Subproof. Suppose some decision gadget DG_1 is aligned with a $\$_i$ symbol in string T_i for some $i \in [2, k-1]$. We will show that this incurs an edit cost greater than our upper bound E^+ established in Claim 18, implying this cannot occur in an optimal edit sequence. We may assume w.l.o.g. that DG_1 is aligned with a $\$_i$ symbol on the left side of T_i. It follows that the substring $\mathrm{VG}'_1(\phi)^{(50k+1)n}$ of T_1 must occur to the left of the alignment, and the substring P'_i of T_i must occur to the right of the alignment (see Figure 4). Then this alignment of T_1 and T_i has a combined length greater than or equal to $|\mathrm{VG}'_1(\phi)^{(50k+1)n}| + |P'_i|$. We observe that $|\mathrm{VG}'_1(\phi)^{(50k+1)n}| > 100kn\ell_4$ and $|P'_i| > 400kn\ell_4$, so our alignment of T_1 and T_i has a combined length greater than $500kn\ell_4$. On the other hand, $|T_k| = (202k+1)n|\mathrm{VG}'_k| < 203kn(3\ell_3 + 2\ell_4)$. Our alignment of T_1 and T_i must be edited to have the same length as T_k in every complete edit sequence, so it follows that $\mathrm{EDIT}(T_1, T_i, T_k) > 500kn\ell_4 - 203kn(3\ell_3 + 2\ell_4) = kn(94\ell_4 - 609\ell_3) > 1000k^4dn\ell_3$. Then our edit sequence requires $1000k^4dn\ell_3 + E_1^+ > E^+$ edits, so this alignment cannot occur in an optimal edit sequence. ◁

Let c be a component in $\mathcal{C}_{3.1}$. Suppose $\#(c, i) = 0$ for some $i \in [2, k-1]$. Then by definition, our gadgets in c have no alignments with any vector level gadget in T_i. It follows that we must perform at least $|\mathrm{VG}_i| > D^+$ edits among the vector gadgets in c. This is because the vector gadgets in c are either aligned with no symbols in T_i and therefore require at least $|\mathrm{VG}_i|$ insertions or deletions in c to make all strings the same length, or the vector gadgets in c are aligned exclusively with 8 symbols in T_i and therefore require at least $|\mathrm{VG}_i|$ substitutions to make them the same. Note that the vector gadgets in c cannot be aligned with any $\$_i$ symbols in T_i by Claim 23. This is key for proving that these edits are disjoint from the E_1^- cost of editing the $\$_i$ symbols.

Now consider the case that $\#(c, i) \neq 0$ for all $i \in [2, k-1]$. Then we have that $\#(c, i) = 1$ for all $i \in [1, k]$, and by our analysis in Lemma 14, the edit cost of aligning the k vector level gadgets is at least D^+. ◀

▶ **Lemma 24.** *Let c be a component in $\mathcal{C}_{3.2}$ and let $\lambda = |c|$, then the edit cost incurred by the vector gadgets in c is $(d + r + 1)(2k - 1)(\lambda - 1)$.*

Proof. Here we make use of the following claim, which has proof similar to Claim 23.

▷ Claim 25. Let $v_i \in S_i$ for some $i \in [2, k]$, then no optimal edit sequence aligns the vector gadget $\mathrm{VG}_i(v_i)$ in T_i with a $\$_1$ symbol in T_1, nor a dummy vector gadget $\mathrm{VG}_1(\phi)$ in T_1.

Subproof. Suppose some vector gadget $\mathrm{VG}_i(v_i)$ in string T_i with $i \in [2,k]$ and $v_i \in S_i$ is aligned with a dummy vector gadget $\mathrm{VG}_1(\theta)$ in string T_1. We will show that this incurs an edit cost greater than our upper bound E^+, implying this cannot occur in an optimal edit sequence. We may assume w.l.o.g. that $\mathrm{VG}_i(v_i)$ is aligned with a $\mathrm{VG}_1(\theta)$ gadget on the left side of T_1. It follows that the substring L_i of T_i must occur to the left of the alignment and the substring $\mathrm{DG}'_1(\phi)^{50kn} \circ P_1 \circ R_1$ of T_1 must occur to the right of the alignment. Then we can consider this alignment of T_i and T_1 to have a combined length greater than or equal to $|L_i| + |\mathrm{DG}'_1(\phi)^{50kn} \circ P_1 \circ R_1|$.

We observe that $|L_i| > 200kn\ell_4$ and $|\mathrm{DG}'_1(\phi)^{50kn} \circ P_1 \circ R_1| > 400kn\ell_4$, so our alignment of T_i and T_1 has a combined length greater than $600kn\ell_4$. On the other hand, $|T_k| = (202k+1)n|\mathrm{VG}'_k| < 203kn(3\ell_3 + 2\ell_4)$.

Our alignment of T_i and T_1 must be edited to have the same length as T_k in every complete edit sequence, so it follows that $\mathrm{EDIT}(T_1, T_i, T_k) > 600kn\ell_4 - 203kn(3\ell_3 + 2\ell_4) = kn(194\ell_4 - 609\ell_3) > 1000k^4dn\ell_3$. Then our edit sequence requires $1000k^4dn\ell_3 + E_1^+ > E^+$ edits, so this alignment cannot occur in an optimal edit sequence. It follows that $\mathrm{VG}_i(v_i)$ in T_i cannot align with a $\mathrm{VG}_1(\theta)$ gadget (and by extension a $\$_1$ symbol) in T_1. ◁

Let c be in $\mathcal{C}_{3.2}$. Suppose there is some $v_i \in S_i$ for $i \in [2,k]$ such that vector gadget $\mathrm{VG}_i(v_i)$ corresponds to a vertex in component c. Then the gadgets in our component cannot align with any decision gadgets DG_1, vector gadgets $\mathrm{VG}_1(\phi)$, or $\$_1$ symbols in T_1. It follows that we must perform at least $|\mathrm{VG}_i| > (d+r+1)(2k-1)(\lambda-1)$ insertions in T_i. Else, all vertices in component c correspond only to vector gadgets $\mathrm{VG}_i(\phi)$ for $i \in [1,k]$. By a similar argument as in Claim 17, the edit cost of component c is $(d+r+1)(2k-1)(\lambda-1)$. ◀

We have lower bounded the edit cost of all components in $\mathcal{C}_1, \mathcal{C}_2$, and $\mathcal{C}_3$. Now we must combine our component level arguments to obtain an overall lower bound on the edit cost. Let $W = \sum_{c \in \mathcal{C}_1 \cup \mathcal{C}_2} \mathrm{width}(c)$. Then we know that the components in $\mathcal{C}_1 \cup \mathcal{C}_2$ incur a cost of at least $E_2^+ = WQ$ edits by Lemma 20 and Lemma 21.

We now lower bound the total number of edits from components in $\mathcal{C}_3$. Note that components in $\mathcal{C}_{3.1}$ incur a much higher cost than components in $\mathcal{C}_{3.2}$. Then to lower bound the edits in $\mathcal{C}_3$, we must assume the least possible number of components in $\mathcal{C}_{3.1}$. There are $(100k+1)n$ decision gadgets DG_1 in our final strings and at most W decision gadgets in components in $\mathcal{C}_1 \cup \mathcal{C}_2$, so there must be at least $Z_1 = (100k+1)n - W$ components in $\mathcal{C}_{3.1}$. Note that if $W \geq (100k+1)n$, then $E_1^+ + E_2^+ \geq E^+$, so we may assume Z_1 is positive. Then components from $\mathcal{C}_{3.1}$ incur a cost of at least $E_3^+ = Z_1 D^+$ by Lemma 22.

There are at most $V_0 = kW$ vertices in components in $\mathcal{C}_1 \cup \mathcal{C}_2$, and there are at most $V_1 = kZ_1$ vertices in $\mathcal{C}_{3.1}$. Furthermore, there are $k(201k+2)n$ vertices in our graph G. It follows that there must be at least $V_2 = k(201k+2)n - V_1 - V_0 = k(101k+1)n$ vertices in all components in $\mathcal{C}_{3.2}$.

Because our edit cost lower bound for every component in $\mathcal{C}_{3.2}$ is linear in the component size, we have the following.

▷ Claim 26. Suppose there are Z components in $\mathcal{C}_{3.2}$ and a total of V vertices in all components in $\mathcal{C}_{3.2}$. Then the components in $\mathcal{C}_{3.2}$ incur $(d+r+1)(2k-1)(V-Z)$ edits.

Proof. By Lemma 24, each component of size λ in $\mathcal{C}_{3.2}$ incurs cost $(d+r+1)(2k-1)(\lambda-1)$. Let z_i denote the size of the ith component in $\mathcal{C}_{3.2}$ for $i \in [1,Z]$. Then we may sum the edit costs of all components in $\mathcal{C}_{3.2}$:

$$\sum_{i \in [1,Z]} (d+r+1)(2k-1)(z_i - 1) = (d+r+1)(2k-1)(V-Z)$$

where $z_i > 0$ for $i \in [1,Z]$ and $z_1 + z_2 + \cdots + z_Z = V$. ◁

Claim 26 proves that the edit cost of all the components in $\mathcal{C}_{3.2}$ decreases with the number of components Z. Then to achieve our lower bound we must upper bound the number of components in $\mathcal{C}_{3.2}$. There are exactly $(202k+1)n$ vector level gadgets in T_k, so there can be at most $Z_2 = (202k+1)n - Z_1$ components in $\mathcal{C}_{3.2}$. It follows that the total edit cost contributed by the components of $\mathcal{C}_{3.2}$ is at least $E_4^+ = (d+r+1)(2k-1)(V_2 - Z_2)$.

Then since the edit costs contributed by E_1^+, E_2^+, E_3^+, and E_4^+ are disjoint, we achieve a lower bound $\text{EDIT}(T_1, T_2, \ldots, T_k) \geq E_1^+ + E_2^+ + E_3^+ + E_4^+$. Straightforward calculation will show that $E_1^+ + E_2^+ + E_3^+ + E_4^+ \geq E^+$ for all $W > 0$. It follows that $\text{EDIT}(T_1, \ldots, T_k) = E^+$.

3 Reduction from k-Median-Edit-Distance to k-Center-Edit-Distance

We now provide a simple, yet previously unknown reduction from k-Median-Edit-Distance to k-Center-Edit-Distance. Given a set of strings $X = \{x_1, x_2, \ldots, x_k\}$, each of length at most n over an alphabet Σ, we define another set of strings $Y = \{y_1, y_2, \ldots, y_k\}$ over an alphabet $\Sigma' = \Sigma \cup \{\$\}$ (where $\$ \notin \Sigma$) as follows (fix $\ell = k^2 n$):

$$y_1 = x_1 \circ \$^\ell \circ x_2 \circ \$^\ell \circ \cdots \circ \$^\ell \circ x_{k-1} \circ \$^\ell \circ x_k$$
$$y_2 = x_2 \circ \$^\ell \circ x_3 \circ \$^\ell \circ \cdots \circ \$^\ell \circ x_k \circ \$^\ell \circ x_1$$
$$\vdots$$
$$y_k = x_k \circ \$^\ell \circ x_1 \circ \$^\ell \circ \cdots \circ \$^\ell \circ x_{k-2} \circ \$^\ell \circ x_{k-1}$$

Let $\text{CENTER-EDIT}(y_1, y_2, \ldots, y_k)$ denote the center edit distance of strings $y_1, y_2, \ldots, y_k$. We will prove the following, which will complete the reduction.

▶ **Lemma 27.** $\text{EDIT}(x_1, x_2, \ldots, x_k) = \text{CENTER-EDIT}(y_1, y_2, \ldots, y_k)$

Proof. Suppose that $\text{EDIT}(x_1, x_2, \ldots, x_k) = E$, and there is an optimal edit sequence on $x_1, x_2, \ldots, x_k$ that performs E_i edits on x_i for $i \in [1, k]$. It follows that $E_1 + E_2 + \cdots + E_k = E$.

▷ Claim 28. $\text{EDIT}(y_1, y_2, \ldots, y_k) = kE$

Subproof. It can be seen that $\text{EDIT}(y_1, y_2, \ldots, y_k) \leq kE$ since we may align all \$ symbols in the y_i in zero edits, and then we have k alignments of $x_1, x_2, \ldots, x_k$ substrings, each incurring E edits, for a total of kE edits.

Now note that no optimal edit sequence of $y_1, y_2, \ldots, y_k$ will delete an entire series of \$ symbols because it would incur cost ℓ greater than kE, our upper bound. It follows that for all $i \neq j$ the hth leftmost series of \$ symbols in y_i is aligned with the hth leftmost series of \$ symbols in y_j for $h \in \{1, \ldots, k-1\}$. Then the \$ alignments "lock" the x_i substrings into place so that we have k alignments of $x_1, x_2, \ldots, x_k$ substrings, and because no x_i contains the \$ symbol, it follows that each alignment of the x_i incurs cost greater than or equal to E. Then $\text{EDIT}(y_1, y_2, \ldots, y_k) \geq kE$. ◁

We now have that $\text{EDIT}(y_1, y_2, \ldots, y_k) = kE$. Furthermore, there is an optimal edit sequence that performs exactly E edits on every string in $y_1, y_2, \ldots, y_k$. This can be seen because in every alignment of substrings $x_1, x_2, \ldots, x_k$ in our edit sequence of $y_1, y_2, \ldots, y_k$, we may choose to perform E_i edits on each x_i. Then there exists an optimal edit sequence where for every string y_i with $i \in [1, k]$, we perform $E_i + E_{i+1} + \cdots + E_k + E_1 + E_2 + \cdots + E_{i-1} = E$ edits on y_i.

It follows that $\text{CENTER-EDIT}(y_1, y_2, \ldots, y_k) \leq E$. Furthermore, suppose that $\text{CENTER-EDIT}(y_1, y_2, \ldots, y_k) < E$. Then $\text{EDIT}(y_1, y_2, \ldots, y_k) < kE$, a contradiction. We conclude that $\text{CENTER-EDIT}(y_1, y_2, \ldots, y_k) = E$ and our reduction is complete. Note that for all $i \in [1, k]$, $|y_i| = (k-1)k^2 n + kn = \mathcal{O}(n)$. ◀

Lemma 27 directly implies the following result.

▶ **Theorem 29.** *If there is an $\varepsilon > 0$, a constant $k \geq 2$, and an algorithm that can solve k-Center-Edit-Distance on strings, each of length at most n, over an alphabet of size $\mathcal{O}(k)$ in $\mathcal{O}(n^{k-\varepsilon})$ time, then* SETH *is false.*

4 Discussion

Based on SETH, we have shown conditional hardness results for median string, center string, tree alignment, and bottleneck tree alignment problems, all under edit distance. These results suggest that the algorithms for the median string and tree-alignment problems are optimal (up to logarithmic factors). However, for the center string and bottleneck tree alignment problem, they leave an intriguing gap between the best known upper bounds. For center string (or the star instance of the bottleneck tree alignment) the best known dynamic programming algorithm works in time $O(n^{2k})$ [40], and as far as the authors know, no such algorithm exists for bottleneck tree alignment on more general trees. We conclude by asking: is an $O(n^k)$ algorithm waiting to be found for these problems, or does there exist a more efficient reduction which can prove that an $O(n^{2k-\varepsilon})$ algorithm is highly improbable?

