$-free graphs. The computational complexity of MIS on even-hole-free graphs is still unknown. An FPT algorithm was established recently [26]. We observe that Local Search readily gives a PTAS for that problem. We leave the existence of an EPTAS as an open problem.

▶ **Observation 23.** *MIS can be $(1+\varepsilon)$-approximated in time $n^{O(1/\varepsilon)}$ on even-hole-free graphs.*

Proof. The graph induced by the symmetric difference between any two feasible solutions is bipartite and even-hole-free, hence it is a forest. Let S be a solution obtained by local search on an input graph G, O be a fixed optimum solution, $S' := S \setminus O$, and $O' := O \setminus S$. It is known that when $G[S' \cup O']$ is planar, there is an absolute constant C such that the C/ε^2-Local Search $1+\varepsilon$-approximates the problem [34, 11], that is for a maximization problem, $|S'| \geqslant (1-\varepsilon)|O'|$, implying $|S| \geqslant (1-\varepsilon)|O|$. This gives a PTAS with running time $n^{O(1/\varepsilon^2)}$. When $G[S' \cup O']$ is even a forest, then it can be shown, and it is somewhat folklore, that a C/ε-Local Search is sufficient. ◀

4.3 Strengthening the inapproximability

There are two directions to improve the hardness-of-approximation results of Sections 4.1 and 4.2. As already mentioned, one can try to match upper and lower bounds in the approximation ratio, or at least to increase the exponent δ such that an n^δ-approximation would contradict a standard complexity-theoretic assumption. For triangle-free graphs, for instance, we do *not* expect a matching $n^{1/6}$-approximation. And a likely outcome is that, ignoring logarithmic factors, the $\sqrt{n}$-approximation is best possible. We will actually show that an $n^{1/4-\varepsilon}$-approximation is unlikely. The other direction is to derandomize our reductions. That way the inapproximability would be subject to the more (arguably the most) standard complexity assumption that P is not equal to NP. Derandomizing without degrading the quality of the gap seems challenging. We now encapsulate the reductions of Sections 4.1 and 4.2 so that both improving tasks boil down to exhibiting a randomized or deterministic family of graphs.

We say that an infinite family of graphs $\mathcal{C}$ is *non-disappearing* if there is a constant $K \in (0,1]$ such that for every positive integer n, there is a graph $G \in \mathcal{C}$ with at least Kn and at most n/K vertices. A non-disappearing family is called *efficient* if there is a polynomial-time algorithm which given an integer n (encoded in unary), outputs such a graph G. For example, a family containing at least one graph for every number of vertices is non-disappearing. We denote by $\mathcal{G}_\gamma$ the set of all graphs with girth at least γ.

▶ **Theorem 24.** *Let $\gamma > 3$ be an integer, $\delta \in (0,1)$ be a real (allowed to depend on γ), and $\mathcal{C}$ be an efficient non-disappearing family included in $\mathcal{G}_\gamma$, such that for every $G \in \mathcal{C}$ there is no disjoint pair of sets $A, B \subseteq V(G)$ satisfying both $|A| = |B| \geqslant |V(G)|^\delta$ and $E(A,B) = \emptyset$. Then MIS in $\mathcal{G}_\gamma$ cannot be $n^{\frac{1-\delta}{2}-\varepsilon}$-approximated, unless $P = NP$.*

Proof. We assume all the preconditions hold and follow the construction of Theorems 18 and 22. We again draw a graph F from graphs of size N and gap $N^{1-\varepsilon}$. We substitute every vertex v by an independent set $I(v)$ of size between $KN^{\frac{1+\delta}{1-\delta}}$ and $\frac{1}{K}N^{\frac{1+\delta}{1-\delta}}$ such that there is a $G \in \mathcal{C}$ of the same size as the obtained graph G', and the sets $I(v)$ are balanced (their size differs by at most 1). Both graphs have $\Theta(N^{\frac{1+\delta}{1-\delta}+1}) = \Theta(N^{\frac{2}{1-\delta}})$ vertices, say $cN^{\frac{2}{1-\delta}}$.

We arbitrary identify the vertices of G and G' in a one-to-one mapping. We keep an edge between two vertices u and v if uv is both an edge in G and G'. Thus we do the "intersection" of G and G'. We call J the final result.

Since G has girth at least γ, J has also girth at least γ. By assumption on $\mathcal{C}$, if there is an edge between u and v in F, then for every $A \subset I(u)$ and $B \subset I(v)$ both of size $c^\delta N^{\frac{2\delta}{1-\delta}}$, there is at least one edge in $E_J(A,B)$. We observe that $N^{\frac{2\delta}{1-\delta}} = N^{\frac{1+\delta}{1-\delta}-1}$ which is, up to constant multiplicative factors, the size of an $I(w)$ divided by N. Therefore we have the same important property as in Theorems 18 and 22. Thus we can finish the proof similarly, and conclude that distinguishing between instances with independence number at most $N^{\frac{1+\delta}{1-\delta}+\varepsilon}$ or at least $N^{\frac{2}{1-\delta}-\varepsilon}$ is NP-hard, for an arbitrary small $\varepsilon > 0$. The gap is $N^{1-\varepsilon}$ and $n := |V(J)| = \Theta(N^{\frac{2}{1-\delta}})$, hence a gap of $n^{\frac{1-\delta}{2}-\varepsilon}$. ◀

We now give a randomized counterpart of the previous theorem. For any integer $\gamma > 3$ and real $\delta \in (0,1)$, we say that a distribution of graphs $\mathcal{D}$ is (γ,δ)-*appropriate* if there is a constant $K \in (0,1]$ and a polynomial-time algorithm, that given an integer n (encoded in unary), draws a graph G of size at least Kn and at most n/K out of this distribution such that with high probability, G has girth at least γ and no disjoint pair of sets $A, B \subseteq V(G)$ satisfies both $|A| = |B| \geqslant |V(G)|^\delta$ and $E(A,B) = \emptyset$.

▶ **Theorem 25.** *Let $\gamma > 3$ be an integer, $\delta \in (0,1)$ be a real (allowed to depend on γ), and $\mathcal{D}$ be a (γ,δ)-appropriate distribution. Then MIS in $\mathcal{G}_\gamma$ cannot be $n^{\frac{1-\delta}{2}-\varepsilon}$-approximated, unless NP $\subseteq$ BPP.*

Proof. The proof is the same as Theorem 24, using a graph drawn from the distribution $\mathcal{D}$ instead of a deterministic one from $\mathcal{C}$. Therefore we need the stronger assumption that NP is not contained in BPP. ◀

There are many constructions, all randomized, of triangle-free graphs with smallest possible independence number $\tilde{O}(\sqrt{n})$ [17, 29, 18, 28, 7]. These constructions all follow a simple scheme of starting from the empty graph, ordering the edges of the clique K_n, and then inserting an edge if it does not create a triangle, either among the inserted edges or among all the previous edges. The real difficulty is in the analysis of this probabilistic experiment. The logarithmic or constant factors were improved and the proofs simplified until Kim obtained a matching bound of $O(\sqrt{n \log n})$ [28]. This can be seen as the lower bound of $\Omega(n^2/\log n)$ for the off-diagonal Ramsey number $R(3,n)$, matching the upper bound $O(n^2/\log n)$ of Ajtai et al. [1].

To apply Theorem 25, we would need to check that the triangle-free graphs built in the aforementioned papers do not contain the complement of a large biclique K_{n^δ,n^δ}. As, for our purposes, we do not need the optimal bound of Kim, we follow the original proof of Erdős [17] giving the bound of $O(\sqrt{n}\log n)$. Going through all the lemmas and replacing occurrences of K_x, where $x = O(\sqrt{n}\log n)$, by $K_{x,x}$, the desired result can be obtained. In our language, the process described in the previous paragraph yields a $(4,1/2)$-appropriate distribution. This together with Theorem 25 improves the inapproximability of Theorem 18.

▶ **Corollary 26.** *MIS in $\mathcal{G}_4$ (i.e., triangle-free graphs) cannot be $n^{\frac{1}{4}-\varepsilon}$-approximated, unless NP $\subseteq$ BPP.*

We are not aware of any explicit deterministic construction of triangle-free graphs whose complements do not contain $K_{n^{2/3},n^{2/3}}$ as a subgraph (which would derandomize Theorem 18), let alone, $K_{\sqrt{n},\sqrt{n}}$. Deterministic constructions of graphs with large girth and large chromatic number, such as Ramanujan graphs with non-constant degree, might give some lower bound

via Theorem 24, but not as good as Corollary 26. Actually, being based on a tight construction, the inapproximability of Corollary 26 can only be improved via a totally different route. One should also not completely rule out that there is an $n^{1/4}$-approximation for MIS on triangle-free graphs.

5 Concluding remarks

The Erdős-Hajnal conjecture has proven particularly difficult. For example, the cases of P_5-free or C_5-free graphs are both wide open. For the few graphs H for which a proof that the Erdős-Hajnal property holds, it appears that the proof comes with an efficient algorithm reporting a sufficiently large independent set or clique. This is what we called the constructive Erdős-Hajnal property. We proposed a first and more humble step (see Theorem 6) in proving that a graph H has the constructive Erdős-Hajnal property: show that MIS in H-free graphs can be approximated within ratio $n^{1-\varepsilon}$ for an $\varepsilon > 0$, an unachievable ratio in general graphs. As mentioned in the introduction, this is strictly simpler than Erdős-Hajnal considering the case of P_5. Yet it does not seem to us that this weaker conjecture is that much simpler now considering the graph C_5. We believe that efforts to settle the improved approximation conjecture might turn out useful to make progress on the Erdős-Hajnal conjecture. In general, a cross-fertilization between Approximability Theory and the study of favorable Ramsey properties may prove fruitful. In particular, obtaining an $n^{0.99}$-approximation algorithm for MIS in C_5-free seems like a challenging open question.

Of course, classifying the approximability of Maximum Independent Set in H-free graphs is also an interesting task by its own means. On the one hand, already known reductions rule out PTASes in most H-free graphs classes, namely for any connected H different from a path or a subdivision of a claw. On the other hand, a constant-approximation algorithm can be turned into a PTAS in many H-free classes, by running the approximation on the input graph elevated to some appropriate power (using for instance the lexicographic product). This trick, originally used to rule out approximation algorithms for Max Clique in general graphs [20], works in the setting of H-free classes when H satisfies some properties, such as being a prime graph (i.e., having no non-trivial module). Hence, although MIS admits a constant-factor approximation in $K_{1,t}$-free graphs for any $t \in \mathbb{N}$ (as mentioned in Section 3), it is not in APX when the forbidden graph is a simple tree, such as the 1-subdivision of $K_{1,4}$. Finally, another interesting consequence of the previous observation concerns P_t-free graphs: any constant-factor approximation for MIS in P_t-free graphs implies a PTAS (notice that the current "best" approximation algorithm in P_t-free graphs is a quasi-polynomial approximation scheme [13]).

Abstract

Let G be a graph and T_1, T_2 be two spanning trees of G. We say that T_1 can be transformed into T_2 via an edge flip if there exist two edges $e \in T_1$ and f in T_2 such that $T_2 = (T_1 \setminus e) \cup f$. Since spanning trees form a matroid, one can indeed transform a spanning tree into any other via a sequence of edge flips, as observed in [11].

We investigate the problem of determining, given two spanning trees T_1, T_2 with an additional property Π, if there exists an edge flip transformation from T_1 to T_2 keeping property Π all along.

First we show that determining if there exists a transformation from T_1 to T_2 such that all the trees of the sequence have at most k (for any fixed $k \geq 3$) leaves is PSPACE-complete.

We then prove that determining if there exists a transformation from T_1 to T_2 such that all the trees of the sequence have at least k leaves (where k is part of the input) is PSPACE-complete even restricted to split, bipartite or planar graphs. We complete this result by showing that the problem becomes polynomial for cographs, interval graphs and when $k = n - 2$.

1 Introduction

Given an instance of some combinatorial search problem and two of its feasible solutions, a *reconfiguration problem* asks whether one solution can be transformed into the other in a step-by-step fashion, such that each intermediate solution is also feasible. Reconfiguration problems capture dynamic situations, where some solution is in place and we would like to move to a desired alternative solution without becoming infeasible. A systematic study of the complexity of reconfiguration problems was initiated in [11]. Recently the topic has gained a lot of attention in the context of constraint satisfaction problems and graph problems, such as the independent set problem, the matching problem, and the dominating set problem. Reconfiguration problems naturally arise for operational research problems but also are closely related to uniform sampling using Markov chains (see e.g. [5]) or enumeration of solutions of a problem. Reconfiguration problems received an important attention in the last few years. For an overview of recent results on reconfiguration problems, the reader is referred to the surveys of van den Heuvel [14] and Nishimura [13].

In this paper, our reference problem is the spanning tree problem. Let $G = (V, E)$ be a connected graph on n vertices. A *spanning tree* of G is a tree (chordless graph) with exactly $n - 1$ edges. Given a tree T, a vertex v is a *leaf* if its degree is one and is an *internal node* otherwise. A *branching node* is a vertex of degree at least three.

In order to define valid step-by-step transformations, an adjacency relation on the set of feasible solutions is needed. Depending on the problem, there may be different natural choices of adjacency relations. Let T_1 and T_2 be two spanning trees of G. We say that T_1 and T_2 differs by an *edge flip* if there exist $e_1 \in E(T_1)$ and $e_2 \in E(T_2)$ such that $T_2 = (T_1 \setminus e_1) \cup e_2$. Two trees T_1 and T_2 are adjacent if one can transform T_1 into T_2 via an edge flip. A *transformation* from T_s to T_t is a sequence of trees $\langle T_0 := T_\mathsf{s}, T_1, \ldots, T_r := T_\mathsf{t} \rangle$ such that two consecutive trees are adjacent. Ito et al. [11] remarked that any spanning tree can be transformed into any other via a sequence of edge flips. It easily follows from the exchange properties for matroid. Unfortunately, the problem becomes much harder when we add some restriction on the intermediate spanning trees. One can then ask the following question: does it still exist a transformation when we add some constraints on the spanning tree? If not, is it possible to decide efficiently if such a transformation exists? This problem was already studied for vertex modification between Steiner trees [12] for instance.

In this paper, we consider spanning trees with restrictions on the number of leaves. More precisely, what happens if we ask the number of leaves to be large (or small) all along the transformation? We formally consider the following problems:

Spanning Tree with Many Leaves
Input: A graph G, an integer k, two trees T_1 and T_2 with at least k leaves.
Output: yes if and only if there exists a transformation from T_1 to T_2 such that all the intermediate trees have at least k leaves.

In the Spanning Tree with At Most k Leaves problem, we instead want to find a transformation such that all the intermediate trees have at most k leaves (where k is a fixed constant).

Our results

We prove that both variants are PSPACE-complete. In other words, we show that Spanning Tree with Many Leaves and Spanning Tree with At Most k Leaves for every $k \geq 3$ are PSPACE-complete. This constrasts with many existing results on reconfiguration problems using edge flips which are polynomial such as matching reconfiguration [11], cycle, tree or clique reconfiguration [8]. As far as we know there does not exist any PSPACE-hardness proof for any problem via edge flip. We hope that our results will help to design more.

▶ **Theorem 1.** *Spanning Tree with Many Leaves is PSPACE-complete restricted to bipartite graphs, split graphs or planar graphs.*

These results are obtained from two different reductions. In both reductions, we need an arbitrarily large number of leaves in order to make the reduction work. In particular, one can ask the following question: is Spanning Tree with at least $n - k$ Leaves hard for some constant k (where n is the size of the instance)? We do not answer this question but we prove that, for the "dual" problem, the PSPACE-hardness is obtained even for $k = 3$.

▶ **Theorem 2.** *Spanning Tree with At Most k Leaves is PSPACE-complete for every $k \geq 3$.*

This proof is the most technically involved proof of this article and is based on a reduction from the decision problem of Vertex Cover to the decision problem of Hamiltonian Path. Let (G, k) be an instance of Vertex Cover. We first show that, on the graph H obtained when we apply this reduction, we can associate with any spanning tree T of H a vertex cover of G. The hard part of the proof consists in showing that *(i)* if T has at most three leaves, then the vertex cover associated with T has at most $k + 1$ vertices; and *(ii)* each edge flip consists of a modification of at most one vertex of the associated vertex cover.

One can note that for $k = 2$, the problem becomes the Hamiltonian Path Reconfiguration problem. We were not able to determine the complexity of this problem and we left it as an open problem.

We complete these results by providing some polynomial-time algorithms:

▶ **Theorem 3.** *Spanning Tree with Many Leaves can be decided in polynomial time on interval graphs, on cographs, or if the number of leaves is $n - 2$.*

We show that Spanning Tree with Many Leaves can be decided in polynomial time if the number of leaves is $n - 2$. As we already said, we left as an open question to determine if this result can be extended to any value $n - k$ for some fixed k. If such an algorithm exists, is it true that the problem is FPT parameterized by k?

We then show that in the case of cographs, the answer is always positive as long as the number of leaves is at most $n - 3$. Since there is a polynomial-time algorithm to decide the problem when $k = 2$ that completes the picture for cographs.

Since the problem is known to be PSPACE-complete for split graphs by Theorem 1 (and thus for chordal graphs), the interval graphs result is the best we can hope for in a sense. The interval graph result is based on a dynamic programming algorithm inspired by [2] where it is proved that the Independent Set Reconfiguration problem in the token sliding model is polynomial. Even if dynamic algorithms work quite well to decide combinatorial problems on interval (and even chordal) graphs, they are much harder to use in the reconfiguration setting. In particular, many reconfiguration problems become hard on chordal graphs (see e.g. [1, 9]) since the transformations can go back and forth.

Since the problem is hard on planar graphs, it would be interesting to determine its complexity on outerplanar graphs. We left this question as an open problem.

Related work

In the last few years, many graph reconfiguration problems have been studied through the lens of edge flips such as matchings [11, 4], paths or cycles [8]. None of these works provide any PSPACE-hardness results, only a NP-hardness result is obtained for (non Hamiltonian) path reconfiguration via edge flips in [8]. Even if the reachability problem is known to be polynomial in many cases, approximating the shortest transformation is often hard, see e.g. [4]. Flips are also often considered in computational geometry, for instance to measure the distance between two triangulations. In that setting, a flip of a triangulation is the modification of a diagonal of a C_4 for the other one. Usually, proving the existence of a transformation is straightforward and the main questions are about the length of a transformation which is not the problem addressed in this paper.

If, instead of "edge flips", we consider "vertex flips" the problems become much harder. For instance, the problem consisting in transforming an (induced) tree into another one (of the same size) is PSPACE-complete [8] (while the exchange property ensures that it is polynomial for the edge version). Mizuta et al. [12] also showed that the existence of vertex exchanges between two Steiner trees is PSPACE-complete. But transforming subsets of vertices with some properties is known to PSPACE-complete for a long time, for instance for independent sets or cliques [10].

Definitions

Given two sets S_1 and S_2, we denote by $S_1 \triangle S_2$ the *symmetric difference* of the sets S_1 and S_2, that is $(S_1 \setminus S_2) \cup (S_2 \setminus S_1)$.

For a spanning tree T, every vertex of degree one is a *leaf* and every vertex of degree at least two is an *internal node*. A vertex of degree at least three is called a *branching node*. Recall that the number of leaves of any tree T is equal to $(\sum_{v \in T}(\max\{0, d_T(v) - 2\})) + 2$. We denote by $in(T)$ the number of internal nodes of T. Note that if T contains n nodes, the number of leaves is indeed $n - in(T)$.

Let $G = (V, E)$ be a graph. A *vertex cover* C of G is a subset of vertices such that for every edge $e \in E$, C contains at least one endpoint of e. C is *minimum* if its cardinality is minimum among all vertex covers of G. Note that in particular, C is inclusion-wise minimal and thus for every vertex $u \in C$, there is an edge $e \in E$ which is covered only by u. We denote by $\tau(G)$ the size of a minimum vertex cover of G.

Let X, Y be two vertex covers of G. X and Y are *TAR-adjacent*[1] (resp. TJ-adjacent) if there exists a vertex x (resp. x and y) such that $X = Y \cup \{x\}$ or $Y = X \cup \{x\}$ (resp. $X = Y \setminus \{y\} \cup \{x\}$). We will consider the following problem:

Minimum TAR-Vertex Cover Reconfiguration

Input: A graph G, two minimum vertex covers X, Y of size k.

Output: yes if and only if there exists a sequence from X to Y of TAR-adjacent vertex covers, all of size at most $k + 1$.

[1] TAR stands for "Token Additional Removal".

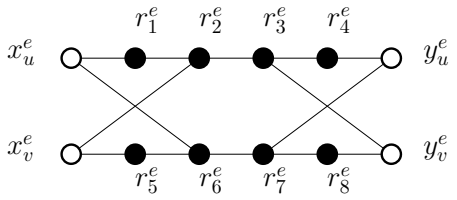

Figure 1 edge-gadget. The white vertices are the only ones connected to the outside.

Similarly, one can define the Minimum TJ-Vertex Cover Reconfiguration (MVCR for short) where we want to determine whether there exists a sequence of TJ-adjacent vertex covers from X to Y. Note that all the vertex covers must be of size $|X| = |Y| = k$.

2 Spanning trees with few leaves

▶ **Theorem 4.** *Spanning Tree with At Most three Leaves is PSPACE-complete.* [2]

In order to prove Theorem 4, we will provide a reduction from Minimum TAR-Vertex Cover Reconfiguration to Spanning Tree with At Most three Leaves.

▶ **Theorem 5** (Wrochna [15])**.** TAR-*Vertex Cover Reconfiguration is PSPACE complete even for bounded bandwidth graphs.*

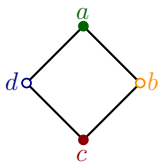
The idea of the proof of Theorem 4 consists in adapting a reduction from Vertex cover to Hamiltonian Path (for the optimization version). Let $(G = (V, E), k)$ be an instance of Vertex Cover. This reduction creates a graph $H(G)$ which contains a Hamiltonian path if and only if G admits a vertex cover of size k. The reduction is given in Section 2.1 together with some properties of the spanning trees with at most three leaves in $H(G)$. In order to adapt the proof in the reconfiguration setting, we need to prove that the proof is "robust" with respect to several meanings of the word. First, we need to show that, if we consider a spanning tree with at most three leaves in $H(G)$ then there is a "canonical" vertex cover of size at most $k + 1$ associated with it (it is the most technical part of the proof). Then, for any edge flip between two spanning trees with at most three leaves, we need to show that the corresponding vertex covers associated with them are TAR-adjacent . We will indeed also need to prove the reverse direction.

2.1 The Reduction

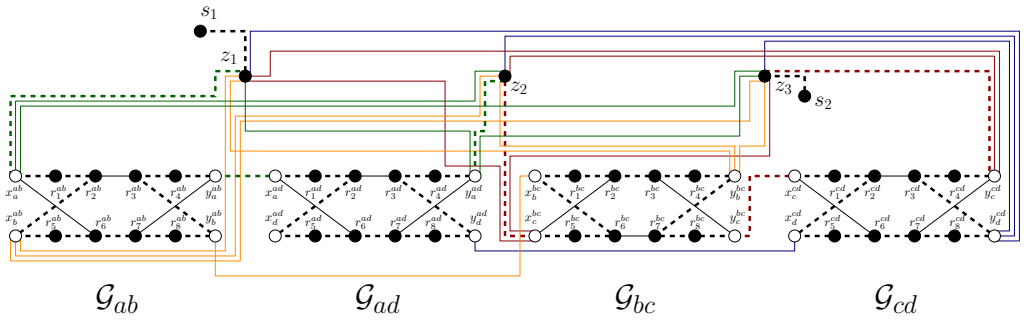
The reduction is a classical reduction (see Theorem 3.4 of [6] for a reference) from the optimization version of Vertex Cover to the optimization version of Hamiltonian Path. Let G be a graph and k be an integer. Let us construct a graph $H(G)$ (abbreviated into H when no confusion is possible) as follows:

Construction of $H(G)$. For each edge $e = uv$ of G, we create the following *edge-gadget* $\mathcal{G}_e$ represented in Figure 1. The edge-gadget $\mathcal{G}_e$ has four *special vertices* denoted by $x_u^e, x_v^e, y_u^e, y_v^e$. The vertices x_u^e and x_v^e are called the *entering vertices* and y_u^e and y_v^e the *exit vertices*. The gadget contains eight additional vertices denoted by $r_1^e, \ldots, r_8^e$. When e is clear from context, we will omit the superscript. The graph induced by these twelve vertices is represented in Figure 1. The vertices $r_1^e, \ldots, r_8^e$ are *local vertices* and their neighborhood will be included in the gadget. The only vertices connected to the rest of the graphs are the special vertices.

[2] Note that the reduction can be easily adapted to more leaves.



(a) Original instance (G, k) of Minimum Vertex Cover with a vertex cover $\{a, b\}$.



(b) Graph $H(G)$ obtained from the reduction. The ordering for the vertices of the vertex cover $\{a, b\}$ of G is the lexicographic ordering, as well as the ordering of the edges incident to each vertex. The corresponding Hamiltonian path is depicted by the thick dashed edges.

Figure 2 Illustration of the reduction of Theorem 4.

We add an independent set $Z := \{z_1, \ldots, z_{k+1}\}$ of $k+1$ new vertices to $V(H)$. And we finally add to $V(H)$ two more vertices s_1, s_2 in such a way that z_1 (resp. z_{k+1}) is the only neighbor of s_1 (resp. s_2) in $H(G)$. Since s_1 and s_2 have degree one in $H(G)$, s_1 and s_2 are leaves in any spanning tree of $H(G)$. In particular, the two endpoints of any Hamiltonian path of $H(G)$ are necessarily s_1 and s_2.

Let us now complete the description of $H(G)$ by explaining how the special vertices are connected to the other vertices of $H(G)$. Let $u \in V(G)$. Let $E' = e_1, \ldots, e_\ell$ be the set of edges incident to u in an arbitrary order. We connect $x_u^{e_1}$ and $y_u^{e_\ell}$ to all the vertices of Z. For every $1 \leq i \leq \ell - 1$, we connect $y_u^{e_i}$ to $x_u^{e_{i+1}}$. The edges $y_u^{e_i} x_u^{e_{i+1}}$ are called the *special edges of* u. The *special edges* of $H(G)$ are the union of the special edges for every $u \in V(G)$ plus the edges incident to Z but $s_1 z_1$ and $s_2 z_{k+1}$. This completes the construction of $H(G)$ (see Figure 2 for an example).

▶ Remark 6. If T is a spanning tree of $H(G)$ with at most ℓ leaves, then at most $\ell - 2$ of them are in $V(H) \setminus \{s_1, s_2\}$.

Let T be a spanning tree of $H(G)$. An edge-gadget is *irregular* if at least one of its twelve vertices is not of degree two in T. An edge-gadget is *regular* if it is not irregular. By abuse of notation we say that $e \in E(G)$ is regular (resp. irregular) if the edge-gadget of e is regular (resp. irregular). A vertex u is *regular* if every edge incident to u is regular. The vertex u is *irregular* otherwise.

Let S be a subset of vertices of $H(G)$. We denote by $\delta_T(S)$ the set of edges with exactly one endpoint in S. When there is no ambiguity, we omit the subscript T. Moreover, if S is the singleton $\{u\}$, we write $\delta_T(u)$ for $\delta_T(\{u\})$. The restriction $T(\mathcal{G}_e)$ of a spanning tree T *around an edge-gadget* $\mathcal{G}_e$ is the set of edges with both endpoints in $\mathcal{G}_e$ plus the edges of $\delta_T(\mathcal{G}_e)$ (which are considered as "semi edge" with one endpoint in $\mathcal{G}_e$).

▶ **Lemma 7.** *Let T be a spanning tree of H and $\mathcal{G}$ be a regular edge-gadget. Then the tree T around the edge-gadget $\mathcal{G}$ is one of the two graphs represented in Figure 3. Note that the graph of Figure 3(b) has to be considered up to symmetry between u and v.*

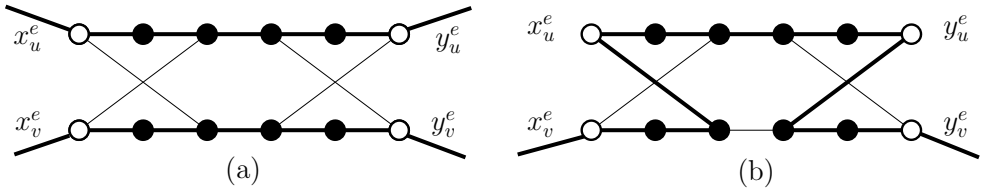


Figure 3 The two possible sub-graphs around a regular edge-gadget $\mathcal{G}$. Bold edges are edges in the tree. Edges with one endpoint in the gadget are edges of $\delta(\mathcal{G})$.

▶ **Lemma 8 (*).** *Let G be a graph, T be a spanning tree of $H(G)$, and u be a regular vertex of T. If there exists an edge $e \in E(G)$ with endpoint u such that x_u^e or y_u^e has degree one in the subgraph of T induced by the vertices of $H[\mathcal{G}_e]$, then, for every edge e' with endpoint u, $x_u^{e'}$ and $y_u^{e'}$ have degree one in the subgraph of T induced by the vertices of $H[\mathcal{G}_{e'}]$.*
In particular, there is an edge of T between Z and the first entering vertex of u and an edge between Z and the last exit vertex of u.

If, for a regular vertex u and an edge $e = uv$, x_u^e or y_u^e have degree one in $H[\mathcal{G}_e]$, then there is a path between two vertices of Z passing through all the special vertices $x_u^{e'}$ and $y_u^{e'}$ for every e' incident to u and all the vertices on this path have degree two. Note that the union of all such vertices forms a vertex cover of G.

2.2 Reconfiguration hardness

Let T be a spanning tree with at most three leaves. By Lemma 7, for every edge-gadget $\mathcal{G}_e$, if $T(\mathcal{G}_e)$ is not one of the two graphs of Figure 3, $\mathcal{G}_e$ contains a branching node or a leaf. So Remark 6 implies:

▶ Remark 9. There are at most two irregular edge-gadgets. Thus there are at most four irregular vertices.

Indeed, if T has two leaves, all the edge-gadgets are regular. If T has three leaves, the third leaf must be in an edge-gadget, creating an irregular edge-gadget. And this leaf might create a new branching node which might be in another edge-gadget than the one of the third leaf. So the number of irregular edge-gadget is at most two, and thus the number of irregular vertices is at most four (if the edges corresponding to these two edge-gadgets have pairwise distinct endpoints).

Let T be a spanning tree of $H(G)$ with at most three leaves. A vertex v is *good* if there exists an edge $e = vw$ for $w \in V(G)$ such that x_v^e or y_v^e has degree one in the subtree of T induced by the twelve vertices of the edge-gadget of e. In other words, if we simply look at the edges of T with both endpoints in $\mathcal{G}_e$, x_v^e or y_v^e has degree one (or said again differently, x_v^e or y_v^e are adjacent to exactly one local vertex). Let us denote by $S(T)$ the set of good vertices. Using the fact that every gadget contains at most one vertex of degree three and one vertex of degree one by Remark 6, we can show:

▶ **Lemma 10 (*).** *Let T be a spanning tree with at most three leaves of $H(G)$ and $e = uv$ be an edge of G. At least one special vertex of the edge-gadget $\mathcal{G}_e$ has degree one in the subgraph of T induced by the vertices of $\mathcal{G}_e$. In particular, $S(T)$ is a vertex cover.*

So, for every tree T with at most three leaves, $S(T)$ is a vertex cover. We say that $S(T)$ is *the vertex cover associated with T*.

The next two technical lemmas ensure that an edge flip transformation provides a TAR-vertex cover reconfiguration sequence.

▶ **Lemma 11 (*).** *Every spanning tree T of $H(G)$ with at most three leaves satisfies $|S(T)| \leq k+1$.*

Sketch of the proof. Assume by contradiction that $|S| \geq k+2$. By Remark 9, at least $k-2$ vertices of S are regular. By Lemma 8, for each regular vertex $w \in S$, there is an edge of T between Z and the first entering vertex of w and Z and the last exit vertex of w. So at least $2k-4$ edges of $\delta_T(Z)$ are incident to regular vertices. Moreover two edges of $\delta_T(Z)$ are incident to s_1 and s_2. So, T already has $2k-2$ edges in $\delta_T(Z)$. Since $|Z| = k+1$ and T has at most three leaves, Remark 6 ensures that $\delta_T(Z)$ has size $2k+1, 2k+2$ or $2k+3$. The main part of the proof, not included in this extended abstract, consists in proving that the edges between Z and entering or exit vertices of irregular vertices is too large. ◀

So the vertex cover $S(T)$ associated with every spanning tree T with at most three leaves has size at most $k+1$. In order to prove that a spanning tree transformation provides a vertex cover transformation for the TAR setting, we have to prove that, for every edge flip, then either S is not modified, or one vertex is added to S or one vertex is removed from S.

▶ **Lemma 12 (*).** *Let T_1 and T_2 be two adjacent trees with at most three leaves. Then the symmetric difference between the sets S associated with the two trees is at most one.*

Lemmas 11 and 12 immediately implies the following:

▶ **Lemma 13.** *If there is an edge flip reconfiguration sequence between two spanning trees T_1 and T_2, then there is a TAR-reconfiguration sequence (with threshold $k+1$) between $S(T_1)$ and $S(T_2)$.*

We refer the reader to the complete version for a proof of the converse direction.

3 Spanning tree with many leaves

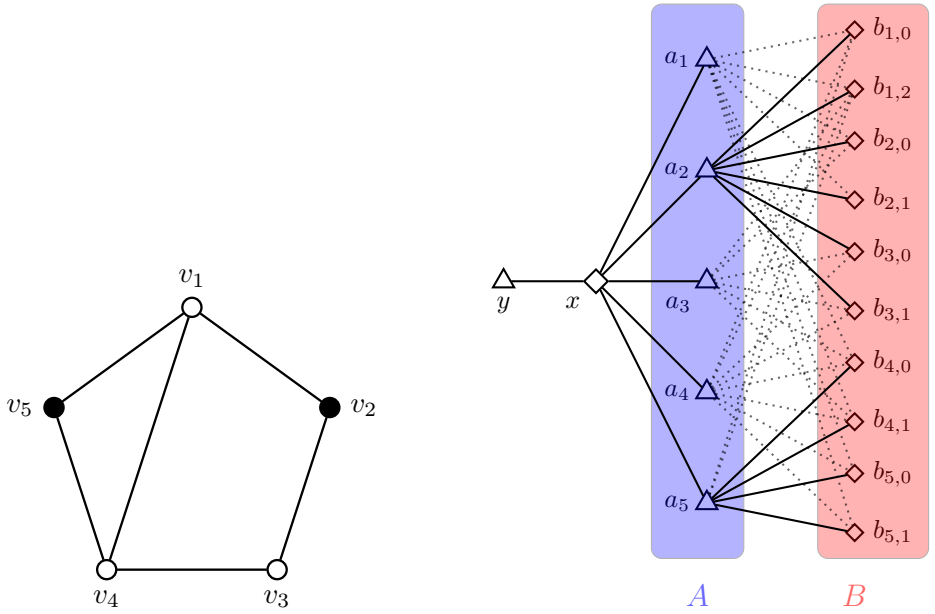
Before stating the main results of this section, let us prove the following:

▶ **Lemma 14 (*).** *Let G be a graph and T_1, T_2 be two trees. There exists a transformation from T_1 to T_2 such that every intermediate tree T satisfies $in(T) \subseteq in(T_1) \cup in(T_2)$.*
In particular, all the trees with the same set of internal nodes are in the same connected component of the reconfiguration graph.

3.1 Hardness results

▶ **Theorem 15.** *Spanning Tree with Many Leaves is PSPACE-complete even restricted to bipartite graphs or split graphs.*

Sketch of the proof. We first briefly explain the proof for bipartite graphs. We provide a polynomial-time reduction from the TAR-Dominating Set Reconfiguration problem (abbreviated in TAR-DSR problem). Haddadan et al [7]. showed that the TAR reconfiguration of dominating sets is PSPACE-complete. More precisely, they proved that given a graph G and D_s, D_t two dominating sets of G, deciding whether there is a reconfiguration sequence between D_s and D_t under the TAR$(\max(|D_s|, |D_t|) + 1)$ rule is PSPACE-complete.



(a) Original graph G. **(b)** Corresponding bipartite graph G'.

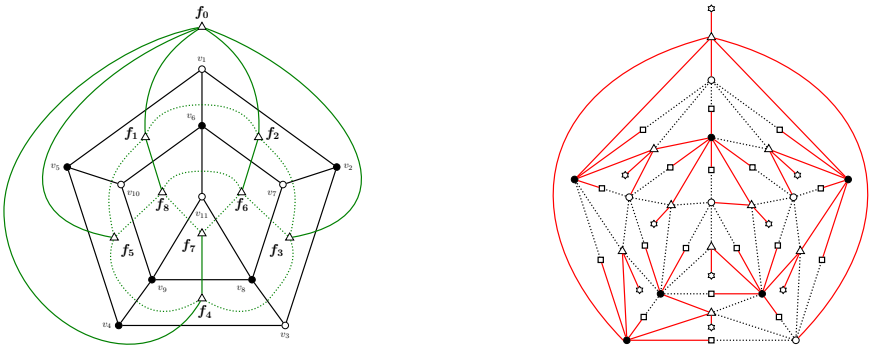
Figure 4 Example for the reduction of Theorem 15: the dominating set $D = \{v_2, v_5\}$ of G is depicted by the black vertices and the spanning tree of G' associated with D is the tree induced by the solid edges. For the split case, we add all the possible edges in $G'[A]$ so that $G'[A \cup \{x\}]$ is a clique and $G'[B \cup \{y\}]$ an independent set.

Let $G = (V, E)$ be a graph with vertex set $V(G) = \{v_1, v_2, \ldots, v_n\}$ and let D_s, D_t be two dominating sets of G. Free to add vertices to the set of smallest size, we can assume without loss of generality that D_s and D_t are both of size k. Let $(G, k+1, D_\mathsf{s}, D_\mathsf{t})$ be the corresponding instance of Dominating Set Reconfiguration under TAR, where $k+1$ is the threshold that we cannot exceed. We construct the bipartite graph G' as follows: we make a first copy $A = \{a_1, a_2, \ldots, a_n\}$ of the vertex set of G, and a second copy $B = \{b_{1,0}, b_{1,1}, b_{2,0}, b_{2,1}, \ldots, b_{n,0}, b_{n,1}\}$ where we double each vertex. We add an edge between $a_i \in A$ and $b_{j,k} \in B$ for $k \in \{0, 1\}$ if and only if $v_j \in N_G[v_i]$. Note that $N(b_{i,0}) = N(b_{i,1})$, for every $1 \leq i \leq n$. We finally add a vertex x adjacent to all the vertices in A and we attach it to a degree-one vertex y. Note that G' is bipartite since $A \cup \{y\}$ and $B \cup \{x\}$ induce two independent sets (see Figure 4 for an illustration).

▷ Claim 16 (*). For every spanning tree T of G', $in(T) \cap A$ is a dominating set of G.

▷ Claim 17 (*). For every spanning tree T of G', there exists a tree T_A in the same connected component of T in the reconfiguration graph such that $in(T_A) \subseteq in(T) \cap (A \cup \{x\})$.

Let D be a dominating set of G of size k. We can associate with D a spanning tree of G' with $k+1$ internal nodes as follows. We attach every vertex in $A \cup \{y\}$ to x. Every vertex $b_i \in B$ is a leaf adjacent to a vertex that dominates v_i in D. If v_i has more than one neighbor in D, we choose the one with the smallest index. This spanning tree is called the *spanning tree associated with* D. Due to space restrictions, the proof that $(G, k+1, D_\mathsf{s}, D_\mathsf{t})$ is yes-instance of TAR-DSR if and only if $(G', k', T_\mathsf{s}, T_\mathsf{t})$ is a yes-instance of Spanning Tree with Many Leaves is not included in this extended abstract.



(a) Original labeled planar graph G. **(b)** Corresponding planar graph G'.

Figure 5 Reduction for Theorem 18. The vertex cover C of G is depicted by the black vertices. The dual graph is the graph induced by the green edges. The spanning tree obtained from the BFS is represented by the solid edges. The face-vertices (respectively edge-vertices) of G' are depicted by triangles (resp. squares). The spanning tree T of G' associated with the vertex cover C is the tree induced by the red edges. The number of leaves of T is $2(|E(G)|+1)-|C| = 32$.

Let us now quickly explain how to adapt this proof for split graphs. We first add an edge between any two vertices in A so that $G'[A]$ is a clique. Then, observe that $G'[A \cup \{x\}]$ is a clique, and $G'[B \cup \{y\}]$ an independent set. The proof that the resulting instance is a yes-instance of Spanning Tree with Many Leaves if and only if $(G, k+1, D_s, D_t)$ is a yes-instance of TAR-DSR is similar to the one for bipartite graphs (see the full version). ◀

▶ **Theorem 18.** *Spanning Tree with Many Leaves is PSPACE-complete even restricted to planar graphs.*

The reduction. First, observe that MVCR is PSPACE-complete, even if the input graph is planar [10][3]. We use a reduction from MVCR, which is a slight adaptation of the reduction used in [12, Theorem 4]. Let $G = (V, E)$ be a planar graph and let (G, C_s, C_t) be an instance of MVCR. We can assume that G is given with a planar embedding of G since such an embedding can be found in polynomial time. Let $F(G)$ be the set of faces of G (including the outer face). We construct the corresponding instance (G', k, T_s, T_t) as follows:

We define G' from G as follows. We start from G and first subdivide every edge $uv \in E(G)$ by adding a new vertex w_{uv}. Then, for every face $f \in F(G)$, we add a new vertex w_f adjacent to all the vertices of the face f. Finally, we attach a leaf u_f to every vertex w_f. Note that G' is a planar graph and $|V(G')| = |V(G)| + |E(G)| + 2 \cdot |F(G)|$. The vertices w_{uv} for $uv \in E$ (resp. w_f for $f \in F$) are *edge-vertices* (resp. *face-vertices*). The vertices u_f for every f are called the *leaf-vertices*. Note that, for every spanning tree T, all the face-vertices are internal nodes of T and all the leaf-vertices are leaves of T. The vertices of $V(G')$ which are neither edge, face of leaf vertices are called *original vertices*. Finally, we choose an arbitrarily ordering of $V(G)$ and F. It will permit us to define later a canonical spanning tree for every vertex cover (see Figure 5 for an example).

▶ **Lemma 19 (*).** *Every spanning tree of G' has at most $2(|E(G)|+1) - \tau(G)$ leaves.*

[3] Actually, Hearn and Demaine [10] showed the PSPACE-completeness for the reconfiguration of maximum independent sets. Since the complement of a maximum independent set is a minimum vertex cover, we directly get the PSPACE-completeness of MVCR.

▶ **Lemma 20 (*).** *For any minimum vertex cover C of $G = (V, E)$, we can define a canonical tree with exactly $k := 2(|E(G)| + 1) - \tau(G)$ leaves which are all the edge-vertices, all the leaf-vertices and all the original vertices but the ones in C. Moreover, this spanning can be computed in polynomial time.*

Recall that (G, C_s, C_t) is an instance of Minimum Vertex Cover Reconfiguration. By Lemma 20, we can compute in polynomial time two spanning trees T_s and T_t from C_s and C_t with $2(|E(G)| + 1) - \tau(G)$ leaves. Finally, we set $k := 2(|E(G)| + 1) - \tau(G))$. Let (G', k, T_s, T_t) be the resulting instance of Spanning Tree with Many Leaves. It remains to prove that (G, C_s, C_t) is a yes-instance if and only (G', k, T_s, T_t) is a yes-instance. Suppose first that we have a reconfiguration sequence S between C_s and C_t. By Lemma 20, we can associate with each vertex cover C_i of S a spanning tree T_i of G'. To show that there is a reconfiguration sequence S' between T_s and T_t, we show that we can transform two consecutive spanning trees of S' without increasing the number of internal nodes. Note that we use the fact that each C_i of S is a minimum vertex cover. For the converse direction, we show that all the edge-vertices of any spanning tree in a reconfiguration sequence S from T_s to T_t is a leaf. Hence, one can directly deduce a vertex cover C_i of G from a spanning tree $T_i \in S$. Finally, we show that *(i)* each vertex cover is of size $\tau(G)$ and; *(ii)* $|C_i \triangle C_{i+1}| \in \{0, 2\}$ for any two consecutive vertex covers.

3.2 Two internal nodes and cographs

Recall that, for every tree, the number of leaves is equal to n minus the number of internal nodes. So, for convenience, our goal would consist in minimizing the number of internal nodes rather than maximizing the number of leaves.

▶ **Theorem 21.** *Let G be a graph and T_s or T_t be two spanning trees with at most two internal nodes. Then we can check in polynomial time if one can transform the other via a sequence of spanning trees with at most two internal nodes.*

Sketch of the proof. If T_s or T_t has one internal node, the problem can be easily decided. So we restrict to the case $|in(T_s)| = |in(T_t)| = 2$. Moreover, if $in(T_s) = in(T_t)$, then (G, k, T_s, T_t) is a yes-instance. So we only consider the case $in(T_s) \neq in(T_t)$.

A vertex u is a *pivot* vertex of G if $\deg u \geq n - 2$ in G ($\deg u$ being the size of the neighborhood of u, u not included). A spanning tree T of G is *frozen* if all the spanning trees in its connected component of the reconfiguration graph have the same internal nodes.

▷ Claim 22 (*). Let T be a spanning tree of G. If $in(T)$ does not contain a pivot vertex, then T is frozen.

▷ Claim 23 (*). Let u be a pivot vertex. All the trees containing u as internal vertex are in the same connected component of the reconfiguration graph.

Using these two claims, we can prove that the result follows. ◀

One can naturally wonder if this can be extended to larger values of k or if it is special for $k = 2$. We left this as an open problem. We were only interested in the case $k = 2$ since it was of particular interest for cographs. Indeed, if $k \geq 3$, one can prove that the answer is always positive for cographs. Together with Theorem 21, it implies:

▶ **Theorem 24 (*).** *Spanning Tree with Many Leaves can be decided in polynomial time on cographs.*

3.3 Interval graphs

A graph G is an *interval graph* if G can be represented as an intersection of segments on the line. More formally, each vertex can be represented with a pair (a, b) (where $a \leq b$) and vertices $u = (a, b)$ and $v = (c, d)$ are adjacent if the intervals (a, b) and (c, d) intersect. Let $u = (a, b)$ be a vertex; a is the *left extremity* of u and b the *right extremity* of u. Given an interval graph, a representation of this graph as the intersection of intervals in the plane can be found in $\mathcal{O}(|V| + |E|)$ time (see e.g. [3]). In the rest of the section we assume that a representation is given.

▶ **Theorem 25.** *Spanning Tree with Many Leaves can be decided in polynomial time on interval graphs.*

The proof techniques are inspired from [2]. The rest of this section is devoted to prove Theorem 25. Moreover, if G is a clique, then G is a cograph and then the problem can be decided in polynomial by Theorem 24. So, from now on, we can assume that G is not a clique and in particular $in(G) \geq 2$.

C-minimum spanning trees. Let k be an integer, G be a graph. We denote by $\mathcal{R}(G, k)$ the edge flip reconfiguration graph of the spanning trees of G with at most k internal nodes.

Let T, T' be two spanning trees with the same set of internal nodes. Lemma 14 ensures that T and T' are in the same connected component of $\mathcal{R}(G, k)$. So in what follows, we will often associate a tree T with its set $in(T)$ of internal nodes.

For every interval graph, we can define a spanning tree T_C called the *canonical tree* which minimizes the number of internal vertices and such that for every i, the right extremity of the i-th internal node is maximized.

A tree T is *C-minimum* if no tree T' in the connected component of T in $\mathcal{R}(G, k)$ contains fewer internal nodes than T. The goal of this part consists in showing that all the trees that are not C-minimum are in the connected component of T_C in $\mathcal{R}(G, k)$. The following lemmas follow from basic transformation on spanning trees:

▶ **Lemma 26 (*).** *Let T be a spanning tree of G and $k \geq in(T)$. If there exist two internal nodes u, v of T such that the interval of u is included in the interval of v then T is not C-minimum in $\mathcal{R}(G, k)$. Moreover a tree with internal nodes included in $in(T) \setminus \{u\}$ in the component of T can be found in polynomial time, if it exists.*

▶ **Lemma 27 (*).** *Let T be a spanning tree of G. If there exist three pairwise adjacent internal nodes u, v, w such that $N[u] \subseteq N[v] \cup N[w]$ then T is not C-minimum. Moreover a tree with internal nodes included in $in(T) \setminus \{u\}$ in the connected component of T can be found in polynomial time.*

Note that if u, v, w induce a triangle, then Lemma 26 or 27 holds. So, free to perform some pre-processing operations, we can assume that the set of internal nodes of a spanning T of G induces a path. Indeed, if an internal node x is incident to three other internal nodes u, v, w, then either at least two of them contain the left extremity (or right extremity) of x, or one interval is strictly included in the interval of x. In the first case there is a triangle and we can apply Lemma 26 or 27. In the second case, we can apply Lemma 26.

▶ **Lemma 28 (*).** *Let G be an interval graph and k be an integer. Any spanning tree T of G satisfying $in(T) < k$ is in the connected component of T_C in $\mathcal{R}(G, k)$.*

Sketch of the proof. The proof consists in showing that we can iteratively increase the number of internal nodes on which T and T_C agree without increasing the number of internal nodes at the end of the sequence (and increase it by at most one during the sequence). ◀

Full access. Let T be a tree such that $in(T)$ induces a path. Recall that the left and right extremities orderings agree. The *leftmost vertex* of T is the vertex of $in(T)$ that is minimal for both l and r. The *i-th internal node* of T is the internal node with the i-th smallest left extremity.

Let G be an interval graph and $v \in V(G)$. The *auxiliary graph* H_v of G on v is defined as follows. The vertex set of H_v is v plus the set W of vertices w which end after v and start after the beginning of v (i.e. vertices whose interval ends after v but does not contain v) plus a new vertex x, called the *artificial vertex*. The set of edges of H_v is the set of edges induced by $G[W \cup \{v\}]$ plus the edge xv.

▷ Claim 29 (*). Let G be an interval graph and v be a vertex of G. The graph H_v is an interval graph.

Let $v \in V(G)$. Every spanning tree of H_v necessarily contains v in its set of internal nodes. Indeed, by construction, the graph H_v contains a vertex x of degree one which is only incident to v. Moreover, v is the leftmost internal node of any spanning tree T of H_v.

Let G be an interval graph, $k \in \mathbb{N}$ and T be a spanning tree with internal nodes I such that $|I| = k$. Let $v \in V(G)$. The *restriction* of a spanning tree T to H_v is any spanning tree of H_v with internal nodes included in $(in(T) \cup \{v\}) \cap V(H_v)$. We denote by k'_v (or k' when no confusion is possible) the value $|(in(T) \cup \{v\}) \cap V(H_v)|$. Let T' be the restriction of T to H_v as defined above. One can easily check that the number of internal nodes of T' is at most k'.

The vertex v is *good* if the restriction of T to H_v is not C-minimum in $\mathcal{R}(H_v, k')$. The vertex v is *normal* otherwise. Let v be a normal vertex. Recall that v is the leftmost internal node of any spanning tree of H_v. Let C be the connected component of the restriction of T to H_v in $\mathcal{R}(H_v, k')$. We denote by $\ell'_v(T)$ the second internal node of a spanning tree of H_v in C that minimizes its left extremity. Similarly we denote by $r'_v(T)$ the second internal node of a spanning tree of H_v in C that maximizes its right extremity. When they do not exist[4], we set $\ell'_v(T) = -\infty$ and $r'_v(T) = +\infty$.

We say that we have *full access to* T if, for every vertex $v \in V(G)$, we have a constant time oracle saying if v is good or normal. And if v is normal, we moreover have a constant time access to $\ell'_v(T)$ and $r'_v(T)$. What remains to be proved is that *(i)* knowing this information for two spanning trees T and T' is enough to determine if they are in the same connected component of $\mathcal{R}(G, k)$, and that *(ii)* this information can be computed in polynomial time.

Dynamic programming algorithm. Let us first state the following useful lemma.

▶ **Lemma 30 (*).** *Let G be an interval graph and $k \in \mathbb{N}$. Let T be a spanning tree of G and v be an internal node of T. Let $J := in(T) \cap V(H_v)$ and $k' = |J|$. If a tree T' with internal nodes J can be transformed into a tree with internal nodes K in $\mathcal{R}(H_v, k')$ then T can be transformed into a tree with internal nodes $(in(T) \setminus J) \cup K$ in $\mathcal{R}(G, k)$.*

In particular, if T' is not C-minimum in $\mathcal{R}(H_v, k')$ then T is not C-minimum in $\mathcal{R}(G, k)$.

Let us now prove that if we have full access to H_v for any v we can determine if T is C-minimum and, if it is, the rightmost possible right extremity of the first internal node of the trees in the connected component of T in $\mathcal{R}(G, k)$.

[4] It is the case if and only if H_v is a clique.

▶ **Lemma 31 (*).** *Let G be an interval graph, $k \in \mathbb{N}$, and T be a spanning tree of G with at most k internal nodes. Assuming full access to T:*

- *We can decide in polynomial time if T is C-minimum in $\mathcal{R}(G,k)$ and,*
- *If T is C-minimum, we can compute in polynomial time the rightmost possible right extremity of the first internal node of a tree in the connected component of T in $\mathcal{R}(G,k)$.*

Sketch of the proof. Let v be the first internal node of T. Since we have full access to T, we can compute $w := \ell'_v(T)$. Lemma 30 ensures that there exists a spanning tree in the component of T in $\mathcal{R}(G,k)$ with second internal node w. We now determine how far we can move to the right the vertex v knowing this vertex. ◀

We say that we have *full access to T after v* if for every vertex $w \in V(G)$ with $w > v$, we have access in constant time to a table that permits us to know whether w is good or normal. And if w is normal, we also have access to $\ell'_w(T)$ and $r'_w(T)$. Using a proof similar to the one of Lemma 31, one can prove the following:

▶ **Lemma 32 (*).** *Let G be an interval graph, $k \in \mathbb{N}$, $v \in V(G)$ and T be a spanning tree of G with at most k internal nodes.*

- *We can decide in polynomial time if v is good if we have full access to T after v.*
- *If T is C-minimum, we can moreover compute $r'_v(T)$ and $\ell'_v(T)$ in polynomial time.*

Lemmas 32 ensures that we can, using backward induction on the ordering of the vertices, decide in polynomial time for all the vertices v of the graph if a vertex is good and if not we can compute $r'_v(T)$ and $\ell'_v(T)$. So we have full access to T in polynomial time.

▶ **Lemma 33 (*).** *Let G be an interval graph and v be a vertex of G. Let T_1, T_2 be two spanning trees of G with internal nodes I_1 and I_2 of H_v such that v is normal for both T_1 and T_2. Let $i_1 := r'_v(I_1)$ and $i_2 := r'_v(I_2)$. The trees T_1 and T_2 are in the same connected component of H_v if and only if:*

- *$i_1 = i_2$ and,*
- *Any spanning trees with internal nodes $(I_1 \setminus \{v\}) \cup \{i_1\}$ and $(I_2 \setminus \{v\}) \cup \{i_2\}$ are in the same connected component of $\mathcal{R}(H_{i_1}, k)$.*

We now have all the ingredients to prove Theorem 25.

Proof of Theorem 25. We can determine in polynomial time if the spanning trees are C-minimum by Lemma 31. If both of them are not, then both of them can be reconfigured to T_C and there exists a transformation from T_1 to T_2 by Lemma 31. If only one of them is, say T_1, we can replace T_1 by T_C (since they are in the same connected component in the reconfiguration graph). So we can assume that T_1 and T_2 are C-minimum. And the conclusion follows by Lemma 33. ◀

Abstract

Consider the natural question of how to measure the similarity of curves in the plane by a quantity that is *invariant under translations* of the curves. Such a measure is justified whenever we aim to quantify the similarity of the curves' *shapes* rather than their positioning in the plane, e.g., to compare the similarity of handwritten characters. Perhaps the most natural such notion is the (discrete) *Fréchet distance under translation*. Unfortunately, the algorithmic literature on this problem yields a very pessimistic view: On polygonal curves with n vertices, the fastest algorithm runs in time $\mathcal{O}(n^{4.667})$ and cannot be improved below $n^{4-o(1)}$ unless the Strong Exponential Time Hypothesis fails. Can we still obtain an implementation that is efficient on realistic datasets?

Spurred by the surprising performance of recent implementations for the Fréchet distance, we perform algorithm engineering for the Fréchet distance under translation. Our solution combines fast, but inexact tools from continuous optimization (specifically, branch-and-bound algorithms for global Lipschitz optimization) with exact, but expensive algorithms from computational geometry (specifically, problem-specific algorithms based on an arrangement construction). We combine these two ingredients to obtain an *exact decision* algorithm for the Fréchet distance under translation. For the related task of computing the distance *value* up to a desired precision, we engineer and compare different methods. On a benchmark set involving handwritten characters and route trajectories, our implementation answers a typical query for either task in the range of a few milliseconds up to a second on standard desktop hardware.

We believe that our implementation will enable, for the first time, the use of the Fréchet distance under translation in applications, whereas previous algorithmic approaches would have been computationally infeasible. Furthermore, we hope that our combination of continuous optimization and computational geometry will inspire similar approaches for further algorithmic questions.

1 Introduction

Consider the following natural task: Given two handwritings of (the same or different) characters, represented as polygonal curves π, σ in the plane, determine how similar they are. To measure the similarity of two such curves, several distance notions could be used, where the most popular measure in computational geometry is given by the *Fréchet distance* $d_F(\pi, \sigma)$: Intuitively, we imagine a dog walking on π and its owner walking on σ, and define $d_F(\pi, \sigma)$ as the *shortest leash length* required to connect the dog to its owner while both walk along their curves (only forward, but at arbitrarily and independently variable speeds). In this paper, we focus on the *discrete* version, in which dog and owner do not continuously walk along the curves, but jump from vertex to vertex.[1] As a fundamental curve similarity notion that takes into account the *sequence* of the points of the curves (rather than simply the set of points, as in the simpler notion of the Hausdorff distance), the discrete Fréchet distance and variants have received considerable attention from the computational geometry community, see, e.g. [4, 19, 12, 17, 3, 8, 11, 15]. While the fastest known algorithms take time $n^{2\pm o(1)}$ on polygonal curves with at most n vertices [4, 19, 3, 11] – which is best possible under the Strong Exponential Time Hypothesis [8] – a recent line of research [6, 13, 18, 10] gives fast implementations for practical input curves.