Abstract

In sum of radii clustering, the input consists of a finite set of points in a metric space. The problem asks to place a set of k balls centered at a subset of the points such that every point is covered by some ball, and the objective is to minimize the sum of radii of these balls. In the capacitated version of the problem, we want to assign each point to a ball containing it, such that no ball is assigned more than U points, where U denotes the *capacity* of the points. While constant approximations are known for the uncapacitated version of the problem, there is no work on the capacitated version. We make progress on this problem by obtaining a constant approximation using a Fixed Parameter Tractable (FPT) algorithm. In particular, the running time of the algorithm is of the form $2^{O(k^2)} \cdot n^{O(1)}$. As a warm-up for this result, we also give a constant approximation for the uncapacitated sum of radii clustering problem with matroid constraints, thus obtaining the first FPT approximation for this problem.

1 Introduction

Clustering problems have received a great deal of attention in theoretical as well as practical research. Different ways of modeling a clustering problem have been proposed. A common way to model clustering problems is to assume that the data is represented as a set of points in a finite metric space, and the distance between a pair of points is a measure of similarity between the corresponding data points. Now, we want to partition the set of input points, such that the points belonging to each group are more similar to each other than the points outside the group. In the following, we focus on a particular set of three related clustering objective functions – k-center, k-median, and sum of radii clustering. We first describe the general setup.

Let P be a set of n input points in a metric space, and let d be the corresponding distance function. Let k denote the number of desired clusters, where k is a parameter of the problem. We want to find a set $C \subseteq P$ of at most k centers, such that a certain clustering objective function $\sigma(C, P)$ is minimized. In the k-center problem, the objective function is the largest distance of a point to its nearest center; whereas in the k-median problem, it is the sum of all such distances.

Now we describe the closely related sum of radii objective. For any $c \in P$, and $\rho \geq 0$, let $B(c, \rho) = \{p \in P : d(c, p) \leq \rho\}$ denote the ball of radius ρ centered at c. In the sum of radii objective, we want to additionally compute a *radius assignment* $r : C \to \mathbb{R}^+$, such that the corresponding set of balls $\mathcal{B} = \{B(c, r(c)) : c \in C\}$ *covers* the entire set of points P. The objective is to minimize the sum of radii of the balls, i.e., $\sum_{c \in C} r(c)$.

The sum of radii problem was studied by Charikar and Panigrahy [8], who gave a constant approximation. This result is obtained by first obtaining a constant approximation via the primal-dual technique to a closely related problem, which is the Lagrangian relaxation of the original sum of radii problem. Subsequently, Behsaz and Salavatipour [4] improved the approximation ratio in a restricted setting, and Gibson et al. [14] gave a $(1+\epsilon)$-approximation in quasi-polynomial time. In light of the latter result, the problem is likely not APX-hard, under standard complexity theoretic assumptions. There has also been significant work on certain generalizations of this problem. More general objective functions, such as the sum of α'th powers of the radii for a fixed $\alpha \geq 1$, and more general constraints, such as multi-covering of points, have been addressed, but these generalizations are outside the scope of this article.

Constant approximations are also known for the metric k-center and k-median problems, and unlike the sum of radii clustering problem, these problems are known to be APX-hard – see [15, 17, 5] and the references therein for these results. We now focus on a particular generalization of clustering problems which is the focus of this work.

1.1 Capacitated Clustering

A commonly considered generalization of clustering problems is the capacitated clustering, which models the situation where a center is able to provide a certain service to a specific number of points, which are sometimes referred to as *clients* in this context. In the uniform capacitated clustering problem, we are given an integer $1 \leq U \leq n$, which represents the *capacity* of any chosen center. Now, we also want to assign each point to a chosen center, such that no center is assigned more than U points. Here, we also require that, if a point p is assigned to a center c, then it is also covered by the ball placed at c. In a generalization called the non-uniform version of the problems, different centers may have different capacities.

The capacitated sum of radii problem has not yet been considered in the literature. Known techniques do not seem to extend to the capacitated sum of radii problem. Firstly, it can be easily shown that the standard Linear Programming (LP) relaxation has large integrality gap. Furthermore, it is not clear whether it is possible to strengthen this LP by imposing additional constraints implied by the problem structure, as done in [2] for capacitated facility location. Another piece of evidence is a hardness result from [3] for a closely related problem, which can be modified to rule out an $o(\log n)$-approximation in polynomial time, if we want to minimize the sum of α-th powers of radii, where $\alpha > 1$. While this hardness result does not rule out an $O(1)$ approximation in polynomial time for $\alpha = 1$, it does tell us that such a result would need to exploit rather special properties that hold in the $\alpha = 1$ case.

Before describing our results, we review the work on the capacitated versions of the k-center and k-median problems, and look at possible approaches that have been successful for these problems.

Related Work

The capacitated versions of the k-center and k-median problems can be defined analogously. These problems have received a great attention from the researchers. Constant approximations for the capacitated k-center are known [18], even for the non-uniform version. On the other hand, obtaining a constant approximation for the capacitated k-median problem has been a long-standing open problem in approximation algorithms. Researchers have explored different approaches for tackling this problem, in particular, relaxing some of the requirements of traditional approximation algorithms. One such relaxation allows for bi-criteria approximations – constant approximations have been obtained by violating the capacities by a small factor ([7, 10, 6, 13]), or by violating the k-constraint (the number of medians) by a constant factor ([20, 21]).

Yet another recent approach relaxes the requirement that the algorithm run in polynomial time. An algorithm with the running time of $f(p) \cdot n^{O(1)}$ is known as a Fixed Parameter Tractable (FPT) algorithm, where p is a parameter of the problem. Note that, although the running time may depend exponentially (or worse) on the parameter p, the dependence on n, the input size, is strictly polynomial. In the context of capacitated clustering, such an FPT algorithm parameterized by k, the number of clusters, may be acceptable, if k is a small constant. Adamczyk et al. [1] give a $(7+\epsilon)$-approximation for the (uniform/non-uniform) capacitated k-median problem in $k^{O(k)} \cdot n^{O(1)}$ time. They use an approximate solution for the *uncapacitated* k-median problem to convert the given instance into a simpler instance that has more structure, at an expense of a small constant factor loss in the approximation guarantee. Then, they obtain a near-optimal solution for this simpler instance in FPT time. Cohen-Addad and Li [11] improved the approximation guarantee to $3+\epsilon$, again using a similar FPT running time. Their algorithm is based on a coreset construction, and they obtain a constant approximation for this smaller coreset in FPT time. They also obtain an $(1+\epsilon)$-approximation in Euclidean metrics. These results are complemented by Adamczyk et al. [1], who observe that one cannot hope to obtain an exact FPT algorithm even for the *uncapacitated* k-median problem. Parameterized algorithms and complexity is a large and active domain of research, and we direct the reader to a textbook such as [12] for a more detailed background.

1.2 Our Results and Techniques

Our main result is a 28-approximation for the uniform capacitated sum of radii problem, that runs in $2^{O(k^2)} \cdot n^{O(1)}$ time. This result is in a similar vein as the aforementioned results ([1, 11]) for the capacitated k-median problem. Adapting techniques they develop for capacitated k-median, we can obtain an FPT approximation for capacitated sum of radii in metrics of constant doubling dimension. However, for general metrics, we have not been able to adapt their approach. Therefore, we develop a novel algorithm, which we discuss at a high level below.

Fix an optimal solution to the problem. First we discretize the optimal solution by rounding the radii up to a power of $1+\epsilon$ for a fixed $\epsilon > 0$, and now suppose that this discretized solution exactly k_i balls of radius r_i, where each r_i is a power of $(1+\epsilon)$. We show that this first step can be implemented in FPT time. Therefore, we can assume henceforth that we know the "radius profile" of the optimal solution. Our main algorithm proceeds in multiple *levels*. Roughly speaking, the goal of the algorithm at a particular level i is to guess the approximate locations of the k_i optimal balls of radius r_i. However, the size of the search space for this guessing is too large to ultimately obtain an FPT algorithm.

Therefore, we employ a certain *greedy* strategy to guess some balls not chosen in the optimal solution. This allows us to bound the size of the search space, while simultaneously allowing us to argue that an appropriate capacity reassignment is possible if our algorithm misses the approximate location of an optimal ball.

Sum of Radii with a Matroid Constraint

Although the high-level idea of our algorithm is relatively simple, the technical arguments to establish that such a capacity reassignment is possible are quite sophisticated and involved. Therefore, we first consider a related, but simpler, problem as a warm-up. The natural candidate is the uncapacitated version (for which constant approximations are known in polynomial time [8]), but we consider a more general version, which replaces the k-constraint by a more general matroid constraint.

A matroid $\mathcal{M}$, on the set of given points P, is the pair $(P, \mathcal{I})$, where $\mathcal{I}$ is a collection of subsets of P with the following properties: (i) $A \in \mathcal{I}$ implies that $\forall B \subseteq A$, $B \in \mathcal{I}$, (ii) If $A, B \in \mathcal{I}$ with $|B| < |A|$, then there exists a $p \in A \setminus B$, such that $B \cup \{p\} \in \mathcal{I}$. If a set C belongs to $\mathcal{I}$, then C is said to be *independent* in the corresponding matroid $\mathcal{M}$. One consequence of this definition is that all inclusion-wise maximal independent sets of a matroid $\mathcal{M}$ have equal size, and they are called the bases of $\mathcal{M}$.

In the Matroid Sum of Radii problem, a feasible solution consists of a set of centers C, and a radius assignment $r : C \to \mathbb{R}^+$ such that the resulting set of balls covers P. Furthermore, we also require that C be an independent set according to a given matroid $\mathcal{M}$. The objective of the problem is to minimize the sum of radii. We assume that we have an oracle access to an algorithm $\mathcal{A}_{\mathcal{M}}$ that answers in polynomial time, whether a candidate set of centers is independent in the matroid $\mathcal{M}$. For many "natural" matroids, the definition of an independent set is simple, and thus the oracle can be simulated in a straightforward manner.

We give a $(9+\epsilon)$-approximation for this problem in $b^{O(b)} \cdot n^{O(1)}$ time, where b is the size of a basis of the matroid $\mathcal{M}$. At a high level, our strategy is similar to our main result for the capacitated sum of radii problem. However, unlike the capacitated version, here we can always find the approximate locations of the optimal centers, which simplifies the algorithm and its analysis. Although this result is not the main contribution of our work, it provides a good vantage point to understand our result for capacitated sum-of-radii clustering.

We note that constant approximations are known for the matroid versions of k-center and k-median [9, 19]. These problems were originally motivated from the so-called red-blue median problem [16], where the centers come in one of the two *types*: red and blue, and we are required to select at most k_r red centers and k_b blue centers to minimize the k-median objective. The matroid formalization captures this scenario as well as its generalization for arbitrary number of types. In particular, the special case of one color corresponds to the k-constraint in the uncapacitated setting.

2 Sum of Radii with a Matroid Constraint

In this problem, we are given a finite metric space (P, d), and a matroid $\mathcal{M} = (P, \mathcal{I})$ on the set of points P. We want to place a set of balls to cover the points in P, while minimizing the sum of radii of the balls. Furthermore, it is required that the set of centers is an independent set in the given matroid.

Formally, we want to find a set of centers that forms an independent set, i.e., $C \in \mathcal{I}$ and assign radii $r : C \to \mathbb{R}^+$, such that $P \subseteq \bigcup_{c \in C} B(c, r(c))$. The objective is to minimize $\sum_{c \in C} r_c$, over all such feasible solutions.

Fix an optimal solution (C^*, r^*), and let $k = |C^*|$. Note that C^* is an independent set in $\mathcal{M}$. First, we guess the value of k by iteratively trying $k' = 1, 2, \ldots, b$, and returning the solution with smallest cost. Here, b denotes the size of any base in $\mathcal{M}$. For a particular value k', the algorithm runs in $k'^{O(k')} \cdot n^{O(1)}$ time. Note that the overall running time of this algorithm is $\sum_{k'=1}^{b} k'^{O(k')} \cdot n^{O(1)} = b^{O(b)} n^{O(1)}$. From now on, we will focus on the iteration where $k' = k$.

Before discussing our main algorithm, we discuss K-Center(U, r), which is an important subroutine. Here, $U \subseteq P$ is a set of points to be covered, and $r \geq 0$ denotes the target radius. It is a simple iterative procedure that selects an as-yet uncovered point p, and marks all points in its $2r$-neighborhood as covered. It also adds p to the set of centers Q, and this iterative procedure continues until all points in U are marked as covered. This is a well-known 2-approximation algorithm for the k-center problem, and is summarized in the following lemma.

▶ **Lemma 1.** *Let $U \subseteq P$ be a subset of points, and suppose there exists a set $C \subseteq P$ of k centers such that $\max_{u \in U} d(u, C) \leq r$. Then, the set of centers Q returned by* K-Center(U, r') *for any value $r' \geq r$ satisfies: (i) $|Q| \leq k$, and (ii) $\max_{u \in U} d(u, Q) \leq 2r'$.*

Algorithm 1 K-Center(U, r).

```
Initially, all points in U are marked as uncovered, Q ← ∅
while there exists an uncovered point in U do
    Let p ∈ U be an uncovered point, add p to Q
    Mark all points in B(p, 2r) as covered
return Q
```

Preprocessing

First, we discretize the possible choices of radii in the following way. Let $\epsilon > 0$ be a constant, and let R denote the smallest power of $1 + \epsilon$ larger than the maximum radius of any optimal ball – note that we can "guess" the value of R in polynomial time. Furthermore, for any ball with radius smaller than $\frac{\epsilon R}{k}$, we round its radius up to $\frac{\epsilon R}{k}$, and the total increase over at most k such balls is at most ϵR, which is at most ϵ times the optimal cost. Now, we round up radii of all balls to the next larger power of $(1 + \epsilon)$. Note that the resulting solution is within a factor of $(1 + \epsilon)^2$ from the cost of the optimal solution. Furthermore, there are $t = \log_{1+\epsilon} \frac{R}{\frac{R\epsilon}{k}} = O(\frac{1}{\epsilon} \log \frac{k}{\epsilon})$ distinct values of radii. Since ϵ is fixed, $t = O(\log k)$. From now onwards, we will slightly abuse the terminology, and use the terms "optimal solution", "optimal ball" etc. to refer to the corresponding entities in the optimal solution modified in this manner.

Define $r_1 = R, r_2 = \frac{R}{1+\epsilon}, \ldots, r_t = \frac{R}{(1+\epsilon)^{t-1}}$, where $r_{t+1} < \frac{R\epsilon}{k} \leq r_t$. Suppose for every $1 \leq i \leq t$, the optimal solution uses exactly $0 \leq k_i \leq k$ balls of radius r_i. Note that $\sum_{i=1}^{t} k_i = k$. Let $\mathcal{O} = \bigcup_{i=1}^{t} \mathcal{O}_i$ be the set of balls in the optimal solution, where $\mathcal{O}_i \subseteq \mathcal{O}_i$ is the subset of balls of radius r_i. Let $C^* \subseteq P$ denote the set of centers, and let $C^*_i \subseteq C^*$ denote the set of centers of the balls in $\mathcal{O}_i$. For a particular value of i, we define $\mathcal{O}_{<i} = \bigcup_{j=1}^{i-1} \mathcal{O}_j$, and the subsets $\mathcal{O}_{\leq i}, \mathcal{O}_{>i}, \mathcal{O}_{\geq i}$ (resp. $C^*_{\leq i}$ etc.) are defined similarly.

First, we guess the "radius profile" of the optimal solution. There are $O(\log k)$ classes of radii, and for each class r_i, $0 \leq k_i \leq k$. Therefore, the number of overall choices for the radius profile can be upper bounded by $k^{O(\log k)} \ll k^{O(k)}$.

Algorithm 2 MatroidSoR$(\mathcal{B}, i)$.

▷ $1 \le i \le t+1$ is the current level – we want to guess at most k_i centers for balls of radius $4r_i$
▷ $\mathcal{B}$ is the set of balls fixed at earlier levels 1 through $i-1$

$U_i \leftarrow P \setminus \left(\bigcup_{B\in\mathcal{B}} B\right)$ ▷ *Set of points not covered by balls in* $\mathcal{B}$

if $|P_i| > k$ **then** ▷ U_i *cannot be covered by at most* k *balls of radius* r_i
  return ▷ $\mathcal{B}$ *is a wrong guess*
else
  For every $C_i \subseteq P_i$ of size at most k_i, call MatroidSoR$(\mathcal{B} \cup \mathcal{B}(C_i), i+1)$
  ▷ $\mathcal{B}(C_i) \coloneqq \{B(c, 4r_i) : c \in C_i\}$

Algorithm

Having guessed the radius profile $(k_1, k_2, \ldots, k_t)$, our algorithm invokes MatroidSoR$(\emptyset, 1)$ (see Algorithm 2). The procedure MatroidSoR$(\mathcal{B}, i)$ is recursive, and proceeds in multiple *levels*. Fix $1 \le i \le t$, which denotes the current level. We are given a set of balls $\mathcal{B}$ selected at *higher* levels, i.e., levels 1 through $i-1$. For $1 \le j \le i-1$, we let C_j denote the set of centers of balls in $\mathcal{B}$ of level j. We know that $|C_j| \le k_j$, and each $c \in C_j$ has a ball of radius $4r_j$ around it. Now, we want to find a set of at most k_i centers to place balls of radius $4r_i$ at this level.

Let us now see how the algorithm MatroidSoR$(\mathcal{B}, i)$ places these balls at level i. We find U_i, the set of points not covered by any ball in $\mathcal{B}$. We then use algorithm K-Center(U_i, r_i) to find a solution to cover the points in U_i using balls of radius $2r_i$. We will later prove in Lemma 2 that if the set of balls $\mathcal{B}$ added to the solution so far is "correct" (formalized in the Lemma), then the solution P_i returned by the K-center algorithm contains at most k centers. Therefore, if $|P_i| > k$, we conclude that the set of balls $\mathcal{B}$ added to the solution so far is incorrect, and we stop.

Now, suppose $|P_i| \le k$. Then, we enumerate every subset $C_i \subseteq P_i$ of size at most k_i, and recurse on each subset. Note that the number of subsets can be upper bounded by $\sum_{i=0}^{k_i} \binom{k}{k_i} \le k^{O(k_i)}$. Assuming the set $\mathcal{B}$ is "correct", one of these $k^{O(k_i)}$ recursive calls is also "correct". Now we formalize this notion in the following Lemma.

▶ **Lemma 2.** *At any level $1 \le i \le t$, in one of the recursive calls to* MatroidSoR$(\mathcal{B}, i)$*, for any optimal center $c_j^* \in C_j^*$ with $1 \le j < i$, one of the following holds:*

1. *There exists $c \in C_\ell$ with $\ell \le j$, and $B(c_j^*, r_j) \subseteq B(c, 4r_\ell)$, OR*
2. *$B(c_j^*, r_j)$ is completely covered by balls in $\mathcal{B}$ of level 1 through $j-1$. In this case, there exists a center $c \in C_\ell$ with $\ell < j$, such that $d(c_j^*, c) \le 4r_\ell$.*

Proof. We prove this claim inductively.

Base case. This corresponds to $i = 2$. We want to show that, there exists a set $\mathcal{B}$ of balls chosen at level 1, such that, at the start of the algorithm MatroidSoR$(\mathcal{B}, 2)$, every ball $B(c_1^*, r_1) \in \mathcal{O}_1$ is contained in some ball in $\mathcal{B}$.

For the base case, consider the situation at the start of the algorithm, after we invoke MatroidSoR$(\emptyset, 1)$. Note that $U_1 = P$. Note that the optimal solution covers P using k balls of radius at most r_1. Consider the set P_1 of points returned by K-Center(U_1, r_1). Using Lemma 1, we have that $|P_1| \leq k$, and for any $c_1^* \in C_1^*$, there is some $\varphi(c_1^*) := c \in P_1$ with $d(c_1^*, c) \leq 2r_1$. Let $C_1 = \{\varphi(c_1^*) \mid c_1^* \in C_1^*\}$. Clearly, $|C_1| \leq |C_1^*| = k_1$, and for any $c_1^* \in C_1^*$, $B(c_1^*, r_1) \subseteq B(\varphi(c_1^*), 4r_1)$. Thus, the recursive call MatroidSoR$(\mathcal{B}(C_1), 2)$ satisfies the required properties.

Inductive hypothesis. Now we assume that the claim holds inductively at the start of iteration i, and prove that it also holds at level $i+1$ in one of the recursive calls. That is, fix a recursive call MatroidSoR$(\mathcal{B}, i)$, where $\mathcal{B}$ is a set of balls chosen at levels 1 through $i-1$, such that, any ball $B^* \in \mathcal{O}_{<i}$ is covered by a ball in $\mathcal{B}$, as guaranteed by the induction hypothesis. Now, let U_i^* be the set of points not covered by any such optimal ball (from $\mathcal{O}_{<i}$). Note that inductive hypothesis implies that $U_i \subseteq U_i^*$, which implies that U_i can be covered using at most k balls of radius at most r_i. Now, Lemma 1 implies that the set P_i of points returned by K-Center(U_i, r_i) has size at most k.

We will define a mapping $\varphi : C_i^* \to P_i \cup \{\perp\}$ that specifies a center in P_i whose ball covers $B(c_i^*, r_i)$, if any. Now, consider an optimal center $c_i^* \in C_i^*$, that has a ball $B^* = B(c_i^*, r_i)$ centered at it. We consider two different cases.

Case 1. If there exists a point $p \in B^* \cap U_i$, then using Lemma 1, there exists a center $c \in P_i$ returned by K-Center(U_i, r_i), such that $d(c, p) \leq 2r_i$. Since $d(c_i^*, c) \leq d(c_i^*, p) + d(p, c) \leq 3r_i$, $B(c_i^*, r_i) \subseteq B(c, 4r_i)$. In this case, we define $\varphi(c_i^*) = c$.

Case 2. Otherwise, $B^* \cap U_i = \emptyset$, which implies that all points in B^* are covered by the balls in $\mathcal{B}$ of levels 1 through $i-1$. In particular c_i^* is also covered by a ball $B(c, 4r_\ell)$, where $\ell < i$. In this case, we set $\varphi(c_i^*) = \perp$.

Note that the two cases correspond to the two criteria in the statement of the lemma. Furthermore, if $\varphi(c_i^*) = \perp$, then $B(c_i^*, r_i)$ is covered by one or more balls in $\mathcal{B}$ of levels 1 through $i-1$, i.e., we do not require a ball at level i to cover this ball. Otherwise, $\varphi(c_i^*) \in P_i$, and $B(c_i^*, r_i) \subseteq B(\varphi(c_i^*), 4r_i)$. Let $C_i := \{c \in P_i : \varphi^{-1}(c) \neq \emptyset\}$. Since $|C_i^*| = k_i$, $|C_i| \leq k_i$, and the recursive call corresponding to MatroidSoR$(\mathcal{B} \cup \mathcal{B}(C_i), i+1)$ satisfies the required properties, recalling that $\mathcal{B}(C_i) := \{B(c, 4r_i) : c \in C_i\}$. ◀

Now, let us discuss the algorithm at level $i = t+1$. Note that Lemma 2 implies that, all points must be covered at level $t+1$ in one of the recursive calls. Therefore, if $U_{t+1} \neq \emptyset$, then we conclude that the set of balls $\mathcal{B}$ is incorrect.

Henceforth, let $\mathcal{B}$ denote the set of balls at level $t+1$ guaranteed by Lemma 2, and focus on the call MatroidSoR$(\mathcal{B}, t+1)$. Note that $\mathcal{B}$ covers all points, which implies that U_{t+1} is empty. We now call the procedure Disjointify$(\mathcal{B})$, which we describe now. In this procedure, we assign each point in P to the largest ball in $\mathcal{B}$ that covers it, breaking ties arbitrarily. Let $D_j(c)$ denote the set of points assigned to a particular ball $B(c, 4r_j) \in \mathcal{B}$. Note that $D_j(c) \subseteq B(c, 4r_j)$; however the inclusion may be strict. In particular, it may be the case that $c \notin D_j(c)$, or $D_j(c)$ may even be empty.

Let $\mathcal{D}$ be the resulting collection of sets in $\mathcal{B}$ that are made disjoint in this manner. In order to distinguish the resulting disjoint sets from the original set of balls, we refer to them as *clusters*. The following observations follow from the definition of $\mathcal{B}$ and the description of Disjointify.

▶ **Observation 3.**

1. *The clusters in $\mathcal{D}$ partition P.*
2. *If an optimal center $c_i^* \in C_i^*$ is contained in a cluster $D_\ell(c) \in \mathcal{D}$, then $\ell \leq i$.*

Next, for every non-empty subset $\mathcal{D}' \subseteq \mathcal{D}$, we call MatroidIndependentSet$(\mathcal{D}', \mathcal{D})$. In this algorithm, we define a matroid $\mathcal{M}(\mathcal{D}', \mathcal{D})$ – see Algorithm 3 for the definition. It is easy to see that for any $\mathcal{D}' \subseteq \mathcal{D}$, that $\mathcal{M}(\mathcal{D}', \mathcal{D})$ is a (partition) matroid on P. We then find a common maximum independent set C in both matroids $\mathcal{M}$ and $\mathcal{M}(\mathcal{D}', \mathcal{D})$. Then, if $c \in C$ is contained in a cluster of level i in $\mathcal{D}$, then we place a ball of radius $9r_i$ around it. Next, we prove that, for at least one subset $\mathcal{D}' \subseteq \mathcal{D}$, the algorithm MatroidIndependentSet$(\mathcal{D}', \mathcal{D})$ finds a set of balls that covers the entire point set P.

Algorithm 3 MatroidIndependentSet$(\mathcal{D}', \mathcal{D})$.

1: Define a new matroid $\mathcal{M}(\mathcal{D}', \mathcal{D}) = (P, \mathcal{I}(\mathcal{D}'))$, where a set $C \subseteq P$ is independent in $\mathcal{I}(\mathcal{D}')$ iff it contains at most one point from each cluster in $\mathcal{D}'$, and no points from cluster in $\mathcal{D} \setminus \mathcal{D}'$
2: The weight of an independent set is equal to its size
3: Solve the maximum-weight matroid intersection problem for matroids $\mathcal{M}$ and $\mathcal{M}(\mathcal{D}', \mathcal{D})$ to find an independent set $C \subseteq P$
4: For every $c \in C$, place a ball of radius $9r_i$, if c is covered by a level i cluster in $\mathcal{D}$
5: **return** the resulting set of balls placed around each center in C

To this end, let $\mathcal{D}^* \subseteq \mathcal{D}$ denote the subset of clusters that contain at least one optimal center. This implies that clusters in $\mathcal{D} \setminus \mathcal{D}^*$ contain no optimal center. In the following claim, we focus on the call MatroidIndependentSet$(\mathcal{D}^*, \mathcal{D})$, and show that the set of balls found in this call covers P.

▶ **Lemma 4.** *The set of balls computed by* MatroidIndependentSet$(\mathcal{D}^*, \mathcal{D})$ *covers the entire set of points. Furthermore, the cost of this set of balls is upper bounded by* 9 *times the cost of* $\mathcal{B}$.

Proof. From every cluster in $\mathcal{D}^*$, pick an arbitrary optimal center, and let the resulting set be $\hat{C}^*$. Since $\hat{C}^* \subseteq C^*$, it is an independent set in $\mathcal{M}$. Furthermore, it contains exactly one point from each cluster in $\mathcal{D}^*$, and no point from any cluster in $\mathcal{D} \setminus \mathcal{D}^*$. Therefore, $\hat{C}^*$ is independent in the matroid $\mathcal{M}(\mathcal{D}^*, \mathcal{D})$.

Let C denote the maximum weight independent subset computed in MatroidIndependentSet$(\mathcal{D}^*, \mathcal{D})$. Thus $|C| \geq |\hat{C}^*|$. As C is independent in $\mathcal{M}(\mathcal{D}^*, \mathcal{D})$, this implies that C (like $\hat{C}^*$) contains exactly one point from each cluster in $\mathcal{D}^*$.

We prove that the set of balls, centered at C, computed at the end of MatroidIndependentSet$(\mathcal{D}^*, \mathcal{D})$, covers all points of P. Fix a point $p \in P$, and suppose it is covered by an optimal ball $B(c_j^*, r_j)$. From Observation 3, there exists a cluster $D_\ell(c) \in \mathcal{D}^*$ of level $\ell \leq j$ such that $c_j^* \in D_\ell(c)$. Therefore, $d(p, c) \leq r_j + 4r_\ell \leq 5r_\ell$. From the previous paragraph, there exists a center $c' \in C \cap D_\ell(c)$. Note that $d(c, c') \leq 4r_\ell$. This implies that, $d(p, c') \leq d(p, c) + d(c, c') \leq 5r_\ell + 4r_\ell = 9r_\ell$. Thus, p is covered by the ball of radius $9r_\ell$ centered at c'.

Finally, note that for every cluster in $\mathcal{D}^*$ of level i, we place at most one ball of radius $9r_i$. Therefore, the cost of the balls thus computed can be bounded by 9 times the cost of balls in $\mathcal{B}$. ◀

▶ **Theorem 5.** *For any fixed* $\epsilon \geq 0$*, there exists a* $(9 + O(\epsilon))$*-approximation algorithm to the Matroid Sum-of-radii problem that runs in* $b^{O(b)} \cdot n^{O(1)}$ *time, where* b *denotes the size of a base in the given matroid.*

Proof. We focus on a particular value of k', and show that the algorithm runs in $k'^{O(k')} \cdot n^{O(1)}$ time. Then, the running time guarantee follows, since $\sum_{k'=1}^{b} k'^{O(k')} = b^{O(b)}$, as previously discussed.

There are $k'^{O(\log k')}$ choices for guessing the "radius profile", and one of these choices corresponds to that of the modified optimal solution. Now fix this choice of the radius profile. At any level $1 \leq i \leq t$, there are at most $k'^{O(k_i)}$ recursive calls to the algorithm at level $i+1$. Therefore, the number of recursive calls at level $t+1$ can be bounded by $k'^{\sum_{i=1}^{t} O(k_i)} = k'^{O(k')}$. At level $t+1$, we call MatroidIndependentSet$(\mathcal{D}', \mathcal{D})$ for every non-empty $\mathcal{D}' \subseteq \mathcal{D}$. Thus, there are at most $2^{|\mathcal{D}|} \leq 2^{k'}$ calls to MatroidIndependentSet, and each matroid intersection problem can be solved in polynomial time, given access to the oracle for $\mathcal{M}$. Therefore, the algorithm terminates in $k'^{O(k')} \cdot n^{O(1)}$ time.

Now, consider the iteration when $k' = k$, and when we correctly guess the radius profile corresponding to the optimal solution. From Lemma 4, one of the calls to MatroidIndependentSet computes a solution that covers all the points, and the cost of this solution can be upper bound by 9 times the cost of the radius profile. Therefore, the cost of this solution can be upper bounded by $9 + O(\epsilon)$ times the cost of the *original* optimal solution. ◀

3 Uniform Capacitated Sum of Radii

Problem Definition

In this problem, we are given a finite metric space (P, d). We are also given a positive integer U, which denotes the *capacity*. We want to place a set of k balls $\mathcal{B}$, and assign each point of P to a ball containing it, such that no ball is assigned more than U points. Furthermore, we want to minimize the sum of radii of the balls in $\mathcal{B}$.