In the setting of handwritten characters, one would expect our notion of similarity to be *invariant under translations* of the curves; after all, translating one character in the plane while fixing the position of the other should not affect their similarity. In this sense, the original Fréchet distance seems inadequate, as it does not satisfy translation invariance. However, we may canonically define a translation-invariant adaptation as the minimum Fréchet distance between π and any translation of σ, yielding the *Fréchet distance under translation*. Note that beyond computing the similarity of handwritten characters, this measure is generally applicable whenever our intuitive notion of similarity is not affected by translations, such as recognition of movement patterns[2]. In some settings, we would expect our notion to additionally be scaling- or rotation-invariant; however, this is beyond the scope of this paper, as already the Fréchet distance under translation presents previously unresolved challenges.

Can we compute the Fréchet distance under translation quickly? The existing theoretical work yields a rather pessimistic outlook: For the discrete Fréchet distance under translation in the plane, the currently fastest algorithm runs in time $\mathcal{O}(n^{4.667})$, and any algorithm requires time $n^{4-o(1)}$ under the Strong Exponential Time Hypothesis [9]. These high polynomial bounds appear prohibitive in practice, and have likely impeded algorithmic uses of this similarity measure. (For the continuous analogue, the situation appears even worse, as the fastest algorithm has a significantly higher worst-case bound of $\mathcal{O}(n^8 \log n)$; we thus solely consider the discrete version in this work.) Given the surprising performance of recent Fréchet distance implementations on realistic curves [35, 10], can we still hope for faster algorithms on realistic inputs also for its translation-invariant version?

Our problem. Towards making the Fréchet distance under translation applicable for practical applications, we engineer a fast implementation and analyze it empirically on realistic input sets. Perhaps surprisingly, our fastest solution for the problem combines inexact

[1] We give a precise definition in Section 2.

[2] One may argue that the similarity of movement patterns also depends on the speed/velocity of the motion. In principle, we can also incorporate such information into any Fréchet-distance-based measure by introducing an additional dimension.

continuous optimization techniques with an exact, but expensive problem-specific approach from computational geometry to obtain an *exact decision* algorithm. We discuss our approach in Section 3 and present the details of our decision algorithm in Section 4. We develop our approach also for the related, but different task to compute the distance value up to a given precision in Section 5, and evaluate our solutions for both settings in comparison to baseline approaches in Section 6.

Further related work. Variations of the distance measure studied in this paper arise by choosing (1) the discrete or continuous Fréchet distance, (2) the dimension d of the ambient Euclidean space, and (3) a class of transformations, e.g., translations, rotations, scaling, or arbitrary linear transformations. A detailed treatment of algorithms for this class of distance measures can be found in [34]. The earliest example of a problem in this class is the continuous Fréchet distance under translations in dimension $d = 2$, which was introduced by Alt et al. [5] together with an $\mathcal{O}(n^8 \log n)$-time algorithm.

In this paper we focus on the discrete Fréchet distance under translation in the plane. This problem was first studied by Mosig and Clausen [31], who gave an $\mathcal{O}(n^4)$ algorithm for approximating the discrete Fréchet distance under rigid motions. Subsequently, Jiang et al. [29] presented an $\mathcal{O}(n^6 \log n)$-time algorithm for the exact Fréchet distance under translation. Their running time was improved by Ben Avraham et al. to $\mathcal{O}(n^5 \log n)$ [7], and then by Bringmann et al. to $\mathcal{O}(n^{4.667})$ [9]. A conditional lower bound of $n^{4-o(1)}$ can be found in [9].

Algorithm engineering efforts for the Fréchet distance were initiated by the SIGSPATIAL GIS Cup 2017 [35], where the task was to implement a nearest neighbor data structure for curves under the Fréchet distance; see [6, 13, 18] for the top three submissions. The currently fastest implementation of the Fréchet distance is due to Bringmann et al. [10]. Further recent directions of Fréchet-related algorithm engineering include k-means clustering of trajectories [14] and locality sensitive hashing of trajectories [16].

2 Preliminaries

Throughout the paper, we consider the Euclidean plane and denote the Euclidean norm by $\|\cdot\|$. A *polygonal curve* π is a sequence $\pi = (\pi_1, \dots, \pi_n)$ of vertices $\pi_i \in \mathbb{R}^2$. For any $\tau \in \mathbb{R}^2$, we write $\pi + \tau$ for the translated curve $(\pi_1 + \tau, \dots, \pi_n + \tau)$.

For any curves $\pi = (\pi_1, \dots, \pi_n), \sigma = (\sigma_1, \dots, \sigma_m)$, we define their *discrete Fréchet distance* as follows. A *traversal* is a sequence $T = ((p_1, s_1), \dots, (p_t, s_t))$ of pairs $(p_i, s_i) \in [n] \times [m]$ such that $(p_1, s_1) = (1, 1)$, $(p_t, s_t) = (n, m)$ and $(p_{i+1}, s_{i+1}) \in \{(p_i+1, s_i), (p_i, s_i+1), (p_i+1, s_i+1)\}$ for all $1 \leq i < t$. The width of a traversal is $\max_{i=1,\dots,|T|} \|\pi_{p_i} - \sigma_{s_i}\|$. The discrete Fréchet distance is then defined as the smallest width over all traversals, i.e.,

$$d_F(\pi, \sigma) := \min_{\text{traversal } T} \max_{i=1,\dots,|T|} \|\pi_{p_i} - \sigma_{s_i}\|.$$

As we only consider the discrete Fréchet distance in this paper, we drop "discrete" in the remainder. To avoid confusion, we also refer to it as the *fixed-translation* Fréchet distance.

As the canonically translation-invariant variant of the discrete Fréchet distance, we define the *discrete Fréchet distance under translation* as $d_{\text{trans-}F}(\pi, \sigma) := \min_{\tau \in \mathbb{R}^2} d_F(\pi, \sigma + \tau)$. We typically view the problem as a two-dimensional optimization problem with objective function $f(\tau) := d_F(\pi, \sigma + \tau)$. Specifically, we consider the task to decide $\min_{\tau \in \mathbb{R}^2} f(\tau) \leq \delta$? (*exact decider*) or to return a value in the range $[(1-\epsilon) \min_{\tau \in \mathbb{R}^2} f(\tau), (1+\epsilon) \min_{\tau \in \mathbb{R}^2} f(\tau)]$ (*approximate value computation*, multiplicative version). In fact, for implementation reasons

(for a discussion, see the full version of the paper), our implementation returns a value in $[\min_{\tau\in\mathbb{R}^2} f(\tau) - \epsilon, \min_{\tau\in\mathbb{R}^2} f(\tau) + \epsilon]$ (*approximate value computation*, additive version) using a straightforward adaptation of our approach.

Apart from a black-box Fréchet oracle answering decision queries $d_F(\pi, \sigma + \tau) \leq \delta$?, our algorithms only exploit the following simple properties:

▶ **Observation 1** (Lipschitz property). *The objective function f is 1-Lipschitz, i.e., $|f(\tau) - f(\tau + \tau')| \leq \|\tau'\|$.*

Proof. Note that for any $\pi_i, \sigma_j, \tau, \tau' \in \mathbb{R}^2$, we have

$$|\|\pi_i - (\sigma_j + \tau + \tau')\| - \|\pi_i - (\sigma_j + \tau)\|| \leq \|\tau'\|$$

by triangle inequality. Thus, the widths of any traversal T for $\pi, \sigma + \tau$ and $\pi, \sigma + \tau + \tau'$ differ by at most $\|\tau'\|$, which immediately yields the observation. ◀

We obtain a simple 2-approximation of the Fréchet distance under translation as follows.

▶ **Observation 2.** *Let $\tau_{\text{start}} := \pi_1 - \sigma_1$ be the translation of σ that aligns the first points of π and σ. Then $d_F(\pi, \sigma + \tau_{\text{start}}) \leq 2 \cdot d_{\textit{trans-}F}(\pi, \sigma)$.*

Analogously, for $\tau_{\text{end}} := \pi_n - \sigma_m$, we have $d_F(\pi, \sigma + \tau_{\text{end}}) \leq 2 \cdot d_{\textit{trans-}F}(\pi, \sigma)$.

Proof. Let $\delta^* := d_{\text{trans-}F}(\pi, \sigma)$ and let τ^* be such that $d_F(\pi, \sigma + \tau^*) = \delta^*$, which implies in particular that $\|\pi_1 - (\sigma_1 + \tau^*)\| \leq \delta^*$. Thus, $\|\tau_{\text{start}} - \tau^*\| = \|\pi_1 - (\sigma_1 + \tau^*)\| \leq \delta^*$. Thus by Observation 1, we obtain $d_F(\pi, \sigma + \tau_{\text{start}}) \leq d_F(\pi, \sigma + \tau^*) + \delta^* = 2\delta^*$. ◀

Note that the above observation gives a formal guarantee of a simple heuristic: translate the curves such that the start points match, and compute the corresponding fixed-translation Fréchet distance. Unfortunately, this worst-case guarantee is tight[3] – a correspondingly large discrepancy is also observed on our data sets.

3 Our Approach: Lipschitz meets Fréchet

To obtain a fast exact decider, we approach the problem from two different angles: First, we review previous problem-specific approaches to the Fréchet distance under translation, all relying on the construction of an arrangement of circles as an essential tool from computational geometry. Second, we cast the problem into the framework of global Lipschitz optimization with its rich literature on fast, numerical solutions. In isolation, both approaches are inadequate to obtain a fast, exact decider (as the arrangement can be prohibitively large even for realistic data sets, and black-box Lipschitz optimization methods cannot return an exact optimum). We then describe how to combine both approaches to obtain a fast implementation of an exact decider for the discrete Fréchet distance under translation in the plane. We evaluate our approach, including comparisons to (typically computationally infeasible) baseline approaches, on a data set that we craft from sets of handwritten character and (synthetic) GPS trajectories used in the ACM SIGSPATIAL GIS Cup 2017 [2, 1]. We believe that our approach will inspire similar combinations of fast, inexact methods from continuous optimization with expensive, but exact approaches from computational geometry also in other contexts.

[3] To see this, take any segment in the plane and let π traverse it in one direction, and σ in the other. Then the heuristic would return as estimate two times the segment length (the distance of the translated end points), while the optimal translation aligns the segments and achieves the segment length as Fréchet distance.

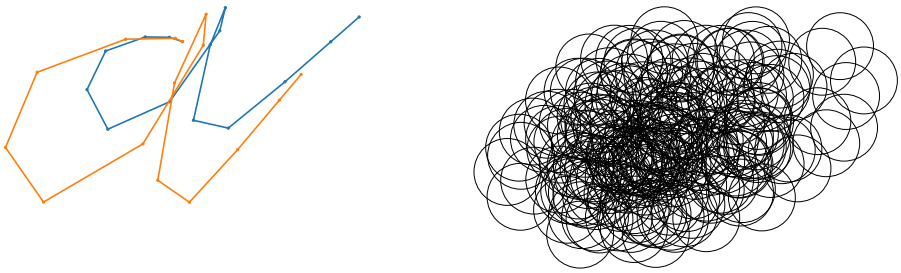

Figure 1 Example curves π, σ (left) together with their arrangement $\mathcal{A}_\delta$ (right), $\delta = d_{\text{trans-}F}(\pi, \sigma)$.

3.1 View I: Arrangement-based Algorithms

Previous algorithms for the Fréchet distance under translation in the plane work as follows. Given two polygonal curves π, σ and a decision distance δ, consider the set of circles

$$\mathcal{C} \coloneqq \{C_\delta(\pi_i - \sigma_j) \mid \pi_i \in \pi,\ \sigma_j \in \sigma\},$$

where $C_r(p)$ denotes the circle of radius $r \in \mathbb{R}$ around $p \in \mathbb{R}^2$. Define the arrangement $\mathcal{A}_\delta$ as the partition of $\mathbb{R}^2$ induced by $\mathcal{C}$. The decision of $d_F(\pi, \sigma + \tau) \leq \delta$ is then uniform among all $\tau \in \mathbb{R}$ in the same face of $\mathcal{A}_\delta$ (for a detailed explanation, we refer to [7, Section 3] or [9]). Thus, it suffices to check, for each face f of $\mathcal{A}_\delta$, an arbitrarily chosen translation $\tau_f \in f$. Specifically, the Fréchet distance under translation is bounded by δ if and only if there is some face f of $\mathcal{A}_\delta$ such that $d_F(\pi, \sigma + \tau_f) \leq \delta$. Since the arrangement $\mathcal{A}_\delta$ has size $\mathcal{O}(n^4)$ and can be constructed in time $\mathcal{O}(n^4)$ [29], using the standard $\mathcal{O}(n^2)$-time algorithm for the fixed-translation Fréchet distance [19, 4] to decide $d_F(\pi, \sigma + \tau_f) \leq \delta$ for each face f, we immediately arrive at an $\mathcal{O}(n^6)$-time algorithm.

Subsequent improvements [7, 9] speed up the decision of $d_F(\pi, \sigma + \tau_f) \leq \delta$ for all faces f by choosing an appropriate ordering of the translations τ_f and designing data structures that avoid recomputing some information for "similar" translations, leading to an $\mathcal{O}(n^{4.667})$-time algorithm. Still, these works rely on computing the arrangement $\mathcal{A}_\delta$ of worst-case size $\Theta(n^4)$, and a conditional lower bound indeed rules out $\mathcal{O}(n^{4-\epsilon})$-time algorithms [9].

Drawback: The arrangement size bottleneck. Despite the worst-case arrangement size of $\Theta(n^4)$ and the conditional lower bound in [9], which indeed constructs such large arrangements, one might hope that realistic instances often have much smaller arrangements. If so, a combination with a practical implementation of the fixed-translation Fréchet distance could already give an algorithm with reasonable running time. Unfortunately, this is not the case: our experiments in this paper exhibit typical arrangement sizes between 10^6 to 10^8 for curves of length $n \approx 200$, see Figure 5 in Section 6. Also see Figure 1 which illustrates a large arrangement already on curves with 15 vertices, subsampled from our benchmark sets of realistic curves.

This renders a purely arrangement-based approach infeasible: As existing implementations for the Fréchet distance typically answer queries within few microseconds, we would expect an average decision time between a few seconds and several minutes already for a single decision query for the Fréchet distance under translation. Thus, a reasonable approximation of the distance value via binary search would take between a minute and over an hour.

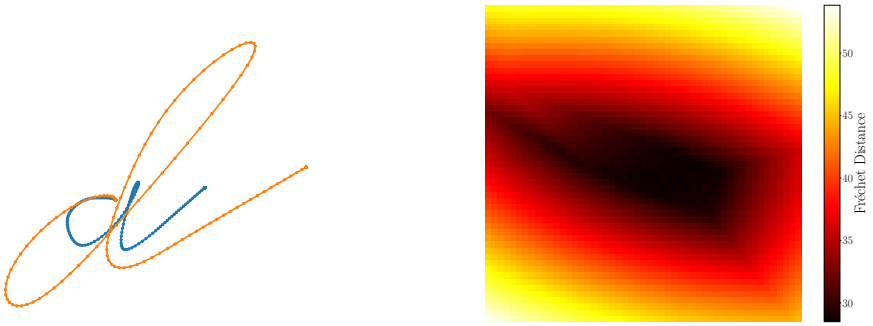

Figure 2 Example curves π, σ (left) together with a plot of the resulting non-convex objective function $f(\tau) = d_F(\pi, \sigma + \tau)$. For a closer look at the area close to the optimal translation (and highly non-convex small-scale artefacts), we refer to Figure 3.

3.2 View II: A Global Lipschitz Optimization problem

A second view on the Fréchet distance under translation results from a simple observation: For any polygonal curves π, σ and any translation $\tau \in \mathbb{R}^2$, we have $|d_F(\pi, \sigma+\tau) - d_F(\pi, \sigma)| \leq \|\tau\|_2$, see Section 2. As a consequence, the Fréchet distance under translation is the minimum of a function $f(\tau) := d_F(\pi, \sigma + \tau)$ that is 1-Lipschitz (i.e., $|f(x) - f(x + y)| \leq \|y\|_2$ for all x, y). This suggests to study the problem also from the viewpoint of the generic algorithms developed for optimizing Lipschitz functions by the continuous optimization community.

Following the terminology of [25], in an *unconstrained bivariate global Lipschitz optimization problem*, we are given an objective function $f : \mathbb{R}^2 \to \mathbb{R}$ that is 1-Lipschitz, and the aim is to minimize $f(x)$ over $x \in B := [a_1, b_1] \times [a_2, b_2]$; we can access f only by evaluating it on (as few as possible) points $x \in B$. Note that in this abstract setting, we cannot optimize f exactly, so we are additionally given an error parameter $\epsilon > 0$ and the precise task is to find a point $x \in B$ such that $f(x) \leq \min_{z \in B} f(z) + \epsilon$.

Global Lipschitz optimization techniques have been studied from an algorithmic perspective for at least half a century [32]. This suggest to explore the use of the fast algorithms developed in this context to obtain at least an *approximate* decider for the discrete Fréchet distance under translation. Indeed, our problem fits into the above framework, if we take the following considerations into account:

(1) Finite Box Domain: While we seek to minimize $f(\tau) = d_F(\pi, \sigma + \tau)$ over $\tau \in \mathbb{R}^2$, the above formulation assumes a finite box domain B. To reconcile this difference, observe that any translation τ achieving a Fréchet distance of at most δ must translate the first (last) point of σ such that the first (last) point of π is within distance at most δ. Thus, any feasible translation τ must be contained in the intersection of the two corresponding disks, and we can use any bounding box of this intersection as our box domain B.

(2) (Approximate) Decision Problem: While we seek to decide "$\min_\tau f(\tau) \leq \delta$", the above formulation solves the corresponding minimization problem. Note that approximate minimization can be used to *approximately* solve the decision problem, but *exactly* solving the decision problem is impossible in the above framework.

(3) Oracle Access to $f(\tau)$: Evaluation of $f(\tau)$ corresponds to computing the Fréchet distance of π and $\sigma + \tau$, for which we can use previous fast implementations [6, 13, 18, 10]. (Actually, these algorithms were designed to answer decision queries of the form "$f(\tau) \leq \delta$?"; we discuss this aspect at the end of this section.)

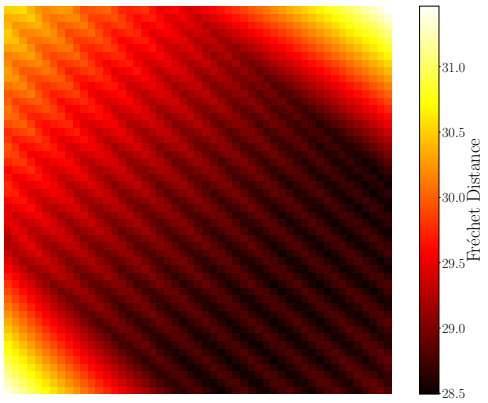

Figure 3 Highly non-convex artefacts of the objective function at a local scale, resulting particularly from the notion of traversals in the *discrete* Fréchet distance.

In Figure 2, we illustrate our view of the Fréchet distance under translation as Lipschitz optimization problem. As the figure suggests, on many realistic instances, the problem appears well-behaved (almost convex) at a global scale; using the Lipschitz property, one should be able to quickly narrow down the search space to small regions of the search space[4]. Particularly for this task, it is very natural to consider branch-and-bound approaches, as pioneered by Galperin [20, 21, 22, 23] and formalized by Horst and Tuy [26, 27, 28], since these have been applied very successfully for low-dimensional Global Lipschitz optimization (and non-convex optimization in general).

On a high level, in this approach we maintain a global upper bound $\tilde{\delta}$ and a list of search boxes $B_1, \ldots, B_b$ with lower bounds $\ell_1, \ldots, \ell_b$ (i.e., $\min_{\tau \in B_i} f(\tau) \geq \ell_i$) obtained via the Lipschitz condition. We iteratively pick some search box B_i and first try to improve the global upper bound $\tilde{\delta}$ or the local lower bound ℓ_i using a small number of queries $f(\tau)$ with $\tau \in B_i$ (and exploiting the Lipschitz property). If the local lower bound exceeds the global upper bound, i.e., $\ell_i > \tilde{\delta}$, we drop the search box B_i, otherwise, we split B_i into smaller search boxes. The procedure stops as soon as $\tilde{\delta} \leq (1+\epsilon) \min_i \ell_i$, which proves that $\tilde{\delta}$ gives a $(1+\epsilon)$-approximation to the global minimum.

Specifically, we arrive at the following branch-and-bound strategy proposed by Gourdin, Hansen and Jaumard [24]. We specify it by giving the rules with which it (i) attempts to update the global upper bound, (ii) selects the next search box from the set of current search boxes, (iii) splits a search box if it remains active after bounding, and (iv) determines the local lower bounds.[5]

- **(i) Upper Bounding Rule:** We evaluate f at the center τ_i of the current search box B_i.
- **(ii) Selection Rule:** We pick the search box with the smallest lower bound (ties are broken arbitrarily).
- **(iii) Branching Rule:** We split the current search box along its longest edge into 2 equal-sized subproblems.
- **(iv) Lower Bounding Rule:** We obtain the local lower bound ℓ_i as $f(\tau_i) - d$ where d is the half-diameter of the current box. (Since f is 1-Lipschitz, we indeed have $\min_{\tau \in B_i} f(\tau) \geq \ell_i$.)

[4] For an illustration that highly non-convex behavior may still occur at a local level, we refer to Figure 3.
[5] See [25] for a precise formalization of the generic branch-and-bound algorithm that leaves open the instantiation of these rules. In any case, we give a self-contained description of our algorithms in Section 4 and 5.

One may observe that the chosen selection rule (also known as Best-Node First) is a no-regret strategy in the sense that no other selection rule, *even with prior knowledge of the global optimum*, considers fewer search boxes (see, e.g., [36, Section 7.4]).

Drawback: Inexactness. Unfortunately, the above branch-and-bound approach for Lipschitz optimization fundamentally cannot return an exact global optimum, and thus yields only an approximate decider.

In a somewhat similar vein, in the above framework we assume that we can evaluate $f(\tau)$ quickly. Previous implementations for the fixed-translation Fréchet distance focus on the decision problem "$f(\tau) \leq \delta$?", not on determining the value $f(\tau)$. Both precise computations (via parametric search) or approximate computations (using a binary search up to a desired precision) are significantly more costly, raising the question how to make optimal use of the cheaper decision queries.

4 Contribution I: An Exact Decider by Combining Both Views

Our first main contribution is engineering an exact decider for the discrete Fréchet distance under translation by combining the two approaches. On a high level, we *globally* perform the branch-and-bound strategy described in the Lipschitz optimization view in Section 3.2, but use as a base case a *local* version of the arrangement-based algorithms of Section 3.1 once the arrangement size in a search box is sufficiently small. As each search box is thus resolved exactly, this yields an exact decider. More precisely, our final algorithm is a result of the following steps and adaptations:

(1) Fréchet Decision Oracle. We adapt the currently fastest implementation of a decider for the continuous fixed-translation Fréchet distance [10] to the discrete fixed-translation Fréchet distance. Furthermore, to handle many queries for the same curve pair *under different translations* quickly, we incorporate an implicit translation so that curves do not need to be explicitly translated for each query translation τ.

(2) Objective Function Evaluation. For our exact decider, the branch-and-bound strategy in Section 3.2 simplifies significantly: We do not maintain a global upper bound and local lower bounds ℓ_i, but for each box only test whether $f(\tau_i) \leq \delta$ (if so, we return YES) or whether $f(\tau_i) > \delta + d$ (this corresponds to updating the local lower bound beyond δ, i.e., we may drop the box completely). Therefore, we may use an arbitrary selection rule. Note that we only require decision queries to the fixed-translation Fréchet algorithm.

(3) Base Case. We implement a *local* arrangement-based algorithm: For a given search box B_i, we (essentially) construct the arrangement $\mathcal{A} \cap B_i$ using CGAL [33], and test, for each face f of $\mathcal{A} \cap B_i$, some translation $\tau' \in f$ for $f(\tau') \leq \delta$. This yields the algorithm that we may use as a base case.

(4) Base Case Criterion. For each search box, we compute an estimate of its arrangement complexity. If this estimate is smaller than a (tunable) parameter γ_{size}, or the depth of the branch-and-bound recursion for the current search box exceeds a parameter γ_{depth}, then we use the localized arrangement-based algorithm.

(5) Benchmark and Choice of Parameters. We choose the size and depth parameters $\gamma_{\text{size}}, \gamma_{\text{depth}}$ guided by a benchmark set that we create from a set of handwritten characters and synthetic GPS trajectories.

The pseudocode of the resulting algorithm is shown in Algorithm 1. For a more detailed description of our Fréchet-under-translation decider, we refer to the full version of this paper.

Algorithm 1 Algorithm for deciding the Fréchet distance under translation. We use τ_B to denote the center of the box B and d_B to denote the length of the diagonal of B.

```

21:     return NO
```

5 Contribution II: Computation of the Distance Value

In this section we present our second main contribution: an algorithm for computing the value of the Fréchet distance under translation. Thus, we now focus on the functional task of computing the value $d_{\text{trans-}F}(\pi,\sigma) = \min_{\tau\in\mathbb{R}^2} d_F(\pi,\sigma+\tau)$, in contrast to the previously discussed decision problem "$d_{\text{trans-}F}(\pi,\sigma) \leq \delta$?". In theory, one could use the paradigm of parametric search [30], see [7, 9] for details for the discrete case. However, it is rarely used in practice as it is non-trivial to code, and computationally costly. Instead, as in most conceivable settings an estimate with small multiplicative error $(1\pm\epsilon)$ with, e.g., $\epsilon = 10^{-7}$, suffices, we consider the problem of computing an estimate in $(1\pm\epsilon)d_{\text{trans-}F}(\pi,\sigma)$.

There are several possible approaches to obtain an approximation with multiplicative error $(1\pm\epsilon)$ for arbitrarily small $\epsilon > 0$:

1. **ϵ-approximate Set:** A natural approach underlying previous approximation algorithms [5] is to generate a set of $f(1/\epsilon)$ candidate translations T such that the best translation $\tau \in T$ gives a $(1+\epsilon)$-approximation for the Fréchet distance under translation. Unfortunately, in the plane such a set is of size $\Theta(1/\epsilon^2)$, which is prohibitively large for approximation guarantees such as $\epsilon = 10^{-7}$.
2. **Binary Search via Decision Problem:** A further canonical approach is to reduce the $(1+\epsilon)$-approximate computation task to the decision problem using a binary search.
3. **Lipschitz-only Optimization:** The main drawback of the generic Lipschitz optimization algorithms discussed in Section 3.2 was that they cannot be used to derive an exact answer. This drawback no longer applies for approximate value computation. We can thus use a pure branch-and-bound algorithm for global Lipschitz optimization. Interestingly,

Algorithm 2 Algorithm of our Lipschitz-Meets-Fréchet (LMF) algorithm for approximate value computation. We use τ_B to denote the center of the box and d_B to denote the length of the diagonal.

procedure LMF(π, σ)
  Preprocessing: build data structures for fast arrangement estimation and construction
  compute initial distance interval $[\delta_{\text{LB}}, \delta_{\text{UB}}]$ containing $d_{\text{trans-}F}(\pi, \sigma)$
  initialize global upper bound $\tilde{\delta} \leftarrow \delta_{\text{UB}}$
  $Q \leftarrow$ PriorityQueue(initial search box B_1 with local lower bound $\ell_{B_1} \leftarrow \delta_{\text{LB}}$)
  while $Q \neq \emptyset$ **do**
    $B \leftarrow$ box with smallest local lower bound ℓ_B in Q
    if $\tilde{\delta} \leq \ell_B(1+\epsilon)$ **then**
      skip B
    if FréchetDistance($\pi, \sigma + \tau_B$) $\leq \tilde{\delta}$ **then** ▷ *Upper/Lower Bounding*
      compute value $d_F(\pi, \sigma + \tau_B)$ with high precision and update $\tilde{\delta}$ and ℓ_B
    else
      if FréchetDistance($\pi, \sigma + \tau_B$) $> \tilde{\delta} + d_B/2$ **then**
        skip B
      compute value $d_F(\pi, \sigma + \tau_B)$ with coarse precision and update ℓ_B
    if $\tilde{\delta} \leq \ell_B(1+\epsilon)$ **then**
      skip B
    $u \leftarrow$ upper bound on arrangement size inside B for $\delta \in [\ell_B, \tilde{\delta}]$
    if $u = 0$ **then** ▷ *Arrangement-based Base Case*
      skip B
    else if $u \leq \gamma_{\text{size}}$ or layer of B is γ_{depth} **then**
      update $\tilde{\delta}$ via binary search over arrangement algorithm on B and $\delta \in [\ell_B, \tilde{\delta}]$
      skip B

    push child boxes of B to Q with local lower bounds set to ℓ_B ▷ *Branching*
  return $\tilde{\delta}$

experiments reveal that on many natural instances, significant time is spent branching inside very small regions. This suggests following our combined approach also for the value computation setting.

4. **Our solution, Lipschitz-meets-Fréchet:** We follow our approach of combining Lipschitz optimization with arrangement-based algorithms (described in Section 3) to compute a $(1+\epsilon)$-approximation of the distance value. As opposed to the decision algorithm, we indeed maintain a global upper bound $\tilde{\delta}$ and local lower bounds ℓ_i for each search box B_i. To update these bounds, we approximately evaluate the objective function $f(\tau)$ using a tuned binary search[6] over the fixed-translation Fréchet decider algorithm. We stop branching in a search box B_i if either the global upper bound $\tilde{\delta}$ is at most $\ell_i(1+\epsilon)$, or a base case criterion similar to the decision setting applies. As selection strategy, we employ the no-regret strategy of choosing the box with the smallest lower bound first. The base case performs a binary search using the local arrangement-based *decision* algorithm; thus, our upper bound on the arrangement size must hold for *all* δ in the search interval. The pseudocode of our solution is shown in Algorithm 2.

[6] We tune the binary search by distinguishing the precision with which we want to evaluate $f(\tau)$; intuitively, it pays off to evaluate $f(\tau)$ with high precision if this evaluation yields a better global upper bound, while for improvements of a local lower bound, a cheaper evaluation with coarser precision suffices.

For a more detailed description of the algorithm, we refer to the full version of this paper. As our experiments reveal, our solution generally outperforms the above described alternatives, see Section 6.

6 Experiments

To engineer and evaluate our approach, we provide a benchmark on the basis of the curve datasets that were used to evaluate the currently fastest fixed-translation Fréchet decider implementation in [10]. In particular, this curve set involves a set of handwritten characters (Characters, [2]) and the data set of the GIS Cup 2017 (Sigspatial, [1]). Table 1 gives statistics of these datasets.

Table 1 Information about the data sets used in the benchmarks.

Data set	Type	#Curves	Mean #vertices
Sigspatial [1]	synthetic GPS-like	20199	247.8
Characters [2]	20 handwritten characters	2858 (142.9 per character)	120.9

The aim of our evaluations is to investigate the following main questions:

1. Is our solution able to decide queries on realistic curve sets in an amount of time that is practically feasible, even when the size of the arrangement suggests infeasibility?
2. Is our combination of Lipschitz optimization and arrangement-based algorithms for value computation superior to the alternative approaches described in Section 5?

Furthermore, we aim to provide an understanding of the performance of our novel algorithms.

Decider experiments. For decision queries of the form "$d_{\text{trans-}F}(\pi,\sigma) \leq \delta$?", we generate a benchmark query set that distinguishes between how close the test distance is to the actual distance of the curves: Given a set of curves C, we sample 1000 curve pairs $\pi, \sigma \in C$ uniformly at random. Using our implementation, we determine an interval $[\delta_{\text{LB}}, \delta_{\text{UB}}]$ such that $\delta_{\text{UB}} - \delta_{\text{LB}} \leq 2 \cdot 10^{-7}$ and $d_{\text{trans-}F}(\pi,\sigma) \in [\delta_{\text{LB}}, \delta_{\text{UB}}]$. For each $\ell \in \{-10, \ldots, -1\}$, we add "$d_{\text{trans-}F}(\pi,\sigma) \leq (1-4^\ell)\delta_{\text{LB}}$?" to the query set C_ℓ^{NO}, which contains only NO instances. Similarly, for each $\ell \in \{-10, \ldots, 2\}$ we add "$d_{\text{trans-}F}(\pi,\sigma) \leq (1+4^\ell)\delta_{\text{UB}}$?" to the query set C_ℓ^{YES}, which contains only YES instances. We depict our timing results in Figure 4 on the Characters and Sigspatial data sets. Further experiments are given in the full version of the paper.

To give an insight for the speed-up achieved over the baseline arrangement-based algorithm that makes a black-box call to the fixed-translation Fréchet decider for each face of the arrangement $\mathcal{A}_\delta$, in Figure 5 we depict both the number of black-box calls to the fixed-translation Fréchet decider made by our implementation, as well as an estimate[7] for the arrangement size, and thus the number of black-box calls of the baseline approach.

[7] We only give an estimate for the arrangement size, since the size of the arrangement is too large to be evaluated exactly for all our benchmark queries within a day. Specifically, we estimate the number of vertices of the arrangement which closely corresponds to the number of faces by Euler's formula. We give the following estimate: We first determine a search box B for the given decision instance $\pi = (\pi_1, \ldots, \pi_n), \sigma = (\sigma_1, \ldots, \sigma_m), \delta$ as described for our algorithm. We then sample $S = 100000$ tuples $i_1, i_2 \in \{1, \ldots, n\}, j_1, j_2 \in \{1, \ldots, m\}$ and count the number I of intersections of the circles of radius δ around $\pi_{i_1} - \sigma_{j_1}$ and $\pi_{i_2} - \sigma_{j_2}$ inside B. The number $(I/S) \cdot (nm)^2$ is the estimated number of circle-circle intersections in B. Adding the number of circle-box intersections, which we can compute exactly, yields our estimate.

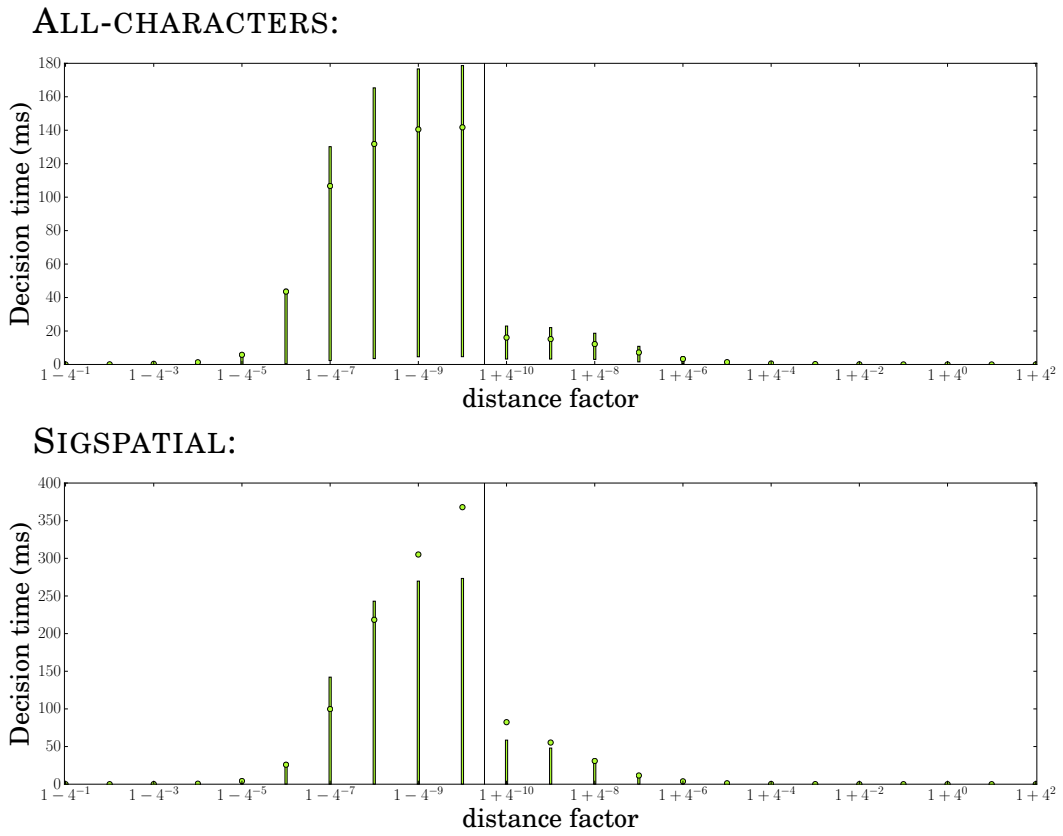

Figure 4 Running time for our decider. We plot the mean running times over 1000 NO (or YES) queries with a test distance of approximately $(1-4^{-\ell})$ (or $(1+4^{-\ell})$) times the true Fréchet distance under translation, as well as the interval between the lower and upper quartile over the queries.

We observe that on the above sets, the average decision time ranges from below 1 ms to 142 ms, deciding our CHARACTERS benchmark (involving 23,000 queries) in 628 seconds. Our estimation suggests that a naive implementation of the baseline arrangement-based algorithm would have been worse by more than *three orders of magnitude*, as for each set, the average number of black-box calls to the fixed-translation Fréchet decider is smaller by a factor of at least 1000 than our estimation of the arrangement size.

Approximate value computation experiments. We evaluate our implementation of the algorithm presented in Section 5 by computing an estimate $\tilde{\delta}$ such that $|\tilde{\delta} - d_{\text{trans-}F}(\pi,\sigma)| \leq \epsilon$ with a choice of $\epsilon = 10^{-7}$.[8] In particular, we compare the performances of the different approaches discussed in Section 5:

- **Binary Search:** Binary search using our Fréchet-under-translation decider of Section 4.
- **Lipschitz-only:** Algorithm 2 without the arrangement, i.e., without lines 18 to 23.
- **Lipschitz-meets-Fréchet (LMF):** Our implementation as detailed in Section 5.

Since simple estimates show that the ϵ-approximate sets are clearly too costly for $\epsilon = 10^{-7}$, we drop this approach from all further consideration. We took care to implement all approaches with a similar effort of low-level optimizations.

[8] Here we use additive rather than multiplicative approximation for technical reasons. Since all computed distances are within $[1.6, 120.7]$, this also yields a multiplicative $(1+\epsilon)$-approximation with $\epsilon \leq 10^{-7}$.

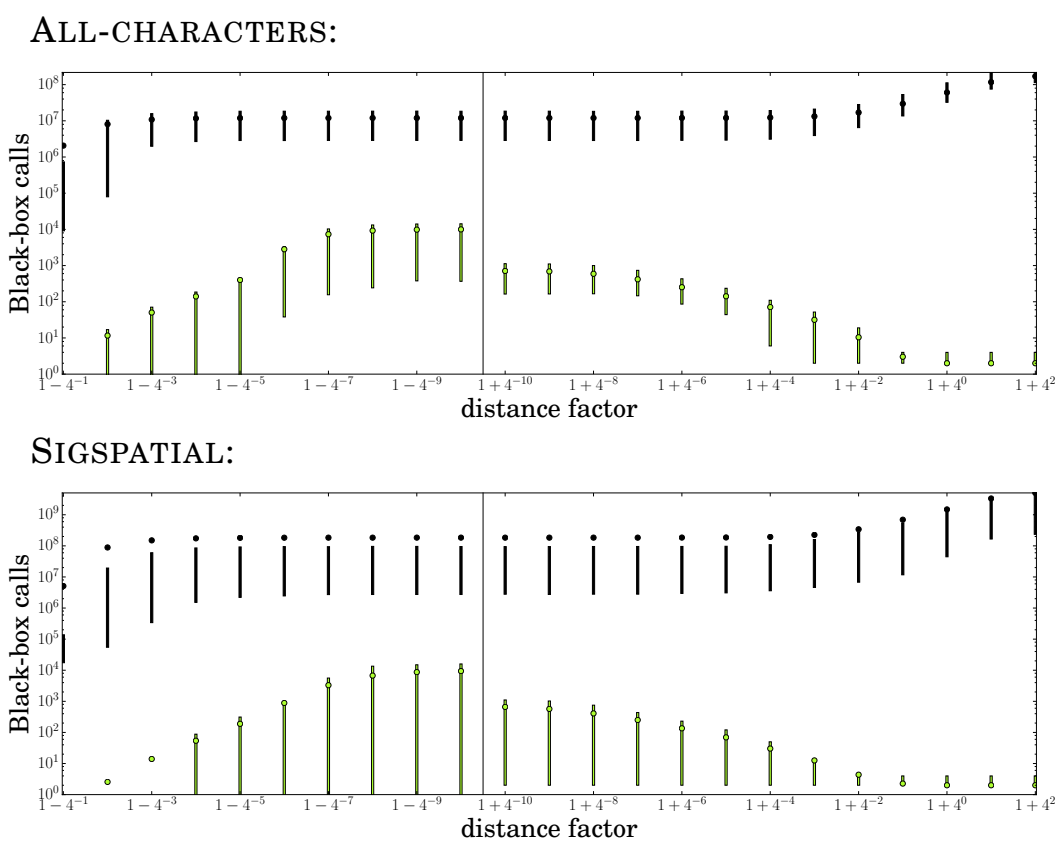

Figure 5 Number of black-box calls to the fixed-translation Fréchet decider made by our decider (below, in green), as well as an estimate of the arrangement complexity, i.e., number of calls of a naive algorithm (above, in black). We plot the mean number of calls and arrangement complexity over 1000 NO (or YES) queries with a test distance of approximately $(1 - 4^{-\ell})$ (or $(1 + 4^{-\ell})$) times the true Fréchet distance under translation, as well as the interval between the lower and upper quartile over the queries.

For our evaluation, we focus on the CHARACTERS data set which allows us to distinguish the rough shape of the curves: We subdivide the curve set into the subsets C_α for $\alpha \in \Sigma$ (where Σ is the set of 20 characters occurring in CHARACTERS). In particular for each character pair $\alpha, \beta \in \Sigma$, we create a sample of N_{samples} curve pairs (π, σ) chosen uniformly at random from $C_\alpha \times C_\beta$. For $N_{\text{samples}} = 5$, computing the value (up to $\epsilon = 10^{-7}$) for all $N_{\text{samples}} \cdot (\binom{|\Sigma|}{2} + |\Sigma|) = 1050$ sampled curve pairs gives the statistics shown in Table 2.

Since already for this example the Lipschitz-only approach is dominated by almost a factor of 30 by LMF (and by a factor of almost 8 by binary search), we perform more detailed analyses with $N_{\text{samples}} = 100$ only for LMF and binary search. The overall performance is given in Table 3. Also here LMF is more than 3 times faster than binary search. To give more insights into the relationship of their running times, we give a scatter plot of the running times of LMF and binary search on the same instances over the complete benchmark in Figure 6, showing that binary search generally outperforms LMF only on instances which are comparably easy for LMF as well. The advantage of LMF becomes particularly clear on hard instances.

We give further experiments in the full version of the paper.

Table 2 Statistics for approximate value computation for $N_{\text{samples}} = 5$. In parentheses we show the mean values averaged over a total of 1050 instances.

Approach	Time	Black-Box Calls
LMF	148,032 ms (141.0 ms per instance)	13,323,232 (12,688.8 per instance)
Binary Search	536,853 ms (511.3 ms per instance)	45,909,628 (43,723.5 per instance)
Lipschitz-only	4,204,521 ms (4,004.3 ms per instance)	820,468,224 (781,398.3 per instance)

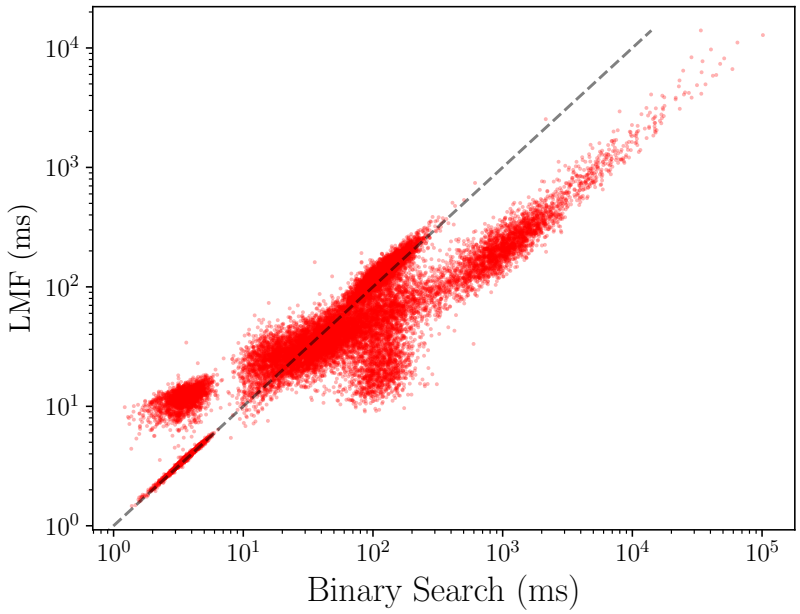

Figure 6 Running times of LMF and binary search on set of randomly sampled CHARACTERS curves.

Table 3 Statistics for approximate value computation for $N_{\text{samples}} = 100$. In parentheses, we give average values over the total of 21,000 curve pairs.

Algorithm	Time		Black-Box Calls
LMF	2,938,512 ms (140.0 ms per instance)		260,128,449 (12,387.1 per instance)
	- Preprocessing	71,728 ms	
	- Black-box calls (Lipschitz)	400,189 ms	
	- Arrangement estimation	166,479 ms	
	- Arrangement algorithm	2,250,493 ms	
	* Construction	1,537,500 ms	
	* Black-box calls	545,442 ms	
Binary Search	10,555,630 ms (502.7 ms per instance)		875,424,988 (41,686.9 per instance)

7 Conclusion

We engineer the first practical implementation for the discrete Fréchet distance under translation in the plane. While previous algorithmic solution for the problem solve it via expensive discrete methods, we introduce a new method from continuous optimization to achieve significant speed-ups on realistic inputs. This is analogous to the success of integer programming solvers which, while optimizing a discrete problem, choose to work over the reals to gain access to linear programming relaxations, cutting planes methods, and more. A novelty here is that we successfully apply such methods to obtain drastic speed-ups for a *polynomial-time problem*.

We leave as open problems to determine whether there are reasonable analogues of further ideas from integer programming, such as cutting plane methods or preconditioning, that could help to get further improved algorithms for our problem. More generally, we believe that this gives an exciting direction for algorithm engineering in general that should find wider applications. A particular direction in this vein is the use of our methods to compute rotation- or scaling-invariant versions of the Fréchet distance. Intuitively, by introducing additional dimensions in our search space, our methods can in principle also be used to optimize over such additional degrees of freedom. However, the Lipschitz condition changes significantly, and it remains subject of future work to determine the applicability of our methods in these settings.

Abstract

Motivated by testing isomorphism of p-groups, we study the alternating matrix space isometry problem (AltMatSpIso), which asks to decide whether two m-dimensional subspaces of $n \times n$ alternating (skew-symmetric if the field is not of characteristic 2) matrices are the same up to a change of basis. Over a finite field $\mathbb{F}_p$ with some prime $p \neq 2$, solving AltMatSpIso in time $p^{O(n+m)}$ is equivalent to testing isomorphism of p-groups of class 2 and exponent p in time polynomial in the group order. The latter problem has long been considered a bottleneck case for the group isomorphism problem.

Recently, Li and Qiao presented an average-case algorithm for AltMatSpIso in time $p^{O(n)}$ when n and m are linearly related (FOCS '17). In this paper, we present an average-case algorithm for AltMatSpIso in time $p^{O(n+m)}$. Besides removing the restriction on the relation between n and m, our algorithm is considerably simpler, and the average-case analysis is stronger. We then implement our algorithm, with suitable modifications, in Magma. Our experiments indicate that it improves significantly over default (brute-force) algorithms for this problem.

1 Introduction

Motivated by testing isomorphism of p-groups, we study the Alternating Matrix Space Isometry (AltMatSpIso) problem. To state this problem, we set up some notation and definitions. Let $[n] = \{1, \ldots, n\}$, and let $\mathrm{M}(n, q)$ be the linear space of $n \times n$ matrices over the finite field $\mathbb{F}_q$ (q is a prime power). A matrix $A \in \mathrm{M}(n, q)$ is *alternating* if for any vector $v \in \mathbb{F}_q^n$, $v^{\mathrm{t}} A v = 0$, where v^{t} denote the transpose of v. (When q is odd, A is alternating if and only if A is *skew-symmetric*, i.e. $A^{\mathrm{t}} = -A$.) Let $\Lambda(n, q)$ be the linear space of all alternating matrices in $\mathrm{M}(n, \mathbb{F}_q)$. Let $\mathcal{A}, \mathcal{B}$ be subspaces of $\Lambda(n, q)$. We say that $\mathcal{A}$ and $\mathcal{B}$ are *isometric*, if there exists an invertible matrix $T \in \mathrm{GL}(n, q)$, such that $T^{\mathrm{t}}\mathcal{A}T := \{T^{\mathrm{t}} A T : A \in \mathcal{A}\}$ and $\mathcal{B}$ are the same subspace. The AltMatSpIso problem then asks, given linear bases of two alternating matrix spaces $\mathcal{A}$ and $\mathcal{B}$, decide whether $\mathcal{A}$ and $\mathcal{B}$ are isometric.

As we will elaborate in detail in Subsection 1.1, the AltMatSpIso problem has been studied for decades. Indeed, it lies at the heart of the Group Isomorphism (GpI) problem, and has an intimate relationship with many other isomorphism problems, including Graph Isomorphism (GI). As a problem in $\mathsf{NP} \cap \mathsf{coAM}$, its worst-case time complexity has barely been improved over the brute-force algorithm, which enumerates all invertible matrices in $\mathrm{GL}(n, q)$ to search for some $T \in \mathrm{GL}(n, q)$ satisfying $T^{\mathrm{t}}\mathcal{A}T = \mathcal{B}$. The brute-force algorithm takes time $q^{\Theta(n^2)} \cdot \mathrm{poly}(n, m, \log q)$ in the worst case. To obtain an algorithm in time $q^{O(n+m)}$ would lead to an algorithm testing isomorphism of *p-groups of class 2 and exponent p* in time polynomial *in the group order*, which is a long-standing open problem.

Recently, Li and Qiao developed an *average-case* algorithm to tackle the AltMatSpIso problem, *when m and n are linearly related* [21]. The algorithm takes time $q^{O(n)}$ and tests isometry between all but at most $q^{-\Omega(n)}$ fraction of $\mathcal{A}$ in $\Lambda(n, q)$, and an arbitrary $\mathcal{B}$. Here a random m-dimensional $n \times n$ alternating matrix space $\mathcal{A}$ is chosen with probability $\begin{bmatrix} \binom{n}{2} \\ m \end{bmatrix}_q^{-1}$, where $\begin{bmatrix} \cdot \\ \cdot \end{bmatrix}_q$ denotes the q-Gaussian binomial coefficient and $\begin{bmatrix} \binom{n}{2} \\ m \end{bmatrix}_q$ is the total number of m-dimensional alternating matrix spaces in $\Lambda(n, q)$. This may be viewed as a linear algebraic analogue of the *Erdős-Rényi model* for graphs [10]. A key idea behind their algorithm is to view the AltMatSpIso problem as a linear algebraic analogue of the GI problem [21], which leads to adapting the individualisation and refinement technique for random graph isomorphism as used by Babai, Erdős, and Selkow in [2]. We summarise these algorithms in Subsection 1.2. For convenience, we shall refer to the algorithm from [21] as the Li-Qiao algorithm.

In this paper, we present another average-case algorithm for AltMatSpIso.

▶ **Theorem 1.** *Suppose $m \geqslant 20$. There is an algorithm that, for all but at most $q^{-\Omega(nm)}$ fraction of m-dimensional alternating matrix spaces $\mathcal{A}$ in $\Lambda(n, q)$, tests the isometry of $\mathcal{A}$ to an arbitrary m-dimensional alternating matrix space $\mathcal{B}$, in time $q^{O(n+m)}$.*

The algorithm in Theorem 1 significantly improves over the Li-Qiao algorithm:

- First, it removes the linear dependence of m on n. The Li-Qiao algorithm inherently requires this linear dependence. That is, for general m, the Li-Qiao algorithm does *not* run in time $q^{O(n+m)}$. Indeed, some of its techniques do not work when m is even $\Omega(n^{1+\epsilon})$ or $O(n^{1-\epsilon})$ with some $0 < \epsilon < 1$.
- Second, even in the case of $m = \Theta(n)$, the average-case analysis of our algorithm is better: it works for all but $q^{-\Omega(n^2)}$ fraction of $\mathcal{A}$, while the Li-Qiao algorithm works for all but $q^{-\Omega(n)}$ fraction.
- Third, our algorithm is considerably simpler than the Li-Qiao algorithm, as the reader may compare in the descriptions of these algorithms in Subsection 1.2 and Subsection 1.3.

Partly because of the simplicity of our algorithm, we implement our algorithm, with suitable modifications and some heuristic shortcuts, in MAGMA [6]. Our experiments indicate that it improves significantly over default (brute-force) algorithms for this problem.

An immediate open problem is to examine whether our isometry testing algorithm can be strengthened to a canonical form algorithm for random alternating matrix spaces. For graph isomorphism, efficient canonical form algorithms for random graphs have long been known [2, 3]. However, to the best of authors' knowledge, there have been no canonical form algorithms for random alternating matrix spaces even in time $q^{o(n^2)}$.

1.1 Motivation and related works

Group isomorphism problem. The main motivation for us to study the AltMatSpIso problem is to understand the complexity of the Group Isomorphism (GpI) problem: Deciding whether two finite groups of order N are isomorphic. The complexities of GpI depend on how groups are represented in algorithms. When groups are specified by their multiplication (Cayley) tables, GpI reduces to the Graph Isomorphism problem (GI); cf. [24, Section 10]. When groups are represented by generators as permutations, matrices, or black-box groups, GI reduces to GpI; cf. [14, 23, 24, 13]. In either input model, the state-of-the-art algorithm runs in time *quasi-polynomial* in the group order [11, 26].

For our purpose, we shall mostly focus on the Cayley table model, since we do not even know an $N^{o(\log N)}$-time algorithm [29] (log to the base 2), despite that a simple $N^{\log N+O(1)}$-time algorithm has been known for decades [11, 26]. We note that Rosenbaum presented an algorithm in time $N^{\frac{1}{2}\log N+O(1)}$ [27]. Moreover, following Babai's breakthrough proof that GI is in quasi-polynomial time [1, 15], GpI in Cayley table model is now a key bottleneck to put GI in P, as Babai himself pointed out [1, Sec. 13.2 & 13.4 in arXiv version]. The past few years have witnessed a resurgence of activity on algorithms for this problem with worst-case analyses in terms of the group order. We refer the reader to [12] which contains a survey of these algorithms.

A natural approach to tackle GpI is to assume our given groups lie in a certain group class. For instance, for Abelian groups, one can test their isomorphism in linear time [19]. However, moving out Abelian a little bit, p-groups of class 2 and exponent p, the next natural group class beyond Abelian groups, pose great difficulty. Recall that a group is of exponent p if any nontrivial element has order p, and a group is of class 2 if its commutator subgroup is contained in its centre. Recent works [20, 9, 7, 21] solved some nontrivial subclasses, and lead to substantial improvement in practical algorithms. But their methods do not lead to any improvement for the worst-case time complexity of the general class.

***p*-groups of class 2 and exponent *p*, and alternating matrix spaces.** Alternating matrix spaces naturally appear in the study of p-groups of class 2 and exponent p via Baer's correspondence [4] for a prime $p > 2$. In fact, because of this correspondence, most recent works on this class of groups study alternating matrix spaces or alternating bilinear maps [20, 9, 7, 21]. We review this correspondence briefly. Given such a p-group, by taking the commutator map, one obtains an alternating bilinear map. Conversely, given an alternating bilinear map, one can construct such a p-group using an explicit formula (see e.g. [12, Fact 4.3]). Given an alternating bilinear map $\mathbb{F}_p^n \times \mathbb{F}_p^n \to \mathbb{F}_p^m$, one can obtain m $n \times n$ alternating matrices representing it, and take the linear span to get an alternating matrix space. Given an alternating matrix space, by taking a linear basis, one can obtain an alternating bilinear map. The above procedures preserve and respect isomorphism types of groups and isometry types of alternating matrix spaces. Moreover, it is easy to verify that the above procedures

are computationally efficient in the Cayley table model [1]. Therefore, testing isomorphism of p-groups of class 2 and exponent p in time polynomial in the group order reduces to solving AltMatSpIso over $\mathbb{F}_p$ in time $p^{O(n+m)}$. Because of the current status of GpI, we see that solving AltMatSpIso in $q^{O(n+m)}$ is already very difficult. Recently, it has been shown that a large number of (hard) isomorphism problems can be reduced to AltMatSpIso in polynomial time; we refer the readers to [13] for more details. As an application, in [18], one can also build post-quantum cryptography schemes based on AltMatSpIso.

Current status of AltMatSpIso. For the AltMatSpIso problem, the brute-force algorithm takes time $q^{\Theta(n^2)} \cdot \mathrm{poly}(n, m, \log q)$. There are two slightly improved worst-case algorithms within certain range of parameters: the $N^{\frac{1}{4}\log_p N+O(1)}$-time algorithm for p-group isomorphism by Rosenbaum [27] and Rosenbaum and Wagner [28] translates to a $p^{\frac{1}{4}(n+m)^2+O(n+m)}$-time algorithm for AltMatSpIso over $\mathbb{F}_p$. Li and Qiao [21] adapted Luks' dynamic programming technique for GI [25] to obtain a $q^{\frac{1}{4}(n^2+m^2)+O(n+m)}$-time algorithm for AltMatSpIso. Note that both algorithms only improve the worst-case time-complexity when $m \leqslant n$; in fact, if $m = \Omega(n^2)$, then the brute-force algorithm already runs in time $q^{O(n+m)}$.

Another extreme case is when $m = O(1)$, where AltMatSpIso can be solved in $\mathrm{poly}(n, q)$ time for odd q. The algorithm is based on reducing AltMatSpIso to the Alternating Matrix Tuple Isometry (AltMatTupIso) problem, which asks the following: Given two m-tuples of alternating matrices $\mathbf{A}, \mathbf{B} \in \Lambda(n, q)^m$, decide whether there is an invertible matrix $T \in \mathrm{GL}(n, q)$ such that $T^{\mathrm{t}}\mathbf{A}T = (T^{\mathrm{t}}A_1T, \ldots, T^{\mathrm{t}}A_mT) = (B_1, \ldots, B_m) = \mathbf{B}$. Unlike AltMatSpIso, the AltMatTupIso problem can be solved in time $\mathrm{poly}(n, m, \log q)$ for *odd* q [17]. The reduction from AltMatSpIso to AltMatTupIso is by fixing a tuple of alternating matrices $\mathbf{A}$ in $\mathcal{A}$ as basis, and enumerate all possible m-tuples of alternating matrices $\mathbf{B}$ in $\mathcal{B}^m$. Then one can invoke the algorithm for AltMatTupIso to test isometry between $\mathbf{A}$ and $\mathbf{B}$ efficiently.