More formally, a feasible solution to the problem consists of a set of centers $C \subseteq P$ of size at most k, and a radius assignment $r : C \to \mathbb{R}^+$. Let $\mathcal{B}$ be the set of resulting balls. Note that the centers of balls in $\mathcal{B}$ are distinct. The solution also consists of an assignment $\mu : P \to \mathcal{B}$, such that p is contained in the ball $\mu(p)$, and $|\mu^{-1}(B)| \leq U$ for every $B \in \mathcal{B}$. Finally, the objective is find such a feasible solution that minimizes the sum of radii: $\sum_{B(c,r) \in \mathcal{B}} r$.

Notation

Let $P' \subseteq P$ be a subset of points, and let $\mathcal{B}'$ be some non-empty set of balls. Then, an assignment $\mu : P' \to \mathcal{B}'$ is said to be a *valid* assignment, if it satisfies the following two properties: (i) for every $p \in P', p \in \mu(p)$, and (ii) $|\mu^{-1}(B)| \leq U$ for any ball $B \in \mathcal{B}'$. In the following discussion, we will allow $\mathcal{B}'$ to contain concentric balls and even be a multi-set. But for simplicity of exposition, we will refer to a multi-set (resp. a multi-subset thereof) as simply a set (resp. a subset). Note that the definition of a valid assignment is consistent even if $\mathcal{B}$ is such a set of balls, by treating each copy of a ball in $\mathcal{B}$ as a distinct object.

Fix an optimal solution and the corresponding optimal assignment. We preprocess this solution in order to discretize the set of radii, exactly as done in the previous section. After this discretization, we assume that the solution uses exactly k_i balls of radius r_i, where $i \leq i \leq t$, and $t = O(\log k)$. Henceforth we will refer to the optimal solution modified in this manner. As in the previous section, let $\mathcal{O}$ denote the set of optimal balls, and $C^* \subseteq P$ be the set of optimal centers. The subsets $\mathcal{O}_i, \mathcal{O}_{\leq i}$ etc. of the optimal balls $\mathcal{O}$, and the subsets $C^*_i, C^*_{\leq i}$ etc. of the optimal centers are also defined as in the previous section. Furthermore, let $\mu_* : P \to \mathcal{O}$ be the optimal assignment. Note that μ_* is a valid assignment by definition.

Algorithm

Our algorithm invokes CapacitatedSoR$(\emptyset, 1)$. Now we describe CapacitatedSoR$(\mathcal{B}, i)$ (Algorithm 4), which is recursive and proceeds in multiple levels. At a particular level $1 \leq i \leq t$, we determine the set of balls of level i in the solution. At the start of the algorithm at level i, we are given a (multi-)set $\mathcal{B}$ of balls chosen earlier. $\mathcal{B}$ consists of balls of level 1 through $i-1$. Before we discuss the algorithm in iteration i, let us define some more notation.

Suppose a ball centered at c was added to $\mathcal{B}$ at level $j < i$ – its radius was $6r_j$ when it was added to $\mathcal{B}$. At every subsequent iteration $j+1 \leq \ell < i$, we expand its radius by an additive $2r_\ell$ factor. Thus, at the beginning of iteration i, the radius of this ball is $6r_j + \sum_{\ell=j+1}^{i-1} 2r_\ell$. Now, in iteration i, we will consider two versions of any ball in $\mathcal{B}$ – expanded and unexpanded. Consider a ball in $\mathcal{B}$, with center c, added during iteration $j < i$. At the beginning of iteration i, this ball has radius $6r_j + \sum_{\ell=j+1}^{i-1} 2r_\ell$; we refer to this as the unexpanded version. On the other hand, the expanded version has radius equal to $6r_j + \sum_{\ell=j+1}^{i} 2r_\ell$, which we denote by $E^i_j(c)$. Note that the expanded version $E^i_j(c)$ is larger than its corresponding version $B^i_j(c)$ by an additive $+2r_i$ factor. Therefore, if $B^* = B(c^*_i, r_i)$ has a non-empty intersection with $B^i_j(c)$, then $B^* \subseteq E^i_j(c)$.

Let $\mathcal{B}' \subseteq \mathcal{B}$ be any subset of balls chosen so far, and let $\overline{\mathcal{B}'} = \mathcal{B} \setminus \mathcal{B}'$. Let $E(\mathcal{B}')$ denote the set of expanded versions of balls in $\mathcal{B}'$. Finally, we define

$$\mathcal{I}(\mathcal{B}') \coloneqq \begin{cases} \left(\bigcap_{E \in E(\mathcal{B}')} E\right) \setminus \left(\bigcup_{B \in \overline{\mathcal{B}'}} B\right) & \text{if } \mathcal{B}' \neq \emptyset \\ P \setminus \left(\bigcup_{B \in \mathcal{B}} B\right) & \text{if } \mathcal{B}' = \emptyset \end{cases}$$

That is, if $\mathcal{B}'$ is non-empty, then $\mathcal{I}(\mathcal{B}')$ is exactly the set of points that belong to the common intersection of the expanded versions of balls in $\mathcal{B}'$, but not in any of the unexpanded versions of balls in $\overline{\mathcal{B}'}$. If $\mathcal{B}'$ is empty, then $\mathcal{I}(\mathcal{B}')$ is the set of points that does not belong to any unexpanded ball in $\mathcal{B}$. Note that if $\mathcal{B}' \subseteq \mathcal{B}$ is exactly the subset of balls that have non-empty intersection with an optimal ball $B(c^*_i, r_i)$, then $B(c^*_i, r_i) \subseteq \mathcal{I}(\mathcal{B}')$.

Let us return to the discussion of CapacitatedSoR$(\mathcal{B}, i)$. For each subset $\mathcal{B}' \subseteq \mathcal{B}$, we call Greedy$(\mathcal{B}', \mathcal{B}, r_i)$ (Algorithm 5). This Algorithm computes a set $P_i(\mathcal{B}')$ of at most $4k$ centers chosen in a certain "greedy" manner. This is the set of potential centers from the region $\mathcal{I}(\mathcal{B}')$ for placing balls of level i. The algorithm ensures that the distance between any two centers in $P_i(\mathcal{B})$ is greater than $4r_i$. Furthermore, if $P_i(\mathcal{B}') < 4k$, then each point in $\mathcal{I}(\mathcal{B}')$ is within distance $4r_i$ of some point in $P_i(\mathcal{B}')$. We repeat this process for every subset $\mathcal{B}'$ of $\mathcal{B}$ (including $\emptyset$).

We will first argue in Lemma 6 that, in some recursive call to the algorithm at level $i = t+1$, the set of balls $\mathcal{B}$ computed captures the optimal solution in an appropriate way. Having shown that this happens, the invocation of PostProcess$(\mathcal{B})$ (Algorithm 7) will appropriately modify the set of balls $\mathcal{B}$ and return a feasible solution. We will discuss the algorithm PostProcess and its analysis later.

▶ **Lemma 6.** *Fix a level $1 \leq i \leq t+1$. In one of the recursive calls to* CapacitatedSoR$(\mathcal{B}, i)$*, there exists an assignment that maps each point $p \in \mu_*^{-1}(\mathcal{O}_{<i})$ to a ball in $\mathcal{B}$ containing p, such that the number of points assigned to each ball does not exceed U.*

Proof. We prove this lemma inductively.

Algorithm 4 CapacitatedSoR$(\mathcal{B}, i)$.

if $i = t + 1$ **then**
  if PostProcess$(\mathcal{B}) \neq$ **fail then**
    return $\mathcal{B}(R)$ returned by PostProcess$(\mathcal{B})$ and **halt**
else
  For every $\mathcal{B}' \subseteq \mathcal{B}$, let $P_i(\mathcal{B}') \leftarrow$ Greedy$(\mathcal{B}', \mathcal{B}, r_i)$
  Let $P_i \leftarrow \bigcup_{\mathcal{B}' \subseteq \mathcal{B}} P_i(\mathcal{B}')$
  for every multi-subset $C_i \subseteq P_i$ of size at most k_i **do**
    Expand every ball in $\mathcal{B}$ by an additive $2r_i$ factor
    CapacitatedSoR$(\mathcal{B} \cup \mathcal{B}(C_i), i + 1)$ ▷ $\mathcal{B}(C_i) := \{B(c, 6r_i) : c \in C_i\}$

Algorithm 5 Greedy$(\mathcal{B}', \mathcal{B}, r)$.

Let $T \leftarrow \mathcal{I}(\mathcal{B}')$; start with all points of T as unmarked
$P(\mathcal{B}') \leftarrow \emptyset$
while $|P(\mathcal{B}')| < 4k$ and there is an unmarked point in T **do**
  $p \in T$ be an unmarked point with maximum number of unmarked points in $B(p, r) \cap T$
  Add p to $P(\mathcal{B}')$; mark all points in $B(p, 4r) \cap T$
return $P(\mathcal{B}')$

Base case

This corresponds to the start of the calls CapacitatedSoR$(\cdot, i)$, where $i = 2$. To this end, consider the invocation of the algorithm at the earlier level, i.e., CapacitatedSoR$(\emptyset, 1)$. Note that since $\mathcal{B} = \emptyset$, $\mathcal{B}' = \emptyset$, and there is only one call Greedy$(\emptyset, \emptyset, r_1)$. Note that the optimal solution uses $k_1 + k_2 + \ldots + k_t \leq k$ balls of radius at most r_1 in order to cover the entire set of points $P = \mathcal{I}(\mathcal{B}')$. Recall that the set of centers $P_1(\emptyset) = P_1$ returned by the Greedy algorithm has the property that any two centers in $P_1(\emptyset)$ are at least $4r_1$ away from each other. Therefore, $P_1(\emptyset)$ contains at most one point from each optimal ball, and thus $|P_1(\emptyset)| \leq k$. It follows that for any optimal center $c_1^* \in C_1^*$, there is a center $c \in P_1$, such that $d(c_1^*, c) \leq 4r_1$. That is, for every optimal ball $B^* = B(c_1^*, r_1) \in \mathcal{O}_1$, there exists $c \in P_1$, such that $B^* \subseteq B(c, 5r_1)$. We let $\varphi(B^*) := c$ (select a nearest c form c_1^* there are multiple such $c \in P_1$). Let $C_1 \subseteq P_1$ be the multi-set that is the image of the mapping $\varphi : \mathcal{O}_1 \to P_1$, where the multiplicity of each $c \in C_1$ is equal to $|\varphi^{-1}(c)|$. Therefore, for each $B^* \in \mathcal{O}_1$ the points in $\mu_*^{-1}(B^*)$ can be reassigned to a unique ball in $\mathcal{B}(C_1)$ centered at $\varphi(B^*) \in C_1$. This completes the proof for the base case.

Note that we were able to "guess" the locations of the optimal centers approximately in the base case. However, we cannot accomplish this in the subsequent levels, because some optimal balls may be contained in larger optimal balls. This is what complicates the algorithm and its analysis. Nevertheless, we will argue that we can find an appropriate set of substitute centers whenever necessary that will facilitate the reassignment process.

Inductive hypothesis

Suppose during some invocation of the algorithm CapacitatedSoR$(\mathcal{B}, i)$ at level i, we have a set of balls $\mathcal{B}$ of levels $1 \leq j < i$, such that the set of points $\mu_*^{-1}(\mathcal{O}_{<i})$ can be assigned to the balls in $\mathcal{B}$. Let us also suppose that we have a mapping $\varphi : \mathcal{O}_{<i} \to C_{<i}$, where $C_{<i}$ denotes the set of centers of balls in $\mathcal{B}$.

Inductive Step

We first sketch the high level idea. Here, we will extend φ to include $\mathcal{O}_i$, i.e., we will map every optimal ball in $\mathcal{O}_i$ to a center in P_i; where P_i is the set of centers computed in lines 5 and 6 of Algorithm 4. Now, let $C_i \subseteq P_i$ be the image of $\varphi(\mathcal{O}_i)$, where the multiplicty of each $c \in P_i$ is set to be $|\varphi^{-1}(c)|$. Note that $|C_i| = |\mathcal{O}_i| = k_i$. Having found such a mapping, we will consider an optimal ball $B_i^* = B(c_i^*, r_i) \in \mathcal{O}_i$, and reassign points in $\mu_*^{-1}(B_i^*)$ to the balls in $\mathcal{B} \cup \mathcal{B}(C_i)$. We will use the ball $\varphi(B_i^*)$ to show that this reassignment can be done without violating the capacities. Doing this for every optimal ball in $\mathcal{O}_i$, we will show that all points in $\mu_*^{-1}(\mathcal{O}_{\leq i})$ are assigned to balls in $\mathcal{B} \cup \mathcal{B}(C_i)$. Now we discuss the details of this inductive argument.

For any $B^* = B(c_i^*, r_i) \in \mathcal{O}_i$, if there is $c \in P_i$ such that $B^* \subseteq B(c, 6r_i)$, then we set $\varphi(B_i^*) = c$ (choosing a nearest such c from c^*, if there are multiple such $c^* \in P_i$). Let $\mathcal{O}_i^1 \subseteq \mathcal{O}_i$ be the subset that is mapped in such way, and let $C_i^1 \subseteq P_i$ be its image (with multiplicity $\varphi^{-1}(c)$ for every $c \in C_i^1$). Note that all the points assigned a ball $B_i^* \in \mathcal{O}_i^1$, are also contained in the ball $B(c, 6r_i)$, where $c = \varphi(B_i^*)$. Therefore, we can reassign points in $\mu_*^{-1}(B_i^*)$ to the ball $B(c, 6r_i)$.

Now, let $\mathcal{O}_i^2 \coloneqq \mathcal{O}_i \setminus \mathcal{O}_i^1$ be the set of optimal balls not mapped so far. We will map each ball in $\mathcal{O}_i^2$ to a unique center in $P_i \setminus C_i^1$, and use this mapping to compute the required reassignment. We describe the assignment in the following mapping procedure – note that this is used only in the analysis.

Algorithm 6 Mapping procedure.

1: Suppose all balls in $\mathcal{O}_i^2$ are unmapped at the beginning; let $C_i^2 \leftarrow \emptyset$
2: **for** each subset $\mathcal{B}' \subseteq \mathcal{B}$ in an arbitrary order **do**
3: Let $\mathcal{O}_i^2(\mathcal{B}') \subseteq \mathcal{O}_i^2$ be the subset of *unmapped* balls contained in $\mathcal{I}(\mathcal{B}')$
▷ *Unmapped balls in $\mathcal{O}_i^2$ are the balls that have not yet been mapped using φ in an earlier iteration.*
4: Let $F_i(\mathcal{B}') \subseteq P_i(\mathcal{B}')$ include every point that:
(i) belongs to C_i^1, or (ii) is chosen as a center of a ball in $\mathcal{B}$, or
(iii) is within $2r_i$ from some center in C_i^2, or
(iv) is within $r_i + r_j$ from some center in C_j^*, where $j \geq i$, or
(v) belongs to $C_{<i}^*$.
5: Extend φ to $\mathcal{O}_i^2(\mathcal{B}')$ by arbitrarily mapping each ball in $\mathcal{O}_i^2(\mathcal{B}')$ to a unique center in $P_i(\mathcal{B}') \setminus F_i(\mathcal{B}')$.
6: Let $C_i^2(\mathcal{B}')$ be the image of $\mathcal{O}_i^2(\mathcal{B}')$, under the above mapping φ.
7: Mark all balls in $\mathcal{O}_i^2(\mathcal{B}')$ as mapped, and add $C_i^2(\mathcal{B}')$ to C_i^2.