1.2 Average-case algorithms for GI and AltMatSpIso

In this subsection, we review the average-case algorithms for GI [2] and for AltMatSpIso [21].

To obtain average-case algorithms for GI (resp. AltMatSpIso), one needs to identify a property which is satisfied by almost all graphs (resp. alternating matrix spaces) chosen from a certain random model. Then for those graphs (resp. AltMatSpIso) satisfying the property, we test its isomorphism (resp. isometry) with an arbitrary graph (resp. alternating matrix space). The efficiency of the algorithm is guaranteed by both the efficiency of testing the property and the efficiency of the isomorphism (resp. isometry) testing.

We clarify the random models. In the graph setting, a natural choice is the celebrated Erdős-Rényi model [10], in which an n-vertex m-edge graph is endowed with probability $\binom{\binom{n}{2}}{m}^{-1}$. In the alternating matrix space setting, Li and Qiao defined a linear algebraic analogue of the Erdős-Rényi model, where each m-dimensional alternating matrix space in $\Lambda(n, q)$ will be chosen with probability $\begin{bmatrix}\binom{n}{2}\\ m\end{bmatrix}_q^{-1}$; see also Definition 2.

Average-case algorithm for GI. We first define a property $\mathcal{P}$ for graphs, which is a variant used in [2]. Let $G = ([n], E)$ be a simple undirected graph. Let $r \leqslant n$ be a positive integer, $S = [r]$ and $S' = [n] \setminus [r]$. Let $B = (S \cup S', F)$ be the bipartite graph induced by the cut (S, S') in G, where $F = \{\{i, j\} \in E : \ i \in S, \ j \in S'\}$. We label each $j \in S'$ by its adjacency

[1] The procedures are even efficient in matrix groups over finite fields [13, Lemma 7.5].

relations with those vertices in S. That is, assign an r-bit string $f_j \in \{0,1\}^r$ to each $j \in S'$ such that $f_j(i) = 1$ if and only if $\{i,j\} \in F$. We say a graph G satisfies property $\mathcal{P}$ if f_j's are distinct over $j \in S'$. It is easy to verify that, choosing $r = \lceil 3 \log n \rceil$, all but at most $n^{-\Omega(1)}$ fraction of graphs in the Erdős-Rényi model satisfy the property $\mathcal{P}$.

Here is an algorithm which tests isomorphism between graph G (satisfying property $\mathcal{P}$) and $H = ([n], E')$ (an arbitrary one), based on the well-known *individualisation and refinement* procedure. Let St_G be the set of r-bit strings obtained from the property $\mathcal{P}$. Note that $|\mathrm{St}_G| = n - r$. In the individualisation step, we enumerate all r-tuples of vertices in H. For each r-tuple $(i_1, \ldots, i_r) \in [n]^r$, we perform the refinement step: assign the remaining vertices in H r-bit strings according to their adjacency relations with the r-tuple $(i_1, \ldots, i_r)$ as before, to obtain another set of bit strings St_H. If $\mathrm{St}_G \neq \mathrm{St}_H$ we neglect this r-tuple; otherwise we obtained a bijective map from $[n]$ to $[n]$ by mapping j to i_j when $j \in [r]$ and the rest according to the labels. The last step is to check whether this bijective map induces an isomorphism between G and H.

The above algorithm runs in time $n^{O(\log n)}$ if G satisfies property $\mathcal{P}$. To recover the algorithm in [2], one can canonicalise the choice of the r-tuples by choosing the one with largest r degrees for both G and H, assuming that the largest r degrees are distinct. (This is another property which is satisfied by most graphs.)

Average-case algorithm for AltMatSpIso. Li and Qiao generalised the aforementioned graph property and the individualisation and refinement procedure to the alternating matrix space setting. It is helpful to think of alternating matrix spaces as a linear algebraic analogue of graphs. That is, we view vectors in $\mathbb{F}_q^n$ as a linear algebraic analogue of vertices. We then viewing alternating matrices as a linear algebraic analogue of edges. This is because we can think of edges as binary relations and alternating matrices as alternating bilinear forms on vectors.

We first define a property $\mathcal{Q}$ for alternating matrix spaces, in light of the one defined for graphs. Let $\mathcal{A}$ be an m-dimensional alternating matrix space in $\Lambda(n,q)$, and let $r \leqslant n$ be a positive integer. Let U_0 and V_0 be the $n \times r$ and $n \times (n-r)$ matrices over $\mathbb{F}_q$, whose columns are the first r and last $(n-r)$ standard basis, respectively. Let $\mathcal{A}_{U_0,V_0} = {U_0}^{\mathrm{t}}\mathcal{A}V_0 = \mathrm{span}\{{U_0}^{\mathrm{t}}AV_0 : \ A \in \mathcal{A}\}$, which is a subspace of $\mathrm{M}(r \times (n-r), q)$. The role of $\mathcal{A}_{U_0,V_0}$ is similar to the role of the bipartite graph $B = (S \cup S', F)$ in the graph setting.[2] Recall that in the graph setting, the hope was to label vertices in S' *uniquely*, meaning that they should have different adjacency relations with vertices in S. An equivalent way of saying this is that the right automorphism group of this bipartite graph B – those permutations of the right-hand-side vertices preserving the graph structure – is trivial. Inspired by this, Li and Qiao define the property $\mathcal{Q}$ on $\mathcal{A}$ as $\mathcal{R} := \{R \in \mathrm{GL}(n-r,q) : \ \mathcal{A}_{U_0,V_0}R = \mathcal{A}_{U_0,V_0}\}$ has size at most q^n, where $\mathcal{A}_{U_0,V_0}R = \{BR : B \in \mathcal{A}_{U_0,V_0}\}$. Here, $\mathcal{R}$ can be thought of as the corresponding to the right automorphism group in the graph setting. In [21], it is shown that when m and n are linearly related ($m = \Theta(n)$) and r is a constant (depending on the ratio m/n), $|\mathcal{R}| \leqslant q^n$ for all but at most $q^{-\Omega(n)}$ fractions of alternating matrix spaces.

Now we outline the Li-Qiao algorithm for isometry testing. Let $\mathcal{B}$ be another m-dimensional alternating matrix space in $\Lambda(n,q)$ for testing isometry with $\mathcal{A}$ (satisfying the property $\mathcal{Q}$). In the individualisation step, we enumerate all $n \times r$ matrices $U \in \mathrm{M}(n \times r, q)$ whose columns are linearly independent. Denote the columns space of U by C_U. We also need to enumerate all $(n-r)$-dimensional subspaces C_V such that $C_U \oplus C_V = \mathbb{F}_q^n$. C_V is specified

[2] Matrix spaces of the form $\mathcal{A}_{U_0,V_0}$ are studied as a linear algebraic analogue of cuts on graphs in [22].

by an $n \times (n-r)$ matrix V whose columns span C_V. Let $\mathcal{B}_{U,V} = \{U^{\mathrm{t}}BV : B \in \mathcal{B}\}$, which is a subspace of $\mathrm{M}(n \times (n-r), q)$. For each (U, V) with $\mathcal{B}_{U,V}$ we perform the refinement step. That is, we enumerate all $R \in \mathrm{GL}(n-r, q)$ such that $\mathcal{A}_{U_0,V_0}R = \mathcal{B}_{U,V}$, which can be done using algorithms from [8, 16][3]. If no such R exists we neglect the pair (U, V). Otherwise, we can recover an invertible $T \in \mathrm{GL}(n, q)$ from the information of (U, V) and R. Finally, check whether T is an isometry between $\mathcal{A}$ and $\mathcal{B}$.

The above algorithm runs in time $q^{O(n)}$, if $\mathcal{A}$ satisfies property $\mathcal{Q}$ (recall that n and m are linearly related and $r = O(1)$). In particular, the two enumerations in the individualisation step take time at most $q^{rn+r(n-r)} = q^{O(n)}$. In the refinement step, since $\mathcal{A}$ satisfies property $\mathcal{Q}$, $|\{R \in \mathrm{GL}(n-r, q) : \mathcal{A}_{U_0,V_0}R = \mathcal{B}_{U,V}\}|$ can be bounded above by q^n, as the set $\{R \in \mathrm{GL}(n-r, q) : \mathcal{A}_{U_0,V_0}R = \mathcal{B}_{U,V}\}$ is either empty, or a coset of the group H, whose order is upper bounded by q^n as $\mathcal{A}$ satisfies property $\mathcal{Q}$ we imposed. Thus the enumeration cost in the refinement step is at most q^n. All the other steps can be carried out in time $\mathrm{poly}(n, m, \log q)$; we refer the readers to [21] for more technical details on how to verify whether $\mathcal{A}$ satisfies the property $\mathcal{Q}$ and how to enumerate elements in $\{R \in \mathrm{GL}(n-r, q) : \mathcal{A}_{U_0,V_0}R = \mathcal{B}_{U,V}\}$ and get the invertible matrix T from R and (U, V).

1.3 A simplified algorithm and its implementation

Although it is a nice linear algebraic analogue of the algorithm in [2], the algorithm in [21] has several drawbacks. First, the algorithm only works when m and n are linear related. Second, the algorithm is still somewhat tricky, which makes it difficult to put into actual implementation. In this subsection, we describe a *simpler* average-case algorithm for AltMatSpIso, which works for all m and n (but only for odd q) and achieves the same performance as the one of Li–Qiao. A detailed description can be found in Subsection 4.1. This simplified algorithm already captures the essence of the strategy. The main algorithm for Theorem 1 in Subsection 4.3 further works for any q and achieves better average-case analysis.

The key idea behind our algorithm. Let $\mathcal{A} \leqslant \Lambda(n, q)$. The key idea behind our algorithm is to replace individualising r-dimensional subspaces of $\mathbb{F}_q^n$ by individualising r-dimensional subspaces of $\mathcal{A}$. This is inspired by the notion of *genus* of p-groups of class 2 and exponent p in [7].

Roughly speaking, genus-r p-groups of class 2 and exponent p correspond to r-dimensional alternating matrix spaces over $\mathbb{F}_p$. In [7], it is shown that even genus-2 p-groups of class 2 and exponent p demonstrate interesting behaviours. That is to say, constant-genus p-groups are already non-trivial objects. This leads us to consider individualising constant-dimensional subspaces of $\mathcal{A}$. In the graph setting, this would correspond to individualising r edges, which does not differ much from individualising $2r$ vertices, as each edge connects to two vertices. In the alternating matrix space setting, it turns out that individualising r-dimensional subspaces of $\mathcal{A}$ could impose severe constraints on the possible isometries, if this subspace satisfies certain generic conditions. This is not so surprising, as one full-rank alternating matrix is much more "powerful" than a single edge. Reflecting back, the combination of individualisation and refinement from graphs and the genus concept from p-groups reveals a nice interaction between graph-theoretic techniques and group-theoretic notions. We would

[3] In fact, the uses of [16, 8] are not necessary, as one can relax the property $\mathcal{Q}$ and then only use certain linear algebra computations; see [21].

also like to add that, the reason for the algorithm in [21] to individualising r-dimensional subspaces of $\mathbb{F}_q^n$ is because it was a close analogy of the average-case graph isomorphism algorithm of Babai, Erdős, and Selkow [2].

Algorithm outline. We first state another property $\mathcal{Q}'$ on a m-dimensional $\mathcal{A} \leqslant \Lambda(n,q)$. Let $\mathbf{A} = (A_1, \ldots, A_m)$ be a tuple of ordered linear basis of $\mathcal{A}$. For $c \in \mathbb{N}$, set $\mathbf{A}_c = (A_1, \ldots, A_c)$. We say $\mathcal{A}$ satisfies the property $\mathcal{Q}'$ if the group $\mathrm{Aut}(\mathbf{A}_c) := \{T \in \mathrm{GL}(n,q) : \ T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{A}_c\}$ has order at most q^n.[4] When c is a large enough constant, all but at most $q^{-\Omega(n)}$ fraction of alternating matrix spaces satisfy property $\mathcal{Q}$, as shown in Theorem 5. Furthermore by algorithms in [9] (cf. Theorem 8), a generating set of $\mathrm{Aut}(\mathbf{A}_c)$ can be computed in time $\mathrm{poly}(n, \log q)$.

Our algorithm can be now stated as follows. Assume we would like to test isometry for $\mathcal{A}$ (satisfying the property $\mathcal{Q}'$) with an arbitrary $\mathcal{B}$, specified as two m-tuples of alternating matrices $\mathbf{A} = (A_1, \ldots, A_m)$ and $\mathbf{B} = (B_1, \ldots, B_m)$ from $\Lambda(n,q)^m$ for sufficiently large m and odd q. In the individualisation step, enumerate all c-tuples of alternating matrices $\mathbf{B}_c = (B_1, \ldots, B_c) \in \mathcal{B}^c$. For each $\mathbf{B}_c$ we perform the refinement step: Test isometry for alternating matrix tuples $\mathbf{A}_c$ and $\mathbf{B}_c$, using the $\mathrm{poly}(n, c, \log q)$-time algorithm in [17] (cf. Theorem 8). If they are not isometric, we neglect $\mathbf{B}_c$. Otherwise, the algorithm from [17] computes a specific isometry. Because we have computed $\mathrm{Aut}(\mathbf{A}_c)$, we can enumerate over all isometry T such that $T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{B}_c$, and check whether $T^{\mathrm{t}}\mathcal{A}T = \mathcal{B}$.

The correctness lies in the simple fact that every isometry of $\mathcal{A}$ and $\mathcal{B}$ maps $\mathbf{A}_c$ to a c-tuple $\mathbf{B}_c$ in $\mathcal{B}^c$. The running time of the above procedure is $q^{O(n+m)}$ if $\mathcal{A}$ satisfies property $\mathcal{Q}'$. In particular, the enumeration cost in the individualisation step is at most q^{cm}. In the refinement step, enumerating all invertible matrix T such that $T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{B}_c$ can be done in time $q^{O(n)} \cdot \mathrm{poly}(n, m, \log q)$ when q is odd, since $\{T \in \mathrm{GL}(n,q) : \ T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{B}_c\}$ is a coset of the group $\{T \in \mathrm{GL}(n,q) : \ T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{A}_c\}$, whose size is upper bounded by q^n by property $\mathcal{Q}'$. This algorithm is clearly simpler than the Li-Qiao algorithm, as it does not need to compute $\mathcal{B}_{U,V}$ etc..

Implementation and Performance. A bonus is our algorithm is more suitable to implement. We do so in Magma with some key adjustments, as detailed in Subsection 4.2. The implementation is publicly available on GitHub as part of a comprehensive collection of tools – developed and maintained by P. A. Brooksbank, J. Maglione, J. B. Wilson and their collaborators – to compute with groups, algebras, and multilinear functions [6].

The implementation is more convenient to describe using alternating bilinear maps (as the default algorithms do). A bilinear map $\alpha : V \times V \to W$ is alternating if for any $v \in V$, $\alpha(v, v) = 0$. Two alternating bilinear maps $\alpha, \beta : V \times V \to W$ are pseudo-isometric, if they are the same up to the natural action of $\mathrm{GL}(V) \times \mathrm{GL}(W)$. Let $V \cong \mathbb{F}_q^n$ and $W \cong \mathbb{F}_q^m$. An alternating bilinear map α can be specified by an m-tuple of alternating matrices from $\Lambda(n,q)$. Let α and β be represented by the alternating matrix tuples $\mathbf{A}$ and $\mathbf{B}$, respectively and $\mathcal{A}$ and $\mathcal{B}$ be the corresponding alternating matrix spaces of $\mathbf{A}$ and $\mathbf{B}$, respectively. It is readily verified that α and β are pseudo-isometric if and only if $\mathcal{A}$ and $\mathcal{B}$ are isometric.

Absent additional characteristic structure that can be exploited, the traditional (brute force) approach to deciding pseudo-isometry between alternating bilinear maps $\alpha, \beta \colon V \times V \to W$ is as follows. Let $\hat{\alpha}, \hat{\beta} \colon V \wedge V \to W$ denote the linear maps induced by α, β ($V \wedge V$ is the wedge product of a vector space V with itself). Compute the natural (diagonal) action of $\mathrm{GL}(V)$ on $V \wedge V$, and decide if $\ker \hat{\alpha}$ and $\ker \hat{\beta}$ – each of codimension $\dim W$ in $V \wedge V$ –

[4] The alert reader would note that the property defined here depends on the choice of bases of $\mathcal{A}$. This is not an essential problem due to the discussion in Section 3.

belong to the same orbit. An alternative version of brute force is to enumerate $\mathrm{GL}(W)$ and check if one of these transformations lifts to a pseudo-isometry from α to β. Which of these two brute-force options represents the best choice depends on the dimensions of V and W.

Our implementation is typically an improvement over both options. For example, in a preliminary experiment, our implementation readily decides pseudo-isometry between randomly selected alternating bilinear maps $\mathbb{F}_3^5 \times \mathbb{F}_3^5 \to \mathbb{F}_3^4$, while both brute-force options failed to complete. Note that the worst-case for all methods should be when α, β are *not* isometric, since in that case one must exhaust the entire enumerated list (or orbit) to confirm non-equivalence. However, the modifications we made tend to detect non-equivalence rather easily, since other (easily computed) invariants typically do not align in this case. We were therefore careful to also run tests with equivalent inputs, so as to ensure a fair comparison with default methods.

2 Preliminaries

Let $[m] = \{1, \ldots, m\}$ for $m \in \mathbb{N}$. Let $\begin{bmatrix} n \\ d \end{bmatrix}_q = \frac{(1-q^n)\cdot\ldots\cdot(1-q^{n-d+1})}{(1-q^d)\cdot\ldots\cdot(1-q)}$ denote the Gaussian binomial coefficient with parameters n, d and base q. Note that $\begin{bmatrix} n \\ d \end{bmatrix}_q$ counts the number of d-dimensional subspaces of $\mathbb{F}_q^n$. The bound $\begin{bmatrix} n \\ d \end{bmatrix}_q \leqslant q^{nd}$ is useful.

Let $\mathrm{M}(n \times n', \mathbb{F})$ (resp. $\mathrm{M}(n, \mathbb{F})$) be the linear space of all $n \times n'$ (resp. $n \times n$) matrices over $\mathbb{F}$. For a matrix $A \in \mathrm{M}(n \times n', \mathbb{F})$, $A^{\mathrm{t}} \in \mathrm{M}(n' \times n, \mathbb{F})$ denotes the transpose of A. We use $A(i, j)$ to denotes the (i, j)th entry of the matrix A. The general linear group of degree n over $\mathbb{F}$ is denoted by $\mathrm{GL}(n, \mathbb{F})$. When $\mathbb{F} = \mathbb{F}_q$ for some prime power q, we write simply $\mathrm{M}(n, q)$ and $\mathrm{GL}(n, q)$ in place of $\mathrm{M}(n, \mathbb{F}_q)$ and $\mathrm{GL}(n, \mathbb{F}_q)$. An $n \times n$ matrix A over $\mathbb{F}$ is alternating if for every $v \in \mathbb{F}^n$, $v^{\mathrm{t}} A v = 0$. When $\mathbb{F}$ is not of characteristic 2, this is equivalent to the skew-symmetric condition. Let $\Lambda(n, \mathbb{F})$ be the linear space of all $n \times n$ alternating matrices over $\mathbb{F}$ (and $\Lambda(n, q)$ when $\mathbb{F} = \mathbb{F}_q$). We denote $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, q)^m$ to be an alternating matrix tuple and $\mathcal{A} = \mathrm{span}\{A_1, \ldots, A_m\} \leqslant \Lambda(n, q)$ be an (the corresponding) alternating matrix space ($\leqslant$ denote the subspace notation).

We say two alternating matrix tuples $\mathbf{A}, \mathbf{B} \in \Lambda(n, \mathbb{F})^m$ are *isometric* if there exists $T \in \mathrm{GL}(n, \mathbb{F})$ such that

$$T^{\mathrm{t}}\mathbf{A}T := (T^{\mathrm{t}}A_1T, \ldots, T^{\mathrm{t}}A_mT) = (B_1, \ldots, B_m) = \mathbf{B}.$$

The set of isometries between $\mathbf{A}$ and $\mathbf{B}$ is denoted as

$$\mathrm{Isom}(\mathbf{A}, \mathbf{B}) = \{T \in \mathrm{GL}(n, \mathbb{F}) : T^{\mathrm{t}}\mathbf{A}T = \mathbf{B}\};$$

the group of *autometries* (or self-isometries) of $\mathbf{A}$ is denoted as $\mathrm{Aut}(\mathbf{A}) = \mathrm{Isom}(\mathbf{A}, \mathbf{A})$. We say two alternating matrix tuples $\mathbf{A}, \mathbf{B} \in \Lambda(n, \mathbb{F})^m$ are *pseudo-isometric* if there exist $T \in \mathrm{GL}(n, \mathbb{F})$ and $R \in \mathrm{GL}(m, \mathbb{F})$ such that

$$T^{\mathrm{t}}\mathbf{A}T = (T^{\mathrm{t}}A_1T, \ldots, T^{\mathrm{t}}A_mT) = (\sum_{j=1}^{m} R(1, j)B_j, \ldots, \sum_{j=1}^{m} R(m, j)B_j) =: \mathbf{B}^R.$$

The set of pseudo-isometries between $\mathbf{A}$ and $\mathbf{B}$ is defined as

$$\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B}) = \{T \in \mathrm{GL}(n, \mathbb{F}) : \exists\ R \in \mathrm{GL}(m, q),\ T^{\mathrm{t}}\mathbf{A}T = \mathbf{B}^R\}.$$

The group of *pseudo-autometries* (or self-pseudo-isometries) of $\mathbf{A}$ is denoted as $\Psi\mathrm{Aut}(\mathbf{A}) = \Psi\mathrm{Isom}(\mathbf{A}, \mathbf{A})$. It is straightforward to see that $\mathrm{Isom}(\mathbf{A}, \mathbf{B})$ (resp. $\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})$) is a (possibly empty) coset of $\mathrm{Aut}(\mathbf{A})$ (resp. $\Psi\mathrm{Aut}(\mathbf{A})$).

We say two alternating matrix spaces $\mathcal{A}, \mathcal{B} \leqslant \Lambda(n, \mathbb{F})$ are *isometric*, if there exists $T \in \mathrm{GL}(n, \mathbb{F})$ such that $T^{\mathrm{t}}\mathcal{A}T := \{T^{\mathrm{t}}AT : A \in \mathcal{A}\} = \mathcal{B}$. We can define the coset of isometries from $\mathcal{A}$ to $\mathcal{B}$ $\mathrm{Isom}(\mathcal{A}, \mathcal{B})$, and the group of autometries $\mathrm{Aut}(\mathcal{A})$, for alternating matrix spaces. If $\mathcal{A}$ and $\mathcal{B}$ are the corresponding alternating matrix spaces spanned by $\mathbf{A}$ and $\mathbf{B}$, respectively, then $\mathcal{A}$ and $\mathcal{B}$ are isometric if and only if $\mathbf{A}$ and $\mathbf{B}$ are pseudo-isometric, i.e. $\mathrm{Isom}(\mathcal{A}, \mathcal{B}) = \Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})$.

For two tuples of alternating matrices $\mathbf{A}, \mathbf{B} \in \Lambda(n, \mathbb{F})^m$, the the *adjoint space* from $\mathbf{A}$ to $\mathbf{B}$ is defined as $\mathrm{Adj}(\mathbf{A}, \mathbf{B}) = \{(T, T') \in \mathrm{M}(n, \mathbb{F}) \oplus \mathrm{M}(n, \mathbb{F}) : T\mathbf{A} = \mathbf{B}T'\}$. The *adjoint algebra* of $\mathbf{A}$ is defined as $\mathrm{Adj}(\mathbf{A}) = \{(T, T') \in \mathrm{M}(n, \mathbb{F}) \oplus \mathrm{M}(n, \mathbb{F}) : T\mathbf{A} = \mathbf{A}T'\}$. Clearly, if $T \in \mathrm{Aut}(\mathbf{A})$, then $(T^{\mathrm{t}}, T^{-1}) \in \mathrm{Adj}(\mathbf{A})$. Furthermore, if $\mathbf{A}$ and $\mathbf{B}$ are isometric, then $|\mathrm{Adj}(\mathbf{A}, \mathbf{B})| = |\mathrm{Adj}(\mathbf{A})|$.

3 Random models and average-case properties

We now formally define the linear algebraic analogue of the Erdős-Rényi model, which has been mentioned frequently in Section 1.

▶ **Definition 2** (The linear algebraic analogue of the Erdős-Rényi model)**.** *The linear algebraic analogue of the Erdős-Rényi model,* $\mathrm{LinER}(n, m, q)$*, is the uniform probability distribution over the set of* m*-dimensional subspaces of* $\Lambda(n, q)$*, that is, each subspace is endowed with probability* $\begin{bmatrix} \binom{n}{2} \\ m \end{bmatrix}_q^{-1}$*.*

We also recall a random model for alternating matrix tuples, introduced in [21].

▶ **Definition 3** (The naive model for alternating matrix tuples)**.** *The naive model for alternating matrix tuples,* $\mathrm{NaiT}(n, m, q)$*, is the probability distribution over the set of all* m*-tuples of* $n \times n$ *alternating matrices over* $\mathbb{F}_q$*, where each tuple is endowed with probability* $q^{-\binom{n}{2}m}$*.*

A useful fact is that if we would like to show a certain property holds with high probability for alternating matrix spaces in $\mathrm{LinER}(n, m, q)$, we can in turn show that a corresponding property holds with high probability for alternating matrix tuples in $\mathrm{NaiT}(n, m, q)$. The statement can be quantified as follows: Suppose we have $\mathcal{P}(n, m, q)$, a property of m-dimensional alternating matrix spaces in $\Lambda(n, q)$, and wish to show that $\mathcal{P}(n, m, q)$ holds with high probability in $\mathrm{LinER}(n, m, q)$. $\mathcal{P}(n, m, q)$ naturally induces $\mathcal{P}'(n, m, q)$, a property of alternating matrix tuples in $\Lambda(n, q)^m$ that span m-dimensional alternating matrix spaces. Let $\mathcal{Q}(n, m, q)$ be a property of all alternating matrix tuples in $\Lambda(n, q)^m$, so that $\mathcal{Q}(n, m, q)$ and $\mathcal{P}'(n, m, q)$ coincide when restricting to those alternating tuples spanning m matrix spaces. The following is proved in [21].

▶ **Proposition 4** ([21, Proposition 13 in arXiv version])**.** *Let* $\mathcal{P}(n, m, q)$ *and* $\mathcal{Q}(n, m, q)$ *be as above. Suppose in* $\mathrm{NaiT}(n, m, q)$*,* $\mathcal{Q}(n, m, q)$ *happens with probability at least* $1 - f(n, m, q)$ *for* $0 \leqslant f(n, m, q) < 1$*. Then in* $\mathrm{LinER}(n, m, q)$*,* $\mathcal{P}(n, m, q)$ *happens with probability at least* $1 - 4f(n, m, q)$*.*

In the rest of this paper, we assume a random alternating matrix space is chosen from the linear algebraic analogue of the Erdős-Rényi model and a random alternating matrix tuple is chosen from the naive model. To prove Theorem 1, it is sufficient to work with alternating matrix tuples and the naive model.

We now present the average-case property, which will be used in our algorithm. Recall that in Subsection 1.3, the desired property is to show that, for a random alternating matrix tuple $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, q)^m$ and some $c = O(1)$, the tuple $\mathbf{A}_c = (A_1, \ldots, A_c)$ has autometry group $\mathrm{Aut}(\mathbf{A}_c)$ of size at most q^n with probability $1 - q^{-\Omega(n)}$. We prove a stronger statement.

▶ **Theorem 5.** *Let $c = 20$. For all but at most $q^{-\Omega(n)}$ fraction of $\mathbf{A}_c = (A_1, \ldots, A_c) \in \Lambda(n,q)^c$, we have $|\operatorname{Adj}(\mathbf{A}_c)| \leqslant q^n$.*

Note that $|\operatorname{Aut}(\mathbf{A}_c)| \leqslant |\operatorname{Adj}(\mathbf{A}_c)|$ for any $\mathbf{A}_c$. To prove Theorem 5, we need the following from [21]. Given a tuple of matrices $\mathbf{A} = (A_1, \ldots, A_r) \in \mathrm{M}(n,q)^r$, define the image of $U \leqslant \mathbb{F}_q^n$ under $\mathbf{A}$ as $\mathbf{A}(U) := \operatorname{span}\{A_i u : \ i \in [r], \ u \in U\}$.

▶ **Definition 6.** We say $\mathbf{A} = (A_1, \ldots, A_r) \in \mathrm{M}(n,q)^r$ is *stable*, if for any nonempty proper subspace $U \leqslant \mathbb{F}_q^n$, we have $\dim(\mathbf{A}(U)) > \dim(U)$.

▶ **Proposition 7** ([21, Proposition 10 in arXiv version])**.** *If $\mathbf{A} \in \mathrm{M}(n,q)^r$ is stable, then $|\operatorname{Adj}(\mathbf{A})| \leqslant q^n$.*

Thus, to prove Theorem 5, we need to upper bound the probability of a random alternating matrix tuple being *not stable*. The proof is somewhat similar to the one in [21], with one interesting observation: We can use some random alternating matrices in $\Lambda(n,q)$ to "mimick" a random matrix $\mathbb{M}(n,q)$. The detail of the proof can be found, e.g. in [5, Section 6.3].

4 Average-case algorithms for AltMatSpIso

4.1 The simplified main algorithm

As we have mentioned in Subsection 1.3, our algorithm invokes the algorithm for testing isometry for alternating matrix tuples as subroutines, which is formally state it here.

▶ **Theorem 8** ([9, 17])**.** *Let $\mathbf{A}, \mathbf{B} \in \Lambda(n,q)^m$ for some odd q. There exists a $\operatorname{poly}(n, m, \log q)$-time algorithm which takes $\mathbf{A}$ and $\mathbf{B}$ as inputs and outputs $\operatorname{Isom}(\mathbf{A}, \mathbf{B})$, specified by (if nonempty) a generating set of $\operatorname{Aut}(\mathbf{A})$ (by the algorithm in [9]) and a coset representative $T \in \operatorname{Isom}(\mathbf{A}, \mathbf{B})$ (by the algorithm in [17]).*

We also need the following observation to enumerate elements in $\operatorname{Aut}(\mathbf{A})$, which follows easily by computing the closure of the given generating set.

▶ **Observation 9.** *Let $C_1, \ldots, C_t \in \mathrm{GL}(n,q)$, and let G be the group generated by C_i's. Let $s \in \mathbb{N}$. Then there exists an algorithm that either reports that $|G| > s$, or lists all elements in G, in time $\operatorname{poly}(s, n, \log q)$.*

Now we formally describe the simplified main algorithm for AltMatSpIso stated in Subsection 1.3, that is Algorithm 1. Note that we are given alternating matrix tuples $\mathbf{A}$ and $\mathbf{B}$, which span $\mathcal{A}$ and $\mathcal{B}$, respectively. By the discussion in Section 2, we can equivalently decide the pseudo-isometry between $\mathbf{A}$ and $\mathbf{B}$.

▶ **Proposition 10.** *Algorithm 1 runs in time $\operatorname{poly}(q^{cm}, s, n)$.*

Proof. If Algorithm 1 outputs $|\operatorname{Aut}(\mathbf{A}_c)| > s$, then its running time is determined by Theorem 8 and Observation 9, which together require $\operatorname{poly}(s, n, \log q)$.

If $|\operatorname{Aut}(\mathbf{A}_c)| \leqslant s$, we analyse the two For-loops at Step 4 and Step 4c, respectively. The first loop adds a multiplicative factor of q^{cm}, since enumerating all matrices in $\mathcal{B}$ costs q^m. The second loop adds a multiplicative factor of $\operatorname{poly}(n, s, \log q)$, due to the fact that $|\operatorname{Isom}(\mathbf{A}_c, \mathbf{B}_c)| = |\operatorname{Aut}(\mathbf{A}_c)| \leqslant s$ (as $\operatorname{Isom}(\mathbf{A}_c, \mathbf{B}_c)$ is a coset of $\operatorname{Aut}(\mathbf{A}_c)$). Other steps can be carried out in time $\operatorname{poly}(n, \log q)$. Therefore the overall running time is upper bounded by $\operatorname{poly}(q^{cm}, s, n)$. ◀

We prove the correctness of Algorithm 1, if it does not report $|\operatorname{Aut}(\mathbf{A}_c)| > s$.

Algorithm 1 The first average-case algorithm for AltMatSpIso.

Input: $\mathbf{A} = (A_1, \ldots, A_m), \mathbf{B} = (B_1, \ldots, B_m) \in \Lambda(n, q)^m$, $c, s \in \mathbb{N}$, and q is odd.
Output: Either (1) "$|\operatorname{Aut}(\mathbf{A}_c)| > s$.", or (2) $\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})$ as a set L, which may be empty.
Algorithm procedure:

1. Set $L \leftarrow \{\}$. Set $\mathbf{A}_c = (A_1, \ldots, A_c)$.
2. Use Theorem 8 to compute a generating set for $\operatorname{Aut}(\mathbf{A}_c)$.
3. Use Observation 9 with input s and the generating set of $\operatorname{Aut}(\mathbf{A}_c)$. (If $|\operatorname{Aut}(\mathbf{A}_c)| > s$, we terminate the algorithm and report that "$|\operatorname{Aut}(\mathbf{A}_c)| > s$.")
4. Set $\mathcal{B} = \operatorname{span}\{B_1, \ldots, B_m\}$; for every $\mathbf{B}_c = (B'_1, \ldots, B'_c) \in \mathcal{B}^c$, do the following.
   (a) Use Theorem 8 to decide whether $\mathbf{A}_c$ and $\mathbf{B}_c$ are isometric.
   (b) If not, go to the next $\mathbf{B}_c$. Otherwise, we get the non-empty coset $\mathrm{Isom}(\mathbf{A}_c, \mathbf{B}_c)$.
   (c) For every $T \in \mathrm{Isom}(\mathbf{A}_c, \mathbf{B}_c)$, do the following.
   Test whether the linear spans of $T^{\mathrm{t}}\mathbf{A}T$ and $\mathbf{B}$ are the same. If not, go to the next T. If so, add T into L.
5. Output L.

▶ **Proposition 11.** *If Algorithm 1 does not report $|\operatorname{Aut}(\mathbf{A}_c)| > s$, then it lists the set of pseudo-isometries (resp. isometries) between $\mathbf{A}$ (resp. $\mathcal{A}$) and $\mathbf{B}$ (resp. $\mathcal{B}$). In particular, $|\mathrm{Isom}(\mathcal{A}, \mathcal{B})| = |\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})| \leqslant q^{cm} \cdot s$.*

Proof. By Step 4c, every T added to L is a pseudo-isometry. We are left to show that L contains all the pseudo-isometries. For this, take any pseudo-isometry T. Since $T^{\mathrm{t}}\mathcal{A}T = \mathcal{B}$, we know $T^{\mathrm{t}}\mathbf{A}_cT$ is equal to some $\mathbf{B}_c \in \mathcal{B}^c$. So when enumerating these $\mathbf{B}_c$ in Step 4, T will pass all the tests in the following, and then be added to L. ◀

It remains to specify the choices of c and s in Algorithm 1. This can be done by Theorem 5.

▶ **Proposition 12.** *Let $c = 20$ and $s = q^n$. For all but at most $q^{-\Omega(n)}$ fraction of $\mathbf{A}_c = (A_1, \ldots, A_c) \in \Lambda(n, q)^c$, we have $|\operatorname{Aut}(\mathbf{A}_c)| \leqslant s$.*

Proof. This is because, if $T \in \operatorname{Aut}(\mathbf{A}_c)$, then $(T^{\mathrm{t}}, T^{-1}) \in \operatorname{Adj}(\mathbf{A}_c)$. So $|\operatorname{Aut}(\mathbf{A}_c)| \leqslant |\operatorname{Adj}(\mathbf{A}_c)|$. ◀

Combining Propositions 10 to 12, we have the following theorem.

▶ **Theorem 13.** *Let $m \geqslant 20$, and let $\mathbb{F}_q$ be a finite field of odd size. For all but at most $q^{-\Omega(n)}$ fraction of $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, q)^m$, Algorithm 1 tests the isometry of $\mathbf{A}$ with an arbitrary $\mathbf{B} \in \Lambda(n, q)^m$ in time $q^{O(n+m)}$.*

4.2 Magma implementation of Algorithm 1

To make this algorithm suitable for practical purposes, recall that the algorithm's running time is dominated by the two For-loops which give multiplicative factors of q^{cm} and s, respectively. For the average-case analysis we used $c = 20$, but having this standing on the exponent is too expensive. In practice, actually using $c = 3$ already imposes a severe restriction on s, the order of $\operatorname{Aut}(\mathbf{A}_c)$. So we use $c = 3$ in the implementation which gives a reasonable performance.

But having q^{3m} in the For-loop is still too demanding. Indeed, in practice the tolerable enumeration is around 5^{10}, namely $q = 5$ and 10 on the exponent. So with $c = 3$, the range of m is still severely limited. (Interestingly, the algorithm seems to have a better dependence on n.) It is most desirable if we could let $c = 1$, namely simply q^m.

To achieve that we use the following heuristic. Note that if $A_1, \ldots, A_c$ are low-rank matrices, then we will only need to match them with the low-rank matrices from $\mathcal{B}$. Our experiement shows that, for a random m-tuple of alternating matrices $\mathbf{A}$ over $\mathbb{F}_q$, when q is a small constant, the number of low-rank (i.e. non-full-rank) matrices in the linear span of $\mathbf{A}$ is expected to be small (i.e. much smaller than q^m) and non-zero (i.e. no less than 3) at the same time. Note that the set of all low-rank matrices can be computed in time $q^m \cdot \mathrm{poly}(n, \log q)$-time. We then choose 3 low-rank matrices from the linear span of $\mathbf{A}$. Then use $q^m \cdot \mathrm{poly}(n, \log q)$-time to compute the set of low-rank matrices from $\mathcal{B}$, denoted as $\mathcal{B}_l$. We can then replace enumerating $\mathcal{B}^c$ with $\mathcal{B}_l^c$, which in general is much smaller.

4.3 The main algorithm and proof of Theorem 1

We now introduce the algorithm (see Algorithm 2) that supports Theorem 1, which differs from Algorithm 1 in two places.

1. The first and major difference is to replace the uses of $\mathrm{Aut}(\mathbf{A}_c)$ and $\mathrm{Isom}(\mathbf{A}_c, \mathbf{B}_c)$ with the adjoint algebra $\mathrm{Adj}(\mathbf{A}_c)$ and adjoint space $\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$, thereby avoiding using Theorem 8. Since $\mathrm{Adj}(\mathbf{A}_c)$ and $\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$ are easy to compute over any field, this removes the odd q issue. On the other hand, although $\mathrm{Adj}(\mathbf{A}_c)$ and $\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$ are also easier to analyse, $\mathrm{Adj}(\mathbf{A}_c)$ and $\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$ could be larger than $\mathrm{Aut}(\mathbf{A}_c)$ and $\mathrm{Isom}(\mathbf{A}_c, \mathbf{B}_c)$, so they are less useful from the practical viewpoint.
2. The second place is step 2 in Algorithm 2: instead of just using the first c matrices as in the algorithm presented in Algorithm 1, Algorithm 2 slices the m matrices of $\mathbf{A}$ into $\lfloor m/c \rfloor$ segments of c-tuples of matrices, and tries each segment until it finds one segment with a small adjoint algebra. This step helps in improving the average-case analysis, and can be applied to the algorithm presented in Algorithm 1 as well.

▶ **Proposition 14.** *Algorithm 2 runs in time* $\mathrm{poly}(q^{cm}, s, n)$.

Proof. If Algorithm 2 outputs "$\mathbf{A}$ does not satisfy the generic condition.", then it just executes the For-loop in Step 2, which together runs in time $\mathrm{poly}(m, n, \log q)$.

Otherwise, there are two For-loops at Step 4 and Step 4c, which add multiplicative factors q^{cm} and s, respectively. Other steps can be carried out in time $\mathrm{poly}(n, \log q)$. Therefore the whole algorithm runs in time $\mathrm{poly}(q^{cm}, s, n)$. ◀

We prove the correctness of Algorithm 2 in the case that it does not report "$\mathbf{A}$ does not satisfy the generic condition."

▶ **Proposition 15.** *Suppose that Algorithm 2 does not report "*$\mathbf{A}$ *does not satisfy the generic condition." Then the algorithm lists the (possibly empty) set of pseudo-isometries between* $\mathbf{A}$ *and* $\mathbf{B}$. *In particular,* $|\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})| \leqslant q^{cm} \cdot s$.

Proof. By Step 4c, every T^{t} added to L is a pseudo-isometry. So we are left to show that L contains all the pseudo-isometries. For this, take an arbitrary pseudo-isometry T. Then T sends $\mathbf{A}_c$ to some $\mathbf{B}_c \in \mathcal{B}^c$, i.e., $T^{\mathrm{t}}\mathbf{A}_c T = \mathbf{B}_c$. In particular, $(T^{\mathrm{t}}, T^{-1}) \in \mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$. So when enumerating this $\mathbf{B}_c \in \mathcal{B}^c$, (T^{t}, T^{-1}) will pass all the tests in the following, and T will be be added to L. ◀

Algorithm 2 The second average-case algorithm for AltMatSpIso.

Input: $\mathbf{A} = (A_1, \ldots, A_m), \mathbf{B} = (B_1, \ldots, B_m) \in \Lambda(n,q)^m$ and $c, s \in \mathbb{N}$.

Output: Either (1) "$\mathbf{A}$ does not satisfy the generic condition."; or (2) $\Psi\mathrm{Isom}(\mathbf{A}, \mathbf{B})$ as a set L, which may be empty.

Algorithm procedure:

1. Set $L \leftarrow \{\}$. Set $F \leftarrow$ `false`.
2. For $i = 1, \ldots, \lfloor m/c \rfloor$, do the following.
   (a) Set $\mathbf{A}_c = (A_{c(i-1)+1}, \ldots, A_{ci})$.
   (b) Compute a linear basis of $\mathrm{Adj}(\mathbf{A}_c) \subseteq \mathrm{M}(n,q) \oplus \mathrm{M}(n,q)$.
   (c) If $|\mathrm{Adj}(\mathbf{A}_c)| \leqslant s$, set F to be `true`, and break the For-loop.
3. If $F =$ `false`, return "$\mathbf{A}$ does not satisfy the generic condition." and terminate. Otherwise,
4. Set $\mathcal{B} = \mathrm{span}\{B_1, \ldots, B_m\}$; for every $\mathbf{B}_c = (B_1, \ldots, B_c) \in \mathcal{B}^c$, do the following.
   (a) Compute a linear basis for $\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c) \subseteq \mathrm{M}(n,q) \oplus \mathrm{M}(n,q)$.
   (b) If $|\mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)| > s$, go to the next $\mathbf{B}_c$.
   (c) For every $(T, T') \in \mathrm{Adj}(\mathbf{A}_c, \mathbf{B}_c)$, do the following.
   If T and T' are invertible and $(T')^{-1} = T^{\mathrm{t}}$, test whether the linear spans of $T\mathbf{A}T^{\mathrm{t}}$ and $\mathbf{B}$ are the same. If not, go to the next (T, T'). If so, add T^{t} into L.
5. Output L.

Now we specify the choice of $c = 20$ and $s = q^n$, based on Theorem 5.

▶ **Proposition 16.** *Let $m \geqslant c = 20$, and let $\ell = \lfloor m/c \rfloor \in \mathbb{N}$. For all but at most $q^{-\Omega(n\cdot\ell)} = q^{-\Omega(nm)}$ fraction of $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n,q)^m$, there exists some $i \in [\ell]$, such that, letting $\mathbf{A}_{c,i} = (A_{c(i-1)+1}, \ldots, A_{ci})$, we have $|\mathrm{Adj}(\mathbf{A}_{c,i})| \leqslant q^n$.*

Proof. We slice $\mathbf{A}$ into $\ell = \lfloor m/c \rfloor$ segments, where each segment consists of c random alternating matrices. Each segment is some $\mathbf{A}_{c,i} \in \Lambda(n,q)^c$, with $\Pr[|\mathrm{Adj}(\mathbf{A}_{c,i})| > q^n] \leqslant q^{-\Omega(n)}$ by Theorem 5. Since $A_1, \ldots, A_m$ are chosen independently and uniformly at random, the probability of every $\mathbf{A}_{c,i} = (A_{c(i-1)+1}, \ldots, A_{ci})$, $i \in [\ell]$, with $|\mathrm{Adj}(\mathbf{A}_{c,i})| > q^n$, is upper bounded by $(q^{-\Omega(n)})^\ell = q^{-\Omega(nm)}$. ◀

Theorem 1 then follows from Propositions 14 to 16.

Abstract

Reliable spanners can withstand huge failures, even when a linear number of vertices are deleted from the network. In case of failures, some of the remaining vertices of a reliable spanner may no longer admit the spanner property, but this collateral damage is bounded by a fraction of the size of the attack. It is known that $\Omega(n \log n)$ edges are needed to achieve this strong property, where n is the number of vertices in the network, even in one dimension. Constructions of reliable geometric $(1+\varepsilon)$-spanners, for n points in $\mathbb{R}^d$, are known, where the resulting graph has $\mathcal{O}(n \log n \operatorname{loglog}^6 n)$ edges.

Here, we show randomized constructions of smaller size spanners that have the desired reliability property in expectation or with good probability. The new construction is simple, and potentially practical – replacing a hierarchical usage of expanders (which renders the previous constructions impractical) by a simple skip list like construction. This results in a 1-spanner, on the line, that has linear number of edges. Using this, we present a construction of a reliable spanner in $\mathbb{R}^d$ with $\mathcal{O}(n \operatorname{loglog}^2 n \operatorname{logloglog} n)$ edges.

1 Introduction

Geometric graphs are such that their vertices are points in the d-dimensional Euclidean space $\mathbb{R}^d$ and edges are straight line segments. The quality or efficiency of a geometric graph is often measured in terms of the ratio of shortest path distances and geometric distances between its vertices. Let $G = (P, E)$ be a geometric graph, where $P \subset \mathbb{R}^d$ is a set of n points and E is the set of edges. The shortest path distance between two points $p, q \in P$ in the graph G is denoted by $\mathsf{d}_G(p, q)$ (or just $\mathsf{d}(p, q)$). The graph G is a t-spanner for some constant $t \geq 1$, if $\mathsf{d}(p, q) \leq t \cdot \|p - q\|$ holds for all pairs of points $p, q \in P$, where $\|p - q\|$ stands for the Euclidean distance of p and q. The spanning ratio, stretch factor, or dilation of a graph G is the minimum number $t \geq 1$ for which G is a t-spanner. A path between p and q is a *t-path* if its length is at most $t \cdot \|p - q\|$.

Table 1.1 Comparison of the size of constructions of reliable spanners and reliable spanners in expectation. The reliability parameter is $\vartheta > 0$, and, for dimensions $d \geq 2$, the graphs are $(1+\varepsilon)$-spanners for $\varepsilon > 0$.

	dim	# edges	constants
Reliable spanners			
Buchin et al. [4]	$d = 1$	$\mathcal{O}(n \log n)$	$\mathcal{O}\left(\vartheta^{-6}\right)$
	$d \geq 2$	$\mathcal{O}\left(n \log n \log\log^6 n\right)$	$\mathcal{O}\left(\varepsilon^{-7d}\vartheta^{-6}\log^7 \varepsilon^{-1}\right)$
Bose et al. [2]	$d \geq 1$	$\mathcal{O}\left(n \log^2 n \log\log n\right)$	?
Reliable spanners *in expectation*			
New results	$d = 1$	$\mathcal{O}(n)$	$\mathcal{O}\left(\vartheta^{-1}\log \vartheta^{-1}\right)$
	$d \geq 2$	$\mathcal{O}(n \log\log^2 n \log\log\log n)$	$\mathcal{O}\left(\varepsilon^{-2d}\vartheta^{-1}\log^3 \varepsilon^{-1}\log \vartheta^{-1}\right)$

We focus our attention to construct spanners that can survive massive failures of vertices. The most studied notion is fault tolerance [5, 7, 8, 9, 10], which provides a properly functioning residual graph if there are no more failures than a predefined parameter k. It is clear, that a k-fault tolerant spanner must have $\Omega(kn)$ edges to avoid small degree nodes, which can be isolated by deleting their neighbors. Therefore, fault tolerant spanners must have quadratic size to be able to survive a failure of a constant fraction of vertices. Another notion is robustness [3], which gives more flexibility by allowing the loss of some additional nodes by not guaranteeing t-paths for them. For a function $f : \mathbb{N} \to \mathbb{R}^+$ a t-spanner G is f-robust, if for any set of failed points B there is an extended set B^+ with size at most $f(|B|)$ such that the residual graph $G \setminus B$ has a t-path for any pair of points $p, q \in P \setminus B^+$. The function f controls the robustness of the graph - the slower the function grows the more robust the graph is. The benefit of robustness is that a near linear number of edges are enough to achieve it, even for the case when f is linear, there are constructions with nearly $\mathcal{O}(n \log n)$ edges. For $\vartheta \in (0, 1)$, a spanner that is f-robust with $f(k) = (1 + \vartheta)k$ is a ϑ-*reliable* spanner [4]. This is the strongest form of robustness, since the dilation can increase beyond t only for a tiny additional fraction of points. The fraction is relative to the number of failed vertices and controlled by the parameter ϑ.

Recently, Buchin et al. [4] showed a construction of reliable 1-spanners of size $\mathcal{O}(n \log n)$ in one dimension, and of reliable $(1+\varepsilon)$-spanners of size $\mathcal{O}\left(n \log n \log\log^6 n\right)$ in higher dimensions (the constant in the $\mathcal{O}$ depends on the dimension, ε, and the reliability parameter). An alternative construction, with slightly worse bounds, was given by Bose et al. [2].

Limitations of previous constructions. The construction of Buchin et al. [4] (and also the construction of Bose et al. [2]) relies on using expanders to get a 1-spanner for points on the line, and then extending it to higher dimensions. The spanner (in one dimension) has $\mathcal{O}(n \log n)$ edges. Unfortunately, even in one dimension, such a reliable spanner requires $\Omega(n \log n)$ edges, as shown by Bose et al. [3]. Furthermore, the constants involved in these constructions [2, 4] are quite bad, because of the usage of expanders. See Table 1.1 for a summary of the sizes of different constructions (together with the new results).

The problem. As such, the question is whether one can come up with simple and practical constructions of spanners that have linear or near linear size, while still possessing some reliability guarantee – either in expectation or with good probability.

Some definitions. Given a graph G, an *attack* $B \subseteq V(G)$ is a set of vertices that are being removed. The *damaged set* B^+, is the set of all the vertices which are no longer connected to the rest the graph, or are badly connected to the rest of the graph – that is, these vertices no longer have the desired spanning property. The *loss* caused by B, is the quantity $|B^+ \setminus B|$ (where we take the minimal damaged set). The *loss rate* of B is $\lambda(G, B) = |B^+ \setminus B| / |B|$. A graph G is *ϑ-reliable* if for any attack B, the loss rate $\lambda(G, B)$ is at most ϑ.

Randomness and obliviousness. As mentioned above, reliable spanners must have size $\Omega(n \log n)$. A natural way to get a smaller spanner, is to consider randomized constructions, and require that the reliability holds in expectation (or with good probability). Randomized constructions are (usually) still sensitive to adversarial attacks, if the adversary is allowed to pick the attack set after the construction is completed (and it is allowed to inspect it). A natural way to deal with this issue is to restrict the attacks to be *oblivious* – that is, the attack set is chosen before the graph is constructed (or without any knowledge of the edges).

In such an oblivious model, the loss rate is a random variable (for a fixed attack B). It is thus natural to construct the graph G randomly, in such a way that $\mathbb{E}[\lambda(G, B)] \leq \vartheta$, or alternatively, that the probability $\mathbb{P}[\lambda(G, B) \geq \vartheta]$ is small.

1-spanner. Surprisingly, the one-dimensional problem is the key for building reliable spanners. Here, the graph G is constructed over the set of vertices $[n] = \{1, \ldots, n\}$. An attack is a subset $B \subseteq [n]$. Given an attack B, the requirement is that for all $i, j \in [n] \setminus B^+$, such that $i < j$, there is a monotonically increasing path from i to j in $G \setminus B$ – here, the length of the path between i and j is exactly $j - i$. Since there is no distortion in the length of the path, such graphs are 1-spanners.

Our results. We give a randomized construction of a 1-spanner in one dimension, that is ϑ-reliable in expectation, and has size $\mathcal{O}(n)$. Formally, the construction has the property that $\mathbb{E}[\lambda(G, B)] \leq \vartheta$. This construction can also be modified so that $\lambda(G, B) \leq \vartheta$ holds with some desired probability. This is the main technical contribution of this work.

Next, following in the footsteps of the construction of reliable spanners, we use the one-dimensional construction to get $(1 + \varepsilon)$-spanners that are ϑ-reliable either in expectation or with good probability. The new constructions have size roughly $\mathcal{O}\big(n \operatorname{loglog}^2 n\big)$.

Main idea. We borrow the notion of shadow from the work of Buchin et al. [4]. A point p is in the α-shadow if there is a neighborhood of p, such that an α-fraction of it belongs to the attack set. One can think about the maximum α such that p is in the α-shadow of B as the *depth* of p (here, the depth is in the range $[0, 1]$). A point with depth close to one, are intuitively surrounded by failed points, and have little hope of remaining well connected. Fortunately, only a few points have depth truly close to one 1. The flip side is that the attack has little impact on shallow points (i.e., points with depth close to 0). Similar to people, shallow points are surrounded by shallow points. As such, only a small fraction of the shallow points needs to be strongly connected to other points in the graph, as paths from (shallow) points around them can then travel via these hub points.

To this end, similar in spirit to skip lists, we define a random gradation of the points $P = P_0 \supseteq P_1 \supseteq \ldots \supseteq P_{\log n}$, where $|P_i| = n/2^i$ – this is done via a random tournament tree. In each level, each point of P_i is connected to all its neighbors within a certain distance (which increases as i increases). Intuitively, because of the improved connectivity, the probability that a point is well-connected (after the attack) increases if they belong to higher level of the

gradation. Thus, the probability of a shallow point to remain well connected is, intuitively, good. Specifically, we can quantify the probability of a vertex to lose its connectivity as a function of its depth. Combining this with bounds on the number of points of certain depths, results in bounds on the expected size of the damaged set.

Reliable skip lists. Our construction can be interpreted as a reliable construction of skip lists. Here, an attack removes certain cells in the skip list, which are no longer available. This can happen, for example, if the skip list is stored in a distributed fashion in a network, and certain nodes of the network are down. Our construction implies that one can withstand an attack with small expected loss. The previous work on skip graphs [1], or [4], presented constructions of variants of skip lists with somewhat similar properties, but using $\mathcal{O}(n \log n)$ pointers. The current construction requires only $\mathcal{O}(n)$ pointers.

Comparison to previous work. While we borrow some components of Buchin et al. [4], the basic scheme in the one-dimensional case, is new, and significantly different – the previous construction used expanders in a hierarchical way. The new construction requires different analysis and ideas. The extension to higher dimension is relatively straightforward and follows the ideas of Buchin et al. [4], although some modifications and care are necessary.

Paper organization. We review some necessary machinery in Section 2. The one-dimensional construction is described in Section 3. We describe the extension to higher dimensions in Section 4.

2 Preliminaries

Let $G = (P, E)$ be a t-spanner for some $t \geq 1$. An ***attack*** on G is a set of vertices B that fail, and no longer can be used. An attack is ***oblivious***, if the set B is picked without any knowledge of E.

▶ **Definition 1** (Reliable spanner)**.** *Let $G = (P, E)$ be a t-spanner for some $t \geq 1$ constructed by a (possibly) randomized algorithm. Given an attack B, its* **damaged set** *B^+ is a smallest set, such that for any pair of vertices $u, v \in P \setminus B^+$, we have*

$$\mathsf{d}_{G \setminus B}(u, v) \leq t \cdot \|u - v\|,$$

that is, t-paths are preserved for all pairs of points not contained in B^+. The quantity $|B^+ \setminus B|$ is the **loss** *of G under the attack B. The* **loss rate** *of G is $\lambda(G, B) = |B^+ \setminus B| / |B|$. For $\vartheta \in (0, 1)$, the graph G is* **ϑ-reliable** *if $\lambda(G, B) \leq \vartheta$ holds for any attack $B \subseteq P$.*

Further, we say that the random graph G is **ϑ-reliable in expectation** *if $\mathbb{E}[\lambda(G, B)] \leq \vartheta$ holds for any oblivious attack $B \subseteq P$. For $\vartheta, \rho \in (0, 1)$, we say that the graph G is* **ϑ-reliable with probability** *$1 - \rho$ if $\mathbb{P}[\lambda(G, B) \leq \vartheta] \geq 1 - \rho$ holds for any oblivious attack $B \subseteq P$.*

▶ Remark 2. We emphasize that in the latter case the graph is random and the expectation and the probability is taken with respect to the distribution of graphs.

Another remark is that the set B^+ is not unique, since one can (possibly) choose the point to include in B^+ for a pair that does not have a t-path in $G \setminus B$. However, this does not cause a problem in defining the loss rate.

▶ **Definition 3.** *Let $[n]$ denote the* interval *$\{1, \ldots, n\}$. Similarly, for x and y, let $[x \ldots y]$ denote the interval $\{x, x + 1, \ldots, y\}$.*

We use the shadow notion as it was introduced by Buchin et al. [4].