▷ Claim 7. For any $\mathcal{B}' \subseteq \mathcal{B}$, if $\mathcal{O}_i^2(\mathcal{B}') \neq \emptyset$, then $|\mathcal{O}_i^2(\mathcal{B}')| \leq |P_i(\mathcal{B}') \setminus F_i(\mathcal{B}')|$. That is, there are enough centers available in $P_i(\mathcal{B}') \setminus F_i(\mathcal{B}')$ to be mapped in Line 5.

Proof. Since $\mathcal{O}_i^2(\mathcal{B}') \neq \emptyset$, let $B(c_i^*, r_i) \in \mathcal{O}_i^2(\mathcal{B}')$. Note that $c_i^* \in \mathcal{I}(\mathcal{B}')$, and $B(c_i^*, r_i) \subseteq \mathcal{I}(\mathcal{B}')$.

Consider the call $\textsc{Greedy}(\mathcal{B}', \mathcal{B}, r_i)$. We first claim that the while loop ends with $|P_i(\mathcal{B}')| = 4k$. Suppose for the contradiction that the while loop ends because all points in $P_i(\mathcal{B}')$ are marked. Let c be the point added to $P_i(\mathcal{B}')$ when c_i^* is marked. Then, $d(c_i^*, c) \leq 4r_i$. Thus, $B(c_i^*, r_i) \subseteq B(c, 6r_i)$, which implies that $B(c_i^*, r_i) \in \mathcal{O}_i^1$. This is a contradiction, since $B(c_i^*, r_i) \in \mathcal{O}_i^2$.

Now we claim that $|F_i(\mathcal{B}')| \leq 3k$, by considering each of the five conditions ($F_i(\cdot)$ stands for centers *forbidden* due to one of the five conditions). Conditions (i) and (ii) include at most $\sum_{j=1}^{i-1} k_j$, and at most k_i points respectively. Therefore, k is an upper bound for points satisfying conditions (i) and (ii).

We now claim that k_i is also an upper bound for points satisfying condition (iii). To this end, we claim that for $c \in C_i^2$, there is at most one $c \in P_i(\mathcal{B}')$ such that $d(c, c') \leq 2r_i$. Suppose that there are two distinct such points $c_1, c_2 \in P_i(\mathcal{B}')$. Then, $d(c_1, c_2) \leq d(c, c_1) + d(c, c_2) \leq 4r_i$. This is a contradiction, since the distance between any two points in $P_i(\mathcal{B}')$ is greater than $4r_i$. Finally, since $|C_i^2| \leq k$, k is also an upper bound on the centers excluded due to condition (iii).

A similar proof also shows that for any fixed $c_j^* \in C_j^*$ with $j \geq i$, there is at most one $c \in P_i(\mathcal{B}')$ with $d(c_j^*, c) \leq r_i + r_j$. Therefore, $\sum_{j=i}^{t} k_j$ is an upper bound for points satisfying condition (iv). $\sum_{j=1}^{i-1} k_j$ is an upper bound on condition (v). Therefore, k is an upper bound on conditions (iv) and (v) together.

Putting everything together, $|F_i(\mathcal{B}')| \leq 3k$, which implies that $|P_i(\mathcal{B}') \setminus F_i(\mathcal{B}')| \geq k$. Therefore, each ball in $\mathcal{O}_i^2(\mathcal{B}')$ can be mapped to a unique point in $|P_i(\mathcal{B}')|$. ◁

The next claim is used later to argue that the reassignment can be done using the mapping φ constructed in this manner.

▷ Claim 8. Fix $\mathcal{B}' \subseteq \mathcal{B}$ and a ball $B^* = B(c_i^*, r_i) \in \mathcal{O}_i^2(\mathcal{B}')$. If $\varphi(B^*) = c$, then $|B(c, r_i) \cap \mathcal{I}(\mathcal{B}')| \geq |B^*| \geq |\mu_*^{-1}(B^*)|$.

Proof. We first claim that no point in B^* is marked in $\textsc{Greedy}(\mathcal{B}', \mathcal{B}, r_i)$. Otherwise, let $c' \in \mathcal{I}(B^*)$ be the point added to $P_i(\mathcal{B}')$ when a point $p \in B^*$ was marked. Then, $d(c', c_i^*) \leq d(c', p) + d(p, c_i^*) \leq 5r_i$, which implies that $B^* \subseteq B(c', 6r_i)$, which implies that $B(c_i^*, r_i) \in \mathcal{O}_i^1$. This is a contradiction, since $B(c_i^*, r_i) \in \mathcal{O}_i^2$. Therefore no point in $B^* \cap \mathcal{I}(\mathcal{B}') = B^*$ is marked until the end of the while loop.

Now, consider the beginning of the iteration when c was added to $P_i(\mathcal{B}')$. At this point, c_i^* is also a candidate. Since c is chosen over c_i^*, it implies that $|B(c, r_i) \cap \mathcal{I}(\mathcal{B}')| \geq |B^*| \geq |\mu_*^{-1}(B^*)|$, where the last inequality holds by definition. ◁

We use this claim to show that we can reassign points from $\mu_*^{-1}(\mathcal{O}_i^2)$ to balls in $\mathcal{B} \cup \mathcal{B}(C_i)$, where $C_i = C_i^1 \cup C_i^2$. Recall that we have already reassigned points $\mu_*^{-1}(\mathcal{O}_i^1)$ to C_i^1.

Now let us consider the optimal balls in $\mathcal{O}_i^2$ in the same order in which they were mapped in Algorithm 6. Consider an optimal ball $B^* = B(c_i^*, r_i)$, and suppose it was mapped in the iteration corresponding to $\mathcal{B}' \subseteq \mathcal{B}$. That is, $B^* \in \mathcal{O}_i^2(\mathcal{B}')$. Let $c = \varphi(B^*)$. Because of condition (v), there is no optimal center $c_j^* \in C_j^*$ with $j \geq i$, such that $B(c_j^*, r_j) \cap B(c, r_i) \neq \emptyset$. Therefore, all points in $B = B(c, r_i)$ are assigned to balls in $\mathcal{O}_{<i}$ in the optimal assignment μ_*. Furthermore, because of condition (iv), there is no other center $c' \in C_i^2$ within distance $2r_i$ from c, which implies that points in B have not been currently assigned to a ball in $\mathcal{B}(C_i)$. Therefore, by the inductive hypothesis, these points are assigned to balls in $\mathcal{B}$.

Now we reassign m points from the set $B \cap \mathcal{I}(\mathcal{B}')$ to the ball $B(c, 6r_i)$, where $m = \min\{U, |B \cap \mathcal{I}(\mathcal{B}')|\}$. These points are originally assigned to balls in $\mathcal{B}$. As they are contained in $\mathcal{I}(\mathcal{B}')$, no such point belongs to a ball in $\mathcal{B} \setminus \mathcal{B}'$, by the definition of $\mathcal{I}(\mathcal{B}')$. Thus, these points are assigned to balls in $\mathcal{B}'$. Their reassignment to $B(c, 6r_i)$ collectively frees up m units of capacity from balls in $\mathcal{B}'$. Note that B^* is also completely contained in $\mathcal{I}(\mathcal{B}')$, and $m \geq |\mu_*^{-1}(B^*)|$ by Claim 8. Therefore, we can use the freed capacity of balls in $\mathcal{B}'$ to assign points in $\mu_*^{-1}(B^*)$.

We perform this reassignment process for each ball in $\mathcal{O}_i^2$. Therefore, at the end, every point in $\mu_*^{-1}(\mathcal{O}_{\leq i})$ is assigned to a ball in $\mathcal{B} \cup \mathcal{B}(C_i)$. This finishes the proof of Lemma 6. ◀

Using Lemma 6 at level $t+1$, we know that there exists a recursive call to CapacitatedSoR$(\mathcal{B}, t+1)$, such that the set of points in $\mu_*^{-1}(\mathcal{O}) = P$ can be assigned to the balls in $\mathcal{B}$ without violating capacities. Fix such a recursive call. With this, let us define $C^1 = \bigcup_{i=1}^{t} C_i^1$, and $C^2 = \bigcup_{i=1}^{t} C_i^2$, and let $C = C^1 \cup C^2$. Note that there may be several concentric balls in $\mathcal{B}$. We want to move the concentric balls to "nearby" unique centers in order to obtain a feasible solution. The following observations, which follow from the description of the mapping procedure (see Algorithm 6), will aid us in doing this.

▶ **Observation 9.**

1. *For any $c \in C_i^1$, define $R^*(c)$ to be the set of optimal centers of the balls in $\varphi^{-1}(c)$.*
   (A) The sets $\{R^*(c)\}_{c \in C^1}$ are pairwise disjoint, i.e., for distinct $c_1, c_2 \in C^1$, we have that $R^*(c_1) \cap R^*(c_2) = \emptyset$.
   (B) $R^*(c) \subseteq B(c, 5r_i)$ for any $c \in C_i^1$.
2. *For any $c \in C^2$, define $R^*(c) \coloneqq \{c\}$*
   (A) $|\varphi^{-1}(c)| = 1$ for all $c \in C^2$
   (B) $C^2 \cap C^* = \emptyset$, and
   (C) $C^2 \cap C^1 = \emptyset$.
3. *Items 1 and 2 imply that the sets $\{R^*(c)\}_{c \in C}$ are pairwise disjoint.*

Proof. For item 1.A, note that $\varphi : \mathcal{O} \to C$ is a many-to-one function, and that every ball in $\mathcal{O}$ has a distinct center. Item 1.B follows from the definition of φ.

Claims in item 2 follow from the definition of set of *forbidden* centers $F_i(\mathcal{B}')$ in the mapping procedure (see line 4). ◀

Now we are ready to show that, when PostProcess$(\mathcal{B})$ (Algorithm 7) is called from CapacitatedSoR$(\mathcal{B}, t+1)$, where $\mathcal{B}$ is the set of balls guaranteed by Lemma 6, it successfully returns a feasible solution.

Algorithm 7 PostProcess$(\mathcal{B})$.

1: For every $1 \le i \le t$, and every $c \in C_i$, find a set $R(c) \subseteq B(c, 5r_i)$ where $|R(c)|$ equals the multiplicity of c in C_i and the sets $R(c)$ are pairwise disjoint for all $c \in C$
   This can be solved using a max-flow problem
2: **if** such a collection of sets $R(c)$ does not exist: **return fail**
3: Let $R = \bigcup_{c \in C} R(c)$, and let $\mathcal{B}(R) \coloneqq \{B(c, \alpha \cdot r_i) : c \in R\}$
   ▷ *α is defined below in the proof of Lemma 10*
4: Check whether there exists a feasible assignment from P to the balls in $\mathcal{B}(R)$
   This can be solved using a max-flow problem
5: **if** a feasible assignment exists: **return** $\mathcal{B}(R)$; **else**: **return fail**

▶ **Lemma 10.** PostProcess$(\mathcal{B})$ *succeeds in finding a set of balls $\mathcal{B}(R)$, and there is a feasible assignment $\mu' : P \to \mathcal{B}(\mathcal{R})$.*

Proof. From Lemma 6, there exists a feasible assignment $\mu : P \to \mathcal{B}$, however there may be concentric balls in the set $\mathcal{B}$. However, Observation 9 implies that the sets $R^*(c)$ are pairwise disjoint for $c \in C$, and that $R^*(c) \subseteq B(c, 5r_i)$ for a center $c \in C_i$. Therefore, in line 1 of Algorithm PostProcess$(\mathcal{B})$, we can successfully find the sets $R(c)$ as claimed. Note that $R(c) \subseteq B(c, 5r_i)$.

From Lemma 6, for any $B = B(c, 6r_i) \in \mathcal{B}$, $\mu^{-1}(B) \subseteq E_i^t(c)$. Note that the radius of the expanded version of the ball $E_i^t(c)$ is equal to $6r_i + \sum_{\ell=i+1}^{t} 2r_\ell \leq \alpha' \cdot r_i$, for some α'. Therefore, for any point $p \in \mu^{-1}(B)$, and any $c' \in R(c)$, we have that $d(p, c') \leq 5r_i + \alpha' r_i = (\alpha' + 5)r_i = \alpha r_i$ [1]. This implies that, in line 4 of the Algorithm 7, we can find such a feasible assignment μ'. ◀

▶ **Lemma 11.** CapacitatedSoR$(\emptyset, 1)$ *runs in* $2^{O(k^2)} \cdot n^{O(1)}$ *time.*

Proof. Fix a level $1 \leq i \leq t$, and consider CapacitatedSoR$(\mathcal{B}, i)$. At the beginning of the algorithm, $|\mathcal{B}| \leq k$, therefore the number of subsets can be upper bound by 2^k, which implies that $|P_i| \leq 4k \cdot 2^k$. Now, let $k_i' \leq k_i$ denote the size of the set C_i without multiplicities. Therefore, there are $\sum_{k_i'=1}^{k_i} \binom{4k \cdot 2^k}{k_i'} = \left(4k \cdot 2^k\right)^{O(k_i)} = 2^{O(k \cdot k_i)}$ number of choices for selecting the set C_i (without multiplicities). For a fixed choice of C_i, there are at most $(k_i)^{k_i'} = k^{O(k_i)}$ choices for placing one or more copies at each location in C_i. We make a recursive call for each such choice of the multi-set C_i. The overall number of recursive calls to level $i+1$ can be upper bounded by $k^{O(k_i)} \cdot 2^{O(k \cdot k_i)} = 2^{O(k \cdot k_i)}$.

Let $T(i)$ denote the running time of the algorithm at level i. Then, we have the following recurrence relation: $T(i) = 2^{O(k \cdot k_i)} \cdot T(i+1) + 2^{O(k \cdot k_i)} \cdot n^{O(1)}$.
Furthermore, $T(t+1) = n^{O(1)}$, since PostProcess runs in time polynomial in n. This recurrence solves to $T(1) = 2^{O(k^2)} \cdot n^{O(1)}$, where we use the fact that $\sum_{i=1}^{t} k_i = k$. ◀

▶ **Theorem 12.** *There exists a* 28*-approximation for the Capacitated Sum of Radii problem that runs in* $2^{O(k^2)} \cdot n^{O(1)}$ *time.s*

Proof. There are $O(n^2)$ choices for guessing the maximum radius, and $k^{O(\log k)}$ choices for guessing the radius profile of the optimal solution. Note that we lose a factor of $(1+\epsilon)^2$ in the latter step. Now, fix the correct value of maximum radius and the radius profile that corresponds to the modified optimal solution. By Lemma 11, the algorithm CapacitatedSoR$(\emptyset, 1)$ runs in $2^{O(k^2)} \cdot n^{O(1)}$ time for any fixed choice of the radius profile.

Furthermore, By Lemma 10, there exists a recurse call at level $t+1$, that returns a feasible solution. Finally, for any $1 \leq i \leq t$ we use k_i balls of radius αr_i in this solution, whereas the optimal solution uses k_i balls of radius r_i. Therefore, the approximation guarantee is at most $(1+\epsilon)^2 \cdot \alpha$, where α is as in Lemma 10. Choosing $\epsilon \approx 0.267$, the above quantity can be upper bounded by 28. ◀

4 Conclusion

We obtain constant approximations for the uniform capacitated sum of radii problem in FPT time. It is unclear whether a similar result can be obtained in polynomial time. Finally, obtaining a constant approximation for the matroid version of the problem in polynomial time remains open.