▶ **Definition 4.** *Consider an arbitrary set $B \subseteq [n]$ and a parameter $\alpha \in (0,1)$. A number i is in the* **left α-shadow** *of B, if and only if there exists an integer $j \geq i$, such that $\left|[i \ldots j] \cap B\right| \geq \alpha \left|[i \ldots j]\right|$. Similarly, i is in the* **right α-shadow** *of B, if and only if there exists an integer h, such that $h \leq i$ and $|[h \ldots i] \cap B| \geq \alpha |[h \ldots i]|$. The left and right α-shadow of B is denoted by $\mathcal{S}_{\rightarrow}(\alpha, B)$ and $\mathcal{S}_{\leftarrow}(\alpha, B)$, respectively. The combined shadow is denoted by $\mathcal{S}(\alpha, B) = \mathcal{S}_{\rightarrow}(\alpha, B) \cup \mathcal{S}_{\leftarrow}(\alpha, B)$.*

▶ **Lemma 5** ([4]). *For any set $B \subseteq [n]$, and $\alpha \in (0,1)$, we have that $|\mathcal{S}(\alpha, B)| \leq \left(1 + 2\lceil 1/\alpha \rceil\right)|B|$. Further, if $\alpha \in (2/3, 1)$, we have that $|\mathcal{S}(\alpha, B)| \leq |B| / (2\alpha - 1)$.*

▶ **Definition 6.** *Given a graph G over $[n]$, a* **monotone path** *between $i, j \in [n]$, such that $i < j$, is a sequence of vertices $i = i_1 < i_2 < \cdots < i_k = j$, such that $i_{\ell-1} i_\ell \in E(G)$, for $\ell = 2, \ldots, k$.*

A monotone path between i and j has length $|j - i|$. Throughout the paper we use $\log x$ and $\ln x$ to denote the base 2 and natural base logarithm of x, respectively. For any set $A \subseteq P$, let $A^c = P \setminus A$ denote the complement of A. For two integers $x, y > 0$, let $x_{\uparrow y} = \lceil x/y \rceil \, y$.

3 Reliable spanners in one dimension

We show how to build a random graph on $[n]$ that still has monotone paths almost for all vertices that are not directly attacked. First, in Section 3.2, we show that our construction is ϑ-reliable in expectation. Then, in Section 3.3, we show how to modify the construction to obtain a 1-spanner that is ϑ-reliable with probability $1 - \rho$.

3.1 Construction

The input consists of a parameter $\vartheta > 0$ and the point set $P = [n] = \{1, \ldots, n\}$. The backbone of the construction is a random elimination tournament. We assume that n is a power of 2 as otherwise one can construct the graph for the next power of two, and then throw away the unneeded vertices.

The tournament is a full binary tree, with the leafs storing the values from 1 to n, say from left to right. The value of a node is computed randomly and recursively. For a node, once the values of the nodes were computed for both children, it randomly copies the value of one of its children, with equal probability to choose either child. Let P_i be the values stored in the ith bottom level of the tree. As such, $P_0 = P$, and $P_{\log n}$ is a singleton. Each set P_i can be interpreted as an ordered set (from left to right, or equivalently, by value).

Let

$$\alpha = 1 - \frac{\vartheta}{8} \qquad \text{and} \qquad \varepsilon = \frac{8(1-\alpha)}{c \ln \vartheta^{-1}} = \frac{\vartheta}{c \ln \vartheta^{-1}}, \tag{3.1}$$

where $c > 1$ is a sufficiently large constant. Let M be the smallest integer for which $|P_M| \leq 2^{M/2}/\varepsilon$ holds (i.e., $M = \lceil (2/3) \log(\varepsilon n) \rceil$). For $i = 0, 1, \ldots, M$, and for all $p \in P_i$ connect p with the first

$$\ell(i) = \left\lceil \frac{2^{i/2}}{\varepsilon} \right\rceil \tag{3.2}$$

successors (and hence predecessors) of p in P_i. Let E_i be the set of all edges in level i. The graph G on P is defined as the union of all edges over all levels – that is, $E(G) = \cup_{i=0}^{M} E_i$. Note, that top level of the graph G is a clique.

▶ Remark 7. Before dwelling on the correctness of the construction, note that the obliviousness of the attack is critical. Indeed, it is quite easy to design an attack if the structure of G is known. To this end, let B_i be the set of $\ell(M) = O(n^{1/3}/\varepsilon)$ values of P_i closest to $n/2$ – namely, we are taking out the middle-part of the graph, that belongs to the ith level. Consider the attack $B = \cup B_i$. It is easy to verify that this attack breaks G into at least two disconnected graphs, each of size at least $n/2 - O(n^{1/3}\varepsilon^{-1}\log n)$.

3.2 Analysis

▶ **Lemma 8.** *The graph G has $\mathcal{O}\left(n\vartheta^{-1}\log\vartheta^{-1}\right)$ edges.*

Proof. The number of edges contributed by a point in P_i is at most $\ell(i)$ at level i, and $|P_i| = n/2^i$. Thus, we have

$$|E(G)| \leq \sum_{i=0}^{M} |P_i| \cdot \ell(i) \leq \sum_{i=0}^{M} \frac{n}{2^i} \cdot \left\lceil \frac{2^{i/2}}{\varepsilon} \right\rceil \leq \sum_{i=0}^{M} \frac{n}{2^i} \cdot \frac{2 \cdot 2^{i/2}}{\varepsilon} \leq \frac{n}{\varepsilon} \cdot \sum_{i=0}^{\infty} \frac{2}{2^{i/2}} = \mathcal{O}\left(\frac{n}{\varepsilon}\right). \quad \blacktriangleleft$$

Fix an attack $B \subseteq P$. The high-level idea is to show that if a point $p \in P \setminus B$ is far enough from the faulty set, then, with high probability, there exist monotone paths reaching far from p in both directions. For two points $p < q$, we show that if both p and q have far reaching monotone paths, then the path going to the right from p, and the path going to the left from q must cross each other, which in turn implies, that there is a monotone path between p and q. Therefore, it is enough to bound the number of points that does not have far reaching monotone paths.

▶ **Definition 9** (Stairway)**.** *Let $p \in P$ be an arbitrary point. The path $p = p_0, p_1, \ldots, p_j$ is a right (resp., left)* **stairway** *of p to level j, if*

- **(i)** *$p = p_0 \leq p_1 \leq \cdots \leq p_j$ (resp., $p \geq p_1 \geq \cdots \geq p_j$),*
- **(ii)** *if $p_i \neq p_{i+1}$, then $p_i p_{i+1} \in E_i$, for $i = 0, 1, \ldots, j-1$,*
- **(iii)** *$p_i \in P_i$, for $i = 1, \ldots, j$.*

Furthermore, a stairway is **safe** *if none of its points are in the attack set B. A right (resp., left) stairway is* **usable**, *if $[p_j \ldots n] \cap P_j$ (resp., $[1 \ldots p_j] \cap P_j$) forms a clique in G. Let $T \subseteq P$ denote the set of points that have a safe and usable stairway to both directions.*

Let $\alpha_k = \alpha/2^k$, for $k = 0, 1, \ldots, \log n$. Let $\mathcal{S}_k = \mathcal{S}(\alpha_k, B)$ be the α_k-shadow of B, for $k = 0, 1, \ldots, \log n$. Observe that $\mathcal{S}_0 \subseteq \mathcal{S}_1 \subseteq \cdots \subseteq \mathcal{S}_{\log n}$, and there is an index j such that $\mathcal{S}_j = P$, if $B \neq \emptyset$. A point is classified according to when it gets "buried" in the shadow. A point p, for $k \geq 1$, is a ***k*th round** point, if $p \in \mathcal{S}_k \setminus \mathcal{S}_{k-1}$. Intuitively, a kth round point is more likely to have a safe stairway the larger the value of k is.

▶ **Definition 10.** *A point is* **bad** *if it belongs to B, or it does not have a right or left stairway that is safe and usable. Formally, a point $p \in P$ is bad, if and only if $p \in P \setminus T$.*

▶ **Lemma 11.** *For any two points $p, q \in T$ that are not bad, there is a monotone path connecting p and q in the residual graph $G \setminus B$.*

Proof. Suppose we have $p < q$. Let $(p, p_1, \ldots, p_{j(p)})$ be a safe usable right stairway starting from p and $(q, q_1, \ldots, q_{j(q)})$ be a safe usable left stairway from q. These stairways exist, since $p, q \in T$. Let $j = \min(j(p), j(q))$ and consider the stairways $(p, p_1, \ldots, p_j)$ and $(q, q_1, \ldots, q_j)$. Notice that both are safe and at least one of them is usable.

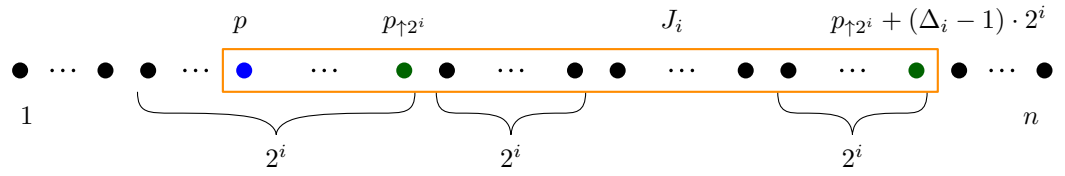

Figure 3.1 The interval $J_i = \left[p \dots p_{\uparrow 2^i} + (\Delta_i - 1) \cdot 2^i\right]$.

Let i be the first index such that $p_i \geq q_i$, if there is any. We distinguish two cases based on whether $p_i < q_{i-1}$ holds or not. In case $p_i < q_{i-1}$, the path $(p, p_1, \dots, p_{i-1}, p_i, q_{i-1}, \dots, q_1, q)$ is a monotone path from p to q, since $q_i q_{i-1} \in E_{i-1}$ implies $p_i q_{i-1} \in E_{i-1}$. On the other hand, if we have $p_i \geq q_{i-1}$, the path $(p, p_1, \dots, p_{i-1}, q_{i-1}, \dots, q_1, q)$ is a monotone path between p and q, since $p_{i-1} p_i \in E_{i-1}$ implies $p_{i-1} q_{i-1} \in E_{i-1}$.

Finally, if $p_i < q_i$ holds for all $i = 1, \dots, j$, then the path $(p, p_1, \dots, p_j, q_j, \dots, q_1, q)$ is a monotone path between p and q. We have $p_j q_j \in E_j$, since at least one of the stairways is usable. This concludes the proof that there is a monotone path from p to q. ◀

▶ **Lemma 12.** *For a fixed set $Q \subseteq [n]$, we have that $\mathbb{P}[Q \cap P_i = \emptyset] \leq \exp(-|Q|/2^i)$.*

Proof. Let $Q = \{q_1, \dots, q_r\}$, and observe that knowing that certain points of Q are not in P_i, increases the probability of another point to be in P_i. That is, $\mathbb{P}[q_j \in P_i \mid q_1, \dots, q_{j-1} \notin P_i] \geq \mathbb{P}[q_j \in P_i] = 1/2^i$. As such, we have

$$\begin{aligned}\mathbb{P}\left[Q \cap P_i = \emptyset\right] &= \mathbb{P}\left[\bigcap_j (q_j \notin P_i)\right] = \prod_{j=1}^{r} \mathbb{P}[q_j \notin P_i \mid q_1, \dots, q_{j-1} \notin P_j] \\ &\leq \left(1 - 1/2^i\right)^r \leq \exp(-r/2^i).\end{aligned}$$

◀

▶ **Lemma 13.** *Assume that $\vartheta \in (0, 1/2)$ and let $p \in \mathcal{S}_k \setminus \mathcal{S}_{k-1}$ be a kth round point for some $k \geq 1$. The probability that p is bad is at most $(\vartheta/2)^k/32$.*

Proof. For any integer $i \geq 1$, let $\Delta_i = \left\lfloor 2^{(i-1)/2}/(2\varepsilon) \right\rfloor$ and let $J_i = \left[p \dots p_{\uparrow 2^i} + (\Delta_i - 1) \cdot 2^i\right]$, see Figure 3.1. Recall that $p \in [n]$, so $p_{\uparrow 2^i} = \left\lceil p/2^i \right\rceil 2^i$ is the next multiple of 2^i. Let ξ be the largest integer such that $J_\xi \subseteq P$. For $i = 0, \dots, \xi$, the points of $J_{i+1} \cap P_i$ form a clique in G, since

$$|J_{i+1} \cap P_i| \leq \left\lceil |J_{i+1}|/2^i \right\rceil \leq \left\lceil 2^{i+1} \Delta_{i+1}/2^i \right\rceil = 2\Delta_{i+1} \leq \left\lceil 2^{i/2}/\varepsilon \right\rceil = \ell(i).$$

Indeed, any two vertices of P_i with distance at most $\ell(i)$ are connected by an edge of E_i. As such, it is enough to prove that there is a right safe stairway from p, that climbs on the levels to level ξ. Since $J_{\xi+1} \cap P_\xi$ forms a clique, it follows that such a stairway would be usable.

Let $\mathcal{E}_i$ be the event that $(J_i \setminus B) \cap P_i$ is empty, for $i = 1, \dots, \xi$. Since $p \notin \mathcal{S}_{k-1}$, we have that $|J_i \cap B| < \alpha_{k-1} |J_i| \leq 2^i \alpha_{k-1} \Delta_i$. On the other hand, we have $|J_i \cap P_i| \geq 2^i(\Delta_i - 1)/2^i = \Delta_i - 1$. As such, if $|J_i \cap B| < |J_i \cap P_i|$ then $\mathbb{P}[\mathcal{E}_i] = 0$. This happens if $2^i \alpha_{k-1} \Delta_i \leq \Delta_i - 1 \iff 2^{i-k+1} \alpha \leq (\Delta_i - 1)/\Delta_i$, which happens if $i \leq k - 2$, given that $\Delta_i \geq 2$. Notice that $\Delta_i \geq 2$ holds for all $i \geq 1$, if $\varepsilon \leq \frac{1}{4}$.

So assume that $i \geq k - 1$. Let $q_1, \dots, q_r$ be all points of $J_i \setminus B$, which are the possible candidates to be contained in $(J_i \setminus B) \cap P_i$. By Eq. (3.1), there are at least

$$r = |J_i| - |J_i \cap B| \geq (1 - \alpha_{k-1}) |J_i| \geq (1 - \alpha_{k-1}) 2^i (\Delta_i - 1)$$

$$\geq (1-\alpha_{k-1})2^i\Big(\frac{2^{(i-1)/2}}{2\varepsilon}-2\Big) = \frac{c(1-\alpha_{k-1})\ln\vartheta^{-1}}{16(1-\alpha)}2^{3i/2-1/2} - (1-\alpha_{k-1})2^{i+1}$$
$$\geq c2^{3i/2-9/2}\ln\vartheta^{-1} - 2^{i+1}$$

such points. Observe, that by the structure of the construction, a point is more likely to be contained in P_i conditioned on the event there are some other points which are not contained in P_i. Therefore, by Lemma 12, we have $\mathbb{P}\big[\mathcal{E}_i\big] \leq \exp\big(-r/2^i\big) \leq \tau_i$, for $\tau_i = \exp\big(2 - c2^{i/2-9/2}\ln\vartheta^{-1}\big)$. The sequence τ_i has a fast decay in i, since

$$\frac{\tau_{i+1}}{\tau_i} = \exp\Big(-(\sqrt{2}-1)c2^{i/2-9/2}\ln\vartheta^{-1}\Big) \leq \exp\big(-c2^{-6}\ln 2\big) = 2^{-c2^{-6}} \leq \frac{1}{2},$$

if $c \geq 2^6$ holds. Thus, we have

$$\mathbb{P}\Big[\cup_{i=1}^{\xi}\mathcal{E}_i\Big] \leq \sum_{i=1}^{\xi}\mathbb{P}\big[\mathcal{E}_i\big] \leq \sum_{i=k-1}^{\xi}\tau_i \leq 2\tau_{k-1} = 2\exp\Big(2 - c2^{(k-1)/2-9/2}\ln\vartheta^{-1}\Big)$$
$$\leq 16\exp\Big(-\frac{c}{32}2^{k/2}\ln\vartheta^{-1}\Big) = 16\cdot\vartheta^{\frac{c}{32}\cdot 2^{k/2}} \leq 2^4\cdot\vartheta^{\frac{c}{2^6}\cdot k}$$
$$\leq 2^4\cdot\left(\frac{1}{2}\right)^{\frac{c}{2^7}\cdot k}\cdot\left(\vartheta^{\frac{c}{2^7}}\right)^k \leq \frac{(\vartheta/2)^k}{64}$$

for $c \geq 2^{11}$, using the conditions $0 < \vartheta \leq \frac{1}{2}$, $k \geq 1$ and the fact that $x \leq 2^x$.

Let p_i be the leftmost point in $(J_i \setminus B) \cap P_i$, for $i \geq 0$. Since $P_i \subseteq P_{i-1}$, for all i, it follows that $p = p_0 \leq p_1 \leq \cdots \leq p_\xi$. Furthermore, since $J_{i+1} \cap P_i$ is a clique in level i of G, and $p_i, p_{i+1} \in J_{i+1} \cap P_i$, it follows that $p_ip_{i+1} \in E_i$, if $p_i \neq p_{i+1}$, for all i. We conclude that $p, p_1, \ldots, p_\xi$ is a safe and usable right stairway in G.

The bound now follows by applying the same argument symmetrically for the left stairway. Indeed, using the union bound, we obtain $\mathbb{P}[p \text{ is bad}] \leq 2(\vartheta/2)^k/64 = (\vartheta/2)^k/32$. ◀

▶ **Lemma 14.** *Let $\vartheta \in (0, 1/2)$ and $B \subseteq P$ be an oblivious attack. Recall, that T^c is the set of bad points. Then, we have $\mathbb{E}[|T^c|] \leq (1+\vartheta)\,|B|$.*

Proof. We may assume that all the points of $\mathcal{S}_0$ are bad. Fortunately, by Lemma 5, we have $|\mathcal{S}_0| \leq |B|/(2\alpha-1) = |B|/(1-\vartheta/4) \leq (1+\vartheta/2)\,|B|$, since $\alpha = 1-\vartheta/8$ and $1/(1-x/4) \leq 1+x/2$ for $0 \leq x \leq 2$. Again, using Lemma 5, we have

$$|\mathcal{S}_k \setminus \mathcal{S}_{k-1}| \leq |\mathcal{S}_k| \leq \big(1 + 2\lceil 2^k/\alpha\rceil\big)\,|B| \leq \left(3 + \frac{2^{k+1}}{\alpha}\right)|B| \leq 2^{k+3}\,|B|\,.$$

For $k \geq 1$, we have, by Lemma 13, that

$$b_k = \mathbb{E}[|(\mathcal{S}_k \setminus \mathcal{S}_{k-1}) \cap T^c|] \leq \sum_{p\in\mathcal{S}_k\setminus\mathcal{S}_{k-1}}\mathbb{P}[p \text{ is bad}] \leq 2^{k+3}\,|B|\cdot\frac{(\vartheta/2)^k}{32} \leq \frac{\vartheta^k}{4}\,|B|\,.$$

Since, $T^c = (\mathcal{S}_0 \cap T^c) \cup \bigcup_{k\geq 1}\big[(\mathcal{S}_k \setminus \mathcal{S}_{k-1}) \cap T^c\big]$, we have, by linearity of expectation, that

$$\frac{\mathbb{E}\Big[|T^c|\Big]}{|B|} \leq \frac{1}{|B|}\left(|\mathcal{S}_0| + \sum_{k=1}^{\infty}b_k\right) \leq 1 + \frac{\vartheta}{2} + \sum_{k=1}^{\infty}\frac{\vartheta^k}{4} \leq 1 + \frac{\vartheta}{2} + \frac{\vartheta}{4(1-\vartheta)} \leq (1+\vartheta),$$

since $\vartheta < 1/2$. ◀

▶ **Theorem 15.** *Let $\vartheta \in (0, 1/2)$ and $P = [n]$ be fixed. The graph G, constructed in Section 3.1, has $\mathcal{O}\big(n\vartheta^{-1}\log\vartheta^{-1}\big)$ edges, and it is a ϑ-reliable 1-spanner of P in expectation. Formally, for any oblivious attack B, we have $\mathbb{E}[\lambda(G, B)] \leq \vartheta$.*

Proof. By Lemma 8 the size of the construction is $|E(G)| = \mathcal{O}\big(n\vartheta^{-1}\log\vartheta^{-1}\big)$. Let $B \subseteq P$ be an oblivious attack and consider the bad set $P \setminus T$. By Lemma 11, for any two points outside the bad set, there is a monotone path connecting them. Further, by Lemma 14, we have $\mathbb{E}[|P \setminus T|] \leq (1 + \vartheta)\,|B|$ for any oblivious attack. Therefore, we obtain $\mathbb{E}[\lambda(G, B)] \leq \mathbb{E}[|T^c \setminus B| \,/\, |B|] \leq \vartheta$. ◀

3.3 Probabilistic bound

One can replace the guarantee, in Theorem 15, on the bound of the loss rate (which holds in expectation), by an upper bound that holds with probability at least $1 - \rho$, for some prespecified $\rho > 0$. A straightforward application of Markov's inequality implies that taking the union of $\log \rho^{-1}$ independent copies (G') of the construction of Theorem 15 with parameter $\vartheta/2$, results in a graph with the desired property. Indeed, we have

$$\mathbb{P}[\lambda(G, B) > \vartheta] \leq \mathbb{P}[\lambda(G', B) > \vartheta]^{\log \rho^{-1}} \leq \left(\frac{\mathbb{E}[\lambda(G', B)]}{\vartheta}\right)^{\log \rho^{-1}} \leq \left(\frac{1}{2}\right)^{\log \rho^{-1}} = \rho.$$

Here we show how one can do better to avoid the multiplicative factor $\log \rho^{-1}$.

Construction. The input consists of two parameters $\vartheta, \rho > 0$ and the set $P = [n]$. Let G be the graph constructed in Section 3.1 with parameters

$$\alpha = 1 - \frac{\vartheta}{8} \qquad \text{and} \qquad \varepsilon = \frac{8(1-\alpha)}{c(\ln\vartheta^{-1} + \ln\rho^{-1})} = \frac{\vartheta}{c(\ln\vartheta^{-1} + \ln\rho^{-1})},$$

where $c > 1$ is a sufficiently large constant. First, we need a variant of Lemma 13 to bound the probability of a kth round point being bad, using the new value of ε.

▶ **Lemma 16.** *Assume that $\vartheta \in (0, 1/2)$, $\rho \in (0, 1)$ and let $p \in \mathcal{S}_k \setminus \mathcal{S}_{k-1}$ be a kth round point for some $k \geq 1$. The probability that p is bad is at most $\vartheta \cdot \rho/2^{3k+4}$.*

Proof. The proof is the same as the proof of Lemma 13. The only difference is due to the new value of ε, which results in $\tau_i = \exp\big(2 - c2^{i/2-9/2}(\ln\vartheta^{-1} + \ln\rho^{-1})\big)$, using the same notation. Therefore, we have

$$\begin{aligned}
\mathbb{P}[p \in \mathcal{S}_k \setminus \mathcal{S}_{k-1} \text{ is bad}] &\leq 4\tau_{k-1} = 4\exp\Big(2 - c2^{k/2-5}(\ln\vartheta^{-1} + \ln\rho^{-1})\Big) \\
&\leq 2^5 \exp\Big(-\frac{c}{2^6}k(\ln\vartheta^{-1} + \ln\rho^{-1})\Big) = 2^5 \cdot \vartheta^{\frac{c}{2^6}k} \cdot \rho^{\frac{c}{2^6}k} \\
&\leq 2^5 \cdot \left(\frac{1}{2}\right)^{\frac{c}{2^6}k-1} \cdot \vartheta \cdot \rho = 2^{-\frac{c}{2^6}k+6} \cdot \vartheta \cdot \rho \leq 2^{-3k-4} \cdot \vartheta \cdot \rho,
\end{aligned}$$

for $c \geq 2^{10}$. See Lemma 13 for a complete proof. ◀

▶ **Lemma 17.** *Let $\vartheta \in (0, 1/2)$, $\rho \in (0, 1)$ be fixed and $B \subseteq P$ be an oblivious attack. Then, with probability $\geq 1 - \rho$, the number of bad points is at most $(1 + \vartheta)\,|B|$. That is, we have $\mathbb{P}[|T^c| \leq (1 + \vartheta)\,|B|] \geq 1 - \rho$.*

Proof. The idea is to give bounds on the number of bad kth round points for all $k \geq 1$. Let $\mathcal{E}_k$ be the event that $|(\mathcal{S}_k \setminus \mathcal{S}_{k-1}) \cap T^c| > \frac{\vartheta}{2^{k+1}} |B|$ happens, for $k \geq 1$. Recall, by the choice of α, we have $|\mathcal{S}_0 \cap T^c| \leq |\mathcal{S}_0| \leq \left(1 + \frac{\vartheta}{2}\right) |B|$. Notice, that at least one of the events $\mathcal{E}_k$ must happen, for $k \geq 1$, in order to have $|T^c| > (1+\vartheta)|B|$, since

$$|T^c| = |\mathcal{S}_0 \cap T^c| + \sum_{k=1}^{\infty} |(\mathcal{S}_k \setminus \mathcal{S}_{k-1}) \cap T^c| \leq \left(1 + \frac{\vartheta}{2}\right) |B| + \sum_{k=1}^{\infty} \frac{\vartheta}{2^{k+1}} |B| = (1+\vartheta)|B|.$$

Using Markov's inequality and Lemma 16 we get

$$\mathbb{P}[\mathcal{E}_k] \leq \frac{\mathbb{E}[|(\mathcal{S}_k \setminus \mathcal{S}_{k-1}) \cap T^c|]}{\frac{\vartheta}{2^{k+1}}|B|} \leq \frac{|\mathcal{S}_k| \cdot \mathbb{P}[p \in \mathcal{S}_k \setminus \mathcal{S}_{k-1} \text{ is bad}]}{\frac{\vartheta}{2^{k+1}}|B|} \leq \frac{2^{k+3}|B| \cdot \frac{\vartheta \cdot \rho}{2^{3k+4}}}{\frac{\vartheta}{2^{k+1}}|B|} = \frac{\rho}{2^k}.$$

Therefore, we obtain

$$\mathbb{P}[|T^c| > (1+\vartheta)|B|] \leq \mathbb{P}[\cup_{k \geq 1} \mathcal{E}_k] \leq \sum_{k=1}^{\infty} \mathbb{P}[\mathcal{E}_k] \leq \sum_{k=1}^{\infty} \frac{\rho}{2^k} \leq \rho,$$

which is equivalent to $\mathbb{P}[|T^c| \leq (1+\vartheta)|B|] \geq 1 - \rho$. ◀

▶ **Theorem 18.** *Let $\vartheta \in (0, 1/2)$, $\rho \in (0,1)$ and $P = [n]$ be fixed. The graph G, constructed above, is a ϑ-reliable 1-spanner of P, with probability at least $1 - \rho$. Formally, we have $\mathbb{P}[\lambda(G, B) \leq \vartheta] \geq 1 - \rho$ for any oblivious attack B. Furthermore, the graph G has $\mathcal{O}\big(n\vartheta^{-1}(\log \vartheta^{-1} + \log \rho^{-1})\big)$ edges.*

Proof. The bound on the size follows directly from Lemma 8. Let $B \subseteq P$ be an oblivious attack and consider the bad set $P \setminus T$. By Lemma 11, for any two points outside the bad set, there is a monotone path connecting them. Further, by Lemma 17, we have $\mathbb{P}[\lambda(G, B) \leq \vartheta] \geq \mathbb{P}[|T^c| \leq (1+\vartheta)|B|] \geq 1 - \rho$ for any oblivious attack. ◀

4 Reliable spanners in higher dimensions

Now we turn to the higher-dimensional setting, and show that one can construct spanners with near linear size that are reliable in expectation or with some fixed probability (which can be provided as part of the input). We use the same technique as Buchin et al. [4], that is, we use our one-dimensional construction as a black box in combination with a result of Chan et al. [6]. Let the dimension $d > 1$ be fixed. In the following we assume $P \subset [0,1)^d$, which can be achieved by an appropriate scaling and translation of the d-dimensional Euclidean space $\mathbb{R}^d$. For an ordering σ of $[0,1)^d$, and two points $p, q \in [0,1)^d$, such that $p \prec q$, let $(p,q)_\sigma = \left\{z \in [0,1)^d \;\middle|\; p \prec z \prec q\right\}$ be the set of points between p and q in the order σ.

▶ **Theorem 19** ([6])**.** *For $\varsigma \in (0,1)$, there is a set $\Pi^+(\varsigma)$ of $M(\varsigma) = \mathcal{O}(\varsigma^{-d} \log \varsigma^{-1})$ orderings of $[0,1)^d$, such that for any two (distinct) points $p, q \in [0,1)^d$, with $\ell = \|p - q\|$, there is an ordering $\sigma \in \Pi^+$, and a point $z \in [0,1)^d$, such that*

- **(i)** $p \prec_\sigma q$,
- **(ii)** $(p,z)_\sigma \subseteq \mathrm{ball}\big(p, \varsigma\ell\big)$,
- **(iii)** $(z,q)_\sigma \subseteq \mathrm{ball}\big(q, \varsigma\ell\big)$, *and*
- **(iv)** $z \in \mathrm{ball}\big(p, \varsigma\ell\big)$ *or* $z \in \mathrm{ball}\big(q, \varsigma\ell\big)$.

Furthermore, given such an ordering σ, and two points p, q, one can compute their ordering, according to σ, using $\mathcal{O}(d \log \varsigma^{-1})$ arithmetic and bitwise-logical operations.

The above theorem ensures that it is enough to maintain only a "few" linear orderings, and for any pair of points $p, q \in P$ there exists an ordering where all points that lie between p and q are either very close to p or q. It is natural to build the one-dimensional construction for each of these orderings with some carefully chosen parameter. Then, since there is a reliable path in the one-dimensional construction, there is an edge $p'q'$ along the path between p and q that connects the locality of p and the locality of q. We fix the edge $p'q'$ and apply recursion on the subpaths from p to p' and q to q'.

4.1 Construction

Let $\vartheta, \varepsilon \in (0,1)$ be fixed parameters and $P \subseteq [0,1)^d$ be a set of n points. Set $\varsigma = \varepsilon/16$ in Theorem 19 and let $\Pi^+ = \Pi^+(\varsigma)$ be the set of $M = M(\varsigma)$ orderings that fulfills the conditions of the theorem. We define $\vartheta' = \frac{\vartheta}{3MN}$, where $N = \lceil \log\log n \rceil$. Now, for each ordering $\sigma \in \Pi^+$, we build N independent spanners $G^1_\sigma, \ldots, G^N_\sigma$, using the construction in Section 3.1 with parameter ϑ'. The (random) graph G is defined as the union of graphs G^i_σ for all $\sigma \in \Pi^+$ and $i \in [N]$, that is, $E(G) = \cup_{\sigma\in\Pi^+, i\in[N]} E\big(G^i_\sigma\big)$.

4.2 Analysis

▶ **Lemma 20.** *The graph G, constructed above, has $\mathcal{O}\big(c\, n \log\log^2 n \log\log\log n\big)$ edges, where the $\mathcal{O}$ hides constant that depends on the dimension d, and $c = \mathcal{O}(\varepsilon^{-2d}\vartheta^{-1}\log^3\varepsilon^{-1}\log\vartheta^{-1})$.*

Proof. There are $M = \mathcal{O}\big(\varepsilon^{-d}\log\varepsilon^{-1}\big)$ orderings, and for each ordering there are N copies, for which we build the one-dimensional construction with parameter ϑ'. The size of the one-dimensional construction is $\mathcal{O}\big(n\cdot\vartheta'^{-1}\cdot\log\vartheta'^{-1}\big)$, by Lemma 8. Therefore, G has size

$$\begin{aligned}
|E(G)| = \big|\cup_{\sigma\in\Pi^+, i\in[N]} E\big(G^i_\sigma\big)\big| &\le \sum_{\sigma\in\Pi^+, i\in[N]} |E(G'_\sigma)| \le NM\cdot\mathcal{O}\big(n\cdot\vartheta'^{-1}\cdot\log\vartheta'^{-1}\big)\\
&= \mathcal{O}\big(n\cdot N^2M^2\vartheta^{-1}\cdot\big(\log\vartheta^{-1}+\log N+\log M\big)\big)\\
&= \mathcal{O}\big(n\cdot\log\log^2 n\cdot\varepsilon^{-2d}\log^2\varepsilon^{-1}\cdot\vartheta^{-1}\cdot(\log\vartheta^{-1}+\\
&\qquad + \log\log\log n + d\log\varepsilon^{-1} + \log\log\varepsilon^{-1})\big)\\
&= \mathcal{O}\big(c\, n\log\log^2 n\log\log\log n\big), \qquad \text{where } c = \mathcal{O}(\varepsilon^{-2d}\vartheta^{-1}\log^3\varepsilon^{-1}\log\vartheta^{-1}).
\end{aligned}$$

◀

Fix an attack set $B \subseteq P$. In order to bound $\lambda(G, B)$ in expectation, we define a sequence of sets $B_0 \subseteq B_1 \subseteq \cdots \subseteq B_N$ as follows. First, we set $B_0 = B$. Then, for $i = 1, \ldots, N$, we define B^σ_i for each $\sigma \in \Pi^+$ to contain all points that do not have a right or left stairway in G^i_σ that is safe and usable with respect to B_{i-1}, that is, B^σ_i contains the bad points with respect to B_{i-1}. We set $B_i = \cup_{\sigma\in\Pi^+} B^\sigma_i$. Our goal is to show that the expected size of B_N is small, and there is a $(1+\varepsilon)$-path for all pairs of points outside of B_N.

▶ **Lemma 21.** *Let B be an oblivious attack and let $B_0 \subseteq B_1 \subseteq \cdots \subseteq B_N$ be the sequence defined above. Then, for $i = 1, \ldots, N$, we have $\mathbb{E}[|B^\sigma_i| \mid B_{i-1}] \le (1+\vartheta')\,|B_{i-1}|$, for all $\sigma \in \Pi^+$.*

Proof. The set B_{i-1} has information only about graphs G^j_σ for $j \le i-1$. Thus, the attack B_{i-1} on the graph G^i_σ is oblivious and we have $\mathbb{E}[|B^\sigma_i| \mid B_{i-1}] \le (1+\vartheta')\,|B_{i-1}|$ by Lemma 14. ◀

▶ **Lemma 22.** *Let B_N be the set defined above. For any oblivious attack B, the expected size of B_N is at most $(1+\vartheta)\cdot|B|$.*

Proof. By Lemma 21 we have $\mathbb{E}[|B_i^\sigma| \mid B_{i-1}] \leq (1+\vartheta')\,|B_{i-1}|$ for all $\sigma \in \Pi^+$. Therefore,

$$\mathbb{E}[|B_i| \mid B_{i-1}] \leq \big((1+\vartheta')\,|B_{i-1}| - |B_{i-1}|\big) \cdot M + |B_{i-1}| = \left(1 + \frac{\vartheta}{3N}\right)|B_{i-1}|$$

holds, for $i = 1, \ldots, N$, which gives

$$\begin{aligned}\mathbb{E}[|B_N|] \leq \mathbb{E}[\mathbb{E}[|B_N| \mid B_{N-1}]] &\leq \left(1 + \frac{\vartheta}{3N}\right) \cdot \mathbb{E}[|B_{N-1}|] \\ &\leq \left(1 + \frac{\vartheta}{3N}\right)^N \cdot \mathbb{E}[|B_0|] = \left(1 + \frac{\vartheta}{3N}\right)^N \cdot |B|\,.\end{aligned}$$

Using $1 + x \leq e^x \leq 1 + 3x$, for $x \in [0,1]$, we obtain

$$\mathbb{E}[|B_N|] \leq \left(1 + \frac{\vartheta}{3N}\right)^N \cdot |B| \leq \exp\left(N\frac{\vartheta}{3N}\right) \cdot |B| = e^{\frac{\vartheta}{3}} \cdot |B| \leq (1+\vartheta) \cdot |B|\,. \qquad \blacktriangleleft$$

▶ **Lemma 23.** *Let B_N be the set defined above. Then, for any two points $p, q \in P \setminus B_N$, there is a $(1+\varepsilon)$-path in the graph $G \setminus B$.*

Proof. The proof is essentially the same as the proof of Theorem 15 in [4].

Let $p, q \in P \setminus B_N$ be fixed. According to Theorem 19, there is an ordering $\sigma \in \Pi^+$, such that all the points $z \in (p,q)_\sigma$ lie in one of the balls of radius $\varsigma\,\|p-q\|$ around p and q. Recall that the graph G contains G_σ^N as a subgraph. Since $p, q \notin B_N$ and G_σ^N is reliable, there is a path connecting p and q that is monotone with respect to σ and avoids any point in B_{N-1} by Theorem 15. Therefore, there is a unique edge $p'q'$ along this path such that p' is in the close neighborhood of p and q' is in the close neighborhood of q. Furthermore, we also have that $p', q' \in P \setminus B_{N-1}$. We fix the edge $p'q'$ in path π and find subpaths between the pairs pp' and qq' in a recursive manner. The bounds on the distances are

- **(i)** $\|p'-q'\| \leq (1+2\varsigma)\,\|p-q\|\,,$
- **(ii)** $\|p-p'\| \leq \varsigma\,\|p-q\|$ and similarly $\|q-q'\| \leq \varsigma\,\|p-q\|$.

We repeat this process $N-1$ times. Let Q_i be the set of pairs that needs to be connected in the ith round, that is, $Q_0 = \{pq\}, Q_1 = \{pp', qq'\}$ and so on. There are at most 2^i pairs in Q_i and for any pair $xy \in Q_i$ we have $x, y \in P \setminus B_{N-i}$. For each pair $xy \in Q_i$, there is an ordering σ such that the argument above can be repeated. That is, there is a monotone path in the graph $G_\sigma^{N-i} \setminus B_{N-i-1}$ according to σ and there is an edge $x'y'$ along this path such that

- **(i)** $\|x'-y'\| \leq (1+2\varsigma)\,\|x-y\| \leq (1+2\varsigma)\varsigma^i\,\|p-q\|\,,$
- **(ii)** $\|x-x'\| \leq \varsigma\,\|x-y\| \leq \varsigma^{i+1}\,\|p-q\|$ and similarly $\|y-y'\| \leq \varsigma^{i+1}\,\|p-q\|$.

The edge $x'y'$ is added to path π and the pairs xx' and yy' are added to Q_{i+1}, unless they are trivial (i.e., $x = x'$ or $y = y'$). After $N-1$ rounds, Q_{N-1} is the set of active pairs that still needs to be connected. Notice that $x, y \in P \setminus B_1$ holds for any pair $xy \in Q_{N-1}$. Again, for each pair in Q_{N-1}, we apply Theorem 19 and Theorem 15 to obtain a monotone path according to some ordering σ in the graph G_σ^1. None of these paths use any points in B. In order to complete the path π we add the whole paths obtained in the last step. It is not hard to see that the number of edges of each of the paths added in the last step is at most $2\log n$. Indeed, it is clear from the analysis of our one-dimensional construction that a path using the stairways can have at most two points per level. Since the number of levels in the construction is fewer than $\log n$, we get the bound $2\log n$.

Now, that we have a path π that connects the points p and q without using any points in the failed set B, we give an upper bound on the length of π. First, we calculate the total length added in the last step. There are $|Q_{N-1}| \leq 2^{N-1}$ pairs in the last step and for each pair $xy \in Q_{N-1}$ we have $\|x-y\| \leq \|p-q\| \varsigma^{N-1}$. Thus, we obtain

$$\begin{aligned}\sum_{\{x,y\}\in Q_{N-1}} \text{length}(\pi[x,y]) &\leq 2^{N-1}\big((1+2\varsigma)\|p-q\|\varsigma^{N-1} + 2\log n \|p-q\|\varsigma^N\big)\\ &\leq 2\cdot 2\varsigma\|p-q\| + (2\varsigma)^N \log n \|p-q\| = \Big(4\varsigma + (2\varsigma)^N \log n\Big)\|p-q\|\\ &\leq \left(\frac{\varepsilon}{4} + \left(\frac{\varepsilon}{8}\right)^{\log\log n}\log n\right)\|p-q\|\\ &\leq \left(\frac{\varepsilon}{4} + \frac{\varepsilon}{4}\cdot\left(\frac{1}{2}\right)^{\log\log n}\log n\right)\|p-q\| = \frac{\varepsilon}{2}\|p-q\|,\end{aligned}$$

where we simply use $2\varsigma \leq 1$ in the second line and $\varsigma = \varepsilon/16$ and $N = \lceil \log\log n \rceil$ in the third line. Second, we bound the total length of the edges that were added to path π in any round except the last. This contributes at most

$$\begin{aligned}\sum_{i=0}^{N-2} 2^i\cdot(1+2\varsigma)\varsigma^i\|p-q\| &\leq (1+2\varsigma)\|p-q\|\cdot\sum_{i=0}^{\infty}(2\varsigma)^i = (1+2\varsigma)\|p-q\|\cdot\frac{1}{1-2\varsigma}\\ &= \left(1+\frac{4\varsigma}{1-2\varsigma}\right)\|p-q\| = \left(1+\frac{\varepsilon/4}{1-\varepsilon/8}\right)\|p-q\| \leq \left(1+\frac{\varepsilon}{2}\right)\|p-q\|\end{aligned}$$

to the length of π. Therefore the total length of the path π connecting p and q, without using any points of B, is at most $(1+\varepsilon)\|p-q\|$. ◀

▶ **Theorem 24.** *Let $\vartheta, \varepsilon \in (0,1)$ be fixed parameters and $P \subseteq [0,1)^d$ be a set of n points. The graph G, constructed in Section 4.1, is a ϑ-reliable $(1+\varepsilon)$-spanner of P in expectation and has size $\mathcal{O}\big(c\,n\log\log^2 n\log\log\log n\big)$, where $\mathcal{O}$ hides constant that depends on the dimension d, and $c = \mathcal{O}(\varepsilon^{-2d}\vartheta^{-1}\log^3\varepsilon^{-1}\log\vartheta^{-1})$.*

Proof. The size of the construction is proved in Lemma 20. Let B_N be the set defined above. By Lemma 22, the expected size of B_N is at most $(1+\vartheta)|B|$. By Lemma 23, for any two points $p, q \in P \setminus B_N$, there is a $(1+\varepsilon)$-path between p and q in the graph $G \setminus B$. Thus, we have $\mathbb{E}[\lambda(G,B)] \leq \vartheta$. ◀

4.3 Probabilistic bound

The same construction, as we used in Section 4.1, can be applied to construct spanners with near linear edges that are reliable with probability $1-\rho$. The idea is to use the probabilistic version of the one-dimensional construction with parameters $\rho' = \frac{\rho}{MN}$ and $\vartheta' = \frac{\vartheta}{3MN}$. Then, similarly to Lemma 22, it is not hard to show that $|B_N| \leq (1+\vartheta)|B|$ holds with probability $1-\rho$.

▶ **Lemma 25.** *Let B_N be the set defined in Section 4.2. The probability that the size of B_N is larger than $(1+\vartheta)\cdot|B|$ is at most ρ.*

Proof. By Lemma 17, and since all attacks are oblivious, we have $\mathbb{P}[|B_i^\sigma| > (1+\vartheta')\,|B_{i-1}|] \leq \rho'$ for all $\sigma \in \Pi^+$ and $i \geq 1$. Therefore,

$$\begin{aligned}\mathbb{P}[|B_i| > (1+M\vartheta')\,|B_{i-1}|] &= \mathbb{P}[|B_i \setminus B_{i-1}| > M\vartheta'\,|B_{i-1}|] \\ &\leq \mathbb{P}[\cup_{\sigma\in\Pi^+} |B_i^\sigma \setminus B_{i-1}| > \vartheta'\,|B_{i-1}|] \leq \sum_{\sigma\in\Pi^+} \mathbb{P}[|B_i^\sigma \setminus B_{i-1}| > \vartheta'\,|B_{i-1}|] \\ &= \sum_{\sigma\in\Pi^+} \mathbb{P}[|B_i^\sigma| > (1+\vartheta')\,|B_{i-1}|] \leq M\rho'\end{aligned}$$

holds for $i = 1, \ldots, N$. Since $\left(1+\frac{\vartheta}{3N}\right)^N \leq \left(e^{\frac{\vartheta}{3N}}\right)^N \leq 1+\vartheta$, we get

$$\begin{aligned}\mathbb{P}[|B_N| > (1+\vartheta)\,|B|] &\leq \mathbb{P}\left[|B_N| > \left(1+\frac{\vartheta}{3N}\right)^N |B|\right] \leq \mathbb{P}\left[\bigcup_{i=1}^N |B_i| > \left(1+\frac{\vartheta}{3N}\right)|B_{i-1}|\right] \\ &\leq \sum_{i=1}^N \mathbb{P}\left[|B_i| > \left(1+\frac{\vartheta}{3N}\right)|B_{i-1}|\right] = \sum_{i=1}^N \mathbb{P}\left[|B_i| > \left(1+M\vartheta'\right)|B_{i-1}|\right] \leq NM\rho' = \rho.\end{aligned}$$

◀

Therefore, using the same argument as for Theorem 24, we obtain the following result, which gives a slight improvement in the constants, compared to the trivial multiplicative factor $\mathcal{O}\big(\log \rho^{-1}\big)$ by simply repeating the construction of Section 4.1.

▶ **Theorem 26.** *Let $\vartheta, \varepsilon, \rho \in (0,1)$ be fixed parameters and $P \subseteq [0,1)^d$ be a set of n points. The graph described above is a ϑ-reliable $(1+\varepsilon)$-spanner of P with probability $1-\rho$. Furthermore, the size of the construction is $\mathcal{O}\big(c\, n \operatorname{loglog}^2 n \operatorname{logloglog} n\big)$, where $\mathcal{O}$ hides constant that depends on the dimension d, and $c = \mathcal{O}\big(\varepsilon^{-2d}\vartheta^{-1}\log^3\varepsilon^{-1}(\log\vartheta^{-1} + \log\rho^{-1})\big)$.*

5 Conclusions

Reliable spanners require $\Omega(n \log n)$ edges. In this paper, we showed that fewer edges are sufficient, if the spanner only has to be reliable against oblivious attacks (in expectation or with a certain probability). Our new construction avoids the use of expanders, and as a result has much smaller constants than previous constructions, making it potentially practical. The number of edges in the new spanner is significantly smaller – it is linear in one dimension, and roughly $\mathcal{O}(n \operatorname{loglog}^2 n)$ in higher dimensions. An open problem is whether these loglog-factors in higher dimensions can be avoided. Furthermore, similar results for reliable spanners for general metrics would be of interest.

Abstract

The long-standing dynamic optimality conjecture postulates the existence of a dynamic binary search tree (BST) that is $O(1)$-competitive to all other dynamic BSTs. Despite attempts from many groups of researchers, we believe the conjecture is still far-fetched. One of the main reasons is the lack of the "right" potential functions for the problem: existing results that prove various consequences of dynamic optimality rely on very different potential function techniques, while proving dynamic optimality requires a single potential function that can be used to derive all these consequences. In this paper, we propose a new potential function, that we call *extended (geometric) inversion*. Inversion is arguably the most natural potential function principle that has been used in competitive analysis but has never been used in the context of BSTs. We use our potential function to derive new results, as well as streamlining/strengthening existing results.

First, we show that a broad class of BST algorithms (including Greedy and Splay) are $O(1)$-competitive to Move-to-Root algorithm and therefore have simulation embedding property – a new BST property that was recently introduced and studied by Levy and Tarjan (SODA 2019). This result, besides substantially expanding the list of BST algorithms having this property, gives the first potential function proof of the simulation embedding property for BSTs (thus unifying apparently different kinds of results). Moreover, our analysis is the first where the costs of two dynamic binary search trees are compared against each other directly and systematically. Secondly, we use our new potential function to unify and strengthen known BST bounds, e.g., showing that *Greedy* satisfies the weighted dynamic finger property within a multiplicative factor of $(5 + o(1))$.

1 Introduction

The dynamic optimality conjecture [23] is among the most fundamental problems in data structures. The conjecture postulates the existence of an online[1] and dynamic[2] binary search tree (BST) that is $O(1)$-competitive (or simply *competitive*) to the optimal offline BST algorithm. So far, the main candidates for being dynamically optimal are Splay and Greedy[17, 12, 18] (a.k.a. *Greedy Future* and *Greedy ASS*) since they possess many desirable properties that are consequences of dynamic optimality [5, 14, 11, 10, 19], although the best known competitive ratio of $O(\log \log n)$ is given by Tango trees [13]. Despite various attempts from many groups of researchers, the conjecture remains elusive. There are several observed reasons that make the conjecture long-standing, and one such reason (that this work tries to address) is the difficulty of comparing the behavior of two dynamic BSTs (see, for instance, [16]), which can be attributed to the lack of "generic" and "intuitive" potential function in this context: The simplest bound, static optimality, was derived via sum-of-logs [23, 6], and Splay's dynamic finger (which extends static optimality) uses sophisticated potential function that in some way extends sum-of-logs [10, 11]; Greedy's weighted dynamic finger [14] relies on very different potential function that neither seems related to sum-of-logs nor Splay's dynamic finger; the recent simulation embedding properties [16, 21] as well as best known bound for Splay's deque property [19, 20] do not even use potential function. Finally, none of these techniques was used to prove that Greedy or Splay is $o(\log n)$-competitive. Given this state of the art, it is relatively unclear which potential function should be used/extended for proving dynamic optimality. This paper is inspired by the following question:

> Is there a natural, generic potential function technique that allows us to compare the cost of two dynamic BSTs in a modular way?

1.1 Our Contribution

Our main conceptual contribution is a new potential function that, in our opinion, seems to be the right way to handle binary search trees. Our idea is inspired by *inversions*[3], which are arguably the most natural potential function for the purpose of analyzing online algorithms (see, for instance, [2, 22, 1] in the context of list update and [9] in the context of the k-server problem). We illustrate the power of our techniques in two directions.

Let us first introduce some notation before stating our results. We consider keys in $[n] = \{1, 2, \ldots, n\}$ and access sequence $X = (x_1, x_2, \ldots, x_m) \in [n]^m$. For an online dynamic BST algorithm $\mathcal{A}$, denoted by $cost_{\mathcal{A}}(X)$ the cost of serving sequence X using algorithm $\mathcal{A}$. We illustrate the power of our new concept in two ways.

First contribution: MTR-Competitiveness and Simulation Embedding

Recently, Levy and Tarjan [16] (and independently Russo [21]) noted the difficulty of comparing two dynamic BSTs and proposed an alternative path towards dynamic optimality. They rephrase dynamic optimality as two intrinsic properties (which they call, *simulation*

[1] A BST is online if an input sequence is revealed one at a time, i.e. the request for x_t appears at time t.
[2] A binary search tree is dynamic if it is allowed to change its form after each access, paying the cost of pointer movements.
[3] In general, the inversion potential function (or its generalization to "distance potential") measures the difference between the algorithm and the optimal, so it is suitable for analyzing the case when the optimal can change.

embeddings and *approximately monotone*) of an algorithm. Roughly speaking, a BST has simulation embeddings if it can "simulate"[4] any other BST algorithm, and it is approximately monotone if the cost of running the algorithm on an input sequence X is asymptotically at least the cost of running it on an arbitrary subsequence of X. An algorithm is $O(1)$-competitive if and only if it has both properties. They argue that Splay trees satisfy simulation embeddings and outlined a plan to prove that Splay trees are approximately monotone.

In this paper, we show that a broad class of algorithms (as defined in [6]) in fact satisfies simulation embeddings. This result is derived as a corollary to the following theorem.

▶ **Theorem 1.** *All BST algorithms (including Greedy and Splay) described in [6] are $O(1)$-competitive to Move-to-Root.*

Move-to-Root (MTR) is a classical BST algorithm that always rotates the requested key up until it becomes the root of the tree. It is known to be sub-optimal but not subsumed by any existing BST bounds (such as working set [23], lazy finger [14], pattern avoidance [5], or multiple fingers [8]). See discussion in the full version. Interestingly, so far no dynamic BSTs have been shown to be competitive even to this simplest dynamic algorithm.

▶ **Corollary 2.** *Let $\mathcal{A}$ be any BST algorithm according to [6]. Then, $\mathcal{A}$ has simulation embedding property. Therefore, it is dynamically optimal if and only if $\mathcal{A}$ is approximately monotone.*

Corollary 2 gives the first potential function proof of simulation property of any BST algorithm, therefore unifying the classical potential function techniques with the new attempt by Levy, Tarjan and Russo. The fact that infinitely many BST algorithms (that have simple description) have simulation embedding property can be interpreted in many ways. For an optimist, this could give us an access to a large design toolbox for studying the Levy-Tarjan approach: Instead of focusing on Splay or Greedy, we have the freedom to seek an algorithm that is approximately monotone by fine-tuning.

Another interesting aspect of MTR-competitiveness is perhaps a conceptual resemblance between Move-to-Root and the second Wilber bound [24] which is believed to be stronger than the first Wilber bound but so far no algorithm has ever exploited such bound[5]. Being able to charge the cost of an algorithm to Move-to-Root is a very first step towards this direction. (Informally, the second Wilber bound is equal to *crossing* Move-to-Root, see [16] for a more detailed discussion).

Second contribution: Streamlining known bounds

Now, we discuss how to use our potential function to streamline the BST bounds. Our second main result is an improved bound for the lazy finger property of Greedy. For a sequence $X = (x_1, \ldots, x_m)$ and a fixed BST R, denoted by $\mathsf{LF}_R(X) = \sum_t d_R(x_t, x_{t+1})$ where $d_R(a, b)$ denotes the number of edges on the unique path in R from a to b. Let $\mathsf{LF}(X) := \min_R \mathsf{LF}_R(X)$, we say that an algorithm $\mathcal{A}$ has lazy finger property if $cost_{\mathcal{A}}(X) \leqslant O(\mathsf{LF}(X))$. For any sequence X, denote by $G(X)$ the cost of Greedy in the geometric view[6]. Iacono and Langerman showed that $G(X) \leqslant C' \cdot (\mathsf{LF}(X) + m)$ where C' is around 50 (A quick glance at

[4] The definition of simulation is quite technical and we will only discuss this formally later.

[5] The best known competitive ratio is due to Tango Trees and its variants [13] which charge the cost to the first Wilber bound, which is provably insufficient for dynamic optimality [15, 4]

[6] Recall that, when turning the Greedy algorithm into a standard BST view, there is a constant factor blowup in the cost, that is, $cost_{Greedy}(X)$ (in the tree view) is at most $O(G(X))$.

their paper would show that the value of C' is 24, but there is also another multiplicative factor hidden in converting the result from "leaf-oriented" tree[7] setting to the BST setting). We show the following.

▶ **Theorem 3.** *For each access sequence X, $G(X) \leqslant 5 \cdot \mathsf{LF}(X) + O(m+n)$.*

In particular, when the input sequence is sufficiently costly, this bound converges to a multiplicative factor of 5 in front of the lazy finger term. We highlight that the interesting aspect of this result is not the improvement of constant but rather (1) the fact that our lazy finger proof directly and intuitively extends the proof of static optimality, and (2) the fact that we are able to charge the cost directly to the reference BST R instead of a leaf-oriented tree, in contrast to [14]. We hope that these two points open up natural new paths to adapt our techniques to handle stronger BST bounds where leaf-oriented settings become unnatural (e.g. BST rotation is less natural in the leaf-oriented setting).

Conclusion & Open Problems. We introduce a new potential function that allows us to, for the first time, compare two dynamic BSTs directly in a systematic way. Moreover, to our knowledge, ours is the first potential function in the BST context that uses a natural concept of inversions. We show many applications of our potential function. We note that, once the potential function is formally defined, the proofs of our results do not require any ground-breaking ideas but rather a careful adaptation of existing proofs [23, 6, 14] to our potential function.

Though the most intriguing open question is to prove dynamic optimality, we feel that it is still very far from the current understanding. We list here some open questions that we believe they are not overly far-fetched.

- **(i)** Can we use our method to analyze weighted dynamic finger (or even just dynamic finger) for Splay trees?
- **(ii)** Can we show that Greedy satisfies multi-finger properties as defined in [8]? We find this non-trivial even when there are two fingers.
- **(iii)** The property of being $O(\sqrt{\log n})$-competitive BST can be cast as a "local" BST property, e.g. see a survey paper [7]. Can we show that Greedy satisfies this property?

Further Related Work. Most prior works in this area focus on proving consequential properties of dynamic optimality. In particular, dynamic BSTs satisfy various forms of locality of reference properties that allow efficient access when the input sequence is in some way "local". For instance, the dynamic finger bound allows an efficient access when the access is close to the previous one (on average). It is often not so difficult to prove that these locality properties are satisfied by an optimal offline BST, so a candidate for optimal online BST must satisfy them as well. Proving that an online BST algorithm satisfies such properties has, however, been very challenging (for instance, Cole's proof [11, 10] of Splay's dynamic finger property spans 80 pages in total). Recently, a much stronger locality of reference bound, called Lazy Finger [3], was proved in a breakthrough result of Iacono and Langerman [14]. One way to view these locality of reference properties is as a "mildly dynamic" BST algorithm, i.e. each such property can be described by a restricted way of using the power of dynamic BST algorithms. Therefore, proving these bounds has naturally been seen as intermediate steps to study the dynamic optimality conjecture.

[7] A leaf-oriented binary search tree is one where all keys in $[n]$ are maintained as leafs, and each internal BST node is auxiliary (corresponding to a subset of leafs in the subtree under it).

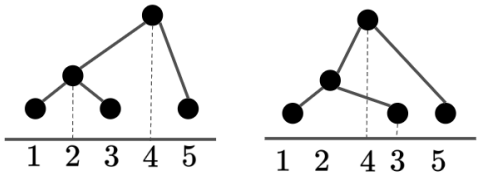

Figure 1 Examples of good (left) and bad (right) drawing of the same binary search tree.

2 Overview of Techniques

Let us recall the BST search model. The algorithm $\mathcal{A}$ maintains a binary search tree T on keys $[n]$, and when access $x_t \in [n]$ comes at time t, the cost incurred is equal to the depth of x_t in T. Elements on the search path of x_t (including x_t) are said to be *touched* by T. After that, the algorithm may adjust the shape of the tree, paying the cost which is equal to the number of keys that are involved in the adjustment. The total cost is then equal to the sum of search cost and adjustment cost. In all algorithms we consider, it suffices to analyze only the search cost (in particular, for BST algorithms that only change the search path, the update cost is at most a constant factor of the length of the search path. Therefore, such cost can be charged to the search cost). We follow this standard practice.

For convenience, we will abuse notation and use $\mathcal{A}$ to stand for both the BST algorithm and the state of BST at certain time.

2.1 Interval geometry for BST & Extended Inversion

Our potential function is defined based on geometry that requires correct drawing of BSTs. When drawing a BST, one should always use two rules: (1) imagine placing node containing key z on the plane at point p where $p.x = z$ (the x-coordinate is z). (2) If u is a parent of v, always draw u higher than v (See Figure 1)

Let $\mathcal{A}$ be a BST. For each key $z \in [n]$, let $I_{\mathcal{A}}(z)$ be the largest open interval in $(0, n+1)$ containing only all keys in the subtree of $\mathcal{A}$ rooted at z (in Figure 1 we have $I_{\mathcal{A}}(2) = (0, 4)$). More formally, $I_{\mathcal{A}}(z) = (\mathsf{left}_{\mathcal{A}}(z), \mathsf{right}_{\mathcal{A}}(z))$ where $\mathsf{left}_{\mathcal{A}}(z)$ is the nearest left ancestor of z (0 if not exist) and $\mathsf{right}_{\mathcal{A}}(z)$ is the nearest right ancestor of z ($n+1$ if not exist). When drawing the BST correctly, we have that the intervals $\{I_{\mathcal{A}}(z)\}_{z\in[n]}$ form a laminar family (that is, each pair of intervals is either disjoint or nested); see Figure 2.

▶ **Observation 4.** *If z' is a left child of z, then $I_{\mathcal{A}}(z') = (\mathit{left}_{\mathcal{A}}(z'), \mathit{right}_{\mathcal{A}}(z')) = (\mathit{left}_{\mathcal{A}}(z), z)$. If z' is a right child of z, then $I_{\mathcal{A}}(z') = (\mathit{left}_{\mathcal{A}}(z'), \mathit{right}_{\mathcal{A}}(z')) = (z, \mathit{right}_{\mathcal{A}}(z))$. Also, for any keys $y, z \in [n]$, we have $y \in I_{\mathcal{A}}(z)$ iff y is in the subtree rooted at z.*

Let $\mathcal{A}$ be an algorithm we want to analyze and $\mathcal{O}$ be an optimal algorithm. In this paper, we only consider $\mathcal{A}$ that changes only search path (this includes Greedy and Splay). Both $\mathcal{A}$ and $\mathcal{O}$ store the keys in $[n]$. We want to have a potential function that captures the "difference" between $\mathcal{A}$ and $\mathcal{O}$. The most natural scheme (which does not always work) often used in the context of online algorithm for this purpose is *inversion*.

▶ **Definition 5** (Inversion). *Let $z, \alpha \in [n]$. We say that z forms an* inversion *with α if $z \in I_{\mathcal{O}}(\alpha)$ and $\alpha \in I_{\mathcal{A}}(z)$.*

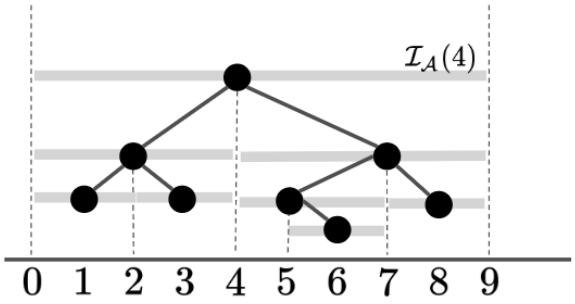

Figure 2 Example of intervals (in grey) for all keys. In this figure, $I_{\mathcal{A}}(4) = (0, 9)$ and $I_{\mathcal{A}}(5) = (4, 7)$.

Notice that an inversion is an indicator of α being in the subtree of z in one BST, but z is in the subtree of α in the other. See Figure 3. Unfortunately, we are unable to use this natural and intuitive scheme to prove any meaningful result. We will use *extended inversion* instead.

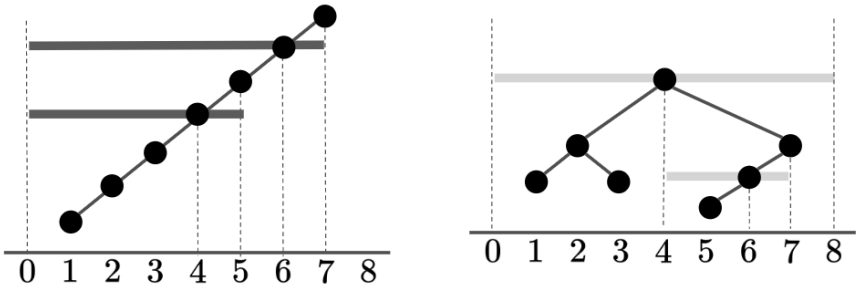

Figure 3 An example of inversion between the keys 4 and 6. The intervals of $\mathcal{A}$ are shown in dark grey and intervals of $\mathcal{O}$ in light grey. The left and right BSTs are $\mathcal{A}$ and $\mathcal{O}$ respectively.

For each interval in BST $\mathcal{O}$, $I_{\mathcal{O}}(\alpha)$, we define three **important points** of α in $\mathcal{O}$ as $\mathcal{P}_{\mathcal{O}}(\alpha) = \{\alpha, \mathsf{left}_{\mathcal{O}}(\alpha), \mathsf{right}_{\mathcal{O}}(\alpha)\}$.

▶ **Definition 6** (Extended Inversion). *Let $z, \alpha \in [n]$. We say that z forms an extended inversion with α if and only if $z \in I_{\mathcal{O}}(\alpha)$ and $\exists \beta \in \mathcal{P}_{\mathcal{O}}(\alpha)(\beta \in I_{\mathcal{A}}(z))$. See Figure 4.*

Unlike inversion, the notion of extended inversion is not symmetric. Clearly, if z forms an inversion with α, then z also forms an extended inversion with α.

Figure 4 The darker intervals are those intervals $I_{\mathcal{A}}(z)$, and the lighter ones are $I_{\mathcal{O}}(z)$. In the first figure from left, z forms an inversion with α. In the second, z forms an extended inversion with α but not an inversion. In the 3rd figure, there is no extended inversion, since $I_{\mathcal{A}}(z)$ does not contain any point in $\mathcal{P}_{\mathcal{O}}(\alpha)$. In the 4th figure, there is no extended inversion because $z \notin I_{\mathcal{O}}(\alpha)$.

2.2 Our potential function and its basic properties

All proofs in this paper build upon the following base function.

▶ **Definition 7** (Base Potential function). *Define the potential $\Phi = \Phi_{\mathcal{A},\mathcal{O}}$ at any state of execution of our algorithm $\mathcal{A}$ and optimal $\mathcal{O}$ as follows. Let $\Phi(z,\alpha) = 1$ if z forms an extended inversion with α; otherwise, $\Phi(z,\alpha) = 0$. The potential is defined as $||\Phi|| = \sum_{z,\alpha} \Phi(z,\alpha)$. This is the total number of extended inversions.*

We "visualize" our potential function value as a collection of "coins". Whenever $\Phi(z,\alpha) = 1$, one can imagine there is a coin of label z (or z-coin) placed at node α in $\mathcal{O}$ whenever z forms an extended inversion with α (see Figure 5). By definition, z always forms an extended inversion with itself, so there is always a z-coin at z. We use $\Phi(\bullet,\alpha) = \sum_{z\in[n]} \Phi(z,\alpha)$ to denote the total number of coins at α, and $\Phi(z,\bullet) = \sum_{\alpha\in[n]} \Phi(z,\alpha)$ the total number of z-coins. The coin interpretation will be used crucially in our analysis.

The main properties we would need are the following:

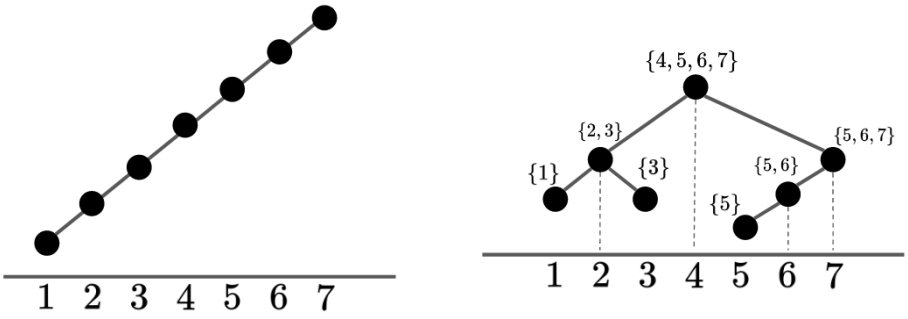

Figure 5 The left and right BSTs are $\mathcal{A}$ and $\mathcal{O}$ respectively. The set notation shown at each node is a collection of coins placed at that node. For instance, there are 5- and 6-coins at node 6. The path of 3-coins (according to Lemma 8) is a path containing nodes 3 and 2.

▶ **Lemma 8.** *[Upward path property] For each $z \in [n]$, the set of nodes having z-coin (that is, $Q_z = \{\alpha : \Phi(z,\alpha) = 1\}$) is a contiguous subpath of the path from z to the root of $\mathcal{O}$.*

Proof. Let $\alpha_1, \alpha_2 \in Q_z$. Since $z \in I_{\mathcal{O}}(\alpha_1) \cap I_{\mathcal{O}}(\alpha_2)$, we must have that $I_{\mathcal{O}}(\alpha_1) \subseteq I_{\mathcal{O}}(\alpha_2)$ (from laminar property). Since $z \in Q_z$, we have that Q_z is a subset of path from z to the root. Next, we argue that Q_z is connected. Suppose α' is on the path from z to the root such that $\alpha' \notin Q_z$. See Figure 6. We argue that the parent of α' (say α, where α' is the right child of α) is also not in Q_z: From Observation 4, $I_{\mathcal{O}}(\alpha') = (\alpha, \mathsf{right}_{\mathcal{A}}(\alpha))$. Recall that $\mathcal{P}_{\mathcal{O}}(\alpha) = \{\alpha, \mathsf{left}_{\mathcal{A}}(\alpha), \mathsf{right}_{\mathcal{A}}(\alpha)\}$. Since $\alpha' \notin Q_z$, we have that $I_{\mathcal{A}}(z)$ is completely contained in $(\alpha, \mathsf{right}_{\mathcal{O}}(\alpha))$. This means that it does not contain any point in $\mathcal{P}_{\mathcal{O}}(\alpha)$. ◀

By the above lemma, we view the potential function $\Phi(z,\bullet)$ as the coins on an upward path in $\mathcal{O}$ and Φ as a collection of upward paths.

▶ **Lemma 9.** *Consider an access to key $x \in [n]$. Let z be a key on the search path $\mathcal{S}_{\mathcal{A}}(x)$ of our algorithm. Then x forms an inversion with $LCA_{\mathcal{O}}(x,z)$. Hence, there is a z-coin at node $LCA_{\mathcal{O}}(x,z)$.*

Proof. Fix $z \in \mathcal{S}_{\mathcal{A}}(x)$. Recall that $x \in I_{\mathcal{A}}(z)$. Denote by $\ell = LCA_{\mathcal{O}}(x,z)$. Since ℓ is between x and z, $\ell \in I_{\mathcal{A}}(z)$. Since ℓ is an ancestor of z in $\mathcal{O}$, $z \in I_{\mathcal{O}}(\ell)$, and thus an inversion occurs between z and ℓ. ◀

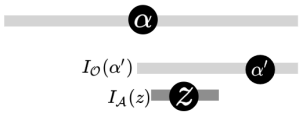

Figure 6 Illustration of the proof of Lemma 8.

The above lemma is the main advantage of the inversion principle: Each $z \in \mathcal{S}_{\mathcal{A}}(x)$ contributes $+1$ to the cost of $\mathcal{A}$ when accessing x. The lemma shows that such cost can be "deducted" from the z-coin at $LCA_{\mathcal{O}}(x, z)$.

▶ **Definition 10** (Canonical payment function)**.** *Consider algorithm $\mathcal{A}$ and optimal $\mathcal{O}$. The* ***canonical payment function*** *for accessing x is a function $\mathcal{CP} = \mathcal{CP}_{\mathcal{A},\mathcal{O},x}$ such that for each $z \in \mathcal{S}_{\mathcal{A}}(x)$, we have $\mathcal{CP}(z, LCA_{\mathcal{O}}(z, x)) = 1$. The function is 0 everywhere else (Figure 7).*

We will simply write $\mathcal{CP}$ instead of $\mathcal{CP}_{\mathcal{A},\mathcal{O},x}$ when it is clear from the context. Notice that, for each $z \in \mathcal{S}_{\mathcal{A}}(x), \mathcal{CP}(z, \alpha) = 1$ only if α is on the search path $\mathcal{S}_{\mathcal{O}}(x)$ of the optimal. From Lemma 9, we have that $\mathcal{CP}(z, \alpha) \leqslant \Phi(z, \alpha)$ for all $z, \alpha \in [n]$.

▶ **Observation 11.** *We have $\sum_{z,\alpha} \mathcal{CP}(z, \alpha) = |\mathcal{S}_{\mathcal{A}}(x)|$.*

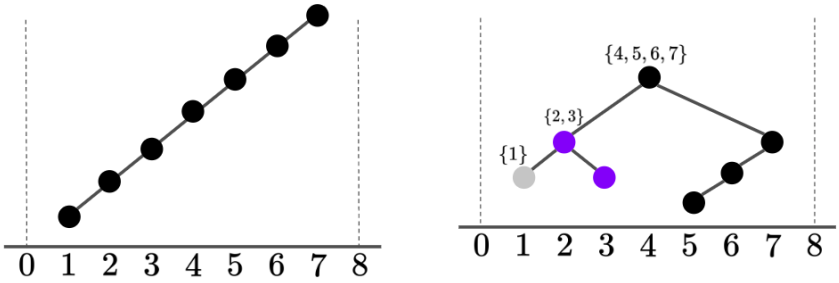

Figure 7 An example of coins in the support of $\mathcal{CP}$. In this example, when access 1, we touch every key in $\mathcal{A}$, but we touch only {1,2,4} in $\mathcal{O}$. Each $z \in \{4, 5, 6, 7\}$ has its coin at node 4 in the support of $\mathcal{CP}$. Each z in $\{2, 3\}$ has its coin at node 2. Finally, 1 has a coin at node 1.

2.3 Overview of our proofs

We first recall the basic ideas of potential function proofs.

▶ **Definition 12.** *We say that potential function Φ* ***proves*** *$\mathcal{A} \leqslant_\eta \mathcal{O}$ if for any state $\mathcal{A}$ and $\mathcal{O}$ of execution, when an access $x \in [n]$ arrives, we have*

$$(||\Phi_{\mathcal{A},\mathcal{O}}|| - ||\Phi_{\mathcal{A}',\mathcal{O}'}||) + \eta|\mathcal{S}_{\mathcal{O}}(x)| \geqslant |\mathcal{S}_{\mathcal{A}}(x)|$$

where $\mathcal{A}'$ and $\mathcal{O}'$ are the BSTs after the algorithm and the optimal update their trees.

The following claim follows from a standard potential function analysis. See, for instance, [23] for the formal proof.

▶ **Proposition 13.** *If potential function Φ proves $\mathcal{A} \leqslant_\eta \mathcal{O}$, then for any input $X \in [n]^m$, we have $cost_{\mathcal{A}}(X) \leqslant \eta \cdot cost_{\mathcal{O}}(X) + \Phi_{\max}$ where $\Phi_{\max}$ is the maximum value of $||\Phi_{\mathcal{A},\mathcal{O}}||$ over all possible states of execution of $\mathcal{A}$ and $\mathcal{O}$.*

Finally, since the size of support of $\mathcal{CP}$ is exactly $|\mathcal{S}_{\mathcal{A}}(x)|$, one can rewrite the condition in Definition 12 as $||\Phi_{\mathcal{A}',\mathcal{O}'}|| \leqslant ||\Phi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}|| + \eta|\mathcal{S}_{\mathcal{O}}(x)|$. All our proofs follow this high-level idea: (i) Upper bound $||\Phi_{\mathcal{A}',\mathcal{O}}|| - ||\Phi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}||$, and (ii) upper bound $||\Phi_{\mathcal{A}',\mathcal{O}'}|| - ||\Phi_{\mathcal{A}',\mathcal{O}}||$. The extended inversion potential function allows us to analyze Step (i) of various kinds of BST bounds in a modular way. The following is a key property.

▶ **Proposition 14.** *Consider algorithm $\mathcal{A}$ that, after access x arrives, updates the trees into $\mathcal{A}'$, while $\mathcal{O}$ does not change. Let $\widehat{\Phi} = \Phi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}$.*

(i) *For each $z \notin \mathcal{S}_{\mathcal{A}}(x)$ and $\alpha \in [n]$, we have $\Phi_{\mathcal{A}',\mathcal{O}}(z,\alpha) \leqslant \widehat{\Phi}(z,\alpha)$.*

(ii) *For each $\alpha \notin \mathcal{S}_{\mathcal{O}}(x)$ and $z \in [n]$, we have $\Phi_{\mathcal{A}',\mathcal{O}}(z,\alpha) \leqslant \widehat{\Phi}(z,\alpha)$.*

These imply that the potential change $||\Phi_{\mathcal{A}',\mathcal{O}}|| - ||\widehat{\Phi}||$ is upper bounded by the "change on search paths", that is, $||\Phi_{\mathcal{A}',\mathcal{O}}|| - ||\Phi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}|| \leqslant \sum_{z\in\mathcal{S}_{\mathcal{A}}(x)} \sum_{\alpha\in\mathcal{S}_{\mathcal{O}}(x)} \left(\Phi_{\mathcal{A}',\mathcal{O}}(z,\alpha) - \widehat{\Phi}(z,\alpha)\right)$

Proof. First, for each such $z \notin \mathcal{S}_{\mathcal{A}}(x)$, the intervals $I_{\mathcal{A}}(z) = I_{\mathcal{A}'}(z)$, so the number of extended inversions for them remains the same. Since $\mathcal{CP}(z,\alpha) = 0$, $\Phi_{\mathcal{A}',\mathcal{O}}(z,\alpha) \leqslant \widehat{\Phi}(z,\alpha) = \Phi_{\mathcal{A},\mathcal{O}}(z,\alpha)$.

Now we prove the second item. Fix $\alpha \notin \mathcal{S}_{\mathcal{O}}(x)$. Due to the previous observation, only $z \in \mathcal{S}_{\mathcal{A}}(x)$ may create a new inversion. By Lemma 9, $\Phi_{\mathcal{A},\mathcal{O}}(z, LCA_{\mathcal{O}}(x,z)) = 1$. Since $LCA_{\mathcal{O}}(x,z)$ is an ancestor of α, by Lemma 8, $\Phi_{\mathcal{A},\mathcal{O}}(z,\alpha) = 1$. This means that there was already a z-coin at α. Since $\mathcal{CP}(z,\alpha) = 0$, $\Phi_{\mathcal{A}',\mathcal{O}}(z,\alpha) \leqslant \widehat{\Phi}(z,\alpha) = \Phi_{\mathcal{A},\mathcal{O}}(z,\alpha)$. ◀

All our proofs rely on this proposition to upper bound the change from $\mathcal{A}$ to $\mathcal{A}'$.

2.4 The First Showcase: Splay's Ziz-zig

We consider the Splay tree currently maintaining a path with n as a root and 1 as a leaf; and $\mathcal{O}$ does not change (that is, $\mathcal{O} = \mathcal{O}'$). Define the potential $\Psi(z,\alpha) = 2\Phi(z,\alpha)$ for all $z,\alpha \in [n]$ (there are 2 coins for each extended inversion). Let us consider the situation when an access $x = 1$ arrives. We will upper bound the change of potential function Ψ as follows:

$$||\Psi_{\mathcal{A}',\mathcal{O}}|| \leqslant ||\Psi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}|| + 6|\mathcal{S}_{\mathcal{O}}(x)|$$

Deducting $\mathcal{CP}$ from Ψ can be seen as removing some coins from the search path $\mathcal{S}_{\mathcal{O}}(x)$. Recall that in $\Psi - \mathcal{CP}$, for each z on the search path of $\mathcal{A}$, we had removed one z-coin at $LCA(z,x)$. The proof has two steps. In the first step, we move the coins around from "bad" to "good" keys. Refer to Figure 8 for the shape of $\mathcal{A}'$. For simplicity assume that n is odd. Except for the root, we pair i with $i+1$ for $i = 2,4,\ldots,n-1$. We say that the even keys are good and the odd keys are bad. For each i, we turn one $(i+1)$-coin at $LCA(i+1,x)$ into an i-coin at $LCA(i,x)$. Let $\widehat{\Psi}$ be the function after moving the coins, so $||\widehat{\Psi}|| = ||\Psi_{\mathcal{A},\mathcal{O}} - \mathcal{CP}||$.

▶ **Lemma 15.** *We have $||\Psi_{\mathcal{A}',\mathcal{O}}|| - ||\widehat{\Psi}|| \leqslant O(|\mathcal{S}_{\mathcal{O}}(x)|)$. (In other words, we can add at most $O(|\mathcal{S}_{\mathcal{O}}|)$ to achieve the coin level of $\Psi_{\mathcal{A}',\mathcal{O}}$.)*

The rest of this section is devoted to proving the lemma. Denote $\Psi_{\mathcal{A}',\mathcal{O}}$ by Ψ' for convenience. From Proposition 14, we have $||\Psi_{\mathcal{A}',\mathcal{O}}|| - ||\widehat{\Psi}|| \leqslant \sum_{z\in\mathcal{S}_{\mathcal{A}}(x)} \sum_{\alpha\in\mathcal{S}_{\mathcal{O}}(x)} \left(\Psi'(z,\alpha) - \widehat{\Psi}(z,\alpha)\right)$. The following claim therefore finishes the proof.

▷ Claim 16. We have $\sum_{z\in\mathcal{S}_{\mathcal{A}}(x)} \sum_{\alpha\in\mathcal{S}_{\mathcal{O}}(x)} \left(\Psi'(z,\alpha) - \widehat{\Psi}(z,\alpha)\right) \leqslant 14|\mathcal{S}_{\mathcal{O}}(x)|$.

Proof. Refer to Figure 8 that illustrate the shape of $\mathcal{A}'$ (Splay) after the access of x. For $z = 1$, we use the crude bound of $\sum_{\alpha\in\mathcal{S}_{\mathcal{O}}(x)} \left(\Psi'(1,\alpha) - \widehat{\Psi}(1,\alpha)\right) \leqslant 2|\mathcal{S}_{\mathcal{O}}(x)|$. For $z \geqslant 2$, we divide the analysis into two cases:

(i) new extended inversions, i.e. $\Psi'(z,\alpha) = 1$ and $\widehat{\Psi}(z,\alpha) = \Psi_{\mathcal{A},\mathcal{O}}(z,\alpha) = 0$

(ii) existing extended inversions that pay their coins out, i.e. $\Psi'(z,\alpha) = 1, \widehat{\Psi}(z,\alpha) = 0$ and $\Psi(z,\alpha) = 1$.

We upper bound the potential increase by the notion of *witness intervals*. For the first case, a new extended inversion can appear in $\Psi'(z,\alpha)$ due to the fact that the interval $I_{\mathcal{A}'}(z)$ becomes larger than $I_{\mathcal{A}}(z)$. In this case, we define $J(z,\alpha) = I_{\mathcal{A}'}(z) \backslash I_{\mathcal{A}}(z)$ as a **witness** for the new inversion (z,α). From Figure 8, these witness intervals (drawn in red) are non-overlapping. Since there are 3 important points for each $\alpha \in \mathcal{S}_{\mathcal{O}}(x)$ and each point can be in at most one witness interval, there are at most $3|\mathcal{S}_{\mathcal{O}}(x)|$ witness intervals. Each witness interval requires 2 coins, so we need at most $6|\mathcal{S}_{\mathcal{O}}(x)|$ coins in total.

For the second case, this happened due to z being a bad key that pays its coin out of canonical payment (the good ones received their coins back from the transfer in the first step). In this case, we say that $J(z,\alpha) = I_{\mathcal{A}'}(z)$ is a witness for the inversion (z,α). From Figure 8, the witness intervals of this type (drawn in blue) are disjoint. Therefore, with the same argument as in the first case, we need at most $6|\mathcal{S}_{\mathcal{O}}(x)|$ coins in total. ◁

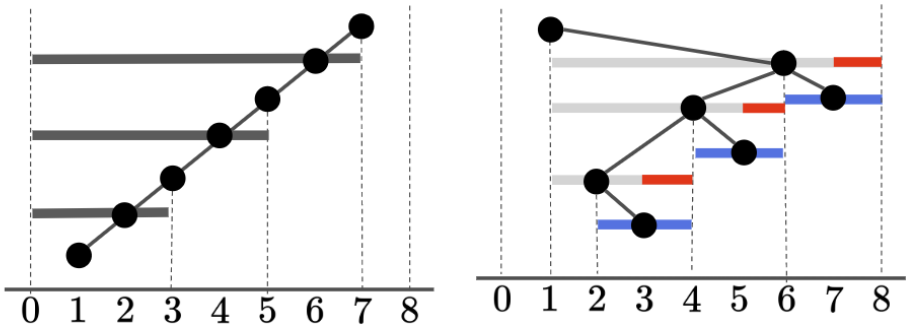

Figure 8 A BST before (left) and after (right) splaying $x = 1$. After splaying, intervals of odd keys (except access key) are disjoint. The red and blue intervals are the witnesses as in Claim 16.

There are two remarks about this proof. First, this proof only gives an analysis of a zig-zig case in Splay trees. A full Splay trees analysis can be found as a special case of our Theorem 1 whose proof is deferred to the full version. Second, if $\mathcal{O}$ is not a static tree, we add one more step to the analysis, that is, upper bounding the change due to updating $\mathcal{O}$; the second step for MTR-competitiveness results is simple, while for lazy finger, the second step is more involved, relying on a modified concept of extended inversions and on some ideas from [14].

2.5 Geometric Inversion for Geometric BST Algorithms

In order to use our scheme, all algorithms must be described in terms of *intervals*. In the previous section, we already explained how BST algorithms $\mathcal{A}$ in the tree view can be described as intervals $I_{\mathcal{A}}(z)$. In this section, we explain how to do the same for BST algorithms in the geometric view. As discussed in [12], the tree and geometric views are equivalent up to constant factor in the competitive ratios.

Let $[n]$ be the set of keys. An access sequence of binary search trees (BST) is specified as searching for key $x_t \in [n]$ at time $t = 1, \ldots, m$. Given an access sequence $X = (x_1, \ldots, x_m) \in [n]^m$, we view X as points $\mathcal{Q}_X = \{(x_t, t) : t = 1, \ldots, m\}$ in the plane where t-th access appears on row t (starting from bottom). We abuse the notation and simply write $\mathcal{Q}_X$ as X.

For $\mathbf{p},\mathbf{q} \in \mathbb{R}^2$, define $\square_{\mathbf{p},\mathbf{q}}$ as the set of integral points in the minimally closed rectangular area defined by $\mathbf{p}$ and $\mathbf{q}$. Let $Z \subseteq \mathbb{R}^2$, we say that such the rectangle $\square_{\mathbf{p},\mathbf{q}}$ is *empty* in Z (or Z-empty) if $Z \cap \square_{\mathbf{p},\mathbf{q}}$ contains no other point than $\mathbf{p}$ or $\mathbf{q}$. Also, the point set Z is *arborally satisfied* if for every pair $\mathbf{p}, \mathbf{q} \in Z$, the rectangle $\square_{\mathbf{p},\mathbf{q}}$ is not Z-empty.

Geometric BST problem (MinASS)

Let $X_{\leqslant t}$ denote the set of points in X in rows t and below. In the MinASS problem, given an input X of points, we are interested in computing a superset $Y \supseteq X$ such that Y is arborally satisfied, while minimizing $|Y|$. In the online version, at any time $t = 1, 2, \ldots, m$, a point in X arrives on the t-th row, and the algorithm must produces a feasible solution $Y_{\leqslant t}$ at each time t by adding points on the t^{th} row. Points in Y are said to be *touched* by the algorithm $\mathcal{A}$. We denote a set of touched keys at time t by $\mathcal{S}_{\mathcal{A}}(x_t)$ (same notation as search path of x_t in the tree view).

▶ **Theorem 17** (Demaine et al. [12]). *Let $\mathcal{A}$ be an algorithm for the MinASS problem. Then for each sequence X, there is a BST algorithm $\mathcal{A}'$ whose total cost on X is at most $O(cost_{\mathcal{A}}(X))$.*

Greedy

For each time t and key $z \in [n]$, let $\tau(z,t)$ denote the last touched time of z on or before time t. At time t, Greedy touches key $z \in [n]$ if and only if $(z, \tau(z,t))$ forms an empty rectangle with (x_t, t). The final output of Greedy on input X is defined as $G(X)$; denote the first t rows of such output by $G_{\leqslant t}(X)$. See Figure 9 for an illustration.

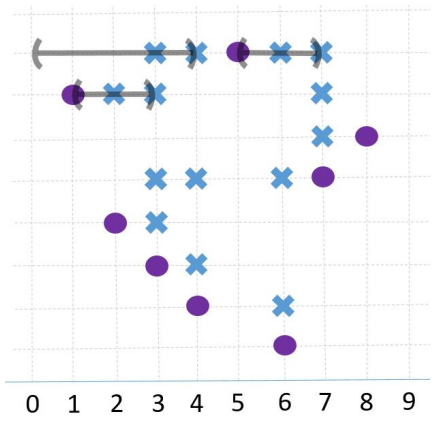

Figure 9 An example of intervals of Greedy. Here, circles represent access keys X and crosses represent touched points $Y \backslash X$. Interval of each key is defined by the top point (i.e. the last touched point) of such key. Intervals of 2,3, and 6 are shown in this figure.

Intervals for Geometric BSTs

Since the intervals of BST algorithms in a tree view depend on sub-trees, for Greedy, we need an analogue of sub-trees in geometric view. Let $z \in [n]$ be a key. The interval $I_G(z)$ is defined as $(\mathsf{left}_G(z), \mathsf{right}_G(z))$ where $\mathsf{left}_G(a)$ is the maximum key less than z that is touched at the same time as when a was last touched (0 if it does not exist). Similarly, we define $\mathsf{right}_G(z)$ as the minimum key greater than $a = z$, touched at the last touched time of z

$(n+1$ if it does not exist). So the interval $I_G(z)$ only change whenever z is touched. See Figure 9. Given an optimal tree $\mathcal{O}$, Lemma 8, Lemma 9 and Proposition 14 still hold for these geometric intervals. The following observations are important. (See Figure 10a)

▶ **Observation 18.** *Suppose key x_t is accessed. Let $\{I_G(b)\}_{b\in[n]}$ and $\{I'_G(b)\}_{b\in[n]}$ be the intervals before and after Greedy updates. Let $b_1 < b_2 < \ldots < b_k$ be the touched keys, $b_0 = 0$ and $b_{k+1} = n+1$. Then we have that $I'_G(b_i) = (b_{i-1}, b_{i+1})$ for all $i = 1, \ldots, k$.*

▶ **Corollary 19.** *For each point $p \in \mathbb{R}$, there are at most two touched keys z for which $p \in I'_G(z)$. In other words, the clique size of this interval graph is 2 and therefore, the touched intervals $I'_G(z)$ can be decomposed into two disjoint sets of intervals.*

2.6 The Second Showcase: Greedy

We show the following static optimality bound for Greedy using our potential.

▶ **Theorem 20.** *For each X and each static tree $\mathcal{O}$, $G(X) \leqslant 4 \cdot cost_{\mathcal{O}}(X) - m + n^2$.*

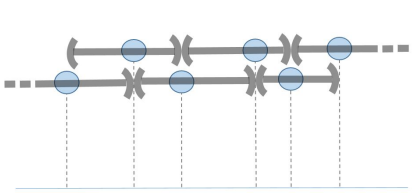
We note that the term n^2 is from the number of initial coins. Later, we will show that these initial coins can be bounded by $cost_{\mathcal{O}}(X)$, therefore we have $G(X) \leqslant 5 \cdot cost_{\mathcal{O}}(X)$.

The potential function we use is simply the extended inversion Φ. Let $\mathcal{O}$ be any tree. After accessing x, the Greedy intervals change from $\{I_G(z)\}_{z\in[n]}$ to $\{I'_G(z)\}_{z\in[n]}$, and the potential changes from Φ to Φ'. We will prove that $||\Phi'|| \leqslant ||\Phi - \mathcal{C}P|| + 4|\mathcal{S}_{\mathcal{O}}(x)| - 1$.

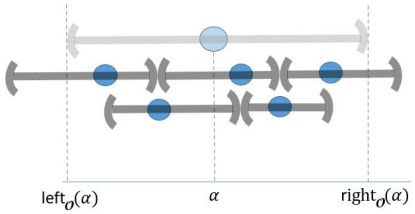
Summing over all accesses over a sequence X of length m will give us the desired bound. Denote $\Phi - \mathcal{C}P$ by $\widehat{\Phi}$. Due to Proposition 14, the change of potential function is only due to the inversions (z, α) where $z \in \mathcal{S}_G(x)$ and $\alpha \in \mathcal{S}_{\mathcal{O}}(x)$.

▶ **Lemma 21.** *For each $\alpha \in \mathcal{S}_{\mathcal{O}}(x)$, we have $||\Phi'(\bullet, \alpha)|| - ||\widehat{\Phi}(\bullet, \alpha)|| \leqslant 4$. Moreover, $||\Phi'(\bullet, x)|| - ||\widehat{\Phi}(\bullet, x)|| \leqslant 3$.*

Proof. Fix $\alpha \in \mathcal{S}_{\mathcal{O}}(x)$. Notice that the term $\Phi'(z, \alpha) - \widehat{\Phi}(z, \alpha) = 1$ only if $z \in \mathcal{S}_G(x)$ and $\Phi'(z, \alpha) = 1$. To have $\Phi'(z, \alpha) = 1$, the interval $I'_G(z)$ must contain a point in $\mathcal{P}_{\mathcal{O}}(\alpha) = \{l, \alpha, r\}$ (where $l = \mathsf{left}_{\mathcal{O}}(\alpha)$ and $r = \mathsf{right}_{\mathcal{O}}(\alpha)$) and point z must be inside $I_{\mathcal{O}}(\alpha)$. From the fact that z is inside $I_O(\alpha)$ and the geometry of Greedy (Observation 18), only one interval can contain l, only one interval can contain r, and at most two intervals can contain α (this is all illustrated in Figure 10b); moreover, when $\alpha = x$, only one interval may contain α ($I_G(x)$ itself). This concludes the proof. ◀



(a) Intervals of keys that are touched at the same time in Greedy. Think of all of them as in the same height, we perturb them in order to show their intervals clearly.



(b) Intervals in G are represented in black, while interval in $\mathcal{O}$ is represented in grey.

Figure 10

To recap, the framework is as follows. Let $\mathcal{A}$ be an algorithm and $\mathcal{O}$ be an optimal algorithm. Suppose, after accesssing key $x \in [n]$, $\mathcal{A}$ changes to $\mathcal{A}'$ and $\mathcal{O}$ to $\mathcal{O}'$. We wan to upper bound $|\mathcal{S}_{\mathcal{A}}(x)| + ||\Phi_{\mathcal{A}',\mathcal{O}'}|| - ||\Phi_{\mathcal{A},\mathcal{O}}|| \leqslant O(|\mathcal{S}_{\mathcal{O}}(x)|)$. We upper bound this in two steps:

- The change of $\mathcal{A}$ to $\mathcal{A}'$ after subtracting the cost: $||\Phi_{\mathcal{A}',\mathcal{O}}|| - ||\Phi_{\mathcal{A},\mathcal{O}} - \mathcal{C}P||$
- And then the change of $\mathcal{O}$ to $\mathcal{O}'$: $||\Phi_{\mathcal{A}',\mathcal{O}'}|| - ||\Phi_{\mathcal{A}',\mathcal{O}}||$

We have shown how to bound the term $||\Phi_{\mathcal{A}',\mathcal{O}}|| - ||\Phi_{\mathcal{A},\mathcal{O}} - \mathcal{C}P||$ for Greedy and (a special case of) Splay. This is the "systematic" part of our framework that allows us to prove MTR-competitiveness for a family of BSTs. In the next subsection, we outlined how to upper bound $||\Phi_{\mathcal{A}',\mathcal{O}'}|| - ||\Phi_{\mathcal{A}',\mathcal{O}}||$ for Splay and Greedy, thus implying their $O(1)$-competitiveness to MTR. The proof for weighted dynamic finger is omitted due to the lack of space. Full details appear in the full version.

2.7 MTR-Competitiveness

In this section, we present the proof that Greedy and Splay have simulation embeddings. Due limitation of space, we defer the rest of the proofs to the full version.

First, we present necessary preliminaries.

▶ **Definition 22** (Static Optimality). *A BST algorithm $\mathcal{A}$ is statically optimal if, for all input X and static (reference) tree R, $cost_{\mathcal{A}}(X) \leqslant O(cost_R(X))$.*

Remark that a more precise definition of static optimality involves "initial tree" (the initial state of algorithm $\mathcal{A}$). In the context of our potential function, it is not difficult to see that the initial tree only affects the cost by at most an additive factor of $cost_R(X)$. Hence we omit the reference to initial trees for brevity. Denote the move-to-root algorithm by MTR.

▶ **Definition 23** (MTR-Competiveness). *A BST algorithm $\mathcal{A}$ is MTR-competitive if, for all input X, $cost_{\mathcal{A}}(X) \leqslant O(cost_{MTR}(X))$.*

▶ **Definition 24** (Simulation Embeddings). *A BST algorithm $\mathcal{A}$ has simulation embeddings if, for all access sequence X and algorithm $\mathcal{O}$, there exists a supersequence $Y \supseteq X$ such that $cost_{\mathcal{A}}(Y) \leqslant O(cost_{\mathcal{O}}(X))$.*

Levy and Tarjan [16] show that Splay has simulation embeddings by constructing a transition graph G_4 of Splay. Transition graph G_k is a directed graph where each node represents an instance of k-node BST. There is an edge (u, v) if a tree instance u can be changed to a tree instance v using one access. Also, they show that, in order for BST $\mathcal{A}$ to have simulation embeddings, it suffices to show that G_k of $\mathcal{A}$ is strongly connected for some constant $k \geqslant 3$.

▷ Claim 25. The transition graph G_3 of MTR is strongly connected. Hence, MTR has simulation embeddings. (See Figure 11)

This implies the following theorem.

▶ **Theorem 26.** *If a BST algorithm $\mathcal{A}$ is $O(1)$-competitive to MTR, then $\mathcal{A}$ has simulation embeddings.*

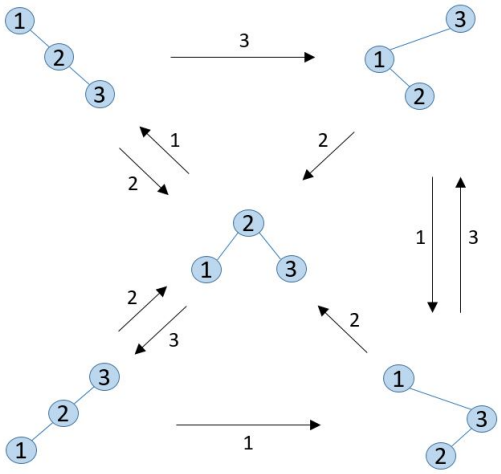


Figure 11 G_3 of MTR. The number on each arrow represents the key that MTR has to access in order to change its tree to the specific structure.

Proof. Suppose $\mathcal{A}$ is c-competitive to MTR. Now fix an input sequence X and a BST algorithm $\mathcal{O}$. From Claim 25, let d be the factor in the simulation embeddings of MTR, so we know that there exists a super-sequence X' such that $cost_{\mathsf{MTR}}(X') \leqslant d \cdot cost_{\mathcal{O}}(X)$. Since algorithm $\mathcal{A}$ is c-competitive to MTR, we have

$$cost_{\mathcal{A}}(X') \leqslant c \cdot cost_{\mathsf{MTR}}(X') \leqslant (cd) \cdot cost_{\mathcal{O}}(X)$$

This implies that $\mathcal{A}$ has simulation embeddings. ◀

Our potential function is particularly suitable for proving MTR-competitiveness. In fact, to show that $\mathcal{A}$ is $O(1)$-competitive to MTR, it suffices to only prove static optimality for $\mathcal{A}$ using extended inversions (together with a function that depends only on n.)

▶ **Lemma 27.** *A BST algorithm that (1) satisfies static optimality via potential function Ψ that depends linearly on extended inversions (i.e. $||\Psi|| = c_1||\Phi|| + c_2 n$), and (2) moves the accessed key to the root, must be $O(1)$-competitive to MTR.*

Proof. If $\mathcal{A}$ satisfies static optimality via Ψ, we have that:

$$||\Psi_{\mathcal{A}',\mathcal{O}}|| - ||\Psi_{\mathcal{A},\mathcal{O}} - \mathcal{C}P|| \leqslant C \cdot |\mathcal{S}_{\mathcal{O}}(x)|$$

Now, since the second term of potential is $c_2 n$ (only depending on n), to upper bound $||\Psi_{\mathcal{A}',\mathcal{O}'}|| - ||\Psi_{\mathcal{A}',\mathcal{O}}||$, it suffices to show that, we have $||\Phi_{\mathcal{A}',\mathcal{O}'}|| - ||\Phi_{\mathcal{A}',\mathcal{O}}|| \leqslant 0$.

For key $z = x$, $||\Phi_{\mathcal{A}',\mathcal{O}'}(z,x)|| = ||\Phi_{\mathcal{A}',\mathcal{O}}(z,x)|| = c_1$. Now, we consider keys $z \neq x$. Observe that intervals in $\mathcal{O}'$ change as follow:

- **(i)** $I_{\mathcal{O}'}(x) = (0, n+1)$.
- **(ii)** $I_{\mathcal{O}'}(y) = (\mathsf{left}_{\mathcal{O}}(y), x)$ for all y such that $y < x$ and $y \in \mathcal{S}_{\mathcal{O}}(x)$.
- **(iii)** $I_{\mathcal{O}'}(y) = (x, \mathsf{right}_{\mathcal{O}}(y))$ for all y such that $y > x$ and $y \in \mathcal{S}_{\mathcal{O}}(x)$.
- **(iv)** $I_{\mathcal{O}'}(y) = I_{\mathcal{O}}(y)$ for all $y \notin S_{\mathcal{O}}(x)$.

In other words, the only new important point in $\mathcal{O}'$ is x. Since $\mathcal{A}'$ also has x as the root, no $I'_{\mathcal{A}}(z)$ can contain x. Since x is the only new ancestor for z, this means $||\Phi_{\mathcal{A}',\mathcal{O}'}(z,x)|| = 0$. ◀

Since Splays and Greedy satisfy static optimality via our potential function, Lemma 27 implies that they are MTR-competitive, and hence have simulation embeddings.

Abstract

Given a set of n integer-valued coin types and a target value t, the well-known *change-making* problem asks for the minimum number of coins that sum to t, assuming an unlimited number of coins in each type. In the more general *all-targets* version of the problem, we want the minimum number of coins summing to j, for every $j = 0, \ldots, t$. For example, the textbook dynamic programming algorithms can solve the all-targets problem in $O(nt)$ time. Recently, Chan and He (SOSA'20) described a number of $O(t \operatorname{polylog} t)$-time algorithms for the original (single-target) version of the change-making problem, but not the all-targets version.

In this paper, we obtain a number of new results on change-making and related problems:

- We present a new algorithm for the all-targets change-making problem with running time $\tilde{O}(t^{4/3})$, improving a previous $\tilde{O}(t^{3/2})$-time algorithm.
- We present a very simple $\tilde{O}(u^2 + t)$-time algorithm for the all-targets change-making problem, where u denotes the maximum coin value. The analysis of the algorithm uses a theorem of Erdős and Graham (1972) on the Frobenius problem. This algorithm can be extended to solve the all-capacities version of the *unbounded knapsack* problem (for integer item weights bounded by u).
- For the original (single-target) coin changing problem, we describe a simple modification of one of Chan and He's algorithms that runs in $\tilde{O}(u)$ time (instead of $\tilde{O}(t)$).
- For the original (single-capacity) unbounded knapsack problem, we describe a simple algorithm that runs in $\tilde{O}(nu)$ time, improving previous near-u^2-time algorithms.
- We also observe how one of our ideas implies a new result on the *minimum word break* problem, an optimization version of a string problem studied by Bringmann et al. (FOCS'17), generalizing change-making (which corresponds to the unary special case).

1 Introduction

In the *change-making* problem (also known as *coin changing*), a set of n positive-integer-valued coin types is given, and the cashier wants to use the minimum number of coins to sum to a target value t exactly, where the number of coins in each type can be used an unlimited number of times. This is a well-known textbook problem, which is weakly NP-hard [20], and standard solutions using dynamic programming [27] have $O(nt)$ running time.

Change-making is closely related to another textbook problem, *subset sum* (the differences are that in subset sum, each item may be used at most once and there is no objective function to minimize). A series of work in the last few years [5, 16, 15, 17] have given improved algorithms for subset sum, using convolution (FFT). Very recently, at SOSA'20, Chan and He [8] revisited the change-making problem and described a number of $O(t \operatorname{polylog} t)$-time algorithms, using FFT; their fastest deterministic and randomized algorithms have $O(t \log t \log\log t)$ and $O(t \log t)$ running time respectively.

All-targets change-making. In this paper, we consider a more general, *all-targets* version of the change-making problem: the aim is to compute, for each target value $j = 0, \ldots, t$, the minimum number of coins that can be used to sum to j exactly. This version of the problem is equally natural. For instance, the standard $O(nt)$-time dynamic programming algorithms are actually designed to solve this more general version. Some of the newer subset-sum algorithms [5, 16, 17, 15] also solved the analogous all-targets version of subset sum, but in contrast, Chan and He's algorithms for change-making do *not* work for the all-targets version.

The best previous result for the all-targets change-making problem that we are aware of was an $\tilde{O}(t^{3/2})$-time[1] algorithm by Karl Bringmann and Tomasz Kociumaka (2019), cited as a personal communication (and briefly sketched) in a very recent paper by Lincoln, Polak, and Vassilevska Williams (ITCS'20) [19]. Lincoln et al.'s paper gave a web of fine-grained reductions connecting a variety of problems, including a reduction from all-targets change-making to the "monochromatic convolution" problem, the latter of which is shown to have near $n^{3/2}$ time complexity iff 3SUM has near quadratic time complexity. Their work implicitly hints at the possibility that the all-targets change-making problem might have near $t^{3/2}$ complexity as well, but the reduction is in the opposite direction.

Our first result is an $\tilde{O}(t^{4/3})$-time algorithm for the all-targets change-making problem, interestingly beating $t^{3/2}$ and placing the problem in a different category than monochromatic convolution and all its surrounding problems. Our algorithm is conceptually simple, exploiting an easy lemma on a binary special case of $(\min, +)$-convolution (using FFTs).

All-targets change-making in terms of u. Next, we consider the complexity of the all-targets change-making problem in terms of some other natural parameters besides n and t: specifically,

- the largest coin value, denoted by u;
- the sum of the n given coin values, denoted by σ.

Some prior works have analyzed algorithms in terms of u and σ for the subset sum problem [22, 16]. A few recent papers have also analyzed algorithms in terms of u for the *0-1 knapsack* and the *unbounded knapsack* problem [2, 4, 12, 14, 24]. The unbounded knapsack problem is particularly relevant: given integer weights $w_1, \ldots, w_n$ and profits $p_1, \ldots, p_n$ and capacity value t, find nonnegative integers $m_1, \ldots, m_n$ to maximize $\sum_i m_i p_i$ such that $\sum_i m_i w_i \leq t$. Change-making is a special case, for example, by setting $w_i = v_i$ and $p_i = Mv_i - 1$ for a sufficiently large M. Improving some previous algorithms [4, 24], Axiotis and Tzamos (ICALP'19) [2] and Jansen and Rohwedder (ITCS'19) [14] independently described algorithms[2] for unbounded knapsack running in $\tilde{O}(u^2)$ time with $u := \max_i w_i$ (the

[1] The $\tilde{O}$ notation hides polylogarithmic factors.

[2] We found that an $\tilde{O}(u^2)$ algorithm (basically the same as Axiotis and Tzamos') appeared earlier in a commentary on a 2016 programming contest problem by Arthur Nascimento, solved by Yan Soares Couto; see Problem L of `https://www.ime.usp.br/~maratona/assets/seletivas/2016/comentarios.pdf`.

time bound can be reduced slightly to $O(u^2/2^{\Theta(\sqrt{\log u})})$ by using known slightly subquadratic algorithms for $(\min,+)$-convolution [26]). However, these algorithms do not solve the all-targets or all-capacities version (computing the optimal profit for every capacity $j = 0, \ldots, t$).[3]

For the all-targets version of change-making, it is not difficult to obtain an $O(u^3 + t)$-time algorithm, based on a known observation that when the target is sufficiently large, it is always advantageous to use the largest coin. We describe a new algorithm that improves the running time to $O(u^2 \log u + t)$. Note that the algorithm is optimal for large $t \gg u^2 \log u$, since the output size for the all-targets problem is $\Omega(t)$.

The new algorithm is remarkably simple – just a slight variation of one of the standard dynamic programming solutions, with a 3-line pseudocode! (See page 8.) It is easily implementable and does not require FFT. However, the correctness argument is far from obvious, and requires a nice application of a number-theoretic theorem by Erdős and Graham [13] on the *Frobenius problem* (about the smallest target value that cannot be represented by a coin system). Arguably, algorithms that are simple but nontrivial to analyze are the most interesting kinds of algorithms.

All-capacities unbounded knapsack in terms of u. Our algorithm can be easily modified to solve the unbounded knapsack problem in the all-capacities version, with the same $O(u^2 \log u + t)$ time bound. This also implies an $O(u^2 \log u)$-time algorithm for the single-capacity version, which is a bit simpler than the previous $\tilde{O}(u^2)$ algorithms [2, 14] (in addition to extending it to all-capacities). For unbounded knapsack, a nearly matching conditional lower bound is known [9, 18]: more precisely, if single-capacity unbounded knapsack could be solved in truly subquadratic time for instances with $t, u = \Theta(n)$, then so could $(\min,+)$-convolution.

In terms of σ. We describe a variant of our algorithm with time bound $\tilde{O}((t\sigma)^{2/3} + t)$ for the all-targets change-making or all-capacities unbounded knapsack problem. Note that if $\sigma \ll t$, this is better than our earlier $\tilde{O}(t^{4/3})$ bound for the all-targets change-making.

Single-target change-making. For the single-target (original) change-making problem, we also describe how to improve the running time of one of Chan and He's FFT-based algorithms [8] from $\tilde{O}(t)$ to $\tilde{O}(u)$, which is faster than applying the previous $\tilde{O}(u^2)$-time algorithms [2, 14] for single-capacity unbounded knapsack.

Single-capacity unbounded knapsack. For the single-capacity (original) unbounded knapsack problem, we also describe a simple algorithm with running time $\tilde{O}(nu)$, which (ignoring $n^{o(1)}$ factors) simultaneously improves the standard $O(nt)$-time dynamic programming algorithm and the previous $\tilde{O}(u^2)$-time algorithms [2, 14] (since $u \le t$ without loss of generality, and $n \le u$ after pruning unnecessary items). There was a previous $O(nu)$-time algorithm by Pisinger [22] for subset sum, but not for unbounded knapsack.

Minimum word break. Finally, we consider a generalization of the problem for strings, known as the *minimum word break* problem: Given a string s with length n and a set D of strings (a "dictionary" of "words") with total length m, express s as a concatenation of words

[3] Cygan et al. [9] refered to the all-capacities version as Unbounded-Knapsack$^+$; Kunnemann et al. [18] called it the *output-intensive* version.

from D, using the smallest number of words, where a word may be used multiple times. It is easy to see that if the alphabet is unary, then the problem is the same as change-making (the single-target version, with n and m corresponding to t and σ). A straightforward dynamic programming algorithm runs in $\tilde{O}(nd + m)$ time, where d denotes the number of distinct lengths among the words in D, by using randomized fingerprints [3] (which can be made deterministic [28]). Because $m \geq \frac{d(d+1)}{2}$, the bound is $\tilde{O}(n\sqrt{m} + m)$.

The decision version of the problem – deciding whether a solution exists, without minimizing the number of words – was considered by Bringmann, Grønlund, and Larsen (FOCS'17) [6], who gave an $\tilde{O}(nm^{1/3} + m)$-time algorithm, using FFT (improving a previous algorithm by Backurs and Indyk [3] with running time $\tilde{O}(nm^{1/2-1/18} + m)$). Bringmann et al. also proved a nearly matching conditional lower bound for combinatorial algorithms, assuming the conjecture that k-clique requires near n^k time for combinatorial algorithms. However, they did not obtain results on the *minimum* word break problem: part of the difficulty is that for the optimization problem, the various convolution operations needed change to $(\min, +)$-convolutions, which appear to be more expensive.

Nevertheless, we note that Bringmann et al.'s algorithm can still be adapted to solve the minimum word break problem. In fact, the time bound $\tilde{O}(nm^{1/3} + m)$ remains the same. This shows that surprisingly the optimization problem is not harder but has the same fine-grained complexity as the decision problem (at least for combinatorial algorithms, assuming the k-clique conjecture). The only new ingredient in our adaptation of Bringmann et al.'s algorithm is the same lemma on $(\min, +)$-convolutions that we have used in our $\tilde{O}(t^{4/3})$ algorithm for change-making.

2 Preliminaries

The all-targets version of the change-making problem can be formally defined as follows:

▶ **Problem 1** (All-Targets Change-Making). *Given a set $V = \{v_1, \ldots, v_n\}$ of n positive integers (coin values) and an integer t, for each $j = 0, \ldots, t$, find the size of the smallest multiset S (duplicates allowed) of coin values from V such that S sums to exactly j, i.e., find the minimum m_j^* of $\sum_{i=1}^n m_i$ subject to the constraint that $\sum_{i=1}^n m_i v_i = j$, where $m_i \in \mathbb{N}$.*

Besides n (the number of coin values) and t (the maximum target value), we introduce two more parameters: let $u = \max_{i=1}^n v_i$ denote the maximum coin value, and $\sigma = \sum_{i=1}^n v_i$ denote the sum of input coin values. Simple observation reveals some inequalities relating the parameters: we have $n = O(\sqrt{\sigma})$ (because the distinctness of the v_i's implies $\sigma \geq \frac{n(n+1)}{2}$), $n \leq u$, $u \leq t$ (without loss of generality), and $\sigma \leq nu$. Note that unlike in the subset sum problem, t may be smaller or larger than σ.

Boolean convolution. The Boolean convolution $A \circ B$ of two Boolean arrays $A[0, \ldots, t_1]$ and $B[0, \ldots, t_2]$ is a Boolean array with $t_1 + t_2 + 1$ elements, where $(A \circ B)[j] = \bigvee_{j'=0}^{t_1} (A[j'] \wedge B[j - j'])$ (we assume out-of-range values are 0).

Change-making is closely related with Boolean convolution. For any integer k, let $C_V^{(k)}[0, \ldots, t]$ denote the Boolean array where

$C_V^{(k)}[j] = 1$ iff there exist k coins from V with their sum being j.

Then $C_V^{(k)}$ can be obtained from the first $t + 1$ elements of $C_V^{(k_1)} \circ C_V^{(k_2)}$, for any $k_1, k_2 > 0$ where $k = k_1 + k_2$.

The Boolean convolution of two arrays of size $O(t)$ can be computed in $O(t \log t)$ time by FFT.

$(\min,+)$-convolution. The $(\min,+)$-convolution $A \star B$ of two arrays $A[0,\ldots,t_1]$ and $B[0,\ldots,t_2]$ is an array with t_1+t_2+1 elements, where $(A\star B)[j] = \min_{j'=0}^{t_1}(A[j']+B[j-j'])$ (we assume out-of-range values are ∞).

Change-making is also related to $(\min,+)$-convolution. For a set V of coin values, let $D_V[0,\ldots,t]$ denote the array where

$$D_V[j] = \text{the minimum number of coins from } V \text{ needed to sum to } j$$

(if no solution exists, $D_V[j]=\infty$). Then $D_{V_1\cup V_2}$ can be obtained from the first $t+1$ elements of $D_{V_1} \star D_{V_2}$.

It has been conjectured by some researchers that $(\min,+)$-convolution cannot be solved in truly subquadratic time (e.g., see [9, 18]). However, the following lemma shows that a subquadratic algorithm is possible for the special case of $(\min,+)$-convolution where the second array is "binary", i.e., all entries of B are in $\{1,\infty\}$. This "trick" is not new and is known before, for example, in the context of matrix multiplication (for computing the $(\min,+)$-product when one of the matrices is binary [25, 11, 7]), with the basic idea tracing back to Matoušek's dominance algorithm [21].

▶ **Lemma 1.** *Given two arrays $A[0,\ldots,t]$ and $B[0,\ldots,t]$ where all entries of B are in $\{1,\infty\}$, we can compute the $(\min,+)$-convolution of A and B in $\tilde{O}(t^{3/2})$ time.*

Furthermore, if we just want t' user-specified entries of the $(\min,+)$-convolution, the time bound may be reduced to $\tilde{O}(t\sqrt{t'})$.

Proof. By sorting and replacing elements by their ranks, we may assume the values of A are in $[t]$, and are distinct (without loss of generality). Divide the range $[t]$ into $\sqrt{t'}$ subintervals of length $t/\sqrt{t'}$. For each such subinterval I, define a Boolean array A'_I with $A'_I[j]=1$ iff $A[j]\in I$, and define a Boolean array B' with $B'[j]=1$ iff $B[j]\neq\infty$; compute the Boolean convolution between A'_I and B'; this requires $\sqrt{t'}$ FFTs and takes $\tilde{O}(t\sqrt{t'})$ time. Then for each index j for which we want to compute the output entry, we can now identify which subinterval contains the minimum answer (namely, the smallest subinterval I such that $(A'_I \circ B')[j]$ is true) in $O(\sqrt{t'})$ time, so we can do a brute-force search in $O(t/\sqrt{t'})$ time; the total time for t' output entries is $O(t'\cdot(\sqrt{t'}+t/\sqrt{t'})) = O(t\sqrt{t'})$. ◀

3 $\tilde{O}(t^{4/3})$ Algorithm

Previous algorithm. Before presenting the new algorithm, we first give a sketch on the previous $\tilde{O}(t^{3/2})$-time algorithm by Bringmann and Kociumaka (as mentioned in [19]). Let ℓ_0 be a parameter to be chosen later. Let $H=\{v_i : v_i > \ell_0\}$ be the set of all *heavy* coin values, and let $L=\{v_i : v_i \le \ell_0\}$ be the set of all *light* coin values. Because the coin values are distinct, $|L|\le \ell_0$. To sum to any value $j\le t$, we can use at most t/ℓ_0 heavy coins. We use Boolean convolution to compute the array $C_H^{(k)}$ from $C_H^{(k-1)}$ for each $k=1,\ldots,\lfloor t/\ell_0\rfloor$. The total time for these $\lfloor t/\ell_0\rfloor$ convolutions is $\tilde{O}(t^2/\ell_0)$. We can thus obtain $D_H[j]$ by taking the minimum $k\le t/\ell_0$ such that $C_H^{(k)}[j]>0$. To finish, we use the classical dynamic programming algorithm to add the light coins. Namely, for each $j=1,\ldots,t$, we set $D_V[j]=\min\{D_H[j], \min_{v_i\in L} D_V[j-v_i]+1\}$. This step takes $O(\ell_0 t)$ time. The overall running time is

$$\tilde{O}\left(\frac{t^2}{\ell_0}+\ell_0 t\right).$$

To balance cost, we choose $\ell_0=\sqrt{t}$ and obtain a time bound of $\tilde{O}(t^{3/2})$.