[1] It can be shown that $\alpha = \frac{2+11 \cdot \epsilon(1+\epsilon)}{\epsilon(1+\epsilon)}$.

Abstract

In the Boolean maximum constraint satisfaction problem – Max CSP(Γ) – one is given a collection of weighted applications of constraints from a finite constraint language Γ, over a common set of variables, and the goal is to assign Boolean values to the variables so that the total weight of satisfied constraints is maximized. There exists a concise dichotomy theorem providing a criterion on Γ for the problem to be polynomial-time solvable and stating that otherwise it becomes NP-hard. We study the NP-hard cases through the lens of kernelization and provide a complete characterization of Max CSP(Γ) with respect to the optimal compression size. Namely, we prove that Max CSP(Γ) parameterized by the number of variables n is either polynomial-time solvable, or there exists an integer $d \geq 2$ depending on Γ, such that:

1. An instance of Max CSP(Γ) can be compressed into an equivalent instance with $\mathcal{O}(n^d \log n)$ bits in polynomial time,
2. Max CSP(Γ) does not admit such a compression to $\mathcal{O}(n^{d-\varepsilon})$ bits unless NP $\subseteq$ co-NP/poly.

Our reductions are based on interpreting constraints as multilinear polynomials combined with the framework of constraint implementations. As another application of our reductions, we reveal tight connections between optimal running times for solving Max CSP(Γ). More precisely, we show that obtaining a running time of the form $\mathcal{O}(2^{(1-\varepsilon)n})$ for particular classes of Max CSPs is as hard as breaching this barrier for Max d-SAT for some d.

1 Introduction

Background and motivation. The framework of constraint satisfaction problems (CSPs) allows the computational complexity of a large class of problems to be studied through a common lens [11]. A typical instance of such a problem asks whether it is possible to assign each of the variables $x_1, \ldots, x_n$ a value from a finite domain D, such that a given list of constraint applications is satisfied. A constraint is applied to a fixed number of variables, and indicates which combinations of values are legal. In the Max CSP problem, the goal is to maximize the number of satisfied constraints. See Section 2 for formal definitions.

The investigation of CSPs has led to deep theorems characterizing the complexity of a CSP based on the type of constraints allowed in the instance [7, 24]. For example, the long-awaited CSP dichotomy theorem [6, 35] provides a criterion separating the NP-complete from the polynomial-time solvable CSPs; the work of Khanna, Sudan, Trevisan, and Williamson characterizes how well the maximization version of a Boolean CSP can be approximated [21] (see [13, 20] for larger domains; see [12, 27] for optimal approximation factors); and Cai and Chen [8] present a dichotomy that separates CSPs for which the number of complex-weighted solutions can be counted in polynomial time, from those where the problem is #P-hard.

In this work we analyze the complexity of constraint satisfaction in an algorithmic regime that is currently far from understood: polynomial-time compression and kernelization [15]. Here, the goal is to analyze how much (in terms of the number of variables n) an instance can be compressed by a polynomial-time algorithm without changing the answer, and to understand how the compressibility depends on the type of available constraints. A *compression* is a polynomial-time algorithm that reduces instances of one problem to equivalent, small instances of a potentially different problem; a *kernelization* compresses to an instance of the same problem (see Section 2.4). A kernelization of small size allows an instance to be stored, manipulated, and solved more efficiently. It is therefore of interest to find the smallest possible kernelizations. Since every kernelization yields a compression, one can prove lower bounds on the size of kernelizations by establishing lower bounds on compressions.

In recent years, there have been a number of advances in the understanding of compressibility of CSPs [9, 14, 18, 25]. A foundational result by Dell and van Melkebeek [14] states that for $d \geq 3$, CNF-SAT with clauses of size at most d (d-CNF-SAT) parameterized by the number of variables n admits no (polynomial-time) compression of size $\mathcal{O}(n^{d-\varepsilon})$ for any $\varepsilon > 0$, unless NP $\subseteq$ co-NP/poly (which is known to imply a collapse of the polynomial hierarchy [34]). As an instance of d-CNF-SAT can trivially be compressed to $\mathcal{O}(n^d)$ bits via a bitstring that encodes for each of the $\mathcal{O}(n^d)$ possible clauses whether or not it is present in the instance, the d-CNF-SAT problem does not admit any non-trivial compression. The situation is different for the related problem d-Not-All-Equal SAT (d-NAE-SAT), which is the variant where a clause is satisfied when its literals do not all evaluate to the same value. Jansen and Pieterse showed [17, 18] that for $d \geq 3$, the d-NAE-SAT problem has a compression of size $\mathcal{O}(n^{d-1} \log n)$, but not of size $\mathcal{O}(n^{d-1-\varepsilon})$ unless NP $\subseteq$ co-NP/poly. This example shows that the type of constraints affects the compressibility of a CSP.

The notion of a *constraint language* is used to rigorously analyze how the complexity of a CSP depends on the type of constraints. In this work, we will only consider CSPs over the Boolean domain: we work exclusively with Boolean constraints and constraint languages. A constraint is therefore a function of the form $f\colon \{0,1\}^k \to \{0,1\}$, where $k \geq 1$ is the *arity* of the constraint, also denoted as $\text{AR}(f)$. A constraint language Γ is a *finite* set of constraints. The input of the corresponding decision problem, denoted CSP(Γ), consists of a set of constraint applications of the form $f(x_{j_1}, \ldots, x_{j_{\text{AR}(f)}}) = 1$ over n common variables, where f is some constraint from Γ. The question is whether there is an assignment $\{x_1, \ldots, x_n\} \to \{0,1\}$ satisfying all the constraint applications.

In this terminology, Chen, Jansen, and Pieterse [9] characterized for all (Boolean) constraint languages Γ consisting of constraints of arity at most three, what the optimal compression size is for CSP(Γ). Lagerkvist and Wahlström [25] gave universal-algebraic conditions on Γ which ensure that CSP(Γ) has a compression of size $\mathcal{O}(n \log n)$, and a characterization is known of the constraint languages Γ_{sym} consisting entirely of *symmetric* functions for which CSP(Γ_{sym}) has a compression of near-linear size [9, §5]. Hence there is some understanding of the optimal compressibility of CSP(Γ).

However, when we move from the question of whether *all* constraints can be satisfied to the task of maximizing the number of satisfied constraints (Max CSP), the situation is much less understood. To the best of our knowledge, no non-trivial compressions are known for any Max CSP(Γ), and no compression lower bounds are known for Max CSP(Γ) other than those already implied from CSP(Γ). In this paper, we therefore analyze the compressibility of Max CSP(Γ).

Before presenting our results, we briefly summarize the main algorithmic approach for compressing CSP(Γ) and illustrate why it fails completely for Max CSP. Consider for example 3-NAE-SAT. The number of constraint applications in an n-variable instance of this problem can be reduced to $\mathcal{O}(n^2)$ without changing the solution space, which allows it to be encoded in $\mathcal{O}(n^2 \log n)$ bits. The *sparsification* to $\mathcal{O}(n^2)$ constraint applications is achieved by a linear-algebraic approach. Note that a not-all-equal constraint on variables $(x, y, z) \in \{0,1\}^3$ is satisfied if and only if $x + y + z - xy - xz - yz - 1 = 0$. Observe that if $p_1(x_1, \ldots, x_n) = 0, \ldots, p_m(x_1, \ldots, x_n) = 0$ are polynomial equalities which are satisfied by an assignment to $x_1, \ldots, x_n$, then also $\sum_{i=1}^{m} \alpha_i \cdot p_i(x_1, \ldots, x_n) = 0$ holds for any linear combination as determined by $\alpha_1, \ldots, \alpha_m$. To sparsify a 3-NAE-SAT instance with this insight, proceed as follows. Transform each constraint c_i into an equality $p_i(x_1, \ldots, x_n) = 0$ for a degree-2 polynomial p_i, substituting $1 - v$ for negated variables $\neg v$ in the constraint. This yields a system of equations of degree-2 polynomials in n variables, which have $\mathcal{O}(n^2)$ distinct monomials. The rank of a corresponding vector space is therefore $\mathcal{O}(n^2)$, which yields a basis of $\mathcal{O}(n^2)$ equalities such that all others can be expressed as their linear combinations. All constraints not corresponding to an element of this basis can be safely omitted from an instance of 3-NAE-SAT, since they will be automatically satisfied by any assignment that satisfies *all* basis constraints. This yields the claimed sparsification of $\mathcal{O}(n^2)$ constraints. Note, however, that this approach fails completely for the variant Max 3-NAE-SAT: if an assignment *does not* satisfy all constraints of the basis, this does not give any satisfaction guarantees on the linearly-dependent constraints. Hence the sparsification approach for CSP(Γ) is not applicable for Max CSP(Γ).

Our results. We provide a new route to compression for Max CSP(Γ), and prove that the resulting compressions are *essentially optimal* for all constraint languages Γ, assuming NP $\not\subseteq$ co-NP/poly. Our results characterize the optimal compressibility of all Boolean Max CSPs in terms of degrees of characteristic polynomials, and uncover a wide range of Max CSP(Γ) problems that admit a non-trivial compression. For a Boolean function $f\colon \{0,1\}^k \to \{0,1\}$, its *characteristic polynomial* is the *unique* k-variate multilinear polynomial $P_f(x)$ over $\mathbb{R}$ that agrees with f on all $x \in \{0,1\}^k$. The fact that this representation is unique is well-known (cf. [29]). For a constraint language Γ, define $\deg(\Gamma) = \max_{f \in \Gamma} \deg(P_f)$. We prove that $\deg(\Gamma)$ characterizes the compressibility of Max CSP(Γ).

To state our results precisely, we have to address a feature of the problem that is particular to the maximization variant: repetitions of constraint applications. While such repetitions are irrelevant in the CSP setting when all constraint applications have to be satisfied, they become relevant when maximizing the number of satisfied constraint applications. The standard approach in the Max CSP literature is therefore to give each constraint application a positive integer weight value [11, 21]. The decision problem Max CSP(Γ) then takes as input a system of Γ-constraint applications with weights from $\mathbb{N}$, and a threshold value t, and asks whether there is an assignment such that the weight of the satisfied constraint applications is at least t.

Let Γ be a (finite, Boolean) constraint language.[1] Our main positive result is the following.

▶ **Theorem 1.1.** *Max CSP(Γ) parameterized by the number of variables n, with positive integer weights bounded by $n^{\mathcal{O}(1)}$, admits a compression of size $\mathcal{O}\big(n^{\deg(\Gamma)} \log n\big)$.*

In fact, we are even able to reduce any instance of Max CSP(Γ) to an equivalent instance of the *same* problem, having $\mathcal{O}\big(n^{\deg(\Gamma)}\big)$ weighted constraint applications. We prove matching lower bounds whenever Max CSP(Γ) is NP-complete. It is known [10, 11, 21] that for inputs with positive integer weights, Max CSP(Γ) is polynomial-time solvable if Γ is 0-valid, 1-valid, or 2-monotone (see Section 2.1), and NP-complete otherwise.

▶ **Theorem 1.2.** *If Γ is not 0-valid, 1-valid, or 2-monotone, then assuming NP $\not\subseteq$ co-NP/poly, Max CSP(Γ) parameterized by the number of variables n, with positive integer weights bounded by $n^{\mathcal{O}(1)}$, does not admit a compression of size $\mathcal{O}\big(n^{\deg(\Gamma)-\varepsilon}\big)$ for any $\varepsilon > 0$.*

Our results uncover an interesting contrast in compressibility between decision CSPs and maximization CSPs. While both involve the analysis of the degrees of polynomials, the type of polynomials which is used differs, leading to differences in compressibility. For example, while d-NAE-SAT has a compression of size $\mathcal{O}(n^{d-1} \log n)$ for *all* $d \geq 3$, the corresponding Max d-NAE-SAT problem with weights of absolute value $n^{\mathcal{O}(1)}$ has a compression of size $\mathcal{O}(n^{d-1} \log n)$ for *odd* $d \geq 3$, but no compression of size $\mathcal{O}(n^{d-\varepsilon})$ for *even* d. Another example is d-Exact SAT, where we require exactly one literal in each clause to be true. Whereas d-Exact SAT admits a compression of size $\mathcal{O}(n \log n)$ for every fixed d [9], we show that Max d-Exact SAT cannot be compressed to $\mathcal{O}(n^{d-\varepsilon})$ bits.

Techniques. On a high level, our results are obtained by combining two ingredients: (1) a characterization of the complexity of a constraint language as $\deg(\Gamma)$, via the degree of the characteristic polynomials, and (2) reductions between different problems Max CSP(Γ) and Max CSP(Γ') by implementing constraints of one language by combinations of constraints from the other. While both ingredients have been used in isolation [10, 11, 21, 26, 33], their combination is novel and is the key to understanding compressibility. To comprehend how characteristic polynomials help to compress an instance of Max CSP(Γ), observe that since the characteristic polynomial gives 1 when a constraint is satisfied and 0 otherwise, the total value of satisfied constraint applications can be written as a weighted sum of applications of characteristic polynomials. If $\deg(\Gamma) = k$, then this weighted sum contains $\mathcal{O}(n^k)$ distinct monomials. An instance can therefore be compressed by expanding this weighted sum, and storing the coefficient of each monomial. If all weights in the input instance are bounded by $n^{\mathcal{O}(1)}$, each coefficient will have value $n^{\mathcal{O}(1)}$ and can therefore be encoded in $\mathcal{O}(\log n)$ bits.

Our lower bounds are obtained by parameterized reductions between Max CSPs in which the number of variables does not grow significantly. By a careful analysis of the terms of the characteristic polynomial, we show that if $\deg(\Gamma) = \deg(\Gamma')$, then constraint applications from Γ can effectively be simulated by combinations of constraints from Γ'. Here, we use the framework of *implementations* from an earlier work [21]. Since the characteristic polynomial of d-CNF clauses has degree d, this yields a reduction from d-CNF-SAT to Max CSP(Γ) for $\deg(\Gamma) = d$ that preserves the asymptotic size of the variable set, therefore transferring the cited lower bound for d-CNF-SAT [14] to Max CSP(Γ). A similar reduction is also used for our positive results, to turn the monomial-based compression sketched above into a self-reduction which outputs an instance of the original problem.

[1] While some recent work on sparsification for CSPs allows infinite constraint languages Γ [18], they are not interesting from our perspective as $\deg(\Gamma) = +\infty$.

Consequences for exponential-time algorithms. The framework we develop for parameterized reductions among Max CSPs also has consequences for exponential-time algorithms, which we believe to be of independent interest. The *Max 3-SAT Hypothesis* [26] states that Max 3-CNF-SAT with n variables cannot be solved in time $\mathcal{O}(2^{(1-\varepsilon)n})$ for any $\varepsilon > 0$ (cf. [1, 5]). Our reductions imply that this hypothesis is *equivalent* to the version where Max 3-CNF-SAT is replaced by Max CSP(Γ) for any constraint language Γ with $\deg(\Gamma) = 3$ in which negated literals can be expressed (§2.2). In particular, the Max 3-SAT hypothesis is equivalent to the statement that Max E3-Lin cannot be solved in time $\mathcal{O}(2^{(1-\varepsilon)n})$. What is more, for any $k \geq 2$, our reductions uncover an equivalence class of NP-hard problems whose optimal exponential-time running times coincide with the one for Max k-SAT.