New algorithm. To improve the running time, we describe a more efficient way to add the light coins, by using $(\min,+)$-convolution. As before, we first compute D_H for the heavy coins in $\tilde{O}(t^2/\ell_0)$ time. Initialize S to H.

Now, consider a fixed value $\ell \le \ell_0/2$, and consider the subset of light coins $L_\ell = \{v_i : v_i \in (\ell, 2\ell]\}$. In order to add L_ℓ to S, we need to compute $D_{S\cup L_\ell}$ from D_S. Naively, one could perform a single $(\min,+)$-convolution of D_S with D_{L_ℓ}, but this is expensive, and D_{L_ℓ} is not known yet (and is not binary). A better approach is to do *multiple* $(\min,+)$-convolutions by dividing the array into smaller blocks of size $O(\ell)$, as follows:

For each $i = 0, \ldots, t/\ell$, we compute $D_{S\cup L_\ell}[\ell i, \ldots, \ell(i{+}1)]$ by taking a $(\min,+)$-convolution D' of $D_{S\cup L_\ell}[\ell(i-2), \ldots, \ell i]$ with a binary array $B[\ell, \ldots, 2\ell]$ using Lemma 1, where $B[j] = 1$ if $j \in L_\ell$, and $B[j] = \infty$ otherwise. Then $D_{S\cup L_\ell}[\ell i, \ldots, \ell(i+1)]$ is the entry-wise minimum of $D'[\ell i, \ldots, \ell(i+1)]$ and $D_S[\ell i, \ldots, \ell(i+1)]$. Each of the above $O(t/\ell)$ $(\min,+)$-convolutions is done to arrays of size $O(\ell)$ (after shifting indices). Thus, the total running time is $\tilde{O}((t/\ell)\cdot \ell^{3/2}) = \tilde{O}(\sqrt{\ell} t)$.

We repeat the above steps for all ℓ's that are powers of 2 and smaller than ℓ_0, until all coin values are added to S. This requires $O(\log \ell_0)$ rounds, and the total running time forms a geometric series bounded by $\tilde{O}(\sqrt{\ell_0} t)$. The overall running time is

$$\tilde{O}\left(\frac{t^2}{\ell_0} + \sqrt{\ell_0} t\right).$$

To balance cost, we choose $\ell_0 \approx t^{2/3}$ and obtain a time bound of $\tilde{O}(t^{4/3})$.

▶ **Theorem 2.** *The all-targets change-making problem can be solved in $\tilde{O}(t^{4/3})$ time.*

▶ Remark. If we choose $\ell_0 = u$ instead, the heavy coin case can be ignored and we obtain an $\tilde{O}(t\sqrt{u})$-time algorithm, which is faster for small u. We will give still faster algorithms for small u in the next section.

4 $O(u^2 \log u + t)$ Algorithm

We now explore more algorithms with running time sensitive to u.

Warm-up. We first observe that there is a simple algorithm with $O(u^3 + t)$ running time. We use the following lemma, which is "folklore":[4]

▶ **Lemma 3.** *For any target value $j \ge u^2$, any optimal solution to the change-making problem must use the largest coin value u.*

Proof. Suppose that an optimal solution X for a target value j does not use the coin value u.

A simple argument shows that $j < u^3$: If X uses a coin value v_i at least u times, we can replace u copies of v_i with v_i copies of u, and the number of coins in X would decrease: a contradiction. Thus, each of the at most u coin values is used fewer than u times, and so the sum of X must be less than u^3.

[4] Bateni et al. [4, Lemma 7.2] gave a proof for the (more general) unbounded knapsack problem, using the pigeonhole principle, similar to what we give here (Eisenbrand and Weismantel [12] also proved a similar statement for higher-dimensional unbounded knapsack). But it was known much earlier: we personally learned of the pigeonhole proof for coin changing from comments by Bruce Merry in 2006 on a US Olympiad question (`https://contest.usaco.org/TESTDATA/DEC06.fewcoins.htm`), and the same pigeonhole proof for unbounded knapsack from a Chinese web post in 2016 (`https://www.zhihu.com/question/27547892/answer/133582594`).

We give a better argument showing $j < u^2$ by using the pigeonhole principle: Let $\langle x_1, \ldots, x_h \rangle$ be the sequence of coins used in X, with duplicates included, in an arbitrary order. Define the prefix sum $s_i = x_1 + \cdots + x_i$. Suppose $h \geq u$. By the pigeonhole principle, there must exist $0 \leq i < j \leq h$ with $s_i \equiv s_j \pmod{u}$. Then the subsequence $x_{i+1}, \ldots, x_j$ sums to a number divisible by u. We can replace this subsequence with some number of copies of u, and the number of coins in X would decrease (since u is the largest coin value): a contradiction. Thus $h < u$, and so the sum of X is less than u^2. ◀

The above lemma ensures that it is sufficient to compute $D_V[j]$ for all $j < u^2$; by the naive dynamic programming algorithm, this step takes $O(nu^2) \leq O(u^3)$ time. Afterwards, for $j = u^2, \ldots, t$, we can simply set $D_V[j] = D_V[j-u] + 1$; this step takes $O(t)$ time. We thus get the time bound $O(u^3 + t)$.

If in the first part we instead use the $\tilde{O}(t\sqrt{u})$-time algorithm in the remark after Theorem 2 (with t replaced by u^2), then the first part takes $\tilde{O}(u^2\sqrt{u})$ time. The total time is then reduced to $O(u^{2.5} \operatorname{polylog} u + t)$. (This requires FFT, however.)

New algorithm. To improve the running time further, we use number-theoretic results on the *Frobenius problem*, which has received much attention from mathematicians: given k positive integer coin values $v_1 > \cdots > v_k$ with $\gcd(v_1, \ldots, v_k) = 1$, what is the largest number that cannot be represented? For $k = 2$, classical results show that the number is exactly $v_1 v_2 - v_1 - v_2$. For $k \geq 3$, the problem becomes much more challenging, for which there are no closed-form formulas. In 1972, Erdős and Graham [13] proved an upper bound of $2\left\lfloor \frac{v_1}{k} \right\rfloor v_2 - v_1$, which will be useful in our algorithmic application:

▶ **Lemma 4** (Erdős–Graham). *Given integers $v_1 > \ldots > v_k > 0$ ($k \geq 2$) with $\gcd(v_1, \ldots, v_k) = 1$, any integer greater than $2\left\lfloor \frac{v_1}{k} \right\rfloor v_2 - v_1$ can be expressed as a nonnegative integer linear combination of $v_1, \ldots, v_k$.*

In terms of $u = \max_i v_i$, Erdős and Graham's bound is $O(u^2/k)$, which is known to be tight in the worst case, within a constant factor (see [10] for improvements on the constant factor). For constant k, the bound remains quadratic, as in the 2-coins case. In our algorithmic application, we will consider non-constant k – here, the k in the denominator will prove crucial.

First, let us restate the bound more generally without assuming $\gcd(v_1, \ldots, v_k) = 1$:

▶ **Corollary 5.** *Given integers $v_1 > \cdots > v_k > 0$ ($k \geq 2$) with $\gcd(v_1, \ldots, v_k) = d$, any integer that is greater than $2\left\lfloor \frac{v_1}{dk} \right\rfloor v_2 - v_1$ and is divisible by d can be expressed as a nonnegative integer linear combination of $v_1, \ldots, v_k$.*

Proof. Apply Lemma 4 to the numbers $v_1/d, \ldots, v_k/d$. The bound becomes $\left(2\left\lfloor \frac{v_1/d}{k} \right\rfloor v_2/d - v_1/d\right) \cdot d$. ◀

We use Corollary 5 to prove a more refined version of Lemma 3, which takes into account the k largest coin values instead of just the largest value:

▶ **Lemma 6.** *Let $v_1, \ldots, v_k \leq u$ be the k largest input coin values. For any target value $j \geq 2u^2/k$, any optimal solution to the change-making problem must use at least one coin from $\{v_1, \ldots, v_k\}$.*

Proof. We may assume $k \geq 2$ (because of Lemma 3). Let $d = \gcd(v_1, \ldots, v_k)$. Suppose that an optimal solution X for a target value j does not use any coins from $\{v_1, \ldots, v_k\}$.

Consider the sequence of coins used in X, with duplicates included, in an arbitrary order. Divide the sequence into subsequences $X_1, \ldots, X_h$, each of which has sum in $(\frac{2u^2}{dk} - u, \frac{2u^2}{dk}]$, except that the last has sum at most $\frac{2u^2}{dk} - u$. Suppose $h > d$. Define s_i to be the sum of the concatenation of $X_1, \ldots, X_i$. By the pigeonhole principle, there exist $0 \le i < j < h$ with $s_i \equiv s_j \pmod{d}$. Then the subsequence formed by concatenating $X_{i+1}, \ldots, X_j$ sums to a number divisible by d and greater than $\frac{2u^2}{dk} - u$. By Corollary 5, we can replace this subsequence with coins from the set $\{v_1, \ldots, v_k\}$, and the number of coins in X would decrease (since $v_1, \ldots, v_k$ have larger values): a contradiction. Thus $h \le d$, and so the sum of X is less than $d \cdot \frac{2u^2}{dk} = 2u^2/k$. ◀

Thus, the optimal solution for target value j must use at least one coin value which is among the $\lceil 2u^2/j \rceil$ largest. This leads to the following extremely simple algorithm, which is just a small modification to the standard dynamic programming algorithm (no FFT required):

Algorithm 1 All-targets change-making.

1: Sort $v_1, \ldots, v_n$ in decreasing order, and set $D_V[0] = 0$.
2: **for** $j = 1, \ldots, t$ **do**
3: Set $D_V[j] = \min_{1 \le i \le \lceil 2u^2/j \rceil : v_i \le j} D_V[j - v_i] + 1$.

The total running time is bounded by a Harmonic series:

$$O\left(\sum_{j=1}^{t} \left(\frac{u^2}{j} + 1\right)\right) = O(u^2 \log u + t).$$

▶ **Theorem 7.** *The all-targets change-making problem can be solved in $O(u^2 \log u + t)$ time.*

As a corollary of the above algorithm, we can also obtain an algorithm with running time sensitive to σ, the total sum of the input coin values: Define the heavy coins H and light coins L as before, with respect to a parameter ℓ_0 to be chosen later. We first compute D_L for the light coins by the above algorithm in $\tilde{O}(\ell_0^2 + t)$ time. Then we add the heavy coins by dynamic programming: $D_V[j] = \min\{D_L[j], \min_{v_i \in H} D_V[j - v_i] + 1\}$. Since there are at most σ/ℓ_0 heavy coins, this step takes $O(\sigma/\ell_0 \cdot t)$ time. The overall running time is

$$\tilde{O}\left(\ell_0^2 + \frac{t\sigma}{\ell_0} + t\right).$$

To balance cost, we choose $\ell_0 = (t\sigma)^{1/3}$ and obtain the time bound $\tilde{O}((t\sigma)^{2/3} + t)$. (Again, no FFT is required.)

▶ **Corollary 8.** *The all-targets change-making problem can be solved in $\tilde{O}((t\sigma)^{2/3} + t)$ time.*

▶ Remark. The $O(t)$ term can be eliminated in Theorem 7 (and thus Corollary 8) if we are fine with an *implicit* representation of the output (i.e., a structure that allows us to return the answer for any given target in constant time), since by Lemma 3, we can first reduce the target j to below u^2 by using some number (i.e., $\max\{\lceil (j - u^2)/u \rceil, 0\}$) of copies of the largest coin value u.

5 All-Capacities Unbounded Knapsack

We note that the algorithm in the preceding section can be extended to solve the all-capacities version of the unbounded knapsack problem, defined as follows:

▶ **Problem 2** (All-Capacities Unbounded Knapsack). *Given n items where the i-th item has a positive integer weight w_i and a positive profit p_i, and given an integer t, for each $j = 0, \ldots, t$, find the maximum total profit of a multiset of items such that the total weight is at most j, i.e., find the maximum of $\sum_{i=1}^{n} m_i p_i$ subject to the constraint that $\sum_{i=1}^{n} m_i w_i \le j$, where $m_i \in \mathbb{N}$.*

Like before, let $u = \max_{i=1}^{n} w_i$ and $\sigma = \sum_{i=1}^{n} w_i$. We may assume that the weights are distinct (since if there are two items with the same weight, we may remove the one with the smaller profit).

We use the following analog to Lemma 6:

▶ **Lemma 9.** *Suppose items $1, \ldots, k$ have the k largest profit-to-weight ratios. For any capacity value $j \ge 3u^2/k$, any optimal solution to the unbounded knapsack problem must use at least one item from $\{1, \ldots, k\}$.*

Proof. Similar to the proof of Lemma 6, since replacing a subsequence with items that have larger profit-to-weight ratios while maintaining the same total weight would increase the total profit. One difference in the unbounded knapsack problem is that the total weight in the optimal solution may not be exactly j. But it must be at least $j - u$ (otherwise, we could add one more item to get a better solution). When $j \ge 3u^2/k$, we have $j - u \ge 2u^2/k$. ◀

The same analysis shows correctness of the following very simple algorithm, which runs in $O(u^2 \log u + t)$ time:

Algorithm 2 All-capacities unbounded knapsack.

```
Sort the items in decreasing order of p_i/w_i.
for j = 0, ..., t do
    Set D[j] = max{0, max_{1≤i≤⌈3u²/j⌉: w_i≤j} (D[j − w_i] + p_i)}.
```

The $\tilde{O}((t\sigma)^{2/3} + t)$ algorithm can be extended as well.

▶ **Corollary 10.** *The all-capacities unbounded knapsack problem can be solved in $O(u^2 \log u + t)$ or $\tilde{O}((t\sigma)^{2/3} + t)$ time.*

▶ Remark. As before, the $O(t)$ term can be eliminated with an implicit representation of the output (since by an analog to Lemma 3, we can first reduce the capacity to below u^2 by using some number of copies of the item with the largest profit-to-weight ratio). In particular, for the single-capacity version, we obtain a very simple $O(u^2 \log u)$-time algorithm.

The algorithm works even when the profits are reals but the weights are integers. Alternatively, a variant of the algorithm works when the weights are reals but the profits are integers: the same time bound $O(u^2 \log u)$ holds but with $u = \max_{i=1}^{n} p_i$. Here, we recast the problem as minimizing $\sum_{i=1}^{n} m_i w_i$ subject to the constraint that $\sum_{i=1}^{n} m_i p_i \ge j$, and modify the algorithm appropriately (applying Erdős–Graham to the profits instead of the weights). From the implicitly represented output, we can determine the answer for any given capacity by predecessor search.

6 $\tilde{O}(u)$ Algorithm for Single-Target Change-Making

In this section, we present an $\tilde{O}(u)$-time algorithm for the single-target change-making problem. It is obtained by modifying the third algorithm of Chan and He [8], which originally ran in $O(t \log^2 t)$ time. They first solved the decision problem: deciding whether we can sum to t using at most m coins for a given value m. By adding 0 to the input set of coin values, "at most m" can be changed to "exactly m".

Their decision algorithm relies on the following partition lemma, which shows the multiset of coins S can be almost evenly partitioned simultaneously in terms of cardinality *and* the total value (see [8] for a short self-contained proof for the even case; the odd case is similar):

▶ **Lemma 11** (Partition Lemma). *Suppose S is a multiset with $|S| = m$ and $\sigma(S) = t$. If m is odd, then there exists a partition of S into three parts S_1, S_2 and a singleton $\{s_0\}$, such that $|S_1| = |S_2| = \frac{m-1}{2}$ and $\sigma(S_1), \sigma(S_2) \le \frac{t}{2}$.*

If m is even, then there exists a partition of S into three parts S_1, S_2 and two singletons $\{s_0, s_1\}$, such that $|S_1| = |S_2| = \frac{m}{2} - 1$, and $\sigma(S_1), \sigma(S_2) \le \frac{t}{2}$.

Notice that since the maximum coin value is u, we also have $\sigma(S_1), \sigma(S_2) \ge \frac{t}{2} - 2u$ (as we take out one or two coins).

The Partition Lemma suggests a simple recursive algorithm to compute $C_V^{(m)}[0, \dots, t]$: we just take the first $t+1$ entries of

$$\begin{cases} C_V^{(\frac{m-1}{2})}[0, \dots, \frac{t}{2}] \circ C_V^{(\frac{m-1}{2})}[0, \dots, \frac{t}{2}] \circ C_V^{(1)}[0, \dots, t] & \text{if } m \text{ is odd,} \\ C_V^{(\frac{m}{2}-1)}[0, \dots, \frac{t}{2}] \circ C_V^{(\frac{m}{2}-1)}[0, \dots, \frac{t}{2}] \circ C_V^{(1)}[0, \dots, t] \circ C_V^{(1)}[0, \dots, t] & \text{if } m \text{ is even.} \end{cases}$$

That was essentially Chan and He's previous algorithm.

We describe a more efficient recursive algorithm to compute a smaller subarray $C_V^{(m)}[t - 4u, \dots, t]$: we just take the relevant entries of

$$\begin{cases} C_V^{(\frac{m-1}{2})}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] \circ C_V^{(\frac{m-1}{2})}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] \circ C_V^{(1)}[0, \dots, u] & \\ \qquad\qquad \text{if } m \text{ is odd,} & \\ C_V^{(\frac{m}{2}-1)}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] \circ C_V^{(\frac{m}{2}-1)}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] \circ C_V^{(1)}[0, \dots, u] \circ C_V^{(1)}[0, \dots, u] & \\ \qquad\qquad \text{if } m \text{ is even.} & \end{cases}$$

Each of the above Boolean convolutions is done to arrays of size $O(u)$ (after shifting indices), and thus takes $O(u \log u)$ time. The subarrays $C_V^{(\frac{m-1}{2})}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] = C_V^{(\frac{m-1}{2})}[\frac{t}{2} - 4u, \dots, \frac{t}{2}]$ and $C_V^{(\frac{m}{2}-1)}[\frac{t-4u}{2} - 2u, \dots, \frac{t}{2}] = C_V^{(\frac{m}{2}-1)}[\frac{t}{2} - 4u, \dots, \frac{t}{2}]$ can be computed by recursion. Thus, the running time satisfies the recurrence

$$T(m, t) = T(\lfloor \tfrac{m-1}{2} \rfloor, \tfrac{t}{2}) + O(u \log u),$$

which solves to $T(m, t) = O(u \log u \log t)$.

The decision problem can now be solved by inspecting the entry $C_V^{(m)}[t]$. We can find the optimal number of coins by binary search with $O(\log t)$ calls to the decision algorithm. By Lemma 3, we can first reduce t to below u^2 by repeatedly using the largest coin value. Therefore, the total running time is $O(u \log u \log^2 t) \le O(u \log^3 u)$.

▶ **Theorem 12.** *The single-target change-making problem can be solved in $O(u \log^3 u)$ time.*

▶ Remark. The above algorithm shares some similarity with the $\tilde{O}(u^2)$ algorithm by Axiotis and Tzamos [2] for unbounded knapsack, which also involves logarithmically many convolutions on subarrays of size $O(u)$, except that they used $(\min, +)$-convolutions and a more naive parititioning that approximately halves t, but not m. In contrast, the above Partition Lemma is crucial to our faster algorithm for change-making.

7 $\tilde{O}(nu)$ Algorithm for Single-Capacity Unbounded Knapsack

In this section, we revisit the standard (single-capacity) version of the unbounded knapsack problem and present a new $\tilde{O}(nu)$-time algorithm (recall that $u = \max_i w_i$). This algorithm is simple (no FFT needed), and is based on the following combinatorial lemma, which is obtained by another pigeonhole argument:

▶ **Lemma 13.** *For the unbounded knapsack problem for a given capacity $j < t_0$, there exists an optimal solution that uses at most $\log t_0$ different types of items.*

In particular, in some optimal solution, there exists an item i that is used at least $\frac{j}{w_i \log t_0}$ times.

Proof. Consider an optimal solution that uses the minimum number of types of items. Let S be the set of items used in this solution, excluding multiplicities. If $|S| > \log t_0$, by the pigeonhole principle there must exist two different subsets S_1 and S_2 of S with the same total weight, multiplicities included (since there are $2^{|S|}$ subsets and t_0 integers between 0 and $t_0 - 1$). We can replace the items in $S_2 \setminus S_1$ with $S_1 \setminus S_2$, or vice versa (depending which of the two has smaller total value), and get a new solution that has the same total weight but has larger or equal total value. And if it has equal total value, the new solution uses a smaller number of types of items (since $S_2 \setminus S_1$ and $S_1 \setminus S_2$ are nonempty): a contradiction.

Thus, $|S| \le \log t_0$. This also implies that some item contributes at least $\frac{j}{\log t_0}$ to the total weight. ◀

Let $b := \lceil \log t_0 \rceil$. Let $D[j]$ be the maximum profit for the unbounded knapsack problem with capacity j. The above lemma implies the following recursive formula for all $j < t_0$:

$$D[j] \;=\; \max\left\{0,\; \max_{i=1}^{n}(D[j - w_i x_{ij}] + p_i x_{ij})\right\} \qquad \text{where } x_{ij} := \left\lfloor \tfrac{j}{w_i b} \right\rfloor.$$

Note that $j - w_i x_{ij} \in \left[(1 - \frac{1}{b})j,\; (1 - \frac{1}{b})j + u\right]$.

The above formula allows us to compute the subarray $D[t, \ldots, t + bu]$ from the subarray $D\left[(1 - \frac{1}{b})t, \ldots, (1 - \frac{1}{b})(t + bu) + u\right] = D\left[(1 - \frac{1}{b})t, \ldots, (1 - \frac{1}{b})t + bu\right]$ in $O(bu \cdot n)$ time. The latter subarray can be computed recursively.

Let $T(t)$ denote the time for computing $D[t, \ldots, t + bu]$. We thus obtain the following recurrence:

$$T(t) \;=\; T((1 - \tfrac{1}{b})t) \;+\; O(bnu).$$

For the base case, we have $T(0) = O(bnu)$ by the standard dynamic programming algorithm (which computes $D[0, \ldots, j]$ in $O(nj)$ time). The number of levels of recursion is $O(b \log t)$. So, $T(t) = O(b^2 nu \log t) = O(nu \log^2 t_0 \log t)$. We can set $t_0 = (t + u)^{O(1)}$. As before, we can initially reduce the capacity t to below u^2 by repeatedly using the item with the largest profit-to-weight ratio. This yields the following result:

▶ **Theorem 14.** *The single-capacity unbounded knapsack problem can be solved in $O(nu \log^3 u)$ time.*

▶ Remark. There are alternative ways to exploit the above lemma to get $\tilde{O}(nu)$ algorithms (by computing $D[j]$ for a different choice of $\tilde{O}(bu)$ indices j), and the polylogarithmic factor is likely improvable.

8 Minimum Word Break

Bringmann, Grønlund, and Larsen [6] studied the decision version of the word break problem, and gave an algorithm with $\tilde{O}(nm^{1/3} + m)$ running time (with a matching conditional lower bound for combinatorial algorithms).

We consider the optimization version of the problem (with unit weight), defined as follows:

▶ **Problem 3** (Minimum Word Break)**.** *Given a string s with length n and a dictionary D with total length m, find the minimum number t^* such that s can be split into t^* words in D (duplicates are allowed).*

The single-target change-making problem can be viewed as a special case of this problem, by representing each coin with value v_i as a string with length v_i over a unary alphabet.

In this section, we briefly note that Bringmann et al.'s algorithm can be modified to solve the minimum word break problem without increasing the running time (ignoring polylogarithmic factors), by using our Lemma 1.

The modification. Since much of the solution proceeds as in Bringmann et al.'s paper [6], we will only describe the difference and assume the reader is already familiar with the previous paper. In particular, we will use the same notation.

Upon close inspection of their paper, we see that most parts of Bringmann et al.'s method require no (or straightforward) changes. Their "first algorithm" is no longer required, and the main change lies in their "second algorithm", specifically, the "query algorithm" in [6, Section 4.2 (arXiv version)]. Instead of computing $S + S_B$ using FFT, we now need to compute the $(\min, +)$-convolution between S and S_B, where $S_B[i] = 1$ if u_i is marked, and $S_B[i] = \infty$ otherwise. We are only interested in q_B entries in the output array, where $\sum_{B\in\mathcal{B}} q_B = O(q)$ and $|\mathcal{B}| \le \frac{m}{q\cdot\lambda_q}$. (Note that $|\mathcal{B}| = 0$ if $\lambda_q > m/q$.) By using the output-sensitive bound from Lemma 1, we can perform the $(\min, +)$-convolution in $\tilde{O}(q\sqrt{q_B})$ time. By the Cauchy–Schwarz inequality, the sum of the cost over all $B \in \mathcal{B}$ is

$$\tilde{O}\left(\sum_{B\in\mathcal{B}} q\sqrt{q_B}\right) = \tilde{O}\left(q\sqrt{q|\mathcal{B}|}\right) = \tilde{O}\left(q\sqrt{\frac{m}{\lambda_q}}\right).$$

The other parts of the query algorithm requires $\tilde{O}(q \cdot \lambda_q)$ time. The total time is

$$\tilde{O}\left(q\lambda_q + q\sqrt{\frac{m}{\lambda_q}}\right).$$

To balance cost, we choose $\lambda_q = m^{1/3}$, and as a result, the query time in [6, Lemma 2 (arXiv version)] becomes $\tilde{O}(qm^{1/3})$, instead of $\tilde{O}(\min\{q^2, \sqrt{qm}\})$.

The final running time as analyzed in [6, page 10] was

$$\tilde{O}\left(\sum_{q=2^\ell} \frac{n}{q} \cdot \min\{q^2, \sqrt{qm}\}\right) = \tilde{O}(nm^{1/3}),$$

plus $\tilde{O}(n + m)$ for preprocessing. With the new query time bound, the sum changes to

$$\tilde{O}\left(\sum_{q=2^\ell} \frac{n}{q} \cdot qm^{1/3}\right) = \tilde{O}(nm^{1/3}),$$

which luckily gives the same result.

▶ **Theorem 15.** *The minimum word break problem can be solved in $\tilde{O}(nm^{1/3} + m)$ time.*

▶ Remark. The algorithm can actually solve an extension of the problem: compute the minimum number of breaks for every prefix of the input string. In particular, when the alphabet is unary, this implies an $\tilde{O}(t\sigma^{1/3} + \sigma)$-time algorithm for the all-targets change-making problem. However, this bound is not as good as those from Theorem 2 and Corollary 8 ($\tilde{O}(\min\{t^{4/3}, (t\sigma)^{2/3} + t\})$).

9 Concluding Remarks

Our change-making algorithms can be modified to compute not just the minimum number of coins but also a representation of the minimum multiset of coins for every target value. For the FFT-based algorithms, we need standard techniques for witness finding [1, 23] (which only increases the running time by polylogarithmic factors).

Although Erdős and Graham's $\Theta(u^2/k)$ bound on the Frobenius problem is asymptotically tight in the worst case (one bad coin set is $\{x, 2x, \ldots, (k-1)x, (k-1)x-1\}$ with $x = \lceil \frac{u}{k-1} \rceil$), the Frobenius number tends to be smaller for "many" k-tuples of coin values (it is usually subquadratic even for $k = 3$). This suggests that our $\tilde{O}(u^2 + t)$-time algorithm for all-targets coin changing might be improvable for many input sets of coins. However, obtaining an improvement in the worst case remains intriguingly open (this might require new results on the Frobenius problem – the interplay between combinatorial and algorithmic results seems worthy of further study).

Abstract

We introduce and investigate the approximability of the *maximum binary tree problem* (MBT) in directed and undirected graphs. The goal in MBT is to find a maximum-sized binary tree in a given graph. MBT is a natural variant of the well-studied longest path problem, since both can be viewed as finding a maximum-sized tree of bounded degree in a given graph.

The connection to longest path motivates the study of MBT in directed acyclic graphs (DAGs), since the longest path problem is solvable efficiently in DAGs. In contrast, we show that MBT in DAGs is in fact hard: it has no efficient $\exp(-O(\log n/\log\log n))$-approximation algorithm under the exponential time hypothesis, where n is the number of vertices in the input graph. In undirected graphs, we show that MBT has no efficient $\exp(-O(\log^{0.63} n))$-approximation under the exponential time hypothesis. Our inapproximability results rely on self-improving reductions and structural properties of binary trees. We also show constant-factor inapproximability assuming $\mathbf{P} \neq \mathbf{NP}$.

In addition to inapproximability results, we present algorithmic results along two different flavors: (1) We design a randomized algorithm to verify if a given directed graph on n vertices contains a binary tree of size k in $2^k\mathsf{poly}(n)$ time. (2) Motivated by the longest heapable subsequence problem, introduced by Byers, Heeringa, Mitzenmacher, and Zervas, *ANALCO 2011*, which is equivalent to MBT in *permutation DAGs*, we design efficient algorithms for MBT in bipartite permutation graphs.

1 Introduction

A general degree-constrained subgraph problem asks for an optimal subgraph of a given graph with specified properties while also satisfying degree constraints on all vertices. Degree-constrained subgraph problems have numerous applications in the field of network design and consequently, have been studied extensively in the algorithms and approximation literature [1, 15–17, 29, 31, 32]. In this work, we introduce and study the *maximum binary tree problem* in directed and undirected graphs. In the maximum binary tree problem (MBT), we are given an input graph G and the goal is to find a *binary tree* in G with maximum number of vertices.

Our first motivation for studying MBT arises from the viewpoint that it is a variant of the longest path problem: In the longest path problem, the goal is to find a maximum-sized tree in which every vertex has degree at most 2. In MBT, the goal is to find a maximum-sized tree in which every vertex has degree at most 3. Certainly, one may generalize both these problems to finding a *maximum-sized degree-constrained tree* in a given graph. In this work we focus on binary trees; however, all our results extend to the maximum-sized degree-constrained tree problem for *constant* degree bound.

Our second motivation for studying MBT is its connection to the *longest heapable subsequence problem* introduced by Byers, Heeringa, Mitzenmacher, and Zervas [10]. Let $\sigma = (\sigma_1, \sigma_2, \ldots, \sigma_n)$ be a permutation on n elements. Byers et al. define a subsequence (not necessarily contiguous) of σ to be *heapable* if the elements of the subsequence can be sequentially inserted to form a binary *min-heap* data structure. Namely, insertions subsequent to the first element, which takes the root position, happen below previously placed elements. The longest heapable subsequence problem asks for a maximum-length heapable subsequence of a given sequence. This generalizes the well-known longest increasing subsequence problem. Porfilio [30] showed that the longest heapable subsequence problem is equivalent to MBT in permutation directed acyclic graphs (abbreviated *permutation DAGs*): a permutation DAG associated with the sequence σ is obtained by introducing a vertex u_i for every sequence element σ_i, and arcs (u_i, u_j) for every pair (i, j) such that $i > j$ and $\sigma_i \geq \sigma_j$. On the other hand, for sequences of intervals the maximum binary problem is easily solvable by a greedy algorithm [6] (see also [21] for further results and open problems on the heapability of partial orders). These results motivate the study of MBT in restricted graph families.

We now formally define MBT in undirected graphs, which we denote as UndirMaxBinaryTree. A *binary tree* of an *undirected* graph G is a subgraph T of G that is connected and acyclic with the degree of u in T being at most 3 for every vertex u in T. In UndirMaxBinaryTree, the input is an undirected graph G and the goal is to find a binary tree in G with maximum number of vertices. In the rooted variant of this problem, the input is an undirected graph G along with a specified root vertex r and the goal is to find a binary tree containing r in G with maximum number of vertices such that the degree of r in the tree is at most 2. We focus on the unrooted variant of the problem and mention that it reduces to the rooted variant. We emphasize that a binary tree T of G is not necessarily spanning (i.e., may not contain all vertices of the given graph). The problem of verifying whether a given undirected graph has a *spanning* binary tree is **NP**-complete. This follows by a reduction from the Hamiltonian path problem: Given an undirected graph $G = (V, E)$, create a pendant vertex v' adjacent to v for every vertex $v \in V$. The resulting graph has a spanning binary tree if and only if G has a Hamiltonian path.

Next, we formally define MBT in directed graphs. A *tree of a directed graph* G is a subgraph T of G such that T is acyclic and has a unique vertex, termed as the root, with the property that every vertex v in T has a unique directed path *to the root* in T. A *binary tree*

of a directed graph G is a tree T such that the incoming-degree of every vertex u in T is at most 2 while the outgoing-degree of every vertex u in T is at most 1. In the rooted variant of the maximum binary tree problem for directed graphs, the input is a directed graph G along with a specified root r and the goal is to find an r-rooted binary tree T in G with maximum number of vertices. The problem of verifying whether a given directed graph has a *spanning* binary tree is **NP**-complete (by a similar reduction as that for undirected graphs).

The connection to the longest path problem as well as the longest heapable subsequence problem motivates the study of the maximum binary tree problem in directed acyclic graphs (DAGs). In contrast to directed graphs, the longest path problem in DAGs can be solved in polynomial-time (e.g., using dynamic programming or LP-based techniques). Moreover, verifying whether a given DAG contains a spanning binary tree is solvable in polynomial-time using the following characterization: a given DAG on vertex set V contains a spanning binary tree if and only if the partition matroid corresponding to the in-degree of every vertex being at most two and the partition matroid corresponding to the out-degree of every vertex being at most one have a common independent set of size $|V| - 1$. These observations raise the intriguing possibility of solving the maximum binary tree problem in DAGs in polynomial-time. For this reason, we focus on DAGs within the family of directed graphs in this work. We denote the maximum binary tree problem in DAGs as DAGMaxBinaryTree.

The rooted and the unrooted variants of the maximum binary tree problem in DAGs are polynomial-time equivalent by simple transformations. Indeed, the unrooted variant can be solved by solving the rooted variant for every choice of the root. To see the other direction, suppose we would like to find a maximum r-rooted binary tree in a given DAG $G = (V, E)$. Then, we discard from G all outgoing arcs from r and all vertices that cannot reach r (i.e., we consider the sub-DAG induced by the descendents of r) and find an unrooted maximum binary tree in the resulting DAG. If this binary tree is rooted at a vertex $r' \neq r$, then it can be extended to an r-rooted binary tree by including an arbitrary $r' \to r$ path P – since the graph is a DAG, any such path P will not visit a vertex that is already in the tree (apart from r'). The equivalence is also approximation preserving. For this reason, we only study the rooted variant of the problem in DAGs.

We present inapproximability results for MBT in DAGs and undirected graphs. On the algorithmic side, we show that MBT in directed graphs is fixed-parameter tractable when parameterized by the solution size. We observe that the equivalence of the longest heapable subsequence to MBT in permutation DAGs motivates the study of MBT even in restricted graph families. As a first step towards understanding MBT in permutation DAGs, we design an algorithm for bipartite permutation graphs. We use a variety of tools including self-improving and gadget reductions for our inapproximability results, and algebraic and structural techniques for our algorithmic results.

1.1 Related work

Degree-constrained subgraph problems appeared as early as 1978 in the textbook of Garey and Johnson [18] and have garnered plenty of attention in the approximation community [1, 15–17, 23, 29, 31, 32]. A rich line of works have addressed the minimum degree spanning tree problem as well as the minimum cost degree-constrained spanning tree problem leading to powerful rounding techniques and a deep understanding of the spanning tree polytope [12, 13, 16, 19, 25, 28, 32]. Approximation and bicriteria approximation algorithms for the counterparts of these problems in directed graphs, namely degree-constrained arborescence and min-cost degree-constrained arborescence, have also been studied in the literature [7].

In the *maximum-edge* degree-constrained connected subgraph problem, the goal is to find a connected degree-constrained subgraph of a given graph with maximum number of edges. This problem does not admit a PTAS [3] and has been studied from the perspective of fixed-parameter tractability [4]. MBT could be viewed as a *maximum-vertex* degree-constrained connected subgraph problem, where the goal is to maximize the number of *vertices* as opposed to the number of *edges* – the degree-constrained connected subgraph maximizing the number of vertices may be assumed to be acyclic and hence, a tree. It is believed that the *connectivity constraint* makes the maximum-edge degree-constrained connected subgraph problem to become extremely difficult to approximate. Our results formalize this belief when the objective is to maximize the number of vertices.

Switching the objective with the constraint in the maximum-vertex degree-constrained connected subgraph problem leads to the minimum-degree k-tree problem: here the goal is to find a minimum degree subgraph that is a tree with at least k vertices. Minimum degree k-tree admits a $O(\sqrt{(k/\Delta^*)\log k})$-approximation, where Δ^* is the optimal degree and does not admit a $o(\log n)$-approximation [23]. We note that the hardness reduction here (from set cover) crucially requires the optimal solution value Δ^* to grow with the number n of vertices in the input instance, and hence, does not imply any hardness result for input instances in which Δ^* is a constant. Moreover, the approximation result implies that a tree of degree $O(\sqrt{k\log k})$ containing k vertices can be found in polynomial time if the input graph contains a constant-degree tree with k vertices.

We consider the maximum binary tree problem to be a generalization of the longest path problem as both can be viewed as asking for a maximum-sized degree-constrained connected acyclic subgraph. The longest path problem in undirected graphs admits an $\Omega\left((\log n/\log\log n)^2/n\right)$-approximation [9], but it is APX-hard and does not admit a $2^{-O\left(\log^{1-\varepsilon} n\right)}$-approximation for any constant $\varepsilon > 0$ unless $\mathbf{NP} \subseteq \mathbf{DTIME}\left(2^{\log^{O(1/\varepsilon)} n}\right)$ [22]. Our hardness results for the max binary tree problem in undirected graphs bolsters this connection. The longest path problem in directed graphs is much harder: For every $\varepsilon > 0$ it cannot be approximated to within a factor of $1/n^{1-\varepsilon}$ unless $\mathbf{P} = \mathbf{NP}$, and it cannot be approximated to within a factor of $(\log^{2+\varepsilon} n)/n$ under the Exponential Time Hypothesis [9]. However, the longest path problem in DAGs is solvable in polynomial time. Our hardness results for the max binary tree problem in DAGs are in stark contrast to the polynomial-time solvability of the longest path problem in DAGs.

On the algorithmic side, the color-coding technique introduced by Alon, Yuster, and Zwick [2] can be used to decide whether an undirected graph $G = (V, E)$ contains a copy of a bounded treewidth pattern graph $H = (V_H, E_H)$ where $|V_H| = O(\log |V|)$, and if so, then find one in polynomial time. The idea here is to randomly color the vertices of G by $O(\log |V|)$ colors and to find a maximum colorful copy of H using dynamic programming. We note that the same dynamic programming approach can be modified to find a maximum colorful binary tree. This algorithm can be derandomized, thus leading to a deterministic $\Omega((1/n)\log n)$-approximation to UndirMaxBinaryTree.

In parameterized complexity, designing algorithms with running time $\beta^k\mathsf{poly}(n)$ ($\beta > 1$ is a constant) for problems like k-Path and k-Tree is a central topic. For k-Path, the color-coding technique mentioned above already implies a $(2e)^k\mathsf{poly}(n)$-time algorithm. Koutis [26] noticed that k-Path can be reduced to detecting whether a given polynomial contains a multilinear term. Using algebraic methods for the latter problem, Koutis obtained a $2^{1.5k}\mathsf{poly}(n)$ time algorithm for k-Path. This was later improved by Williams [36] to $2^k\mathsf{poly}(n)$. The current state-of-art algorithm is due to Björklund, Husfeldt, Kaski and Koivisto [8], which is also an algebraic algorithm with running time $1.66^k\mathsf{poly}(n)$. All of

these algorithms are randomized. Our study of the k-BinaryTree problem, which is the problem of deciding whether a given graph G contains a binary tree of size at least k, is inspired by this line of results.

Several **NP**-hard problems are known to be solvable in specific families of graphs. Bipartite permutation graphs is one such family which is known to exhibit this behaviour [24, 33–35]. Our polynomial-time solvability result for these families of graphs crucially identifies the existence of structured optimal solutions to reduce the search space and solves the problem over this reduced search space.

1.2 Our contributions

1.2.1 Inapproximability results

Directed graphs. We first focus on directed graphs and in particular, on directed acyclic graphs. It is well-known that the longest path problem in DAGs is solvable in polynomial-time. In contrast, we show that DAGMaxBinaryTree does not even admit a constant-factor approximation. Furthermore, if DAGMaxBinaryTree admitted a polynomial-time $\exp\left(-O\left(\log n/\log\log n\right)\right)$-approximation algorithm then the Exponential Time Hypothesis would be violated.

▶ **Theorem 1.** *We have the following inapproximability results for DAGMaxBinaryTree on n-vertex input graphs:*

1. *DAGMaxBinaryTree does not admit a polynomial-time constant-factor approximation assuming* $\mathbf{P} \neq \mathbf{NP}$.
2. *If DAGMaxBinaryTree admits a polynomial-time* $\exp\left(-O\left(\log n/\log\log n\right)\right)$*-approximation, then* $\mathbf{NP} \subseteq \mathbf{DTIME}\left(\exp\left(O\left(\sqrt{n}\right)\right)\right)$*, refuting the Exponential Time Hypothesis.*
3. *For any* $\varepsilon > 0$*, if DAGMaxBinaryTree admits a quasi-polynomial time* $\exp\left(-O\left(\log^{1-\varepsilon} n\right)\right)$*-approximation, then* $\mathbf{NP} \subseteq \mathbf{DTIME}\left(\exp\left(\log^{O(1/\varepsilon)} n\right)\right)$*, thus refuting the Exponential Time Hypothesis.*

Remark. The longest path problem in DAGs can be solved using a linear program (LP) based on cut constraints. Based on this connection, an integer program (IP) based on cut constraints can be formulated for DAGMaxBinaryTree. In the full version of this work [11], we show that the LP-relaxation of this cut-constraints-based-IP has an integrality gap of $\Omega(n^{1/3})$ in n-vertex DAGs.

Undirected graphs. Next, we turn to undirected graphs. We show that UndirMaxBinaryTree does not have a constant-factor approximation and does not admit a quasi-polynomial-time $\exp(-O(\log^{0.63} n))$-approximation under the Exponential Time Hypothesis.

▶ **Theorem 2.** *We have the following inapproximability results for UndirMaxBinaryTree on n-vertex input graphs:*

1. *UndirMaxBinaryTree does not admit a polynomial-time constant-factor approximation assuming* $\mathbf{P} \neq \mathbf{NP}$.
2. *For* $c = \log_3 2$ *and any* $\varepsilon > 0$*, if UndirMaxBinaryTree admits a quasi-polynomial time* $\exp\left(-O\left(\log^{c-\varepsilon} n\right)\right)$*-approximation, then* $\mathbf{NP} \subseteq \mathbf{DTIME}\left(\exp\left(\log^{O(1/\varepsilon)} n\right)\right)$*, thus refuting the Exponential Time Hypothesis.*

We summarize our hardness results for MBT on various graph families in Table 1 and contrast them with the corresponding known hardness results for the longest path problem on those families.

Table 1 Summary of inapproximability results. Here, n refers to the number of vertices in the input graph and ϵ is any positive constant. We include the known results for longest path for comparison. Text in gray refer to known results while text in black refer to our contributions.

Family	Assumption	Max Binary Tree	Longest Path
DAGs	$\mathbf{P \neq NP}$	No poly-time $\Omega(1)$-apx (Thm 1)	Poly-time solvable
	ETH	No poly-time $\exp(-O(\frac{\log n}{\log\log n}))$-apx No quasi-poly-time $\exp(-O(\log^{1-\varepsilon} n))$-apx (Thm 1)	Poly-time solvable
Directed	$\mathbf{P \neq NP}$	Same as DAGs	No poly-time $\frac{1}{n^{1-\varepsilon}}$-apx [9]
	ETH	Same as DAGs	Same as $\mathbf{P \neq NP}$
Undirected	$\mathbf{P \neq NP}$	No poly-time $\Omega(1)$-apx (Thm 2)	No poly-time $\Omega(1)$-apx [22]
	ETH	No quasi-poly-time $\exp(-O(\log^{0.63-\varepsilon} n))$-apx (Thm 2)	No quasi-poly-time $\exp(-O(\log^{1-\varepsilon} n))$-apx [22]

1.2.2 Algorithmic results

Fixed-parameter tractability. We denote the decision variant of MBT as k-BinaryTree– here the goal is to verify if a given graph contains a binary tree with at least k vertices. Since k-BinaryTree is **NP**-hard when k is part of the input, it is desirable to have an algorithm that runs in time $f(k)\mathsf{poly}(n)$ (i.e., a fixed parameter algorithm parameterized by the solution size). Our first algorithmic result achieves precisely this goal. Our algorithm is based on algebraic techniques.

▶ **Theorem 3.** *There exists a randomized algorithm that takes a directed graph $G = (V, E)$, a positive integer k, and a real value $\delta \in (0, 1)$ as input, runs in time $2^k\mathsf{poly}(|V|)\log(1/\delta)$ and*

1. *outputs "no" if G does not contain a binary tree of size k;*
2. *outputs a binary tree of size k with probability $1 - \delta$ if G contains one.*

Bipartite permutation graphs. Next, motivated by its connection to the max heapable subsequence problem, we study MBT in *bipartite permutation graphs*. A bipartite permutation graph is a permutation graph (undirected) which is also bipartite. We show that bipartite permutation graphs admit an efficient algorithm for MBT. Our algorithm exploits structural properties of bipartite permutation graphs. We believe that these structural properties could be helpful in solving MBT in permutation graphs which, in turn, could provide key insights towards solving MBT in permutation DAGs.

▶ **Theorem 4.** *There exists an algorithm to solve UndirMaxBinaryTree in n-vertex bipartite permutation graphs that runs in time $O(n^3)$.*

We summarize our algorithmic results for MBT in Table 2 and contrast them with the corresponding best known bounds for the longest path problem.

Table 2 Summary of algorithmic results. Here, n refers to the number of vertices in the input graph. We include the known results for longest path for comparison. Text in gray refer to known results while text in black refer to our contributions.

Problem	Max Binary Tree	Longest Path
FPT parameterized by solution size (Dir.)	$2^k\mathsf{poly}(n)$-time (Thm 3)	$1.66^k\mathsf{poly}(n)$-time [8]
Bipartite permutation graphs (Undir.)	$O(n^3)$-time (Thm 4)	$O(n)$-time [35]

We remark again that our inapproximability as well as algorithmic results are also applicable to the maximum degree-constrained tree problem for larger, but constant degree constraint. We focus on the degree constraint corresponding to binary trees for the sake of simplicity in exposition.

1.3 Proof techniques

In this section, we outline the techniques underlying our results.

1.3.1 Inapproximability results

At a very high level, our inapproximability results for MBT rely on the proof strategy for hardness of longest path due to Karger, Motwani, and Ramkumar [22], which has two main steps: (1) a *self-improving* reduction whose amplification implies that a constant-factor approximation immediately leads to a PTAS, and (2) a proof that there is no PTAS. However, we achieve both these steps in a completely different manner compared to the approach of Karger, Motwani, and Ramkumar. Both their steps are tailored for the longest path problem, but fail for the maximum degree-constrained tree problem. Our results for MBT require several novel ideas, as described next.

Karger, Motwani and Ramkumar's self-improving reduction for the longest path proceeds as follows: given an undirected graph G, they obtain a squared graph G^2 by replacing each edge $\{u, v\}$ of G with a copy of G by adding edges from u and v to all vertices in that edge copy. Let $OPT(G)$ be the length of the longest path in G. They make the following two observations: Obs (i) $OPT(G^2) \geq OPT(G)^2$ and Obs (ii) a path in G^2 of length at least $\alpha OPT(G^2)$ can be used to recover a path in G of length at least $\sqrt{\alpha}OPT(G)$. The first observation is because we can extend any path P in G into a path of length $|E(P)|^2$ by traversing each edge copy also along P. The second observation is because for any path P_2 in G^2 either P_2 restricted to some edge copy of G is a path of length at least $\sqrt{|E(P_2)|}$ or projecting P_2 to G (i.e., replacing each sub-path of P_2 in each edge copy by a single edge) gives a path of length at least $\sqrt{|E(P_2)|}$. We note that a similar construction of the squared graph for directed graphs also has the above mentioned observations: replace each directed arc (u, v) of G with a copy of G by adding arcs from u to all vertices in that edge copy and from all vertices in that edge copy to v.

In order to obtain inapproximability results for the maximum binary tree problem, we first introduce different constructions for the squared graph in the self-improving reduction compared to the ones by Karger et al. Moreover, our constructions of the squared graph differ substantially between undirected and directed graphs. Interestingly, our constructions also generalize naturally to the max degree-constrained tree problem. Secondly, although our reduction for showing the lack of PTAS in undirected graphs for MBT is also from TSP$(1, 2)$, it is completely different from that of Karger et al. and, once again, generalizes to the max degree-constrained tree problem. Thirdly, we show the lack of PTAS in DAGs for MBT by reducing from the max 3-coloring problem. This reduction is altogether new – the reader might recall that the longest path problem in DAGs is solvable in polynomial-time, so there cannot be a counterpart of this step (i.e., lack of PTAS in DAGs) for longest path. We next present further details underlying our proofs.

Self-improving reduction for directed graphs. We focus on the rooted variant of MBT in directed graphs. We first assume that the given graph G contains a source (if not, adding such a source vertex with arcs to all the vertices changes the optimum only by one). In

contrast to the squared graph described above (i.e., instead of adding edge copies), we replace every vertex in G by a copy of G (that we call as a vertex copy) and for every arc (u, v) in G, we add an arc from the root node of the vertex copy corresponding to u to the source node of the vertex copy corresponding to v. Finally, we declare the root node of the root vertex copy to be the root node of G^2. Let $\alpha \in (0, 1]$ and $OPT(G)$ be the number of vertices in the maximum binary tree in G. With this construction of the squared graph, we show that (1) $OPT(G^2) \geq OPT(G)^2$ and (2) an α-approximate rooted binary tree T_2 in G^2 can be used to recover a rooted binary tree T_1 in G which is a $\sqrt{\alpha}$-approximation. We emphasize that if G is a DAG, then the graph G^2 obtained by this construction is also a DAG.

Inapproximability for DAGs. In order to show the constant-factor inapproximability result for DAGs, it suffices to show that there is no PTAS (due to the self-improving reduction for directed graphs described above). We show the lack of a PTAS in DAGs by reducing from the max 3-coloring problem in 3-colorable graphs. It is known that this problem is APX-hard – in particular, there is no polynomial-time algorithm to find a coloring that colors at least 32/33-fraction of the edges properly [20]. Our reduction encodes the coloring problem into a DAGMaxBinaryTree instance in a way that recovers a consistent coloring for the vertices while also being proper for a large fraction of the edges. Our ETH-based inapproximability result is also a consequence of this reduction in conjunction with the self-improving reduction. We again emphasize that there is no counterpart of APX-hardness in DAGs for max binary tree in the longest path literature.

Self-improving reduction for undirected graphs. For UndirMaxBinaryTree, the self-improving reduction is more involved. Our above-mentioned reduction for DirMaxBinaryTree heavily exploits the directed nature of the graph (e.g., uses source vertices) and hence, is not applicable for undirected graphs. Moreover, the same choice of squared graph G^2 as Karger et al. [22] fails since Obs (ii) does not hold any more: the tree T_2 restricted to each edge copy may not be a tree (but it will be a forest). However, we observe that T_2 restricted to each edge copy may result in a forest with up to four binary trees in it. This observation and a more careful projection can be used to recover a tree of size at least $\sqrt{|V(T_2)|}/4$ (let us call this weakened Obs (ii)). Yet, weakened Obs (ii) is insufficient for a self-improving reduction. One approach to fix this would be to construct a *different squared graph* $G^{\boxtimes 2}$ that strengthens Obs (i) to guarantee that $OPT(G^{\boxtimes 2}) \geq 16OPT(G)^2$ while still allowing us to recover a binary tree of size $\sqrt{|V(T_2)|}/4$ in G from a binary tree T_2 in $G^{\boxtimes 2}$. Such a strengthened Obs (i) coupled with weakened Obs (ii) would complete the self-improving reduction. Our reduction is a variant of this approach: we introduce a construction of the squared-graph that strengthens Obs (i) by a factor of 2 while also weakening Obs (ii) only by a factor of 2. We prove these two properties of the construction by relying on a handshake-like property of binary trees which is a relationship between the number of nodes of each degree and the total number of nodes in the binary tree.

Inapproximability for undirected graphs. In order to show the constant-factor inapproximability result, it suffices to show that there is no PTAS (due to the self-improving reduction). We show the lack of a PTAS by reducing from TSP$(1, 2)$. We mention that Karger, Motwani, and Ramkumar [22] also show the lack of a PTAS for the longest path problem by reducing from TSP$(1, 2)$. However, our reduction is much different from their reduction. Our reduction mainly relies on the fact that if we add a pendant node to each vertex of a graph G and obtain a binary tree T that has a large number of such pendants, then the binary tree restricted to G cannot have too many nodes of degree three. Our ETH-based inapproximability result is also a consequence of this reduction in conjunction with the self-improving reduction.

1.3.2 Algorithmic results

A 2^kpoly(n) time algorithm for k-BinaryTree. The proof of this result is inspired by the algebrization technique introduced in [26, 27, 36] for designing randomized algorithms for k-Path and k-Tree – in k-Path, the goal is to recover a path of length k in the given graph while k-Tree asks to recover a *given tree* on k vertices in the given graph. Their idea is to encode a path (or the given tree) as a multilinear monomial term in a carefully constructed polynomial, which is efficiently computable using an arithmetic circuit. Then, a result due to Williams [36] is used to verify if the constructed polynomial contains a multilinear term – Williams' result gives an efficient randomized algorithm, which on input a small circuit that computes the polynomial, outputs "yes" if a multilinear term exists in the sum of products representation of the input polynomial, and "no" otherwise. The subgraph that is sought may then be extracted using an additional pass over the graph. Our main technical contribution is the construction of a polynomial P_G whose multilinear terms correspond to binary trees of size k in G and which is efficiently computable by an arithmetic circuit. We remark that the polynomial constructions in previous results do not readily generalize for our problem. Our key contribution is the construction of a suitable polynomial, based on a carefully designed recursion.

Efficient algorithm for bipartite permutation graphs. Our main structural insight for bipartite permutation graphs is that there exists a maximum binary tree which is *crossing-free* with respect to the so-called *strong ordering* of the vertices. With this insight, MBT in bipartite permutation graphs reduces to finding a maximum crossing-free binary tree. We solve this latter problem by dynamic programming.

Organization. We present the 2^kpoly(n) time algorithm for k-BinaryTree in Section 2. We present our hardness results for DAGs in Section 3. We conclude with a few open problems in Section 4. Due to page limits, we formulate an IP for DAGs and discuss its integrality gap, show our hardness results for undirected graphs, and design an efficient algorithm for bipartite permutation graphs in the full version [11].

1.4 Preliminaries

MBT in directed graphs. Given a directed graph $G = (V, E)$ and a vertex $r \in V$, we say that a subgraph T where $V(T) \subseteq V$ and $E(T) \subseteq E$, is an *r-rooted tree* in G if T is acyclic and every vertex v in T has a *unique* directed path (in T) to r. If the in-degree of each vertex in T is at most 2, then T is an *r-rooted binary tree*. The problem of interest in directed graphs is rooted-DirMaxBinaryTree: Given a directed graph $G = (V, E)$ and a root $r \in V$, the goal is to find an r-rooted binary tree in G with maximum number of vertices. The problem DAGMaxBinaryTree is a special case of rooted-DirMaxBinaryTree in which the input directed graph is a DAG. We recall that the rooted and unrooted variants of the maximum binary tree problem in DAGs are equivalent.

MBT in undirected graphs. Given an undirected graph $G = (V, E)$, we say that a subgraph T, where $V(T) \subseteq V$ and $E(T) \subseteq E$, is a *binary tree* in G if T is connected, acyclic, and $\deg_T(v) \leq 3$ for every vertex $v \in V(T)$. We will focus on the unrooted variant, i.e., UndirMaxBinaryTree, since the inapproximability results for the rooted variant are implied by inapproximability results for the unrooted variant. Here, we are given an undirected graph G and the goal is to find a binary tree in G with maximum number of vertices.

2 A $2^k\mathsf{poly}(n)$ time algorithm for k-BinaryTree

In this section, we present a randomized algorithm that solves k-BinaryTree exactly and runs in time $2^k\mathsf{poly}(n)$ where n is the number of vertices in the input graph. We recall that k-BinaryTree is the problem of deciding whether a given directed graph contains a binary tree of size k. Our algorithm is inspired by an algebraic approach for solving the k-Path problem – the algebraic approach relies on efficient detection of multilinear terms in a given polynomial.

k-Path, polynomials and multilinear terms. We begin with a recap of the algebraic approach to solve k-Path– here, the goal is to verify if a given (directed or undirected) graph G contains a path of length at least k. There has been a rich line of research dedicated to designing algorithms for k-Path with running time $\beta^k\mathsf{poly}(n)$ where $\beta > 1$ is a constant and n is the number of vertices in G (cf. [2, 8, 26, 36]). In particular, the algorithms in [26] and [36] are based on detecting multilinear terms in a polynomial.

We now recall the problem of detecting multilinear terms in a polynomial. Here, we are given a polynomial with coefficients in a finite field $\mathbb{F}_q$ and the goal is to verify if it has a multilinear term. We emphasize that the input polynomial is given *implicitly* by an arithmetic circuit consisting of additive and multiplicative gates. In other words, the algorithm is allowed to evaluate the polynomial at any point but does not have direct access to the sum-of-products expansion of the polynomial. We recall that a multilinear term in a polynomial $p \in \mathbb{F}_q[x_1, x_2, \cdots, x_m]$ is a monomial in the sum-of-products expansion of p consisting of only degree-1 variables. For example, in the following polynomial

$$p(x_1, x_2, x_3) = x_1^2x_2 + x_3 + x_1x_2x_3,$$

the monomials x_3 and $x_1x_2x_3$ are multilinear terms, whereas $x_1^2x_2$ is not a multilinear term since x_1 has degree 2. We will use the algorithm mentioned in the following theorem as a black box for detecting multilinear terms in a given polynomial.

▶ **Theorem 5** (Theorem 3.1 in [36]). *Let $P(x_1, \cdots, x_n)$ be a polynomial of degree at most k, represented by an arithmetic circuit of size $s(n)$ with additive gates (of unbounded fan-in), multiplicative gates (of fan-in two), and no scalar multiplications. There is a randomized algorithm that on input P runs in $2^k s(n)\cdot\mathsf{poly}(n)\log(1/\delta)$ time, outputs "yes" with probability $1-\delta$ if there is a multilinear term in the sum-product expansion of P, and outputs "no" if there is no multilinear term.*

The idea behind solving k-Path with the help of this theorem is to construct a polynomial p_G based on the input graph G so that p_G contains a multilinear term if and only if G contains a simple path of length k. At the same time, p_G should be computable by an arithmetic circuit of size $\mathsf{poly}(n)$. Koutis and Williams achieved these properties using the following polynomial:

$$p_G(x_1, \cdots, x_n) := \sum_{(v_{i_1}, v_{i_2}, \ldots, v_{i_k}): \text{ a walk in } G} x_{i_1}x_{i_2}\ldots x_{i_k}.$$

We recall that a walk in G is a sequence of vertices in which neighbouring vertices are adjacent in G. From the definition, it is easy to observe that there is a one-to-one correspondence between simple k-paths in G and multilinear terms in p_G. Moreover, it can be shown that there is an arithmetic circuit of size $O\left(k^2(m+n)\right)$ that computes p_G, where m is the number of edges and n is the number of vertices in G. See Chapter 10.4 of [14] for alternative constructions of this polynomial.

The polynomial construction for k-BinaryTree. Following the above-mentioned approach, we construct a polynomial P_G with the property that P_G contains a multilinear term if and only if G contains a binary tree of size k. Unfortunately, there is no immediate generalization of walks of length k that characterize binary trees on k vertices. So, instead of defining the polynomial conceptually, we will define the polynomial recursively by building the arithmetic circuit that computes P_G, and will prove the correspondence between multilinear terms in P_G and binary trees of size k in G. In the definition of our polynomial, we also need to introduce an auxiliary variable to eliminate low-degree multilinear terms in P_G (which is not an issue in the construction of the polynomial for k-Path).

Let $G = (V, E)$ be the given directed graph. For $v \in V$, let $\Delta_v^{in} \coloneqq \{u \in V : (u, v) \in E\}$. We begin by defining a polynomial $P_v^{(k)}$ for every $v \in V$ and every positive integer k, in $(n+1)$ variables $\{x_v\}_{v \in V} \cup \{y\}$:

$$P_v^{(k)} \coloneqq \begin{cases} x_v & \text{if } k = 1 \\ x_v \cdot y^{k-1} & \text{if } k > 1 \text{ and } \Delta_v^{in} = \varnothing \\ x_v \left(\sum_{u \in \Delta_v^{in}} P_u^{(k-1)} + \sum_{\ell=1}^{k-2} \left(\sum_{u_1 \in \Delta_v^{in}} P_{u_1}^{(\ell)} \right) \left(\sum_{u_2 \in \Delta_v^{in}} P_{u_2}^{(k-1-\ell)} \right) \right) & \text{if } k > 1 \text{ and } \Delta_v^{in} \neq \varnothing \end{cases}$$

Next, we define $P_G^{(k)} \coloneqq \sum_{v \in V} P_v^{(k)}$. We recall that a polynomial is homogenous if every monomial has the same degree. By induction on k, the polynomial $P_v^{(k)}$ is a degree-k homogeneous polynomial and so is $P_G^{(k)}$. Moreover, by the recursive definition, we see that $P_v^{(k)}$ can be represented as an arithmetic circuit of size $O(k^2 n)$ since there are kn polynomials in total, and computing each requires $O(1)$ addition gates (with unbounded fan-in) and $O(k)$ multiplication gates (with fan-in two). We show the following connection between multilinear terms in $P_G^{(k)}$ and binary trees in G.

▶ **Lemma 6.** *The graph G has a binary tree of size k rooted at r if and only if there is a multilinear term of the form $\prod_{v \in S} x_v$ in $P_r^{(k)}$ where $|S| = k$.*

Proof. We first show the forward direction, i.e., if G has a binary tree T of size k rooted at r, then there is a multilinear term of the form $\prod_{v \in T} x_v$ in $P_r^{(k)}$. We prove this by induction on k. The base case $k = 1$ follows since $P_r^{(1)} = x_r$. Suppose that the forward direction holds when $|T| \leq k - 1$. For $|T| = k$, we consider two cases.

1. The root r has only one child c. The subtree T_c of T rooted at c has size $k - 1$. By induction hypothesis there is a multilinear term $\prod_{v \in T_c} x_v$ in $P_c^{(k-1)}$. Since $c \in \Delta_r^{in}$, for some polynomial Q we can write

$$P_r^{(k)} = x_r \left(P_c^{(k-1)} + Q \right).$$

   Therefore $x_r \cdot \prod_{v \in T_c} x_v$ is a term in $P_r^{(k)}$. This term is multilinear and equals to $\prod_{v \in T} x_v$ since $r \notin T_c$.
2. The root r has two children c_1, c_2. Suppose that the subtree T_{c_1} rooted at c_1 has size ℓ, thus the subtree T_{c_2} rooted at c_2 has size $k - 1 - \ell$. The induction hypothesis implies that $P_{c_1}^{(\ell)}$ has a multilinear term $\prod_{v \in T_{c_1}} x_v$, and $P_{c_2}^{(k-1-\ell)}$ has a multilinear term $\prod_{v \in T_{c_2}} x_v$. Since $c_1, c_2 \in \Delta_r^{in}$, for some polynomial Q we can write

$$P_r^{(k)} = x_r \left(P_{c_1}^{(\ell)} P_{c_2}^{(k-1-\ell)} + Q \right).$$

   Therefore $x_r \left(\prod_{v \in T_{c_1}} x_v \right) \left(\prod_{v \in T_{c_2}} x_v \right)$ is a term in $P_r^{(k)}$. This term is multilinear and equals to $\prod_{v \in T} x_v$ because T is the disjoint union of r, T_{c_1} and T_{c_2}.

In both cases, the polynomial $P_r^{(k)}$ has a multilinear term $\prod_{v \in T} x_v$. This completes the inductive step.

Next, we show that if $P_r^{(k)}$ has a multilinear term of the form $\prod_{v \in S} x_v$ where $|S| = k$, then there is a binary tree T rooted at r in G with vertex set S. We prove this also by induction on k. The base case $k = 1$ is trivial since $P_r^{(1)} = x_r$ and there is a binary tree of size 1 rooted at r. Suppose that the statement holds for $k-1$ or less ($k > 1$).

Let $\prod_{v \in S} x_v$ be a multilinear term in $P_r^{(k)}$. We note that $r \in S$ since every term in $P_r^{(k)}$ contains x_r. Moreover, we may assume that $\Delta_r^{in} \neq \varnothing$ since otherwise $P_r^{(k)} = x_r \cdot y^{k-1}$ which does not contain any term of the form $\prod_{v \in S} x_v$. According to the definition of $P_r^{(k)}$, we could have two cases.

1. The term $\prod_{v \in S \setminus \{r\}} x_v$ is a multilinear term in $P_c^{(k-1)}$ for some $c \in \Delta_r^{in}$. The induction hypothesis implies that there is a binary tree T_c rooted at c with vertex set $S \setminus \{r\}$. Let T be the binary tree obtained by adding the edge (c, r) to T_c. Then T is a binary tree rooted at r with vertex set S.
2. The term $\prod_{v \in S \setminus \{r\}} x_v$ is a multilinear term in $P_{c_1}^{(\ell)} P_{c_2}^{(k-1-\ell)}$ for some $c_1, c_2 \in \Delta_r^{in}$ and some integer $1 \leq \ell \leq k-2$. In this case, since $P_{c_1}^{(\ell)}$ and $P_{c_2}^{(k-1-\ell)}$ are homogeneous polynomials of degree ℓ and $k-1-\ell$, we can partition $S \setminus \{r\}$ into two sets S_1 and S_2 with $|S_1| = \ell$ and $|S_2| = k-1-\ell$ such that $\prod_{v \in S_1} x_v$ is a multilinear term in $P_{c_1}^{(\ell)}$, and $\prod_{v \in S_2} x_v$ is a multilinear term in $P_{c_2}^{(\ell)}$. Applying the induction hypothesis, we obtain a binary tree T_{c_1} (rooted at c_1) with vertex set S_1 and a binary tree T_{c_2} (rooted at c_2) with vertex set S_2. Let T be the binary tree obtained by adding edges (c_1, r) and (c_2, r) to $T_{c_1} \cup T_{c_2}$. Then T is a binary tree rooted at r with vertex set $S_1 \cup S_2 \cup \{r\} = S$.

In both cases, we can find a binary tree T rooted at r with vertex set S. This completes the inductive step. ◀

With this choice of $P_G^{(k)}$, we call the algorithm appearing in Theorem 5 on input polynomial $\tilde{P}_G^{(k)} \coloneqq y \cdot P_G^{(k)}$, and output the result. We note that every multilinear term of the form $\prod_{v \in S} x_v$ in $P_G^{(k)}$ becomes a multilinear term of the form $y \cdot \prod_{v \in S} x_v$ in $\tilde{P}_G^{(k)}$, and every multilinear term of the form $y \cdot \prod_{v \in S} x_v$ in $P_G^{(k)}$ becomes $y^2 \cdot \prod_{v \in S} x_v$ in $\tilde{P}_G^{(k)}$, which is no longer a multilinear term. In light of Lemma 6, the graph G contains a binary tree of size k if and only if the degree-$(k+1)$ homogeneous polynomial $\tilde{P}_G^{(k)}$ has a multilinear term. The running time is $2^{k+1} \cdot O(k^2 n) \cdot \mathsf{poly}(n+1) \log(1/\delta) = 2^k \cdot \mathsf{poly}(n) \log(1/\delta)$.

We remark that this algorithm does not immediately tell us the tree T (namely the edges in T). However, we can find the edges in T with high probability via a reduction from the search variant to the decision variant. This is formalized in the next lemma.

▶ **Lemma 7.** *Suppose that there is an algorithm $\mathcal{A}$ which takes as input a directed graph $G = (V, E)$, an integer k and $\delta' \in (0,1)$ runs in time $2^k \mathsf{poly}(|V|) \log(1/\delta')$ and*

- *outputs "yes" with probability at least $1 - \delta'$ if G contains a binary tree of size k,*
- *outputs "no" with probability 1 if G does not contain a binary tree of size k.*

Then there also exists an algorithm $\mathcal{A}'$ which for every $\delta \in (0,1)$ outputs a binary tree T of size k with probability at least $1 - \delta$ when the answer is "yes", and runs in time $2^k \mathsf{poly}(|V|) \log(1/\delta)$.

Proof. The algorithm $\mathcal{A}'$ iterates through all arcs $e \in E$ and calls $\mathcal{A}$ on $(G - e, k)$ with $\delta' = \delta/m$ where $G - e = (V, E \setminus \{e\})$ and $m = |E|$. If for some $e \in E$ the call to $\mathcal{A}$ outputs "yes", we remove e from G (i.e., set $G \leftarrow G - e$) and continue the process. We will show that when the algorithm terminates, the arcs in G constitute a binary tree of size k (if there exists one) with probability at least $1 - \delta$.

Suppose the order in which $\mathcal{A}'$ processes the arcs is $e_1, e_2, \cdots, e_m$, and the graph at iteration t is denoted by $G^{(t)}$. Let B_t denote the event "$G^{(t-1)} - e_t$ contains a binary tree of size k, but the call to $\mathcal{A}\left(G^{(t-1)} - e_t, k\right)$ returns no". Due to the assumption we made for $\mathcal{A}$, event B_t happens with probability at most δ'. Since the algorithm $\mathcal{A}$ has perfect soundness, whenever $\mathcal{A}'$ removes an edge we are certain that the remaining graph still contains a binary tree of size k (otherwise the call to $\mathcal{A}$ would never return "yes"). That means if $G^{(0)} = G$ contains a binary tree of size k then $G^{(t)}$ contains a binary tree of size k for all $0 \leq t \leq m$. Therefore if none of the events B_t happens, the final graph $G^{(m)}$ is a binary tree of size k. The probability of failure is upper bounded by

$$\Pr\left[\bigcup_{t=1}^{m} B_t\right] \leq m \cdot \delta' = m \cdot \frac{\delta}{m} = \delta.$$

Since algorithm $\mathcal{A}'$ makes m calls to algorithm $\mathcal{A}$, the running time of $\mathcal{A}'$ is $m \cdot 2^k \mathsf{poly}\left(|V|\right) \log\left(1/\delta'\right) = 2^k \mathsf{poly}\left(|V|\right) \log\left(1/\delta\right)$. ◀

Theorem 5 in conjunction with Lemmas 6 and 7 complete the proof of Theorem 3.

3 Hardness results for DAGs

In this section, we show the inapproximability of finding a maximum binary tree in DAGs. The *size* of a binary tree denotes the number of vertices in the tree.

3.1 Self-improvability for directed graphs

We show that an algorithm for ROOTED-DIRMAXBINARYTREE achieving a constant factor approximation can be used to design a PTAS in Theorem 11. We emphasize that this result holds for arbitrary directed graphs and not just DAGs. The idea is to gradually boost up the approximation ratio by running the constant-factor approximation algorithm on squared graphs. Our notion of *squared graph* will be the following.

▶ **Definition 8.** *Given a directed graph $G = (V, E)$ with root r, the* squared graph G^2 *is the directed graph obtained by performing the following operations on G:*

1. *Construct $G' = (V', E')$ by introducing a source vertex s, i.e., $V' := V \cup \{s\}$. We add arcs from s to every vertex in G, i.e., $E' := E \cup \{(s, v) : v \in V\}$.*
2. *For each $u \in V$ (we note that V does not include the source vertex), we create a copy of G' that we denote as a* vertex copy G'_u. *We will denote the root vertex of G'_u by r_u, and the source vertex of G'_u by s_u.*
3. *For each $(u, v) \in E$, we create an arc (r_u, s_v).*
4. *We declare the root of G^2 to be r_r, i.e. the root vertex of the vertex copy G'_r.*

We define $G^{2^{k+1}}$ recursively as $G^{2^{k+1}} := \left(G^{2^k}\right)^2$ with the base case $G^1 := G$.

Given a directed graph G with $n-1$ vertices, the number of vertices in G^{2^k} satisfies the recurrence relation

$$\left|V\left(G^{2^k}\right)\right| = \left|V\left(G^{2^{k-1}}\right)\right| \cdot \left(\left|V\left(G^{2^{k-1}}\right)\right| + 1\right) = \left|V\left(G^{2^{k-1}}\right)\right|^2 + \left|V\left(G^{2^{k-1}}\right)\right|.$$

Hence, we have

$$\left|V\left(G^{2^k}\right)\right| + 1 \leq \left(\left|V\left(G^{2^{k-1}}\right)\right| + 1\right)^2 \leq \left(\left|V\left(G^{2^{k-2}}\right)\right| + 1\right)^{2^2} \leq \cdots \leq \left(\left|V\left(G^{2^0}\right)\right| + 1\right)^{2^k} = n^{2^k}.$$

(b) G^2 rooted at the black node. Source nodes are represented by diamonds.

Figure 1 Directed Squared Graph.

We use $OPT(G)$ to denote the size (number of vertices) of a maximum binary tree in G. The following lemma shows that $OPT(G)$ is super-multiplicative under the squaring operation.

▶ **Lemma 9.** *For any fixed root r, $OPT(G^2) \geq OPT(G)^2$.*

Proof. Suppose we have an optimal r-rooted binary tree T_1 of G, i.e. $|V(T_1)| = OPT(G)$. We construct an r_r-rooted binary tree T_2 of G^2 as follows:

1. For $v \in V(G)$, define $T'_v = T_v \cup \{s_v\}$ to be the optimal r_v-rooted binary tree in the vertex copy G'_v where T_v is identical to T_1 and the source vertex s_v is connected to an arbitrary leaf node in T_v.
2. For every vertex $v \in T_1$, add T'_v to T_2. This step generates $|V(T_1)| \cdot (|V(T_1)| + 1)$ vertices in T_2.
3. Connect the copies selected in step 2 by adding the arc (r_u, s_v) to T_2 for every arc $(u, v) \in T_1$.

Since T_1 is an r-rooted binary tree (in G), it follows that T_2 is an r_r-rooted binary tree (in G^2). Moreover, the size of T_2 is

$$|V(T_2)| = |V(T_1)| \cdot (|V(T_1)| + 1) \geq OPT(G)^2,$$

which cannot exceed $OPT\left(G^2\right)$. ◀

The following lemma shows that a large binary tree in G^2 can be used to obtain a large binary tree in G.

▶ **Lemma 10.** *For every $\alpha \in (0, 1]$, given an r_r-rooted binary tree T_2 in G^2 with size*

$$|V(T_2)| \geq \alpha OPT\left(G^2\right) - 1,$$

there is a linear-time (in the size of G^2) algorithm that finds an r-rooted binary tree T_1 of G with size

$$|V(T_1)| \geq \sqrt{\alpha} OPT(G) - 1.$$

Proof. Let $U \coloneqq \{v\colon v \in V(G) \text{ such that } r_v \in V(T_2)\}$ and $A \coloneqq \{(v,w) : v,w \in V(G), (r_v, s_w) \in E(T_2)\}$. We note that $T_1' := (U, A)$ is an r-rooted binary tree in G. This is because the path from every $v \in U$ to the root r is preserved, and the in-degree of every node $w \in U$ is bounded by the in-degree of s_w (in T_2), which is thus at most 2, and similarly the out-degree of every node is at most 1. We also remark that T_1' can be found in linear time. If $|U| \geq \sqrt{\alpha}OPT(G) > \sqrt{\alpha}OPT(G) - 1$, then the lemma is already proved. So, we may assume that $|U| < \sqrt{\alpha}OPT(G)$.

We now consider $T_v' \coloneqq (V(T_2) \cap V(G_v'), E(T_2) \cap E(G_v'))$ for $v \in U$. We can view T_v' as the restriction of T_2 to G_v', hence every node of T_v' has out-degree at most 2. Since T_2 is an r_r-rooted binary tree in G^2, every vertex in $V(T_2) \cap V(G_v')$ has a unique directed path (in T_2) to r_r, which must go through r_v, thus every vertex in $V(T_2) \cap V(G_v')$ has a unique directed path to r_v. It follows that T_v' is an r_v-rooted binary tree in the vertex copy G_v'.

We now show that there exists $v \in U$ such that $|V(T_v')| \geq \sqrt{\alpha}OPT(G)$. Suppose not, which means for every $v \in U$ we have $|V(T_v')| < \sqrt{\alpha}OPT(G)$. Then

$$\begin{aligned} |V(T_2)| &= \sum_{v \in U} |V(T_v')| < \sum_{v \in U} \left(\sqrt{\alpha}OPT(G)\right) < \sqrt{\alpha}OPT(G) \cdot \sqrt{\alpha}OPT(G) \\ &= \alpha OPT(G)^2 \leq \alpha \cdot OPT\left(G^2\right), \end{aligned}$$

a contradiction. The last inequality is due to Lemma 9.

In linear time we can find a binary tree T_v' with the desired size $|V(T_v')| \geq \sqrt{\alpha}OPT(G)$. To complete the proof of the lemma, we let $T_1 \coloneqq T_v' \setminus \{s_v\}$ which is (isomorphic to) an r-rooted binary tree in G with size at least $\sqrt{\alpha}OPT(G) - 1$. ◀

▶ **Theorem 11.** *If* rooted-DirMaxBinaryTree *has a polynomial-time algorithm that achieves a constant-factor approximation, then it has a PTAS.*

Proof. Suppose that we have a polynomial-time algorithm $\mathcal{A}$ that achieves an α-approximation for rooted-DirMaxBinaryTree. Given a directed graph G, root r and $\varepsilon > 0$, let

$$k \coloneqq 1 + \left\lceil \log_2 \frac{\log_2 \alpha}{\log_2(1-\varepsilon)} \right\rceil$$

be an integer constant that depends on α and ε. We construct G^{2^k} and run algorithm $\mathcal{A}$ on G^{2^k}. Then, we get a binary tree in G^{2^k} of size at least $\alpha OPT\left(G^{2^k}\right) - 1$. By Lemma 10, we can obtain an r-rooted binary tree in G of size at least

$$\alpha^{2^{-k}} OPT(G) - 1 \geq \alpha^{2^{-k+1}} OPT(G) \geq (1-\varepsilon) OPT(G).$$

The first inequality holds as long as

$$OPT(G) \geq \frac{1}{\sqrt{1-\varepsilon} - (1-\varepsilon)} \geq \frac{1}{\alpha^{2^{-k}} - \alpha^{2^{-k+1}}}.$$

We note that if $OPT(G)$ is smaller than $1/\left(\alpha^{2^{-k}} - \alpha^{2^{-k+1}}\right)$ which is a constant, then we can solve the problem exactly by brute force in polynomial time. Finally, we also observe that for fixed ε, the running time of this algorithm is polynomial since there are at most $n^{2^k} = n^{O(1)}$ vertices in the graph G^{2^k}. ◀

3.2 APX-hardness for DAGs

Next, we show the inapproximability results for DAGs. We begin by recalling DAGMaxBinaryTree: We begin by recalling the problem:

DAGMaxBinaryTree
Given: A directed acyclic graph $G = (V, E)$ and a root $r \in V$.
Goal: An r-rooted binary tree in G with the largest number of nodes.

We may assume that the root is the only vertex that has no outgoing arcs as we may discard all vertices that cannot reach the root. We show that DAGMaxBinaryTree is APX-hard by reducing from the following problem.

Max-3-Colorable-Subgraph
Given: An undirected graph G that is 3-colorable.
Goal: A 3-coloring of G that maximizes the fraction of properly colored edges.

It is known that finding a 3-coloring that properly colors at least 32/33-fraction of edges in a given 3-colorable graph is NP-hard [5,20]. In particular, Max-3-Colorable-Subgraph is APX-hard. We reduce Max-3-Colorable-Subgraph to DAGMaxBinaryTree. Let $G = (V, E)$ be the input 3-colorable undirected graph with $n := |V|$ and $m := |E|$. For $\varepsilon > 0$ to be fixed later, we construct a DAG, denoted $D(G, \varepsilon)$, as follows (see Figure 2 for an illustration):

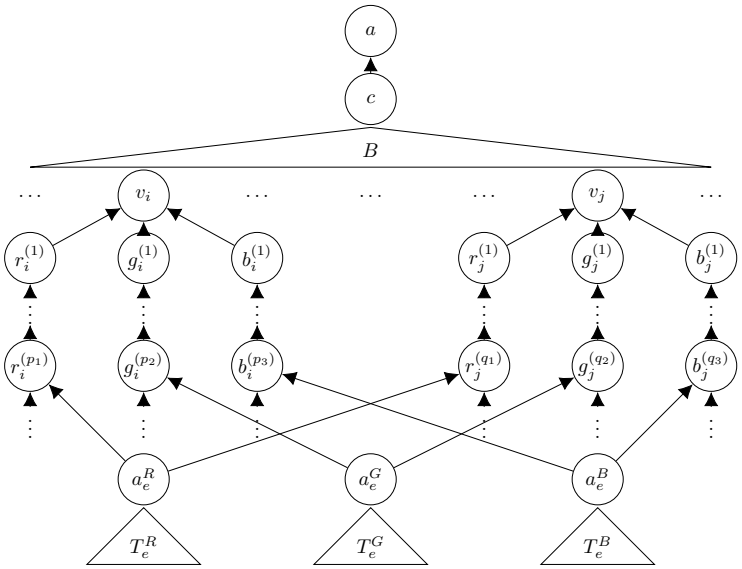

Figure 2 DAG $D(G, \varepsilon)$ constructed in the reduction from Max-3-Colorable-Subgraph to DAGMaxBinaryTree.

1. Create a directed binary tree B rooted at node c with $n := |V|$ leaf nodes. We will identify each leaf node by a unique vertex $v \in V$. Create a super root a and arc $c \to a$. This tree and the super root would have $2n$ nodes, including the super root node a, n leaf nodes, and $n - 1$ internal nodes.
2. For every $i \in V$, we introduce three directed paths of length n that will be referred to as R_i, G_i and B_i. Let R_i be structured as $r_i^{(1)} \leftarrow r_i^{(2)} \leftarrow \cdots \leftarrow r_i^{(n)}$, and similarly introduce $g_i^{(k)}$ and $b_i^{(k)}$ with the same structure. Also add arcs $r_i^{(1)} \to v_i$, $g_i^{(1)} \to v_i$ and $b_i^{(1)} \to v_i$.

3. For every edge $e = \{i, j\} \in E$, introduce three directed binary trees that will be referred to as T_e^R, T_e^G, and T_e^B, each with $t = \left\lceil \frac{2\varepsilon n(n+1)+4n^2}{\varepsilon m} \right\rceil$ nodes. Let the roots of the binary trees T_e^R, T_e^G, and T_e^B be a_e^R, a_e^G, and a_e^B respectively. Add arcs $a_e^R \to r_i^{(p_1)}$ and $a_e^R \to r_j^{(q_1)}$ where $r_i^{(p_1)}$ and $r_j^{(q_1)}$ are two nodes in R_i and R_j with in-degree strictly smaller than 2. We note that R_i is a path with n nodes so such a node always exists. Similarly connect a_e^G to $g_i^{(p_2)}$ and $g_j^{(q_2)}$, and a_e^B to $b_i^{(p_3)}$ and $b_j^{(q_3)}$ in the directed paths G_i and B_i, respectively.

The constructed graph $D(G, \varepsilon)$ is a DAG. We fix a to be the root. The number of nodes N in $D(G, \varepsilon)$ is $N = 3mt + 3n \cdot n + 2n = 3mt + 3n^2 + 2n$. We note that every node $v_i \in V$ has in-degree exactly 2 in every a-rooted maximal binary tree in $D(G, \varepsilon)$. The idea of this reduction is to encode the color of v_i as the unique path among R_i, G_i, B_i that is *not* in the subtree under v_i. The following two lemmas summarize the main properties of the DAG constructed above.

▶ **Lemma 12.** *Let T be a maximal a-rooted binary tree of $D(G, \varepsilon)$. If $|V(T)| \geq (1-\varepsilon/4)(N - n^2)$, then at most εm nodes among $\cup_{e \in E}\{a_e^R, a_e^G, a_e^B\}$ are not in T.*

Proof. Suppose more than εm such nodes are missing from T. For each node a_e^R that is not in T, the corresponding subtree T_e^R is also not in T (same for a_e^G and a_e^B). Therefore

$$|V(T)| < N - \varepsilon mt = 3mt + 3n^2 + 2n - \varepsilon mt = \left(1 - \frac{\varepsilon}{4}\right) \cdot 3mt + 3n^2 + 2n - \frac{\varepsilon}{4} mt.$$

The choice of t implies that $\varepsilon mt/4 > \varepsilon n(n+1)/2 + n^2$. Therefore

$$\begin{aligned} |V(T)| &< \left(1 - \frac{\varepsilon}{4}\right) \cdot 3mt + 3n^2 + 2n - \frac{\varepsilon n(n+1)}{2} - n^2 \\ &< \left(1 - \frac{\varepsilon}{4}\right) \cdot 3mt + \left(1 - \frac{\varepsilon}{4}\right)(2n^2 + 2n) \\ &= \left(1 - \frac{\varepsilon}{4}\right)(N - n^2), \end{aligned}$$

a contradiction. ◀

▶ **Lemma 13.** *If G is 3-colorable, then every a-rooted maximum binary tree in $D(G, \varepsilon)$ has size exactly $N - n^2$.*

Proof. We first note that every binary subtree of $D(G, \varepsilon)$ has size at most $N - n^2$. This is because there are n vertices with in-degree 3 (namely $v_1, v_2, \cdots, v_n$). For each such vertex v_i, there are 3 vertices $r_i^{(1)}, g_i^{(1)}$ and $b_i^{(1)}$ whose only outgoing arc is to v_i. Moreover, each vertex $r_i^{(1)}$ (and similarly $g_i^{(1)}$ and $b_i^{(1)}$) is the end-vertex of an induced path of length n.

Suppose G is 3-colorable. We now construct an a-rooted binary tree T of size $N - n^2$ in $D(G, \varepsilon)$. We focus on the nodes to be discarded so that we may construct a binary spanning tree with the remaining nodes. Let $\sigma \colon V \to \{Red, Green, Blue\}$ be a proper 3-coloring of G. If $\sigma(v_i) = Red$, we discard the path R_i. The cases where $\sigma(v_i) \in \{Green, Blue\}$ are similar. Since there are no monochromatic edges, there do not exist $e = \{v_i, v_j\} \in E$ and $C \in \{R, G, B\}$ such that both parents of a_e^C are not in T. Therefore every binary tree T_e^C is contained as a subtree in T. ◀

▶ **Theorem 14.** *Suppose there is a PTAS for DAGMaxBinaryTree on DAGs, then for every $\varepsilon > 0$ there is a polynomial-time algorithm which takes as input an undirected 3-colorable graph G, and outputs a 3-coloring of G that properly colors at least $(1 - \varepsilon)m$ edges.*

Proof. Let $G = (V, E)$ be the given undirected 3-colorable graph. We construct $D(G, \varepsilon)$ in polynomial time. We note that the constructed graph $D(G, \varepsilon)$ is a directed acyclic graph. We now run the PTAS for DAGMaxBinaryTree on $D(G, \varepsilon)$ and root a to obtain a $(1 - \varepsilon/4)$-approximate maximum binary tree in $D(G, \varepsilon)$. By Lemma 13 and the fact that G is 3-colorable, the PTAS will output an a-rooted binary tree T of size at least

$$\left(1 - \frac{\varepsilon}{4}\right)(N - n^2).$$

We may assume that T is a maximal binary tree in $D(G, \varepsilon)$ (if not, then add more vertices to T until we cannot add any further). Maximality ensures that the nodes v_i are in the tree T and moreover, the in-degree of v_i in T is exactly 2. For each $v_i \in V$, let c_i be the unique node among $\left\{r_i^{(1)}, g_i^{(1)}, b_i^{(1)}\right\}$ that is not in T. We define a coloring $\sigma : V \to \{Red, Green, Blue\}$ of G as

$$\forall v_i \in V, \quad \sigma(v_i) = \begin{cases} Red & \text{if } c_i = r_i^{(1)} \\ Green & \text{if } c_i = g_i^{(1)} \\ Blue & \text{if } c_i = b_i^{(1)}. \end{cases}$$

We now argue that the coloring is proper for at least $(1 - \varepsilon)$-fraction of the edges of G. Suppose we have an edge $e = \{v_i, v_j\}$ which is monochromatic under σ, and suppose w.l.o.g. $\sigma(v_i) = \sigma(v_j) = Red$. This means that neither $r_i^{(1)}$ nor $r_j^{(1)}$ is included in T. Therefore $a_e^R \notin T$ since neither of the two vertices with incoming arcs from a_e^R are in T. By Lemma 12, we know that at most εm vertices among $\cup_{e \in E}\{a_e^R, a_e^G, a_e^B\}$ can be excluded from T. Hence, the coloring σ that we obtained can violate at most εm edges in G. ◀

Finally, we prove Theorem 1 using the self-improving argument (Theorem 11) and the APX-hardness of DAGMaxBinaryTree (Theorem 14).

Proof of Theorem 1.

1. We observe that the graph G^2 constructed in Section 3 for the self-improving reduction is a DAG if G is a DAG. Therefore, by Theorem 11, a polynomial-time constant-factor approximation for DAGMaxBinaryTree would imply a PTAS for DAGMaxBinaryTree, a contradiction to APX-hardness shown in Theorem 14.
2. Next we show hardness under the Exponential Time Hypothesis. Suppose there is a polynomial-time algorithm $\mathcal{A}$ for DAGMaxBinaryTree that achieves an $\exp\left(-C \cdot \log_2 n / \log_2 \log_2 n\right)$-approximation for some constant $C > 0$. Given the input graph G with $n - 1$ vertices, let k be an integer that satisfies

   $$2^{\sqrt{n}} \leq n^{2^k} \leq 2^{2\sqrt{n}},$$

   and run $\mathcal{A}$ on G^{2^k} to obtain a binary tree with size at least

   $$\exp\left(-C \cdot \log_2 N / \log_2 \log_2 N\right) OPT\left(G^{2^k}\right),$$

   where $N = n^{2^k}$ upper bounds the size of G^{2^k}. Recursively running the algorithm suggested in Theorem 11 k times gives us a binary tree in G with size at least

   $$\begin{aligned} &\exp\left(-C \cdot \frac{\log_2 N}{\log_2 \log_2 N \cdot 2^k}\right) OPT(G) - 1 \\ \geq &\exp\left(-C \cdot \frac{2\sqrt{n}}{\log_2 \sqrt{n}} \cdot \frac{\log_2 n}{\sqrt{n}}\right) OPT(G) - 1 \\ \geq &\exp\left(-4C\right) OPT(G) - 1 \geq \frac{1}{2} \cdot \exp\left(-4C\right) OPT(G). \end{aligned}$$

The last inequality holds as long as

$$OPT(G) \geq 2 \cdot e^{4C}.$$

We note that if $OPT(G)$ is smaller than $2e^{4C}$ which is a constant, we can solve the problem exactly by brute force in polynomial time. Otherwise the above procedure can be regarded as a constant-factor approximation for DAGMaxBinaryTree. The running time is polynomial in

$$N = n^{2^k} = \exp\left(O\left(\sqrt{n}\right)\right),$$

which is sub-exponential. Moreover, from item 1 we know that it is **NP**-hard to approximate DAGMaxBinaryTree within a constant factor, thus $\mathbf{NP} \subseteq \mathbf{DTIME}\left(\exp\left(O\left(\sqrt{n}\right)\right)\right)$.

3. The proof of this item is almost identical to the previous one except that we choose a different integer k. Suppose there is an algorithm $\mathcal{A}'$ for DAGMaxBinaryTree that achieves a $\exp\left(-C \cdot \log^{1-\varepsilon} n\right)$-approximation for some constant $C > 0$, and runs in time $\exp\left(O\left(\log^d n\right)\right)$ for some constant $d > 0$. We show that there is an algorithm that achieves a constant-factor approximation for DAGMaxBinaryTree, and runs in time $\exp\left(O\left(\log^{d/\varepsilon} n\right)\right)$.
Given a DAG G on $n-1$ vertices as input for DAGMaxBinaryTree, let $k = \left\lceil \left(\frac{1}{\varepsilon} - 1\right) \log_2 \log n \right\rceil$ be an integer that satisfies

$$\left(2^k \log n\right)^{1-\varepsilon} \leq 2^k \leq 2 \left(\log n\right)^{\frac{1}{\varepsilon}-1}.$$

Running $\mathcal{A}'$ on G^{2^k} gives us a binary tree with size at least

$$\exp\left(-C \cdot \log^{1-\varepsilon} N\right) OPT\left(G^{2^k}\right),$$

where $N = n^{2^k}$ upper bounds the size of G^{2^k}. Recursively running the algorithm suggested in Theorem 11 k times gives us a binary tree in G with size at least

$$\begin{aligned}
&\exp\left(-C \cdot \frac{\log^{1-\varepsilon} N}{2^k}\right) OPT(G) - 1 \\
\geq &\exp\left(-C \cdot \frac{\left(2^k \log n\right)^{1-\varepsilon}}{2^k}\right) OPT(G) - 1 \\
\geq &\exp\left(-C\right) OPT(G) - 1 \geq \frac{1}{2} \cdot \exp\left(-C\right) OPT(G).
\end{aligned}$$

The last inequality holds as long as

$$OPT(G) \geq 2 \cdot e^{C}.$$

We note that if $OPT(G)$ is smaller than $2e^{C}$ which is a constant, we can solve the problem exactly by brute force in polynomial time. Otherwise the above procedure can be regarded as a constant-factor approximation for DAGMaxBinaryTree. The running time is quasi-polynomial in N, i.e. for some constant $C' > 0$, the running time is upper-bounded by

$$\exp\left(C'\left(\log^d N\right)\right) = \exp\left(C'\left(\left(2^k \log n\right)^d\right)\right) \leq \exp\left(C'\left(\log^{d/\varepsilon} n\right)\right). \quad \blacktriangleleft$$

4 Conclusion and Open Problems

In this work, we introduced the maximum binary tree problem (MBT) and presented hardness of approximation results for undirected, directed, and directed acyclic graphs, a fixed-parameter algorithm with the solution as the parameter, and efficient algorithms for bipartite permutation graphs. Our work raises several open questions that we state below.

Inapproximability of DirMaxBinaryTree. The view that MBT is a variant of the longest path problem leads to the natural question of whether the inapproximability results for MBT match that of longest path: Is MBT in directed graphs (or even in DAGs) hard to approximate within a factor of $1/n^{1-\varepsilon}$ (we recall that longest path is hard to approximate within a factor of $1/n^{1-\varepsilon}$ [9])? We remark that the self-improving technique is weak to handle $1/n^{1-\varepsilon}$-approximations since the squaring operation yields no improvement. The reduction in [9] showing $1/n^{1-\varepsilon}$-inapproximability of longest paths is from a restricted version of the vertex-disjoint paths problem and is very specific to paths. Furthermore, directed cycles play a crucial role in their reduction for a fundamental reason: longest path is polynomial-time solvable in DAGs. However, it is unclear if directed cycles are the source of hardness for MBT in digraphs (since MBT is already hard in DAGs).

Bicriteria Approximations. Given our inapproximability results, one natural algorithmic possibility is that of bicriteria approximations: can we find a tree with at least $\alpha \cdot OPT$ vertices while violating the degree bound by a factor of at most β? In particular, this motivates an intriguing direction concerning the longest path problem: Given an undirected/directed graph G with a path of length k, can we find a c_1-degree tree in G with at least k/c_2 vertices for some constants c_1 and c_2 efficiently?

Maximum Binary Tree in Permutation DAGs. Finally, it would be interesting to resolve the complexity of MBT in permutation DAGs (and permutation graphs). This would also resolve the open problem posed by Byers, Heeringa, Mitzenmacher, and Zervas of whether the maximum heapable subsequence problem is solvable in polynomial time [10].

Abstract

Efficient algorithms for computing and processing additively weighted Voronoi diagrams on planar graphs have been instrumental in obtaining several recent breakthrough results, most notably the almost-optimal exact distance oracle for planar graphs [Charalampopoulos et al., STOC'19], and subquadratic algorithms for planar diameter [Cabello, SODA'17, Gawrychowski et al., SODA'18]. In this paper, we show how Voronoi diagrams can be useful in obtaining dynamic planar graph algorithms and apply them to classical problems such as dynamic single-source shortest paths and dynamic strongly connected components.

First, we give a fully dynamic single-source shortest paths data structure for planar weighted digraphs with $\widetilde{O}(n^{4/5})$ worst-case update time and $O(\log^2 n)$ query time. Here, a single update can either change the graph by inserting or deleting an edge, or reset the source s of interest. All known non-trivial planarity-exploiting *exact* dynamic single-source shortest paths algorithms to date had polynomial query time. Further, note that a data structure with strongly sublinear update time capable of answering distance queries between all pairs of vertices in polylogarithmic time would refute the APSP conjecture [Abboud and Dahlgaard, FOCS'16].

Somewhat surprisingly, the Voronoi diagram based approach we take for single-source shortest paths can also be used in the fully dynamic strongly connected components problem. In particular, we obtain a data structure maintaining a planar digraph under edge insertions and deletions, capable of returning the identifier of the strongly connected component of any query vertex. The worst-case update and query time bounds are the same as for our single-source distance oracle. To the best of our knowledge, this is the first fully dynamic strong-connectivity algorithm achieving both sublinear update time and polylogarithmic query time for an important class of digraphs.

1 Introduction

The dynamic shortest paths problem seeks for a data structure maintaining a graph under updates and supporting shortest path queries.[1] Depending on the set of supported updates, we call such a graph data structure *fully dynamic* if both edge insertions and deletions are allowed, *incremental* if only edge insertions (or edge weight decreases) are supported, or *decremental* if only edge deletions (or weight increases) are allowed. In the *all-pairs* variant of dynamic shortest paths problem one has to support shortest path queries between any pair of vertices of the graph. In the *single-source* variant all shortest paths queries have to originate in a fixed distinguished vertex and the only parameter of a query is the target vertex.

For the most general setting where one requires *exact* answers, Demetrescu and Italiano [31] gave a fully dynamic algorithm (improved slightly by Thorup [77]) recomputing the all-pairs shortest paths matrix in nearly optimal $\widetilde{O}(n^2)$ amortized time even if real edge weights are allowed. Note that recomputing the distance matrix from scratch takes $\widetilde{O}(nm) = \widetilde{O}(n^3)$ time [55]. Fully dynamic all-pairs shortest paths data structures with subcubic *worst-case* update bounds are also known [5, 46, 78]. There exist faster algorithms if the input graph is unweighted and *partially dynamic* (i.e., incremental or decremental) [6, 7]. However, none of the known results improves upon a trivial, recompute-from-scratch algorithm with $\widetilde{O}(mn)$ update time and $O(1)$ query time if the graph is *sparse*, i.e., $m = \widetilde{O}(n)$. For the single-source variant, all known non-trivial exact dynamic shortest paths algorithms [37] are partially dynamic and yield no improvement over the respective recompute-from-scratch algorithm in the sparse case either.

The lack of progress on obtaining an exact fully dynamic single-source shortest paths algorithms with $O(n^{3-\epsilon})$ initialization time, $O(m^{1-\epsilon})$ amortized update time and $O(n^{1-\epsilon})$ query time at the same time can be explained by a matching lower bound conditional on the (static) APSP conjecture [73]. In fact, breaking this barrier even in the partially dynamic setting for undirected unweighted graphs would be a large breakthrough [43].

As a result, since finding good exact algorithms for general graphs seems hopeless, one needs to look for either approximate solutions or restrict their attention to more structured graph classes. Indeed, a large body of research has been devoted to designing *approximate* dynamic shortest paths algorithms, especially in partially dynamic settings [9–13, 15, 26, 29, 43–45, 48–50, 59, 60], which find many applications, e.g., in various maximum flow related problems [29, 67]. Unfortunately, many of the known fastest approximate dynamic shortest path algorithms (e.g. [9,44,48]) suffer from assuming an oblivious adversary, which significantly limits their applicability (cf. e.g., [29]).

Similarly, dynamic shortest paths problems have also been studied for important graph classes like planar graphs [3, 4, 38, 56, 63, 66], or low treewidth-graphs [3, 58]. The primary reason why faster dynamic shortest paths algorithms in these cases are possible is the existence of non-trivial *distance oracles* for these classes. A distance oracle is a compact representation of the graph's shortest paths such that the distance (or a distance estimate) between any pair of vertices can be retrieved efficiently. For general graphs, such non-trivial distance oracles exist only for undirected graphs and assuming an approximation ratio of at least 3 [25, 79, 82]. On the contrary, for planar graphs many non-trivial exact distance oracles

[1] We will identify shortest paths queries with distance queries. Almost all known dynamic shortest paths algorithms (for some exceptions see [74, 80]) can also report the actual path in nearly linear (in the number of the path's edges) time after computing a distance estimate.

have been proposed [19,27,33,38,56,63,69]. The first exact oracles with *polylogarithmic* query time and subquadratic space have been obtained only recently [23,30,41], following Cabello's breakthrough of employing Voronoi diagrams for the planar diameter problem [20]. Also near-optimal (in terms of query time, construction time, and used space) $(1+\epsilon)$-approximate distance oracles have been known for nearly two decades [62,76], and a lot of effort has been put to push the known bounds as close to optimal as possible [22,42,61,84].

Dynamic shortest paths in planar graphs. In this paper our focus is on computing shortest paths in dynamic planar graphs and applications. Klein and Subramamian were the first to give a planarity-exploiting dynamic shortest paths algorithm [66] – their data structure worked for undirected graphs, was fully dynamic, $(1+\epsilon)$-approximate and had $\widetilde{O}(n^{2/3})$ update and query time bounds. A data structure with the same bounds (up to polylogarithmic factors), but for *exact* distances in *directed* graphs was obtained in the breakthrough work of Fakcharoenphol and Rao [38] (later extended and slightly improved in [24,40,54,56,63]). Abraham et al. [4] gave a faster $(1+\epsilon)$-approximate dynamic algorithm for undirected graphs with $\widetilde{O}(n^{1/2})$ update and query times. Karczmarz [58] matched this bound for directed planar graphs, albeit only in the $(1+\epsilon)$-approximate decremental setting. Abboud and Dahlgaard [1] showed that by the APSP conjecture, one should not expect an exact dynamic all-pairs shortest paths data structure for planar graphs with strongly sublinear product of update time and query time. However, no exact data structure to date has matched this product lower bound while retaining strongly sublinear update time.

The single-source scenario is much less studied for dynamic planar graphs. Karczmarz [58] showed a decremental $(1+\epsilon)$-approximate single-source shortest paths algorithm for minor-free (and thus also planar) digraphs with $\widetilde{O}(n^{1/2})$ update time and $O(1)$ query time. Although not explicitly stated in the literature, the all-pairs data structure of [63] can be easily converted to a fully dynamic exact single-source distance oracle with $\widetilde{O}(n^{2/3})$ update time and $\widetilde{O}(n^{1/3})$ query time. However, no *fully dynamic* single-source shortest paths algorithm for planar graphs to date has been able to achieve sublinear update time and polylogarithmic query time, or at least break through the $\widetilde{O}(n)$ update-query time product barrier, even in the approximate setting.

Our results. In this paper we show the first exact dynamic single-source shortest paths algorithm for planar graphs with *strongly sublinear* update time and *polylogarithmic* query time. Our algorithm, summarized by the following theorem and described in Section 3, is deterministic and can be easily extended to report paths.

▶ **Theorem 1.** *Let G be a real-weighted planar digraph with a source $s \in V(G)$. There exists an $O(n \log n)$-space data structure maintaining G under edge insertions, edge deletions, and source changes with $O(n^{4/5} \log^2 n)$ worst-case update time that can compute $dist_G(s,v)$ for any $v \in V(G)$ in $O(\log^2 n)$ time. The initialization time is $O(n \log^2 n)$.*

To the best of our knowledge, this result constitutes the first known application of additively weighted Voronoi diagrams machinery (first introduced by Cabello [20]) in dynamic graph algorithms. More specifically, it is obtained by combining fully dynamic maintenance of r-divisions [66,75], the shortest paths algorithm for dense distance graphs [38], the recent efficient construction of dual Voronoi diagrams [23] via FR-Dijkstra [38], and the efficient point location data structure for Voronoi diagrams [41].

We now provide a brief overview of the data structure underlying Theorem 1. We maintain distances in G from the source vertex s to each boundary vertex of each piece of an r-division of G using FR-Dijkstra. For each piece of the r-division, we maintain an additively weighted

Voronoi diagram augmented with a point location data structure, with weights equal to the distances from s. Upon a query for $\text{dist}_G(s, v)$, we perform a point location query on the Voronoi diagram of a piece of the r-division that contains v.

It is worth noting that our data structure (and in fact all data structures obtained in this paper) works in the most general model of dynamic planar graphs where we only require that G remains planar after each update. Some fully dynamic planar graph algorithms assume a weaker *plane* model (e.g., [32, 35, 54]) where some plane embedding of G is fixed and we only allow inserting edges connecting vertices that lie on a common face of (that embedding of) G.

We also generalize our single-source data structure to the case when, instead of a single source s, a set of *facilities* $F \subseteq V$ is given, and our goal is to locate the closest (i.e., minimizing $\text{dist}_G(f, v)$) facility $f \in F$ for a given query vertex.[2] We show that maintaining such a data structure under edge updates issued to G, or updates to the facilities set F, is possible using $\widetilde{O}(n^{3/4} \cdot |F|^{1/4} + n^{4/5})$ worst-case update time. The query time remains $O(\log^2 n)$. Note that even though multiple-source shortest paths or maximum flow problems can be typically easily reduced to the single-source case by adding a super-source, such a reduction does not preserve planarity and indeed handling multiple sources tends to be challenging in planar graphs (cf. e.g., [16, 17]). Our generalized data structure handles up to $O(n^{1/5})$ sources as efficiently as the single-source case. Moreover, the update time remains strongly sublinear unless the number of facilities is not strongly sublinear.

Surprisingly, we show that the same framework that we use to prove Theorem 1 can be applied to obtain interesting results not directly related to the shortest paths problem. Namely, in Section 4 we show a fully dynamic strong-connectivity algorithm for planar graphs, encapsulated in the following theorem.

▶ **Theorem 2.** *Let G be a planar digraph. There exists an $O(n \log n)$-space data structure maintaining G under edge insertions and deletions with $O(n^{4/5} \log^2 n)$ worst-case update time that can compute the identifier of the strongly connected component of any $v \in V(G)$ in $O(\log^2 n)$ time. The initialization time is $O(n \log^2 n)$.*

We now sketch the main ideas behind our fully dynamic strong-connectivity algorithm. As in Subramanian's dynamic all-pairs reachability algorithm [75], the base of our data structure is a graph X, called a *reachability certificate*, that sparsifies the reachability information between boundary vertices $\partial\mathcal{R}$ of a fully dynamic r-division $\mathcal{R}$ with few holes. Naively recomputing the strongly connected components of X gives us the restriction of the strongly connected components of G to the boundary vertices $\partial\mathcal{R}$. The main challenge, of course, is to compute the identifier of a strongly connected component (SCC) of an arbitrary non-boundary vertex v of G, internal to some piece P of the r-division $\mathcal{R}$. To this end, we use the following observation: suppose $b_1, \ldots, b_k$ are some vertices of G lying in distinct strongly connected components of G. Then, v is strongly connected to some b_j if and only if b_j is in the topologically earliest SCC of G reachable from v *and* b_j is in the topologically latest SCC of G that can reach v. Roughly speaking, this observation applied to the boundary vertices of P labeled using the topological order of their respective SCCs in the certificate X, allows us to identify the SCC of v using two point-location queries on the Voronoi diagram of piece P. Each such point location query, computes, instead of the nearest site of v, the highest (or lowest) priority site that can reach v (that v can reach, resp.), and can be simulated using a standard point location query on a Voronoi diagram [41].

[2] One can also view F as a set of sites of a graphic Voronoi diagram – then the query locates the cell of the Voronoi diagram wrt. F that a given vertex v belongs to.

Whereas maintaining strongly connected components is a well-studied problem in partially dynamic settings [8, 14, 47, 53], we are not aware of any non-trivial fully dynamic strongly connected components data structures designed specifically for this problem for *any* digraph class – note that one could use a fully dynamic transitive closure data structure for this task: for example, the dynamic plane transitive closure data structure of [32] which has $\widetilde{O}(n^{1/2})$ update and query time. Such a strongly connected components data structure (i.e., with both update and query bounds $O(n^{1-\epsilon})$) for *general graphs* is in fact ruled out by a conditional (on SETH) lower bound [2]. As a result, to the best of our knowledge, we obtain the first fully dynamic strongly connected components algorithm to achieve sublinear update-query time product for *any* important class of digraphs.

The undirected counterpart of the dynamic strongly connected components problem, the *dynamic connectivity* problem, is very well-studied. Near-optimal deterministic amortized update bounds [51,52,83] and randomized worst-case update bounds [57,81] (see also [71]) are known for fully dynamic general graphs. An almost optimal deterministic worst-case update bound was very recently achieved in [28]. For fully dynamic planar graphs polylogarithmic worst-case update bounds are known to be achievable even deterministically [34].

2 Preliminaries

Throughout the paper we consider as input a simple, directed and weighted planar graph G with n vertices, and no negative weight cycles. We call a planar graph G *plane* if some embedding of G is assumed. We use $|G|$ to denote the number of vertices of G. Since simple planar graphs are sparse, $|E(G)| = O(|G|)$ as well.

We use the terms weight and length for edges and paths interchangeably throughout the paper. For any two vertices $u, v \in V(G)$, we denote by $\mathrm{dist}_G(u, v)$ the length of some shortest $u \to v$ path in the graph G.

Multiple-source shortest paths. The multiple-source shortest paths (MSSP) data structure [21, 63] represents all shortest path trees rooted at the vertices of a single face f in a weighted plane digraph using a persistent dynamic tree. It can be constructed in $O(n \log n)$ time, requires $O(n \log n)$ space, and can report any distance between a vertex of f and any other vertex in the graph in $O(\log n)$ time. MSSP can be augmented to also return the first edge of this path (and each of its subsequent edges) in $O(\log \log n)$ time (cf. [56]).

Separators and recursive decompositions. Miller [68] showed how to compute, in a triangulated plane graph with n vertices, a simple cycle of size $2\sqrt{2}\sqrt{n}$ that separates the graph into two subgraphs, each with at most $2n/3$ vertices. Simple cycle separators can be used to recursively separate a planar graph until pieces have constant size. The authors of [64] show how to obtain a complete recursive decomposition tree $\mathcal{T}(G)$ of a triangulated graph G using cycle separators in $O(n)$ time. $\mathcal{T}(G)$ is a binary tree whose nodes correspond to subgraphs of G (pieces), with the root being all of G and the leaves being pieces of constant size. We identify each piece P with the node representing it in $\mathcal{T}(G)$. We can thus abuse notation and write $P \in \mathcal{T}(G)$. The *boundary vertices* ∂P of a *non-leaf piece* P are vertices that P shares with some other piece $Q \in \mathcal{T}(G)$ that is not P's ancestor. For convenience we extend the boundary set ∂L of a leaf piece L to its entire vertex set $V(L)$. We assume P to inherit the embedding of G. The faces of P that are faces of G are called *natural*, whereas the faces of P that are not natural are the *holes* of P. The construction of [64] additionally guarantees that for each piece $H \in \mathcal{T}(G)$, (a) H is connected, (b) if H is non-leaf, then each natural

face f of H is a face of a unique child of H, (c) H has $O(1)$ holes containing precisely the vertices ∂H. Throughout, to avoid confusion, we use *nodes* when referring to $\mathcal{T}(G)$ and *vertices* when referring to G or its subgraphs. It is well-known [18, 41, 53, 64] that by suitably choosing cycle separators one can also guarantee that (1) $\sum_{H\in\mathcal{T}(G)} |H| = O(n \log n)$, (2) $\sum_{H\in\mathcal{T}(G)} |\partial H|^2 = O(n \log n)$, and (3) $|\partial H| = O(\sqrt{n}/c^d)$, where node H of $\mathcal{T}(G)$ has depth d and $c > 1$ is some constant.

The recursive decomposition algorithm of [64] works with no changes and maintains all the properties of $\mathcal{T}(G)$ even if the initial graph G has a predefined set of boundary vertices ∂G of size $O(\sqrt{|G|})$ located on $O(1)$ of G's faces. These faces are predefined as holes of G and are the only faces of G that are allowed to be non-triangular.

An *r-division* [39] $\mathcal{R}$ of a planar graph, for $r \in [1, n]$, is a decomposition of the graph into $O(n/r)$ pieces, each of size $O(r)$, such that each piece P has $O(\sqrt{r})$ boundary vertices (denoted ∂P), i.e., vertices shared with some other piece of $\mathcal{R}$. We denote by $\partial\mathcal{R}$ the set $\bigcup_{P\in\mathcal{R}} \partial P$. If additionally all pieces are connected, and the boundary vertices of each piece P of the r-division $\mathcal{R}$ are distributed among $O(1)$ faces of P (also called holes[3] of P), we call $\mathcal{R}$ an *r-division with few holes*.

In [64] it was shown that for every r larger than some constant, $\mathcal{T}(G)$ *admits* an r-division with few holes, i.e., there exists a subset of nodes of $\mathcal{T}(G)$ forming an r-division with few holes of G. Using this property, it is shown in [64] that an r-division with few holes of a triangulated graph can be computed in linear time. More generally, given a geometrically decreasing sequence of numbers $(r_m, r_{m-1}, \ldots, r_1)$, where r_1 is a sufficiently large constant, $r_{i+1}/r_i \geq b$ for all i for some $b > 1$, and $r_m = n$, we can obtain r_i-divisions with few holes for all i in time $O(n)$ in total. For convenience, we define the only piece in the r_m-division to be G itself. These r-divisions satisfy the property that a piece in the r_i-division is a – not necessarily strict – descendant (in $\mathcal{T}(G)$) of a piece in the r_j-division for each $j > i$. We also call such sequence of r_i-divisions obtained from $\mathcal{T}(G)$ a recursive $(r_m, \ldots, r_1)$-division of G.

We assume for simplicity that all holes we ever encounter are simple cycles. Unfortunately, this is not true in general. However, non-simple holes do not pose a significant obstacle, and can be avoided by suitably extending the graphs, as discussed numerous times in the past, see e.g., [23, 53, 56, 72].

Dense distance graphs and FR-Dijkstra. For a plane digraph H with weights from $\mathbb{R}_{\geq 0} \cup \{\infty\}$ and a distinguished set $\partial H \subseteq V(H)$ of boundary vertices lying on $O(1)$ faces of H, we denote by DDG_H the complete weighted graph on ∂H whose edge weights represent distances between all pairs of vertices of ∂H in H. DDG_H can be computed in $O\left((|H| + |\partial H|^2) \log n\right)$ time using MSSP [63]. In particular, dense distance graphs for all pieces $H \in \mathcal{T}(G)$ can be computed in $O(n \log^2 n)$ time.

When $\mathcal{H} = \{H_1, \ldots, H_q\}$ is a collection of plane graphs, we set $\mathrm{DDG}(\mathcal{H}) := \bigcup_{H\in\mathcal{H}} \mathrm{DDG}_H$.

▶ **Lemma 3** (FR-Dijkstra [38, 40]). *Given all DDG_{H_i}, one can compute a single-source shortest paths tree from any source s in $\mathrm{DDG}(\mathcal{H})$ in $O\left(\sum_{i=1}^{q} |\partial H_i| \log^2 n\right)$ time, where $n = |V(\mathrm{DDG}(\mathcal{H}))|$.*[4]

[3] This definition is slightly more general than the definition of a hole of a piece $P \in \mathcal{T}(G)$. Namely, the definition of an r-division does not assume a fixed embedding of the entire G; it only assumes some fixed embeddings of individual pieces.

[4] In particular H_i may be single-edge. This way, this lemma captures also the case when we compute shortest paths in a collection of DDGs with some auxiliary vertices and edges.

We now state some fairly standard definitions and lemmas about representing distances between some vertices of G of interest using unions of dense distance graphs of a recursive decomposition's (or r-division's) pieces (for instance cf. [24]), adapted to our notation. We include their proofs for completeness in Appendix A. For example, Lemma 4 captures the well-known observation of [38] that in order to compute a shortest path between any pair of vertices of G, it is enough to compute a shortest path in a union of dense distance graphs from $\mathcal{T}(G)$ with only $O(\sqrt{n})$ vertices in total.