Related work. Representations of Boolean functions by characteristic polynomials have been studied frequently in the literature [3, 4, 26, 28, 29, 31, 32] revealing, e.g., a relation between the degree of the representation and the decision tree complexity [29]. Algorithms for CSPs via their characteristic polynomials were first given by Williams [33]. He used the split-and-list technique to give accelerated exponential-time algorithms for Max 2-SAT and Max CSP(Γ) for $\deg(\Gamma) = 2$. In recent work, Lincoln, Williams, and Vassilevska Williams [26] give an exponential-time split-and-list reduction from Max CSP(Γ) for $\deg(\Gamma) = k$ to detecting an ℓ-hyperclique in a k-uniform hypergraph, for $\ell > k$, in support of the (k, ℓ)-Hyperclique Hypothesis, which states that detecting such a hyperclique in an n-vertex input requires time $n^{\ell - o(1)}$ on a Word-RAM with $\mathcal{O}(\log n)$-bit words. If this hypothesis fails for some k and ℓ, their reduction implies that each Max CSP(Γ) problem with $\deg(\Gamma) = k$ can be solved in time $\mathcal{O}(2^{(1-\varepsilon)n})$ for some $\varepsilon > 0$. Their reductions run in exponential time and are very different from ours.

Alon et al. [2] used a different representation of Boolean functions as polynomials in the work on Max r-SAT parameterized above the guarantee. Here, the goal is to find an assignment satisfying at least $((2^r - 1)m + k)/2^r$ clauses, where m is the total number of clauses and k is the parameter. They have shown that the problem is FPT and admits a polynomial kernel.

Organization. We begin with Section 2 containing the necessary definitions and properties of CSPs, including the implementation framework. In Section 3 we explain the idea of representing constraints by polynomials and provide an algebraic background for our reductions. It is followed by Section 4, where the notion of a reduction between constraint systems is formalized, and the main reductions are presented. It serves as a toolbox for proving the main results for compression (Section 5) and exponential-time algorithms (Section 6). The proofs of statements indicated with (★) can be found in the full version [19].

2 Preliminaries

For a set S and integer $d \geq 0$, let $\binom{S}{d}$ be the set of all size-d subsets of S. We use $[n]$ as a shorthand for $\{1, \ldots, n\}$. A k-ary constraint is a function $f\colon \{0,1\}^k \to \{0,1\}$. We refer to k as the arity of f, denoted $\textsc{ar}(f)$. We always assume that the domain is Boolean. A constraint f is satisfied by an input $s \in \{0,1\}^k$ if $f(s) = 1$. A constraint language (sometimes called constraint family) Γ is a finite collection of constraints $\{f_1, f_2, \ldots, f_\ell\}$, potentially with different arities. A *constraint application*, of a k-ary constraint f to a set of n Boolean variables, is a triple $\langle f, (i_1, i_2, \ldots i_k), w\rangle$, where the indices $i_j \in [n]$ select k of the n Boolean variables to whom the constraint is applied, and w is a weight, described formally below. The variables can be repeated in a single application.

▶ **Definition 2.1.** *A constraint system is a pair $CS(\Gamma, \mathbb{W})$, where Γ is a constraint language and $\mathbb{W}$ (for* weight range*) is either $\mathbb{Z}$ or $\mathbb{N}$. An instance (or formula) of $CS(\Gamma, \mathbb{W})$ is a set of constraint applications from Γ over a common set of variables, each application having a weight from $\mathbb{W}$.*

We denote the number of constraint applications in a formula Φ by $|\Phi|$ and the sum of absolute values of all weights in Φ by $||\Phi||$. For an assignment x, that is, a mapping from the set of variables to $\{0,1\}$, the integer $\Phi(x)$ is the sum of weights of the constraint applications satisfied by x.

In the decision problem Max CSP$(\Gamma, \mathbb{W}, c)$ we are given a formula Φ from CS$(\Gamma, \mathbb{W})$ over n variables such that $||\Phi|| \leq n^c$, together with the integer t, and we ask if there is an assignment x such that $\Phi(x) \geq t$. We specify the constant c to be accurate about the specific decision problems for which we show hardness results (the formal definitions of parameterized problems and compression are given in Section 2.4). When it does not lead to confusion, e.g., when some property holds for all c, we refer to this family of problems shortly as Max CSP$(\Gamma, \mathbb{W})$. Whenever we use the $\mathcal{O}$-notation, we do it with respect to a fixed problem, that is, we treat Γ and c as constants. The most commonly studied case is expressed by $\mathbb{W} = \mathbb{N}$ [13, 21, 27], where the weights can be interpreted as repetitions of constraint applications. It is important to make this distinction because it can be the case that Max CSP$(\Gamma, \mathbb{N})$ is polynomially solvable whereas Max CSP$(\Gamma, \mathbb{Z})$ is NP-hard [20]. Although our main reduction framework works for $\mathbb{W} = \mathbb{Z}$, we are able to transfer the compression lower bounds to the case $\mathbb{W} = \mathbb{N}$ as long as Max CSP$(\Gamma, \mathbb{N})$ is NP-hard.

Another decision problem that is related to constraint systems is Exact CSP$(\Gamma, \mathbb{W})$, where we ask whether there is an assignment for which the satisfied weights sum up exactly to a given integer [26, 33]. Even though we focus on the maximization variant, we formulate our reductions so that they could be employed for other problems over constraint systems or larger weight domains.

2.1 Types of constraints

We start by formally defining the most important constraints and constraint properties. They allow us to formulate the dichotomy theorem for Max CSP. We use the Boolean notation for negation, i.e., $\neg x = 1 - x$ for $x \in \{0,1\}$.

- A constraint is trivial if it is either always 1 or always 0 regardless of the arguments.
- The unary constraints T and F are given by $T(x) = x$ and $F(x) = \neg x$.
- OR_k and AND_k are k-ary constraints, such that $\mathrm{OR}_k(x_1, \ldots, x_k) = \bigvee_{i=1}^{k} x_i$ and analogously $\mathrm{AND}_k(x_1, \ldots, x_k) = \bigwedge_{i=1}^{k} x_i$. The Not-All-Equal constraint is defined as $\mathrm{NAE}_k(x_1, \ldots, x_k) = \mathrm{OR}_k(x_1, \ldots, x_k) \wedge \mathrm{OR}_k(\neg x_1, \ldots, \neg x_k)$.
- XOR_k is a k-ary constraint defined as $\mathrm{XOR}_k(x_1, \ldots, x_k) = x_1 + \ldots + x_k \bmod 2$. We abbreviate $\mathrm{XOR} = \mathrm{XOR}_2$.
- A constraint f is 0-valid (resp. 1-valid) if $f(0, 0, \ldots, 0) = 1$ (resp. $f(1, 1, \ldots, 1) = 1$).
- A constraint f is 2-monotone if $f(x_1, x_2, \ldots, x_k) = (x_{i_1} \wedge x_{i_2} \wedge \cdots \wedge x_{i_p}) \vee (\neg x_{j_1} \wedge \neg x_{j_2} \wedge \cdots \wedge \neg x_{j_q})$, for some $p, q \geq 0$, $(p, q) \neq (0, 0)$, i.e., f is equivalent to a DNF-formula with at most two terms: one containing only positive literals and the other containing only negative literals.
- A constraint f is C-closed (complementation-closed) if for every assignment $x \in \{0,1\}^{\mathrm{AR}(f)}$, $f(x) = f(\bar{x})$, where $\bar{x}$ stands for the bit-wise complement of x.
- A constraint f is symmetric if for any two assignments $x_1, x_2 \in \{0,1\}^{\mathrm{AR}(f)}$ having the same number of ones, it holds that $f(x_1) = f(x_2)$.

A constraint language Γ is called 0-valid, 1-valid, 2-monotone, C-closed, or symmetric, if all non-trivial constraints in Γ satisfy the respective property. We call Γ *non-trivial* if it contains at least one non-trivial constraint. This regime is convenient for formulating the fundamental dichotomy theorem for Boolean Max CSP. For our purposes it is only important that APX-hardness entails NP-hardness.

▶ **Theorem 2.2** ([21, Theorem 2.11], cf. [10]). *Max CSP*$(\Gamma, \mathbb{N})$ *is solvable in polynomial time if* Γ *is either 0-valid, 1-valid, or 2-monotone. Otherwise, the problem is APX-hard.*

2.2 Closures of constraint languages

In some CSPs we are allowed to write constraint applications containing constants or negations of variables, which makes them more convenient to process. We formalize these properties with the notion of a *language closure*.

▶ **Definition 2.3.** *Let f be a k-ary constraint and let g be a d-ary constraint. We say that g is expressible by f with constants if the identity $g(x_1, x_2, \ldots, x_d) = f(\xi_1, \xi_2, \ldots, \xi_k)$ holds for a tuple $(\xi_1, \xi_2, \ldots, \xi_k)$, where each ξ_j is either a variable x_i for some $i \in [d]$ or one of the constants 0, 1.*

We say that g is expressible by f with literals if such an identity holds for a tuple $(\xi_1, \xi_2, \ldots, \xi_k)$, where each ξ_j is a literal: either a variable x_i or its negation $\neg x_i$ for $i \in [d]$.

For a constraint language Γ we introduce the following closures:

- the language $\Gamma^{T,F}$ contains all functions expressible by $f \in \Gamma$ with constants,
- the language Γ^{LIT} contains all functions expressible by $f \in \Gamma$ with literals,
- the language Γ^{NEG} is the *negation-wise closure* of Γ, i.e., $\Gamma^{NEG} = \bigcup_{f \in \Gamma} \{f, \neg f\}$.

It is easy to see that the closures satisfy $(\Gamma^{T,F})^{T,F} = \Gamma^{T,F}$, $(\Gamma^{LIT})^{LIT} = \Gamma^{LIT}$, $(\Gamma^{NEG})^{NEG} = \Gamma^{NEG}$. We will be particularly interested in those constraint languages in which negated literals can be expressed, as in, e.g., d-CNF-SAT or d-NAE-SAT. These are the languages that satisfy $\Gamma = \Gamma^{LIT}$. Below we present examples on how to express important CSPs using our definitions.

- d-CNF-SAT $= \mathrm{CSP}(\Gamma_{d\text{-SAT}})$ for $\Gamma_{d\text{-SAT}} = \{\mathrm{OR}_d\}^{LIT}$,
- d-NAE-SAT $= \mathrm{CSP}(\{\mathrm{NAE}_d\}^{LIT})$,
- Max Ed-Lin $=$ Max CSP$(\{\mathrm{XOR}_d\}^{NEG}, \mathbb{N})$,
- Max Cut $=$ Max CSP$(\{\mathrm{XOR}\}, \mathbb{N})$,
- Max DiCut $=$ Max CSP$(\{f\}, \mathbb{N})$ for $f(x_1, x_2) = x_1 \wedge \neg x_2$.

2.3 Constraint implementations

We describe the technique behind Theorem 2.2 [21]. The idea is to *implement* a constraint f by a collection of other constraints, so that satisfying f is equivalent to maximizing the number of satisfied constraints in that collection. It allows us to express formulas from Max CSP$(\Gamma_1, \mathbb{N})$ by those from Max CSP$(\Gamma_2, \mathbb{N})$, as long as constraints in Γ_1 can be implemented by those in Γ_2.

The caveat is that each implementation may introduce new auxiliary variables whereas for our purposes we need reductions that increase the number of variables only by a multiplicative constant. Therefore the reductions by Khanna et al. [21] do not transfer compressibility bounds; we will use the implementations in a different way. On the other hand, our reductions do not preserve approximation factors.

▶ **Definition 2.4** ([21, Definition 3.1]). *A collection of unit-weighted constraint applications $C_1, C_2, \dots C_m$ over a set of variables $x = \{x_1, x_2, \dots, x_p\}$ called primary variables and $y = \{y_1, y_2, \dots, y_q\}$ called auxiliary variables, is an α-implementation of a constraint $f(x)$ for a positive integer α if the following conditions hold.*

1. *Any assignment to x and y satisfies at most α constraint applications from $C_1, C_2, \dots C_m$.*
2. *$\forall x$ such that $f(x) = 1$, $\exists y$ such that exactly α constraint applications are satisfied.*
3. *$\forall x, y$ such that $f(x) = 0$, at most $\alpha\ -1$ constraint applications are satisfied.*

An α-implementation is called strict *if for every assignment of the primary variables x such that $f(x) = 0$, there exists an assignment of the auxiliary variables y such that exactly $\alpha\ -1$ constraint applications are satisfied.*

We say that a constraint language Γ implements a constraint f if there exists an α-implementation of f using constraints of Γ for some constant α. We use $\Gamma \implies f$ to denote that Γ implements f and $\Gamma \stackrel{s}{\implies} f$ when Γ strictly implements f. The above notation is also extended to allow the target to be a family of constraints. The following lemma encapsulates a toolbox of implementations which we will rely on.

▶ **Lemma 2.5.** *If Γ is a non-trivial constraint language such that*

1. *Γ is C-closed and not 0-valid (or equivalently not 1-valid), then $\Gamma \implies XOR$,*
2. *Γ is neither 0-valid, 1-valid, nor C-closed, then $\Gamma \implies \{T, F\}$,*
3. *Γ is neither 0-valid, 1-valid, nor 2-monotone, then $\Gamma \implies XOR$.*

In order to prove it, we need to refer to several statements from [21], beginning from the transitivity of strict implementations. Then we restate three lemmas that imply points (1, 2) directly, and point (3) is obtained via transitivity.

▶ **Lemma 2.6** ([21, Lemma 3.5]). *If $\Gamma_1 \stackrel{s}{\implies} \Gamma_2$ and $\Gamma_2 \stackrel{s}{\implies} \Gamma_3$, then $\Gamma_1 \stackrel{s}{\implies} \Gamma_3$.*

▶ **Lemma 2.7** ([21, Lemma 4.5]). *Let f be a non-trivial constraint which is C-closed and is not 0-valid (or equivalently not 1-valid). Then $\{f\} \stackrel{s}{\implies} XOR$.*

▶ **Lemma 2.8** ([21, Lemma 4.6]). *Let f_0, f_1, and g be non-trivial constraints, possibly identical, which are not 0-valid, not 1-valid, and not C-closed, respectively. Then $\{f_0, f_1, g\} \stackrel{s}{\implies} \{T, F\}$.*

▶ **Lemma 2.9** ([21, Lemma 4.11]). *Let f be a constraint which is not 2-monotone. Then $\{f, T, F\} \stackrel{s}{\implies} XOR$.*

Proof of Lemma 2.5. Claims (1, 2) follow from Lemmas 2.7 and 2.8, respectively. To see claim (3), first observe that if Γ is C-closed, then we can again use Lemma 2.7. Otherwise, by Lemma 2.8 we have $\Gamma \stackrel{s}{\implies} \{T, F\}$. Next, we take advantage of transitivity (Lemma 2.6) and implement XOR with Lemma 2.9. ◀

2.4 Parameterized complexity

A *parameterized problem* is a decision problem in which every input has an associated positive integer *parameter* that captures its complexity in some well-defined way. In our study of CSPs we use the number of variables as the parameter, but other choices have been considered [16, 22, 23]. For a parameterized problem $A \subseteq \Sigma^* \times \mathbb{N}$, a decision problem $B \subseteq \Sigma^*$, and a function $f\colon \mathbb{N} \to \mathbb{N}$, a *compression* of A into B of size f is an algorithm that, on input $(x, k) \in \Sigma^* \times \mathbb{N}$, takes time polynomial in $|x| + k$ and outputs an instance $y \in \Sigma^*$ such that $(x, k) \in A$ if and only if $y \in B$, and such that $|y| \leq f(k)$. A *kernelization* algorithm of size f for problem A reduces any instance (x, k) to an $f(k)$-sized equivalent instance of the *same problem* in polynomial time.