Let L be some leaf of $\mathcal{T}(G)$. We define the *cone* of L, denoted $\mathrm{cone}_G(L)$, to be the collection of pieces of $\mathcal{T}(G)$ containing L, all ancestors of L, and all siblings of (weak) ancestors of L. For some collection $\mathcal{L}$ of leaf pieces of $\mathcal{T}(G)$, we define $\mathrm{cone}_G(\mathcal{L}) = \bigcup_{L\in\mathcal{L}} \mathrm{cone}_G(L)$.

▶ **Lemma 4** ([24, 38]). *Let $\mathcal{L}$ be some collection of leaf pieces of $\mathcal{T}(G)$. Then:*

1. *For any $u, v \in V(\mathrm{DDG}(\mathrm{cone}_G(\mathcal{L})))$, $dist_G(u,v) = dist_{\mathrm{DDG}(\mathrm{cone}_G(\mathcal{L}))}(u,v)$.*
2. $\sum_{H\in\mathrm{cone}_G(\mathcal{L})} |\partial H| = O\left(\sqrt{n|\mathcal{L}|}\right)$.

Let $\mathcal{R}$ be an r-division with few holes of G and $\mathcal{T}(P)$ be a recursive decomposition of $P \in \mathcal{R}$ with the root boundary set to ∂P. For any $v \in V(G) \setminus \partial G$, let L_v be some leaf containing v in the unique piece $P_v \in \mathcal{R}$ containing v. For any $X \subseteq V(G)$ let us define $\mathrm{cone}_{\mathcal{R}}(X) = \mathcal{R} \cup \bigcup_{v\in X\setminus\partial\mathcal{R}} \mathrm{cone}_{P_v}(L_v)$.

▶ **Lemma 5** ([24, 38]). *Let $X \subseteq V(G)$ be non-empty. Then:*

1. *For any $u, v \in V(\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(X)))$, $dist_G(u,v) = dist_{\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(X))}(u,v)$.*
2. $\sum_{H\in\mathrm{cone}_{\mathcal{R}}(X)} |\partial H| = O\left(n/\sqrt{r} + \min\left(\sqrt{n\cdot|X|}, |X|\cdot\sqrt{r}\right)\right)$.

Fully dynamic r-divisions. Many dynamic algorithms for planar graphs maintain r-divisions and useful auxiliary data structures under dynamic updates. The exact set of supported updates to G varies; e.g., [38,56,63] support only edge weight changes, [54] assumes embedding-preserving insertions, whereas [66, 75] only assume that the graph G remains planar at all times. We stick to the last, most general setting. The core of the construction behind the following theorem is due to Klein and Subramanian [66, 75]; for completeness we give a complete proof in Appendix A.

▶ **Theorem 6.** *Let $G = (V, E)$ be a weighted planar graph. Suppose that adding infinite-weight edges to G does not have effect on any properties of G that we care about. Let $r \in [1, n]$.*

There is a data structure maintaining an r-division with few holes $\mathcal{R}$ of some G^+ such that:

1. *G^+ is obtained from G by adding infinite-weight edges.*
2. *Each P has all its faces except its holes triangular and is accompanied with some auxiliary data structures that can be constructed in $T(r)$ time given P and use $S(r)$ space.*

The data structure uses $O\left(n + \frac{n}{r}\cdot S(r)\right)$ space and can be initialized in $O\left(n + \frac{n}{r}\cdot T(r)\right)$ time. After each edge deletion and edge insertion (preserving the planarity of G), it can be updated in $O(r + T(r))$ worst-case *time.*

Additively weighted Voronoi diagrams. Let G be a directed planar graph of size n with real edge-lengths, and no negative-length cycles. Assume that all faces of G are triangles except, perhaps, a single face f. Let S be the set of vertices that lie on f, called *sites*, i.e., $S = V(f)$. Let us assign to each site $s \in S$ a weight $\omega(s) \in \mathbb{R}_{\geq 0} \cup \{\infty\}$. The additively weighted distance $\mathrm{dist}^{\omega}_G(s, v)$ between a site $s \in S$ and a vertex $v \in V(G)$ is defined as $\omega(s) + \mathrm{dist}_G(s, v)$.

The additively weighted Voronoi diagram of (S, ω) within G, denoted by $\mathsf{VD}(S, \omega)$, is a partition of $V(G)$ into pairwise disjoint sets, one set $\mathsf{Vor}(s)$ for each site $s \in S$. The set $\mathsf{Vor}(s)$, which is called the Voronoi cell of s, contains all vertices in $V(G)$ that are closer (wrt. $\mathrm{dist}^{\omega}_{G}$) to s than to any other site in S.

In the following and throughout, whenever we work with Voronoi diagrams we assume that (1) G is strongly connected, (2) shortest paths in G are unique, and (3) additively weighted shortest paths in G are unique, i.e., for each $v \in V(G)$ there is a unique site s minimizing $\mathrm{dist}^{\omega}_{G}(s, v)$. Note that these assumptions make the Voronoi cells well-defined and simply connected, and guarantee that they indeed form a partition of $V(G)$. We will explicitly ensure that these requirements are met for G, S and the weight function whenever we define a Voronoi diagram on G.

There is a dual representation $\mathsf{VD}^*(S, \omega)$ of Voronoi diagram $\mathsf{VD}(S, \omega)$ as a tree of constant degree with $O(|S|)$ vertices and edges [41]. An efficient FR-Dijkstra based algorithm for computing $\mathsf{VD}^*(S, \omega)$ was presented by Charalampopoulos et al. [23].

▶ **Theorem 7** ([23]). *Suppose that we have at hand a recursive decomposition $\mathcal{T}(G)$ of G, with the only hole of G being f and $S = V(f)$. Further suppose that we have DDG_H computed for each piece $H \in \mathcal{T}(G)$. Then, we can compute $\mathsf{VD}^*(S, \omega)$ in $O(\sqrt{n \cdot |S|} \log^2 n)$ time.*

▶ Remark 8. The algorithm underlying Theorem 7 implicitly assumes that $\mathsf{Vor}(s)$ is non-empty for all $s \in S$. In Appendix B, we discuss why this assumption is not necessary, relying on [41].

In a *point location* query for some Voronoi diagram $\mathsf{VD}(S, \omega)$, we are given a vertex $v \in V(G)$ and are requested to find the site $s \in S$ such that $v \in \mathsf{Vor}(s)$ and also the value of $\mathrm{dist}^{\omega}_{G}(s, v)$. Gawrychowski et al. [41] showed the following result.

▶ **Theorem 9** ([41]). *Suppose that we have at hand an MSSP data structure for G with sources from the face f. Given some dual representation $\mathsf{VD}^*(S, \omega)$, we can preprocess it in $O(|S|)$ time, so that point location queries for $\mathsf{VD}(S, \omega)$ can be answered in $O(\log^2 n)$ time.*

3 Fully Dynamic Single Source Shortest Paths

In this section we show our single-source exact distance oracle for planar graphs with $O(n^{4/5} \log^2 n)$ update time and $O(\log^2 n)$ query time and thus prove Theorem 1. For simplicity, let us assume that G is non-negatively weighted. Negative edges can be handled as in [56] – see Appendix C.

▶ **Theorem 1.** *Let G be a real-weighted planar digraph with a source $s \in V(G)$. There exists an $O(n \log n)$-space data structure maintaining G under edge insertions, edge deletions, and source changes with $O(n^{4/5} \log^2 n)$ worst-case update time that can compute $\mathrm{dist}_G(s, v)$ for any $v \in V(G)$ in $O(\log^2 n)$ time. The initialization time is $O(n \log^2 n)$.*

The base of our data structure is a dynamic r-division $\mathcal{R}$ with few holes, as given in Theorem 6. Note that in our shortest-paths problem, indeed adding infinite-weight edges to G does no harm. Hence, in the following we work with the graph G^+ from Theorem 6 when computing distances, but identify it, without loss of generality, with our original graph G.

For technical reasons, however, we would like to avoid dealing with infinite weights in some of our data structures handling individual pieces. In the real-weighted fully dynamic setting, however, we cannot fix a sufficiently large finite number, larger than all edge weights that will ever appear in the future graph G, beforehand. Instead, we do the following. For

each $P \in \mathcal{R}$, let M_P be a sufficiently large finite number, e.g., larger than the sum of finite edge weights in P. Consider M_P to be an auxiliary data structure of P as in Theorem 6. We will use M_P to simulate infinite edge weights in P, and also for detecting paths non-existent in the original graph G (but having infinite weight in $G^+ \cap P$). As a result, below we assume each infinite weight in P (or any auxiliary data structure related to P) is replaced by M_P in all the computations performed locally on the piece P, whereas globally (when performing some computation for many pieces at once, like the shortest paths algorithm of Lemma 3) we treat all edge or path weights in P that are at least M_P as infinite.

For each piece $P \in \mathcal{R}$ we store the following additional data structures.

- We store the recursive decomposition $\mathcal{T}(P)$ with the initial boundary set to ∂P, and also DDGs for all the pieces $H \in \mathcal{T}(P)$.
- For each hole h of P, let P_h be the piece P after applying the following standard augmentations. First, P is extended into a graph P'_h using $O(r)$ vertices and edges of weight M_P embedded inside either the piece or other (than h) holes of P that would make P strongly connected and triangulated (except for the hole h) without changing the distance between any pair of reachable vertices in P. The graph P_h is in turn obtained from P'_h by changing P'_h's edge weights into $O(1)$-size vectors as described in [36] so that there is a *unique* shortest path (wrt. the lexicographical order on path weights, defined as the coordinate-wise sum of the path's individual edge weights) between any $u, v \in V(P_h)$ with cost of the form $(\mathrm{dist}_{P'_h}(u, v), \cdot)$. As proven in [36], one can compute P_h from P deterministically in linear time. The $O(1)$-size vector weights, in turn, can be easily packed into usual single-number weights.

  For each P_h, we store an MSSP data structure initialized for the hole h. Recall that an MSSP data structure can be computed in $O(r \log r)$ time. Moreover, we store a recursive decomposition $\mathcal{T}(P_h)$ of P_h with the boundary ∂P_h of the root piece set to $\partial P \cap V(h)$ of size $O(\sqrt{r})$. For each node (piece) $H \in \mathcal{T}(P_h)$, we also store DDG_H. Since the sum of sizes of all the pieces of $\mathcal{T}(P_h)$ is $O(r \log r)$, computing all these dense distance graphs takes $O(r \log^2 r)$ time (see Section 2).

Note that computing piecewise auxiliary data structures defined so far takes $O(r \log^2 r)$ time. So, by Theorem 6, they can be updated in $O(r \log^2 r)$ worst-case time after G undergoes an update.

After the initialization and each update, once $\mathcal{R}$ and all auxiliary data structures are updated, we compute for each $P \in \mathcal{R}$ a point location data structure.

▶ **Lemma 10.** *Given a weight function $\omega : \partial P \to \mathbb{R} \cup \infty$, one can compute in $O(r^{3/4} \log^2 r)$ time a data structure $L(P)$ answering the following queries in $O(\log^2 r)$ time: given any $v \in V(P)$, compute the value $\min_{b \in \partial P}\{\omega(b) + dist_P(b, v)\}$ along with the minimizer b.*

Proof. Since ∂P is a union of $O(1)$ sets ∂P_h, we can compute the desired minimum over each ∂P_h separately and then take the minimum over all h.

Let us first note that negative values of ω are not a problem. We can turn negative weights into non-negative by adding some common large value to the weights of all sites. We can thus suppose wlog. that all values of ω are non-negative.

If all the weights are infinite, the queries can be answered trivially in $O(1)$ time. So in the following assume that there is at least one site whose weight is finite.

Let $S = \partial P_h = \{s_1, \ldots, s_k\}$ be the set of sites. In order to guarantee that for each $v \in V(G)$ there is a unique site s minimizing $\mathrm{dist}^{\omega}_G(s, v)$, we will break ties by considering $(\omega(s_i), i)$ instead of $\omega(s_i)$ as the weight of site s_i, adding a second coordinate to each edge weight in P_h, set to 0, and comparing additively weighted distances lexicographically. Clearly, this extension does not break any of the properties of P_h.

Recall that P_h has finite non-negative real weights, is strongly connected, has unique shortest paths, and has a single face h that is possibly non-triangular that contains all the sites S. Moreover, the additively weighted distances in P_h are unique. Therefore, we can invoke Theorem 7 to construct the dual representation $\mathsf{VD}^*(S,\omega)$ of the Voronoi diagram $\mathsf{VD}(S,\omega)$. This requires $O\left(\sqrt{r|\partial P_h|}\log^2 n\right) = O\left(r^{3/4}\log^2 n\right)$ time.

Then, we construct the point location data structure of Theorem 9 for $\mathsf{VD}(S,\omega)$. Note that we have an MSSP data structure for P_h for hole h and hence point location queries, given $\mathsf{VD}^*(S,\omega)$, can be answered in $O(\log^2 n)$ time. ◀

We invoke Lemma 10 with weight function $\omega(b) := \mathrm{dist}_G(a,b)$ in order to construct $L(P)$ for each $P \in \mathcal{R}$. This requires $O\left(n/r^{1/4}\cdot\log^2 n\right)$ time in total. By Lemma 5, the values $\mathrm{dist}_G(s,b)$ for all $b \in \partial R$ can be computed in $O\left(n/\sqrt{r}\cdot\log^2 n\right)$ time if we run the single-source shortest paths algorithm of Lemma 3 (FR-Dijkstra) on the graph $\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(s))$. We also compute $\mathrm{dist}_{P_s}(s,u)$ for all $u \in P_s$, where P_s is an arbitrary piece containing s using Dijkstra's algorithm in $O(r\log r)$ time.

Now, we can compute $\mathrm{dist}_G(s,v)$ for a query vertex v as follows. If the shortest $s \to v$ path in G does not go through $\partial\mathcal{R}$, then it is fully contained in P_s and therefore $v \in P_s$ and $\mathrm{dist}_G(s,v) = \mathrm{dist}_{P_s}(s,v)$, i.e., we have $\mathrm{dist}_G(s,v)$ already computed. Otherwise, let P_v be an arbitrary piece containing v. Observe that we have $\mathrm{dist}_G(s,v) = \min_{b\in\partial P_v}\{\mathrm{dist}_G(s,b) + \mathrm{dist}_{P_v}(b,v)\}$ where the minimizer b corresponds to the a boundary vertex of some shortest $s \to v$ path in G. So this case can be reduced to a single query to the data structure $L(P_v)$. This takes $O(\log^2 n)$ time.

The worst-case update time is $O(r\log^2 r + \frac{n}{r^{1/4}}\log^2 r)$. By setting $r = n^{4/5}$ we get $O(n^{4/5}\log^2 n)$ worst-case update time. Since the space usage per piece is $O(r\log r)$, we need $O(n\log n)$ space.

▶ Remark 11. Our data structure can be extended to report, following the computation of $\mathrm{dist}_G(s,v)$, a shortest $s \to v$ path Q in time nearly linear in the number of edges of Q. This follows easily by the fact that the MSSP data structure [63] can report shortest paths efficiently (see e.g., [56] for details). Therefore, we can efficiently expand the used edges of dense distance graphs and the shortest $b \to v$ path into actual edges in G.

3.1 A Dynamic Closest Facility Data Structure

We can generalize the dynamic single-source shortest paths data structure as follows. Suppose we replace a single source vertex s with a set of *facilities* $F \subseteq V$. Given F, for a query vertex v we would like to compute $\min_{f\in F}\{\mathrm{dist}_G(f,v)\}$, and also possibly $f \in F$ minimizing this expression. A dynamic update would consist of either an edge update or changing the set F. In other words, such a problem can be seen as dynamic point location in a Voronoi diagram wrt. F, where each update either changes the graph or resets the Voronoi diagram of interest.

In this setting, we consider the following simple generalization of the single-source data structure. Let the update procedure first compute the distances $d(b) = \min_{f\in F}\{\mathrm{dist}_G(f,b)\}$ for all $b \in \partial\mathcal{R}$. Note that by Lemmas 5 this can be achieved by computing single-source shortest paths in the graph $\mathrm{DDG}(\mathcal{D}_F)$, where $\mathcal{D}_F = \mathrm{cone}_{\mathcal{R}}(F)$, extended with 0-weight edges sf, where s is an auxiliary super-source. By Lemma 3 this can be done in $O((\sqrt{n|F|}+n/\sqrt{r}+|F|)\log^2 n) = O((\sqrt{n|F|}+n^{4/5})\log^2 n)$ time. By using weights $\omega := d$ in the individual point-location data structures $L(P)$, $P \in \mathcal{R}$, a single point location query on $L(P_v)$ (recall that P_v is some piece containing v) would compute the desired closest facility f_v minimizing $\mathrm{dist}_G(f_v,v)$ unless the sought (weighted) shortest $f_v \to v$ does not go through a boundary

vertex of $\mathcal{R}$. We could in principle handle such paths by proceeding as in the single-source case and computing shortest paths naively in each piece containing a facility. However, this could take time $\Omega(r \cdot \min(n/r, |F|))$, i.e., linear in n even for moderately large facility set sizes, e.g., $|F| = \Omega(n^{1/5})$.

To improve upon this simple approach, we proceed as follows. Let $(\rho_m, \ldots, \rho_1)$ be such a sequence of integers that $\rho_m = r$, $\rho_1 = O(1)$ and $\rho_{i+1}/\rho_i = 2$ for all $i < m$. For each $P \in \mathcal{R}$ we store a recursive $(\rho_m, \ldots, \rho_1)$-division consisting of pieces of $\mathcal{T}(P)$ (cf. Section 2). Let $\mathcal{R}_{P,i}$ be the ρ_i-division of P. All $\mathcal{R}_{P,i}$ can be computed in linear time given $\mathcal{T}(P)$ [64]. Note that $\mathcal{R}_i$, defined as the union of $\mathcal{R}_{P,i}$ over all pieces $P \in \mathcal{R}$, actually forms an ρ_i-division with few holes of the entire graph G. In particular, we have $\mathcal{R}_m = \mathcal{R}$.

We store the extended pieces Q_h (recall how we obtained extended pieces P_h with unique shortest paths from P in the single-source case) plus their recursive decompositions $\mathcal{T}(Q_h)$, DDGs, and an MSSP data structure for all pieces Q of *all* $\mathcal{T}(P)$ instead of just the pieces of $\mathcal{R}_m = \mathcal{R}$ as we did in the single-source case. However, we stress that these auxiliary components for a piece $Q \subseteq P$ where $P \in \mathcal{R}$, are counted as accompanying data structures of the piece P. So, we compute $O(1)$ fresh recursive decompositions $\mathcal{T}(Q_h)$ for each piece $Q \in \mathcal{T}(P)$ – computing each takes $O(|Q| \log^2 n)$ time. As a result, by the bound $\sum_{Q \in \mathcal{T}(P)} |Q| = O(|P| \log |P|)$, the time to compute accompanying data structures of piece P increases to $O(r \log^3 n)$.

Given the set of facilities F, let j be such that $\rho_j = \Theta\left(\min\left(\frac{n}{|F|}, r\right)\right)$. Redefine $\mathcal{D}_F = \mathrm{cone}_{\mathcal{R}_j}(F)$. Again, let us compute distances $d(b) = \min_{f \in F}\{\mathrm{dist}_G(f, b)\}$ (and the closest facilities) for all $b \in \bigcup_{H \in \mathcal{D}_F} |\partial H|$ using FR-Dijkstra on DDG$(\mathcal{D}_F)$ extended with a super-source s and auxiliary edges sf, $f \in F$. This takes $O\left(\left(\sqrt{n|F|} + n/\sqrt{\rho_j}\right) \log^2 n\right) = O(\sqrt{n|F|} \log^2 n)$ time by Lemmas 3 and 5.

It only remains to show how to handle computation of closest facilities for $v \in V \setminus \bigcup_{H \in \mathcal{D}_F} \partial H$. Recall that the pieces $\mathcal{D}_F$ cover the entire G, no facility f is an internal (non-boundary) vertex of a piece $H \in \mathcal{D}_F$, and each $v \in V \setminus \bigcup_{H \in \mathcal{D}_F} \partial H$ is clearly an internal vertex of a unique piece $H_v \in \mathcal{D}_F$. Consequently, by Lemma 10, the closest facility to v can be found in $O(\log^2 n)$ time using a single query to the data structure $L(H_v)$. For this to be possible, upon update we need to build the data structures $L(H)$ for all $H \in \mathcal{D}_F$. By Lemma 10, this takes $O\left(\sum_{H \in \mathcal{D}_F} \sqrt{|H| \cdot |\partial H|} \log^2 n\right)$ time. Let us now bound this sum. First, let us consider the sum restricted to the pieces $H \in \mathcal{D}_F \cap \mathcal{R}_j$, i.e., the pieces of r-division $\mathcal{R}_j$. Since $\rho_j = \Omega(n/|F|)$ or $\rho_j = \Omega(r)$ we get:

$$O\left(\sum_{H \in \mathcal{D}_F \cap \mathcal{R}_j} \sqrt{|H| \cdot |\partial H|} \log^2 n\right) = O\left(\frac{n}{\rho_j} \cdot \rho_j^{3/4} \log^2 n\right) = O\left(\left(n^{3/4} \cdot |F|^{1/4} + \frac{n}{r^{1/4}}\right) \log^2 n\right).$$

On the other hand, if $H \notin \mathcal{D}_F \cap \mathcal{R}_j$, then $H \in \mathrm{cone}_{P_f}(L_f)$, where $f \in F \setminus \mathcal{R}_j$, P_f is the unique piece of $\mathcal{R}_j$ containing f, and L_f is some leaf of $\mathcal{T}(P_f)$ containing f. For a fixed f, by the definition of $\mathrm{cone}_{P_f}(L_f)$, there are $O(\log n)$ pieces H satisfying this, at most two per each level i of $\mathcal{T}(P_f)$. Hence, the sum of $\sqrt{|H| \cdot |\partial H|}$ over such pieces can be bounded by $\sum_{i=0}^{\infty} \sqrt{|P_f| \cdot \sqrt{|P_f|}/c^i} = O(\rho_j^{3/4})$. Summing over all f, and using $\rho_j = O(n/|F|)$, we get

$$O\left(\sum_{H \in \mathcal{D}_F \setminus \mathcal{R}_j} \sqrt{|H| \cdot |\partial H|} \log^2 n\right) = O\left(|F| \cdot \rho_j^{3/4} \log^2 n\right) = O\left(n^{3/4} \cdot |F|^{1/4} \log^2 n\right).$$

To conclude, the update time is $O\left(\left(n^{3/4} \cdot |F|^{1/4} + \frac{n}{r^{1/4}}\right) \log^2 n + r \log^3 n\right)$. By setting $r = (n/\log n)^{4/5}$ we obtain the following theorem.

▶ **Theorem 12.** *Let G be a real-weighted planar digraph with a set $F \subseteq V$ of facilities. There exists an $O(n \log^2 n)$-space data structure maintaining G under edge insertions, edge deletions, and changes of the facilities set F with $O\left(\left(n^{3/4} \cdot |F|^{1/4} + n^{4/5}\right) \log^{11/5} n\right)$ worst-case update time that can compute $\min_{f \in F}\{dist_G(f, v)\}$ along with the respective closest facility of v for any $v \in V(G)$ in $O(\log^2 n)$ time. The initialization time is $O(n \log^3 n)$.*

4 Fully Dynamic Strongly Connected Components

In this section we show that a strategy similar to that of Section 3 can be used to obtain a fully dynamic strong-connectivity algorithm. Again, we maintain an r-division $\mathcal{R}$ and some auxiliary data structures for all the individual pieces. Formally, using a dynamic r-division as in Theorem 6 may require introducing new infinite-weight edges to G which in turn may change the reachability relation in G. We circumvent this problem by setting the weights of the original edges of G to 0, and all auxiliary edges plus infinity (simulated in the implementation by sufficiently large values M_P inside individual pieces, as in Section 3). This way, u can reach v in G if and only if $\text{dist}_G(u, v) = 0$, and otherwise $\text{dist}_G(u, v) = \infty$. All known properties of reachability in plane graphs also extend to reachability using 0-weight paths (assuming non-negative weights). In the following, whenever we say that v is reachable from u, or there exists a $u \to v$ path, we mean $\text{dist}_G(u, v) = 0$.

As in Section 3, for each piece of $\mathcal{R}$ we store a recursive decomposition, dense distance graphs and MSSP data structures. All these data structures are also maintained for pieces of $\mathcal{R}$ with all edges reversed – for a piece P we call this graph the *reverse* of P and denote it by P^{rev}.

Another ingredient is a collection of *reachability certificates* X_P for all the pieces, as defined in the following lemma due to Subramanian [75], slightly adjusted to certify 0-weight paths.

▶ **Lemma 13** ([75])**.** *Let $P \in \mathcal{R}$ be a piece. There exists a directed graph X_P, where $\partial P \subseteq V(X_P)$, of size $O(\sqrt{r} \log r)$ satisfying the following property: for any $u, v \in \partial P$, $dist_P(u, v) = 0$ if and only if there exists a $u \to v$ path in X_P. The graph X_P can be computed in $O(r \log r)$ time.*

We include the reachability certificate in the set of auxiliary piecewise data structures. Since reachability certificates can be computed in $O(r \log r)$ time, maintaining them does not incur any additional asymptotic cost. The following lemma is a direct consequence of Lemma 13.

▶ **Lemma 14.** *For any $u, v \in \partial\mathcal{R}$, u can reach v in G if and only if u can reach v in $X = \bigcup_{P \in \mathcal{R}} X_P$.*

Proof. Let $u, v \in \partial\mathcal{R}$. Since each X_P certifies the reachability between ∂P in P, clearly a $u \to v$ path in X implies an existence of a $u \to v$ path in G. Now suppose there is a $u \to v$ path Q in G. Split P into maximal subpaths $Q_1, \ldots, Q_k$, such that each Q_i is fully contained in a single piece $P_i \in \mathcal{R}$. For each i, the endpoints a, b of Q_i are contained in ∂P_i and hence there exists a $a \to b$ path in $X_P \subseteq X$. Consequently, there exist a $u \to v$ path in X. ◀

To handle an edge update, after $\mathcal{R}$ and auxiliary data structures are updated, we compute the strongly connected components of X (defined as in Lemma 14) in $O(|X|) = O(n/\sqrt{r})$ time using any classical linear-time algorithm. For any $b \in \partial\mathcal{R}$, let $s_X(b)$ denote an integer

identifier of b's strongly connected component in X. By additionally sorting the SCCs of X topologically we can further assume that s_X satisfies the following property: if $a, b \in \partial\mathcal{R}$ are not strongly connected, but a can reach b in X then $s_X(a) < s_X(b)$. By Lemma 14, for $a, b \in \partial\mathcal{R}$, we have $s_X(a) = s_X(b)$ if and only if a and b are strongly connected in G; moreover, if a can reach b in G, then $s_X(a) \leq s_X(b)$.

We also define and maintain similar SCC-identifiers s_P for individual pieces P, i.e., for $u, v \in V(P)$, $s_P(u) = s_P(v)$ implies u, v are strongly connected in P, whereas $s_P(u) < s_P(v)$ implies there is no $v \to u$ path in P. Clearly, the identifiers s_P can be recomputed in $O(r)$ time given P, so we also include them into the set of auxiliary per-piece data structures.

For any $Q \in \{X\} \cup \mathcal{R}$, let S_Q be the set of used identifiers of the form $s_Q(\cdot)$. Observe that we can easily guarantee that the sets S_Q are pairwise disjoint, e.g., by using disjoint integer ranges for different sets S_Q.

The final component of our data structure, is, again a collection of per-piece point location data structures. For each $P \in \mathcal{R}$, we have two point location data structures $L(P^{\text{rev}})$ and $L(P)$ of Lemma 10. After each edge update, $L(P^{\text{rev}})$ is computed for P^{rev} with weight function $\omega = s_X$. On the other hand, $L(P)$ is initialized with weight function $\omega = -s_X$. As in Section 3, all these point location data structures are recomputed in $O(n/r^{1/4} \cdot \log^2 n)$ time (over all pieces).

We now describe how our data structure handles a query for an SCC identifier of a vertex v. The returned identifier always comes from the set $\bigcup_{Q \in \{X\} \cup \mathcal{R}} S_Q$. Let P_v be some piece containing v. Let $s_{\min}$ be the value computed by $L(P_v^{\text{rev}})$ for vertex v. Let $s_{\max}$ be *minus* the value computed by $L(P_v)$ for v. If either of $s_{\min}, s_{\max}$ equals $\pm\infty$ or $s_{\min} \neq s_{\max}$ holds, we return $s_{P_v}(v)$. Otherwise, we return $s_{\min} \in S_X$. The following lemma establishes the correctness of this query procedure.

▶ **Lemma 15.** *Let $u, v \in V(G)$ and let s_u, s_v be the respective identifiers returned by the query procedure. Then, $s_u = s_v$ if and only if u and v are strongly connected in G.*

Proof. Suppose $s_u = s_v$. If $s_u \in S_P$ for some piece P, then $s_u = s_v$ implies that u and v are strongly connected in P and thus also in G. So suppose $s_v \in S_X$. Take any $b \in \partial\mathcal{R}$ such that $s_v = s_X(b)$. We now prove that v and b are strongly connected in G. Similarly we prove that u and b are strongly connected in G. By transitivity it will follow that u and v are indeed strongly connected.

Let $P_v, s_{\min}, s_{\max}$ be defined as in the query procedure's description. Recall that $s_v \in S_X$ implies that $s_{\min}, s_{\max}$ are finite and $s_v = s_{\min} = s_{\max}$. Since all edges of P_v have weight 0, and $s_{\max}$ is finite, $s_{\max}$ in fact represents the maximum value $s_X(a)$ among those $a \in \partial P_v$ such that a path $a \to v$ exists in P_v. Similarly, observe that $s_{\min}$ represents the minimum value $s_X(c)$ among those $c \in \partial P_v$ such that a path $c \to v$ exists in P_v^{rev}, i.e., such that a path $v \to c$ exists in P_v. Let us denote by a and c the respective vertices of ∂P_v attaining the maximum and minimum values of s_X. Since $s_X(a) = s_X(c)$, there exists a path $c \to a$ in G. However, by the definition of a and c, paths $a \to v$ and $v \to c$ also exist in G, and hence a, v and c are strongly connected in G. Since a is clearly strongly connected to b by $s_X(a) = s_X(b)$, indeed v and b are strongly connected in G.

Now let us move to proving the " $\Longleftarrow$ " direction. Suppose u and v are strongly connected in G. First consider the case when there exists some vertex $b \in \partial\mathcal{R}$ located in the same strongly connected component of G as u and v. In this case we prove that $s_v = s_X(b)$. An analogous proof that $s_u = s_X(b)$ will establish $s_u = s_v$. Since v and b are strongly connected, there exist some paths $Q_1 = v \to b$ and $Q_2 = b \to v$ in G. Let v_1 be the first vertex on Q_1 such that $v_1 \in \partial P_v$ – note that v_1 necessarily exists since $b \in \partial\mathcal{R}$. Similarly set v_2 to be

the last vertex on Q_2 such that $v_2 \in \partial P_v$. Observe that the subpaths $v \to v_1$ and $v_2 \to v$ of Q_1 and Q_2 respectively lie entirely inside P_v. Hence, $s_{\min}$ and $s_{\max}$ are finite and we have $s_{\max} \geq s_X(v_2)$ and $s_{\min} \leq s_X(v_1)$. Recall that there exists a walk $v \to v_1 \to b \to v_2 \to v$, so in fact v_1, v_2, b are strongly connected, i.e., $s_X(v_1) = s_X(v_2) = s_X(b)$. Thus, we obtain $s_{\min} \leq s_X(b) \leq s_{\max}$.

On the other hand, let $a \in \partial P_v$ be such that a path $a \to v$ exists in P_v and $s_{\max} = s_X(a)$ (a exists by $s_{\max} \neq \pm\infty$). Similarly, let $c \in \partial P_v$ be such that a path $v \to c$ exists in P_v and $s_{\min} = s_X(c)$. Since a path $a \to c$ through v exists in P_v (so also in G), we have that $s_{\max} \leq s_{\min}$ by the fact that the identifiers S_X respect the topological order of the SCCs of X. Recall that we have already proved $s_{\min} \leq s_X(b) \leq s_{\max}$ so in fact we have $s_{\min} = s_{\max} = s_X(b)$, and consequently $s_v = s_X(b)$.

Finally, suppose there is no vertex of $\partial\mathcal{R}$ in the SCC of G containing u and v. First, this implies that $u, v \notin \partial\mathcal{R}$ and all $u \to v$ and $v \to u$ paths are contained in a single, unique piece P. This implies that $s_P(u) = s_P(v)$. Hence it is sufficient to prove $s_u = s_P(u)$ and $s_v = s_P(v)$. We prove the latter equality; proving the former is analogous. Recall that s_v is *not* set to $s_P(v)$ only if both $s_{\min}, s_{\max}$ are finite and $s_{\min} = s_{\max}$. This can only happen if there exists vertices $a, c \in \partial P$ such that a can reach v in P, v can reach c in P and $s_X(c) = s_{\min} = s_{\max} = s_X(a)$, i.e., a and c are strongly connected in G. But this implies that a, c and v are strongly connected in G, which contradicts the fact that the SCC of v in G does not contain vertices of $\partial\mathcal{R}$. ◀

The running time analyses of both the update and query procedures are identical to the analyses of Section 3. Hence, we have proved the following theorem.

▶ **Theorem 2.** *Let G be a planar digraph. There exists an $O(n \log n)$-space data structure maintaining G under edge insertions and deletions with $O(n^{4/5} \log^2 n)$ worst-case update time that can compute the identifier of the strongly connected component of any $v \in V(G)$ in $O(\log^2 n)$ time. The initialization time is $O(n \log^2 n)$.*

A Omitted Proofs

▶ **Lemma 16.** *Let $\mathcal{Q}$ be some collection of pieces from $\mathcal{T}(G)$ such that:*
1. *for each leaf piece $L \in \mathcal{T}(G)$, either L or some ancestor of L is in $\mathcal{Q}$,*
2. *for each $H \in \mathcal{Q}$, if some ancestor of H is in $\mathcal{Q}$, then the parent of H is also in $\mathcal{Q}$.*

Then for any $u, v \in V(\mathrm{DDG}(\mathcal{Q}))$, $dist_{\mathrm{DDG}(\mathcal{Q})}(u, v) = dist_G(u, v)$.

Proof. Let us note that if for some $H \in \mathcal{T}(G)$ no ancestor of H belongs to $\mathcal{Q}$, then $\partial H \subseteq V(\mathrm{DDG}(\mathcal{Q}))$. We prove this claim by induction on the level ℓ of piece H. For $\ell = 0$, we get $H \in \mathcal{Q}$, so clearly $\partial H \subseteq V(H) \subseteq V(\mathrm{DDG}(\mathcal{Q}))$. Suppose $\ell \geq 1$. The statement is trivial if $H \in \mathcal{Q}$. Otherwise, consider the children $H_1, \ldots, H_k$ of H. By induction we get $\partial H_i \subseteq V(\mathrm{DDG}(\mathcal{Q}))$. So in fact we have $\partial H \subseteq \bigcup_{i=1}^{k} \partial H_i \subseteq V(\mathrm{DDG}(\mathcal{Q}))$.

Since the edges of each DDG_H encode lengths of some paths in G, we have that $\mathrm{dist}_{\mathrm{DDG}(\mathcal{Q})}(u, v) \geq \mathrm{dist}_G(u, v)$. We now prove that there is a path of length at most $\mathrm{dist}_G(u, v)$ in $\mathrm{DDG}(\mathcal{Q})$. Let P be some shortest $u \to v$ path in G. Let H be a piece of $\mathcal{T}(G)$ of minimum level that contains P. We prove our claim by induction on the level ℓ of H.

First note that by property 1 of $\mathcal{Q}$, if $H \notin \mathcal{Q}$ and no descendant of H belongs to $\mathcal{Q}$, then H has a nearest ancestor H^* such that $H^* \in \mathcal{Q}$. Observe that $V(\mathrm{DDG}(\mathcal{Q})) \cap V(H) \subseteq \partial H^*$. Hence, $u, v \in \partial H^*$ and thus $\mathrm{dist}_{\mathrm{DDG}(\mathcal{Q})}(u,v) \leq \mathrm{dist}_{\mathrm{DDG}_{H^*}}(u,v) = \mathrm{dist}_{H^*}(u,v) \leq \mathrm{dist}_H(u,v) = \mathrm{dist}_G(u,v)$.

So we can assume that either $H \in \mathcal{Q}$ or some descendant of H belongs to $\mathcal{Q}$. Then by property 2 of $\mathcal{Q}$, we have that either $H \in \mathcal{Q}$ or no ancestor of H belongs to $\mathcal{Q}$. In either of these cases we have $\partial H \subseteq V(\mathrm{DDG}(\mathcal{Q}))$. Suppose first $\ell = 0$ – then H is a leaf piece and thus $H \in \mathcal{Q}$. So clearly $P \subseteq H \subseteq \mathrm{DDG}(\mathcal{Q})$, i.e., $\mathrm{dist}_{\mathrm{DDG}(\mathcal{Q})}(u,v) \leq \mathrm{dist}_G(u,v)$. On the other hand, if we assume $\ell \geq 1$ then we can split P into maximal subpaths $P_1, \ldots, P_k$ such that each $P_i = u_i \to v_i$ is entirely contained in a single child of H_P. Then for each i we have $\{u_i, v_i\} \subseteq \{u, v\} \cup \partial H \subseteq V(\mathrm{DDG}(\mathcal{Q}))$ so by induction we get that $\mathrm{dist}_{\mathrm{DDG}(\mathcal{Q})}(u_i, v_i) \leq \mathrm{dist}_G(u_i, v_i)$ which implies $\mathrm{dist}_{\mathrm{DDG}(\mathcal{Q})}(u,v) \leq \mathrm{dist}_G(u,v)$. ◀

▶ **Lemma 4** ([24, 38]). *Let $\mathcal{L}$ be some collection of leaf pieces of $\mathcal{T}(G)$. Then:*

1. *For any $u, v \in V(\mathrm{DDG}(\mathrm{cone}_G(\mathcal{L})))$, $dist_G(u,v) = dist_{\mathrm{DDG}(\mathrm{cone}_G(\mathcal{L}))}(u,v)$.*
2. $\sum_{H \in \mathrm{cone}_G(\mathcal{L})} |\partial H| = O\left(\sqrt{n|\mathcal{L}|}\right)$.

Proof. To obtain item 1 it is enough to note that $\mathrm{cone}_G(\mathcal{L})$ satisfies the requirements posed on the collection $\mathcal{Q}$ in Lemma 16.

Let $\mathcal{A}$ be the set containing all ancestors of all the leaf pieces $L \in \mathcal{L}$. We show item 2 by bounding the sum $X = \sum_{H \in \mathcal{A}} |\partial H|$. Since the number of boundary vertices of a piece is bounded by the sum of numbers of boundary vertices of its parent and its sibling, the sum $\sum_{H \in \mathrm{cone}_G(\mathcal{L})} |\partial H|$ of our interest can be larger from X only by a constant factor.

Recall that $\mathcal{T}(G)$ admits an r-division for any $r \in [1, n]$, i.e., there exists such r-division $\mathcal{R}$ that $\mathcal{R} \subseteq \mathcal{T}(G)$ and the boundary of each piece of $\mathcal{R}$ equals the boundary of that piece in $\mathcal{T}(G)$. Let us split $\mathcal{A}$ into two parts: let $\mathcal{A}_1$ contain those $H \in \mathcal{A}$ that are descendants of some piece $P \in \mathcal{R}$, and let $\mathcal{A}_2 = \mathcal{A} \setminus \mathcal{A}_1$. Let $X_i = \sum_{H \in \mathcal{A}_i} |\partial H|$.

Since each $L \in \mathcal{L}$ is a descendant of a unique piece $P \in \mathcal{R}$, we now bound the sum of $|\partial H|$ over all ancestors of L that are descendants of P. Recall (Section 2) that if H is a piece in a recursive decomposition of an n-vertex graph, then $|\partial H| = O(\sqrt{n}/c^d)$ where d is the depth of H in that decomposition. Consider the subtree of $\mathcal{T}(G)$ rooted at P – it forms a recursive decomposition $\mathcal{T}(P)$ of P with some initial boundary vertex set $|\partial P|$ of size $O(\sqrt{r})$. So the sum of $|\partial H|$ over all ancestors of L that are descendants of P is actually equal to the sum of $|\partial H|$ over all ancestors H of L in $\mathcal{T}(P)$. Since each ancestor has distinct integral depth, this sum is $O(\sum_{i=0}^{\infty} \sqrt{|P|}/c^i) = O(\sqrt{|P|}) = O(\sqrt{r})$. Hence $X_1 = O(|\mathcal{L}| \cdot \sqrt{r})$. On the other hand, $X_2 \leq \sum_{P \in \mathcal{R}} |\partial P| = O(n/\sqrt{r})$. So we obtain $X = X_1 + X_2 = O(n/\sqrt{r} + |\mathcal{L}| \cdot \sqrt{r})$. By choosing $r = n/|\mathcal{L}|$, we obtain $X = O(\sqrt{n \cdot |\mathcal{L}|})$ as desired. ◀

▶ **Lemma 5** ([24, 38]). *Let $X \subseteq V(G)$ be non-empty. Then:*

1. *For any $u, v \in V(\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(X)))$, $dist_G(u,v) = dist_{\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(X))}(u,v)$.*
2. $\sum_{H \in \mathrm{cone}_{\mathcal{R}}(X)} |\partial H| = O\left(n/\sqrt{r} + \min\left(\sqrt{n \cdot |X|}, |X| \cdot \sqrt{r}\right)\right)$.

Proof sketch. The proof is completely analogous to that of items 2 and 3 of Lemma 4. It is enough to glue the individual decompositions $\mathcal{T}(P)$ into a single decomposition $\mathcal{T}'(G)$ such that the root has $O(n/r)$ children instead of just 2: the individual pieces of $\mathcal{R}$. Then item 1 follows by Lemma 16. Let $Y = \sum_{H \in \mathrm{cone}_{\mathcal{R}}(X)} |\partial H|$. Note that $Y = O(n/\sqrt{r} + |X| \cdot \sqrt{r})$. If we have $r = n/|X| \leq r$, then we can obtain the bound $Y = O(\sqrt{n \cdot |X|})$ in the proof of Lemma 4. Otherwise, $|X| \leq n/r$, so $Y = O(n/\sqrt{r} + |X| \cdot \sqrt{r}) = O(n/\sqrt{r})$. So $Y = O(n/\sqrt{r} + \sqrt{n \cdot |X|})$ in all cases as well. ◀

▶ **Theorem 6.** *Let $G = (V, E)$ be a weighted planar graph. Suppose that adding infinite-weight edges to G does not have effect on any properties of G that we care about. Let $r \in [1, n]$.*

There is a data structure maintaining an r-division with few holes $\mathcal{R}$ of some G^+ such that:

1. *G^+ is obtained from G by adding infinite-weight edges.*
2. *Each P has all its faces except its holes triangular and is accompanied with some auxiliary data structures that can be constructed in $T(r)$ time given P and use $S(r)$ space.*

The data structure uses $O\left(n + \frac{n}{r} \cdot S(r)\right)$ space and can be initialized in $O\left(n + \frac{n}{r} \cdot T(r)\right)$ time. After each edge deletion and edge insertion (preserving the planarity of G), it can be updated in $O(r + T(r))$ worst-case *time.*

Proof. On initialization, we first connect and triangulate G using infinite-weight edges, thus obtaining G^+. Then, we compute an r-division $\mathcal{R}$ with few holes of G^+ in linear time [64] and subsequently initialize the auxiliary data structures. Let $h \geq 2$ and $c \geq 8$ be constants such that a single piece of the computed r-division has at most $c\sqrt{r}$ boundary vertices distributed over h holes.

We will guarantee at all times that for any single piece P, $|\partial P| \leq 3c\sqrt{r}$, and there exist at most $3h$ faces of P such that any $v \in \partial P$ lies on one of these faces, called holes of P. Moreover, each edge of G^+ is contained in at most two pieces of $\mathcal{R}$: this is satisfied initially since the r-division of [64] forms a partition of faces of G^+.

Suppose that the removal of an edge $e = uv$ is issued to G. We then remove e from each of the at most two pieces P containing it. If P is disconnected afterwards, we replace it with two connected pieces P_1, P_2. Otherwise, since removing e merges two faces of P, the total number of holes of P does not increase. If, on the other hand, a new edge $e = uv$ is inserted, we add a new piece P_e consisting of a single edge e to $\mathcal{R}$. Adding P_e may cause an endpoint of e, say u, to become a boundary vertex of $\mathcal{R}$. If u was not a boundary vertex before the insertion, it had to be a vertex of a single piece P_u. At this point, since a new boundary vertex emerges in P_u, we might have $\partial P_u > 3c\sqrt{r}$ or ∂P might no longer lie on at most $3h$ faces of P_u. However, there surely exist some $3h + 1$ faces whose vertices include the whole set ∂P_u, and $|\partial P_u| \leq 3c\sqrt{r} + 1$. To fix our invariants, we first compute a cycle separator C of P_u wrt. the boundary vertices of P_u in $O(r)$ time, and replace P_u with two pieces $P_{u,1}, P_{u,2}$ – the two subgraphs of P_u induced by vertices weakly on one side of C. Clearly, the vertices of C become new boundary vertices afterwards. Subsequently, we similarly break each of $P_{u,1}, P_{u,2}$ further into two parts using a cycle separator wrt. the holes of this piece (see [64] for details). Each of the at most four resulting pieces has at most $\frac{2}{3}(3c\sqrt{r} + 1) + 2\sqrt{2}\sqrt{r} \leq (2c + 2\sqrt{2} + 2)\sqrt{r} \leq 3c\sqrt{r}$ boundary vertices, and at most $\frac{2}{3} \cdot (3h + 1) + 1 \leq 2h + 2 \leq 3h$ holes.

Observe that a single edge update can introduce $O(1)$ new pieces of size $O(r)$ in the maintained r-division, and the sizes of the existing pieces do not increase. For each of the affected pieces we recompute the auxiliary data structures in $O(T(r))$ time. As a result, after $O(n/r)$ updates, there are still $O(n/r)$ pieces, each of size $O(r)$ and with $O(\sqrt{r})$ boundary vertices distributed over $O(1)$ holes of that piece. Consequently, after every $\Omega(n/r)$ updates, we reinitialize $\mathcal{R}$ for the current graph G in $O\left(n + \frac{n}{r} \cdot T(r)\right)$ time. Hence, the amortized time to update $\mathcal{R}$ is $O(r + T(r))$.

Finally, observe that our data structure can be modified in a standard way (see e.g., [5]) to have $O(r + T(r))$ *worst-case* update time bound instead of just an amortized one. This is possible since our update procedure actually takes $O(r + T(r))$ worst-case time apart from once every $k = \Omega(n/t)$ updates when the whole data structure is rebuilt in $O\left(n + \frac{n}{r} \cdot T(r)\right)$

worst-case time. To this end we apply the time-slicing technique. We use two copies of our data structure switching their roles every $k/2$ updates. One copy is for handling at most $k/2$ updates and answering queries, and another is being gradually reinitialized in chunks of $\Omega(r + T(r))$ time (of either initialization or updates replayed) in the background. ◀

B Empty Voronoi Cells

Here, we briefly explain why the algorithm of [23] that underlies Theorem 7 works irrespective of whether there are empty Voronoi cells.

We need a few more definitions. Let f^* be the vertex of the dual graph of G corresponding to the face f, where the sites lie. For an additively weighted Voronoi diagram $\mathsf{VD}(S, \omega)$ over a triangulated graph (possibly apart from face f), we call a face whose incident vertices belong to three different Voronoi cells *trichromatic*. Let $\mathsf{VD}_0^*(S, \omega)$ be the forest obtained by considering the dual edges of G whose endpoints belong to different Voronoi cells. Then, we obtain $\mathsf{VD}_1^*(S, \omega)$ by repeatedly contracting edges of the forest that have an endpoint of degree 2. We obtain $\mathsf{VD}_2^*(S, \omega)$ by creating one copy of f^* for each of its incident edges – inheriting only that edge. The vertices of $\mathsf{VD}_2^*(S, \omega)$ that are not copies of f^* are in one-to-one correspondence with the trichromatic faces of G, other than f. If $\mathsf{VD}_2^*(S, \omega)$ is a tree then we are done. Otherwise, is some cell of $\mathsf{VD}(S, \omega)$ is empty, $\mathsf{VD}_2^*(S, \omega)$ might be a forest. However, as shown in Section 6 of [41], $\mathsf{VD}_2^*(S, \omega)$ can be turned into the sought tree $\mathsf{VD}^*(S, \omega)$ in $O(|S|)$ time.

The algorithm of [23] for computing $\mathsf{VD}^*(S, \omega)$ implicitly assumes that all Voronoi cells are non-empty, and hence that $\mathsf{VD}_2^*(S, \omega)$ is a tree. This algorithm performs FR-Dijkstra computations on G in order to compute the trichromatic faces of G, and a representation of shortest paths from the sites to the vertices incident to these trichromatic faces. Then, $\mathsf{VD}_2^*(S, \omega)$ can be straightforwardly retrieved from this representation. If we run the same algorithm without assuming that there are no non-empty Voronoi cells, the sites with empty Voronoi cells can be easily read from the shortest paths tree obtained from FR-Dijkstra (more specifically, these are the sites whose some ancestor in this tree is also in S). Since the proof of correctness of the algorithm of [23] for computing the trichromatic faces actually only requires the set S to lie on a single face of G (and not necessarily to be equal to $V(f)$), we can re-run it with S pruned from "empty" sites. From all the trichromatic faces and the corresponding shortest paths from sites to their incident vertices, we can retrieve the forest $\mathsf{VD}_2^*(S, \omega)$ in the same way as if it were a tree. Finally, we can then turn this forest into the sought tree $\mathsf{VD}^*(S, \omega)$ in $O(|S|)$ time as in [41].

C Negative Edges in the Fully Dynamic SSSP Algorithm

Recall that $p : V(H) \to \mathbb{R}$ is called a feasible price function of H if $\mathrm{dist}_H(u, v) + p(u) - p(v) \geq 0$ for all $u, v \in V(H)$. A feasible price function is guaranteed to exist if H contains no negative-cost cycle. It is well-known that, provided that a graph H is strongly connected, a vector of distances from any vertex of H constitutes a feasible price function of H.

As in the fully dynamic all-pairs algorithm of [56], we maintain functions $\phi : \partial\mathcal{R} \to \mathbb{R}$ and $\phi_P : \partial P \to \mathbb{R}$, where $P \in \mathcal{R}$, such that ϕ is some feasible price function of G restricted to $\partial\mathcal{R}$, and each ϕ_P is a feasible price function of P.

Since single-source shortest paths in planar graphs with negative weights can be computed in $O(n \log^2 n)$ time [65,70], each ϕ_P can be seen as an accompanying data structure of piece P computable in $O(r \log^2 r)$ time and maintained by the fully dynamic r-division algorithm.

The functions ϕ_P allow to treat individual graphs P and P_h as non-negatively weighted when computing all the needed DDGs and MSSP data structures, and also point location data structures $L(P)$.

It is known [40, 56] that the FR-Dijkstra algorithm (as in Lemma 3) can handle negative weights in $\mathrm{DDG}(\mathcal{H})$ with no asymptotic overhead if a feasible price function on $\mathrm{DDG}(\mathcal{H})$ is provided. Therefore, we would like to have a feasible price function on $\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(s))$ to compute distances from s in $\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(s))$ needed by the update algorithm. We can extend ϕ from ∂R to all vertices in $\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(s))$ as follows. Note that all pieces in $\mathrm{cone}_{\mathcal{R}}(s)$ except of those in $\mathcal{R}$ have their parents also in $\mathrm{cone}_{\mathcal{R}}(s)$. We call those pieces $H \in \mathrm{cone}_{\mathcal{R}}(s)$ for which we know the value of ϕ on all of ∂H *processed*. Initially, only the pieces $P \in \mathcal{R}$ are processed by the definition of ϕ. While there are still unprocessed pieces, we take any unprocessed piece H whose parent $A \in \mathcal{T}(P)$ has already been processed. Let H' be the sibling of H in $\mathcal{T}(P)$. Observe that ϕ_P is a feasible price function of A as well. We extend ϕ to boundary vertices of H, H' by computing shortest paths on $\mathrm{DDG}(\{H, H'\})$ from vertices ∂A, with the initial distance to each $v \in \partial A$ set to $\phi(v)$, and using FR-Dijkstra (Lemma 3) with price function ϕ_P. This way, only the initial distances of ∂A are possibly negative from the point of view of FR-Dijkstra. This does not constitute a problem for either Dijkstra's algorithm or FR-Dijkstra though (see [56]; one can treat the initial distances as weights of edges going out of a super-source; these weights can be all increased by the same large value to be made positive). One can show from the definition of ϕ that the values of ϕ on ∂A will not be altered and the computed distances form a feasible price function on $\partial H \cup \partial H'$ in G. Hence, given that $\partial A \subseteq \partial H \cup \partial H'$, we can process the children H, H' of a processed piece A in $O((|\partial H| + |\partial H'|) \log^2 n)$ time. Summing over all pieces, we obtain by Lemma 5 that extending ϕ to all $V(\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(s)))$ takes $O(n/\sqrt{r} \log^2 n)$ time. This cost is therefore negligible.

Note that an edge deletion or weight increase cannot break the feasibility of ϕ. We might need to recompute ϕ only upon insertion or weight decrease of some edge uv. As shown by Kaplan et al. [56], the new "global" price function ϕ' (or a negative cycle) can be found by computing distances from v to $\partial\mathcal{R} \cup \{u\}$ in $\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(u, v))$ (before applying the insertion) using FR-Dijsktra and the old price function ϕ. This can be done in $O(n/\sqrt{r} \log^2 n)$ time by first extending the old ϕ to $V(\mathrm{DDG}(\mathrm{cone}_{\mathcal{R}}(u, v)))$ as described above and then running the single-source shortest paths algorithm of Lemma 3.

The Number of Repetitions in 2D-Strings

Abstract

The notions of periodicity and repetitions in strings, and hence these of runs and squares, naturally extend to two-dimensional strings. We consider two types of repetitions in 2D-strings: *2D-runs* and *quartics* (quartics are a 2D-version of squares in standard strings). Amir et al. introduced 2D-runs, showed that there are $\mathcal{O}(n^3)$ of them in an $n \times n$ 2D-string and presented a simple construction giving a lower bound of $\Omega(n^2)$ for their number (*Theoretical Computer Science*, 2020). We make a significant step towards closing the gap between these bounds by showing that the number of 2D-runs in an $n \times n$ 2D-string is $\mathcal{O}(n^2 \log^2 n)$. In particular, our bound implies that the $\mathcal{O}(n^2 \log n + \mathsf{output})$ run-time of the algorithm of Amir et al. for computing 2D-runs is also $\mathcal{O}(n^2 \log^2 n)$. We expect this result to allow for exploiting 2D-runs algorithmically in the area of 2D pattern matching.

A quartic is a 2D-string composed of 2×2 identical blocks (2D-strings) that was introduced by Apostolico and Brimkov (*Theoretical Computer Science*, 2000), where by quartics they meant only *primitively rooted* quartics, i.e. built of a primitive block. Here our notion of quartics is more general and analogous to that of squares in 1D-strings. Apostolico and Brimkov showed that there are $\mathcal{O}(n^2 \log^2 n)$ occurrences of primitively rooted quartics in an $n \times n$ 2D-string and that this bound is attainable. Consequently the number of distinct primitively rooted quartics is $\mathcal{O}(n^2 \log^2 n)$. The straightforward bound for the maximal number of distinct general quartics is $\mathcal{O}(n^4)$. Here, we prove that the number of distinct general quartics is also $\mathcal{O}(n^2 \log^2 n)$. This extends the rich combinatorial study of the number of distinct squares in a 1D-string, that was initiated by Fraenkel and Simpson (*Journal of Combinatorial Theory, Series A*, 1998), to two dimensions.

Finally, we show some algorithmic applications of 2D-runs. Specifically, we present algorithms for computing all occurrences of primitively rooted quartics and counting all general distinct quartics in $\mathcal{O}(n^2 \log^2 n)$ time, which is quasi-linear with respect to the size of the input. The former algorithm is optimal due to the lower bound of Apostolico and Brimkov. The latter can be seen as a continuation of works on enumeration of distinct squares in 1D-strings using runs (Crochemore et al., *Theoretical Computer Science*, 2014). However, the methods used in 2D are different because of different properties of 2D-runs and quartics.

1 Introduction

Periodicity is one of the main and most elegant notions in stringology. It has been studied extensively both from the combinatorial and the algorithmic perspective; see e.g. the books [18, 25, 39]. A classic combinatorial result is the periodicity lemma due to Fine and Wilf [27]. From the algorithmic side, periodicity often poses challenges in pattern matching, due to the following fact: a pattern P can have many occurrences in a text T that are "close" to each other if and only if P has a "small" period. On the other hand, the periodic structure indeed allows us to overcome such challenges; see [18, 25].

Runs, also known as maximal repetitions, are a fundamental notion in stringology. A run is a periodic fragment of the text that cannot be extended without changing the period. Runs were introduced in [35]. Kolpakov and Kucherov presented an algorithm to compute all runs in a string in time linear with respect to the length of the string over a linearly-sortable alphabet [38]. Runs fully capture the periodicity of the underlying string and, since the publication of the algorithm for their linear-time computation, they have assumed a central role in algorithm design for strings. They have been exploited for text indexing [36], answering internal pattern matching queries in texts [16, 37], or reporting repetitions in a string [2, 15, 22], to name a few applications.

Kolpakov and Kucherov also posed the so-called runs conjecture which states that there are at most n runs in a string of length n. A long line of work on the upper [19, 20, 21, 31, 42, 43, 44] and lower bounds [30, 41, 45] was concluded by Bannai et al. who positively resolved the runs conjecture in [10] (see also an alternative proof in [23] and a tighter upper bound for binary strings from [28]).

A square is a concatenation of two copies of the same string. Fraenkel and Simpson [29] showed that a string of length n contains at most $2n$ distinct square factors. This bound was improved in [26, 34]. All distinct squares in a string of length n can be computed in $\mathcal{O}(n)$ time assuming an integer alphabet [11, 22, 33] (see [46] for an earlier $\mathcal{O}(n \log n)$ algorithm).