3 Characteristic polynomials

In this section we provide the technique necessary for expressing one constraint system by another without introducing too many auxiliary variables. This insight is based on interpreting constraints as multilinear polynomials.

▶ **Definition 3.1.** *For a k-ary constraint $f\colon \{0,1\}^k \to \{0,1\}$ its characteristic polynomial P_f is the unique k-ary multilinear polynomial over $\mathbb{R}$ satisfying $f(x) = P_f(x)$ for any $x \in \{0,1\}^k$.*

It is easy to construct P_f. First define $P_s(x_1, x_2, \ldots, x_k) = \prod_{i=1}^{k} R_i^s(x_i)$ for a vector $s \in \{0,1\}^k$, where $R_i^s(x) = x$ if $s_i = 1$ and $R_i^s(x) = 1 - x$ otherwise. Formally, P_s is given by the sequence of coefficients obtained by expanding all parentheses; they are all integers. It holds that $P_s(s) = 1$, while $P_s(x) = 0$ for any $x \neq s$. For a constraint f its characteristic polynomial is given as $P_f(x_1, x_2, \ldots, x_k) = \sum_{s:\, f(s)=1} P_s(x_1, x_2, \ldots, x_k)$. It is known that no other multilinear polynomial can take identical values on $\{0,1\}^k$ [29, 33]. This also means we can interchangeably analyze polynomials as formal objects and as functions on $\{0,1\}^k$.

▶ **Observation 3.2.** *The coefficients of any characteristic polynomial P_f are integers.*

Let $\deg(f) = \deg(P_f)$ and $\deg(\Gamma) = \max_{f\in\Gamma} \deg(f)$. For a k-ary constraint f we refer to the coefficient at the unique k-ary monomial in P_f as the leading coefficient. The leading coefficient is non-zero if and only if $\deg(P_f) = k$. If g is expressible by f with literals, then we can obtain P_g from P_f by replacing each literal with negation $\neg x_i$ by $1 - x_i$ and expanding the parentheses within monomials. If g is expressible by f with constants, then we just substitute 0 or 1 for particular variables and remove monomials containing 0. These transformations imply $\deg(\Gamma^{T,F}) = \deg(\Gamma^{LIT}) = \deg(\Gamma^{NEG}) = \deg(\Gamma)$.

As an example, consider Max 3-NAE-SAT. The function $\mathrm{NAE}_3(x_1, x_2, x_3)$ has the degree-2 characteristic polynomial $x_1 + x_2 + x_3 - x_1x_2 - x_1x_3 - x_2x_3$, which allows us to construct a compression for Max 3-NAE-SAT of size $\mathcal{O}(n^2 \log n)$ by summing coefficients at all $\mathcal{O}(n^2)$ monomials. On the other hand, $\mathrm{OR}_2(x_1, x_2) = x_1 + x_2 - x_1x_2 = \mathrm{NAE}_3(x_1, x_2, 0)$, which indicates that solving Max 3-NAE-SAT should not be easier than Max 2-CNF-SAT. We will formalize these arguments in the next section.

We show that the set of characteristic polynomials of all constraints expressible by f with constants spans the linear space of multilinear polynomials over $\mathbb{Q}$ with degrees at most $\deg(f)$. We first prove that this set contains polynomials of all degrees up to $\deg(f)$ and then use them to express a basis of the linear space.

▶ **Lemma 3.3 (★).** *Let f be a k-ary constraint. For any $1 \leq d \leq \deg(f)$ there exists a d-ary constraint g expressible by f with constants, such that its characteristic polynomial P_g has degree exactly d, i.e., its leading coefficient is non-zero.*

▶ **Lemma 3.4.** *Let f be a non-trivial constraint and P be a multilinear polynomial over $\mathbb{Q}$ on ℓ variables of degree $0 \leq d \leq deg(f)$. There exists a sequence of constraint applications $\langle f_i, (j_i^1, \ldots, j_i^{AR(f_i)}), \alpha_i\rangle_{i=1}^{M}$ on ℓ variables, where each constraint f_i is expressible by f with constants, and $\alpha_i \in \mathbb{Q}$, such that the following polynomial identity holds.*

$$P(x_1, \ldots, x_\ell) = \sum_{i=1}^{M} \alpha_i \cdot P_{f_i}(x_{j_i^1}, \ldots, x_{j_i^{AR(f_i)}}).$$

Before proving this claim, let us demonstrate it on a less obvious example than the one from above with NAE_3 and OR_2. Let $P(x_1, x_2, x_3)$ be the characteristic polynomial of the constraint $\mathrm{OR}_3(x_1, x_2, \neg x_3)$, derived using the method described below Definition 3.1:

$$\begin{aligned} P(x_1, x_2, x_3) &= x_1x_2x_3 + (1-x_1)x_2x_3 + x_1(1-x_2)x_3 + x_1x_2(1-x_3) \\ &\quad + (1-x_1)x_2(1-x_3) + x_1(1-x_2)(1-x_3) + (1-x_1)(1-x_2)(1-x_3) \\ &= 1 - x_3 + x_1x_3 + x_2x_3 - x_1x_2x_3. \end{aligned}$$

We will represent it with characteristic polynomials from $\{\mathrm{EX}_3\}^{T,F}$, where $\mathrm{EX}_3(x_1, x_2, x_3) = 1$ if and only if exactly one variable is 1. Its characteristic polynomial Q is given as:

$$\begin{aligned} Q(x_1, x_2, x_3) &= x_1(1-x_2)(1-x_3) + (1-x_1)x_2(1-x_3) + (1-x_1)(1-x_2)x_3 \\ &= x_1 + x_2 + x_3 - 2x_1x_2 - 2x_1x_3 - 2x_2x_3 + 3x_1x_2x_3. \end{aligned}$$

We can express P as the following linear combination where, e.g., $Q(x_1, x_2, 0)$ is the characteristic polynomial for $\mathrm{EX}_3(x_1, x_2, 0)$, which is a binary constraint expressible by EX_3 with constants:

$$\begin{aligned} P(x_1, x_2, x_3) = &-\frac{1}{3}Q(x_1, x_2, x_3) + \frac{1}{3}Q(x_1, x_2, 0) - \frac{1}{6}Q(x_1, x_3, 0) - \frac{1}{6}Q(x_2, x_3, 0) \\ &+ \frac{1}{6}Q(x_1, 0, 0) + \frac{1}{6}Q(x_2, 0, 0) - \frac{1}{3}Q(x_3, 0, 0) + Q(1, 0, 0). \end{aligned}$$

Proof of Lemma 3.4. We proceed by induction over the degree of P. Since f is non-trivial, it admits a satisfying assignment s_T. If P is constant, then $P(x) = \alpha \cdot f(s_T)$ for some $\alpha \in \mathbb{Q}$. Suppose now $d = \deg(P) \geq 1$. For each $S \in \binom{[\ell]}{d}$ let α_S denote the (potentially zero) coefficient in P at the monomial $\prod_{i \in S} x_i$. By Lemma 3.3 there is a d-ary constraint f_d, which is expressible by f with constants and $\deg(P_{f_d}) = d$. Let β_d denote the leading coefficient of P_{f_d}. The polynomial

$$P'(x_1, \ldots, x_\ell) = P(x_1, \ldots, x_\ell) - \sum_{\substack{\{i_1, \ldots, i_d\} = S \in \binom{[\ell]}{d} \\ i_1 < \ldots < i_d}} \frac{\alpha_S}{\beta_d} \cdot P_{f_d}(x_{i_1}, \ldots, x_{i_d})$$

has no monomials of degree d, since each term in the sum subtracts exactly one of them. The polynomial P' has degree at most $d-1$, so we can apply the induction hypothesis to it and represent P' as a linear combination of characteristic polynomials of constraints from $\{f\}^{T,F}$. We obtain the claim by adding these polynomials to the sum above. ◀

Since f_i and P_{f_i} coincide as functions on $\{0,1\}^{\mathrm{AR}(f_i)}$, Lemma 3.4 allows us to represent any constraint of degree at most $\deg(f)$ as a linear combination of constraints from $\{f\}^{T,F}$.

▶ **Proposition 3.5.** *Let g, f be constraints, such that f is non-trivial and $\deg(g) \leq \deg(f)$. There exists a sequence of constraint applications $\langle f_i, (j_i^1, \ldots, j_i^{\mathrm{AR}(f_i)}), \alpha_i \rangle_{i=1}^M$ on $\mathrm{AR}(g)$ variables, where each constraint f_i is expressible by f with constants, and $\alpha_i \in \mathbb{Q}$, such that $g(x_1, \ldots, x_{\mathrm{AR}(g)}) = \sum_{i=1}^M \alpha_i \cdot f_i(x_{j_i^1}, \ldots, x_{j_i^{\mathrm{AR}(f_i)}})$ for all Boolean assignments.*

This resembles the idea of implementation, where we additionally equip constraints with (potentially negative) rational weights, but does not require introducing new variables.

4 Reductions between constraint systems

We first formalize our notion of reduction. The objects we work with are constraint systems and the reductions between them imply analogous relations between the associated decision problems. The reduction is crafted in such a way that it preserves the numbers of variables and constraints up to a constant factor, and the total weight up to a polynomial factor.

▶ **Definition 4.1.** *A linear transformation from a constraint system $CS(\Gamma_1, \mathbb{W}_1)$ to another constraint system $CS(\Gamma_2, \mathbb{W}_2)$ is a polynomial-time procedure that given a formula Φ_1 of $CS(\Gamma_1, \mathbb{W}_1)$ over n_1 variables and integer t_1, returns a formula $\Phi_2 \in CS(\Gamma_2, \mathbb{W}_2)$ over n_2 variables and integer t_2, so that the following conditions hold:*

1. $n_2 = \mathcal{O}(n_1)$,
2. $|\Phi_2| = \mathcal{O}(|\Phi_1| + n_1)$,
3. $||\Phi_2|| \leq ||\Phi_1|| \cdot n_1^{\mathcal{O}(1)}$,
4. $\exists_x \Phi_1(x) = t_1 \iff \exists_y \Phi_2(y) = t_2$,
5. $\exists_x \Phi_1(x) \geq t_1 \iff \exists_y \Phi_2(y) \geq t_2$.

If there exists a linear transformation from $CS(\Gamma_1, \mathbb{W}_1)$ to $CS(\Gamma_2, \mathbb{W}_2)$, we write concisely $CS(\Gamma_1, \mathbb{W}_1) \leq_{LIN} CS(\Gamma_2, \mathbb{W}_2)$. If (1) can be replaced with the stronger condition $n_2 = n_1 + \mathcal{O}(1)$, we call the transformation additive and write $CS(\Gamma_1, \mathbb{W}_1) \leq_{ADD} CS(\Gamma_2, \mathbb{W}_2)$.

Before moving forward, let us explain the importance of linear and additive transformations. We formulate two claims, which follow from the properties in Definition 4.1.

▶ **Proposition 4.2.** *If $CS(\Gamma_1, \mathbb{W}_1) \leq_{LIN} CS(\Gamma_2, \mathbb{W}_2)$ and Max CSP$(\Gamma_2, \mathbb{W}_2, c)$ admits a compression of size $\mathcal{O}(n^d)$, then Max CSP$(\Gamma_1, \mathbb{W}_1, c - \mathcal{O}(1))$ also admits a compression of size $\mathcal{O}(n^d)$.*

▶ **Proposition 4.3.** *If $CS(\Gamma_1, \mathbb{W}_1) \leq_{ADD} CS(\Gamma_2, \mathbb{W}_2)$ and Max CSP$(\Gamma_2, \mathbb{W}_2, c)$ admits an algorithm with running time $T(n)$, then Max CSP$(\Gamma_1, \mathbb{W}_1, c - \mathcal{O}(1))$ admits an algorithm with running time $T(n + \mathcal{O}(1))$.*

In particular, additive transformations preserve running times of the form $2^{(1-\varepsilon)n} n^{\mathcal{O}(1)}$.

▶ **Lemma 4.4 (★).** *Linear transformations (resp. additive transformations) are transitive.*

We continue with two simple additive transformations, which will allow us to use negations of constraints as an alternative to setting negative weights.

▶ **Lemma 4.5 (★).** *For every constraint language Γ we have*

1. *CS$(\Gamma^{NEG}, \mathbb{Z}) \leq_{ADD}$ CS$(\Gamma, \mathbb{Z})$,*
2. *CS$(\Gamma^{NEG}, \mathbb{Z}) \leq_{ADD}$ CS$(\Gamma^{NEG}, \mathbb{N})$.*

The rest of this section contains four lemmas that form a chain of reductions from CS$(\Gamma_1, \mathbb{Z})$ to CS$(\Gamma_2, \mathbb{N})$, which is valid as long as $\deg(\Gamma_1) \leq \deg(\Gamma_2)$ and Max CSP$(\Gamma_2, \mathbb{N})$ is NP-hard. First, we translate Proposition 3.5 into the language of additive transformations. In the proof we justify that one can replace rational coefficients with integer ones.

▶ **Lemma 4.6 (★).** *Let Γ_1, Γ_2 be non-trivial constraint languages satisfying $\deg(\Gamma_1) \leq \deg(\Gamma_2)$. Then CS$(\Gamma_1, \mathbb{Z}) \leq_{ADD}$ CS$(\Gamma_2^{T,F}, \mathbb{Z})$.*

Now, we formalize an intuitive notation for combining formulas. Consider two formulas Φ_1, Φ_2 over the sets of variables V_1, V_2, respectively, which might have a non-empty intersection. We define the sum of these formulas, $\Phi_1 + \Phi_2$, over the set of variables $V_1 \cup V_2$ by

taking the union of their sets of constraint applications and merging pairs of applications that share the same constraint and the same tuple of variables, i.e., replacing the pair with a single application with a weight being the sum of the respective weights. For an integer α, the formula $\alpha \cdot \Phi$ has the same constraint applications as Φ, with weights multiplied by α.

▶ **Lemma 4.7.** *Let Γ be a non-trivial constraint language, which is neither 0-valid nor 1-valid. Then $CS(\Gamma^{T,F}, \mathbb{Z}) \leq_{ADD} CS(\Gamma, \mathbb{Z})$.*

Proof. Given a formula $\Phi \in \mathrm{CS}(\Gamma^{T,F}, \mathbb{Z})$, we add two auxiliary variables x_T, x_F and we translate each constraint application $\langle \hat{f}, (j_1, \ldots, j_k), w \rangle$, where $\hat{f}$ is expressible by $f \in \Gamma$ with constants, into an application of f by replacing constants 0, 1 with variables x_T, x_F. Let us refer to this formula as $\Phi_1 \in \mathrm{CS}(\Gamma, \mathbb{Z})$ and note that $|\Phi_1| = |\Phi|$ and $||\Phi_1|| = ||\Phi||$.

In the next step, we will use implementations to impose particular conditions on x_T, x_F. We refer to x_T, x_F and all the new variables introduced within the implementations as auxiliary. Let $a = \mathcal{O}(1)$ denote their number. In the new formula we assume that the first n variables $x_1, \ldots, x_n$ are the primary variables and $x_{n+1}, \ldots, x_{n+A}$ are auxiliary. For $x \in \{0,1\}^{n+A}$ let $x|_n$ stand for the projection on the first n coordinates.

Assume first that Γ is not C-closed. Then by Lemma 2.5, point (2), we know that Γ α_1-implements function T and α_2-implements function F for some integers α_1, α_2. Let $\alpha = \alpha_1 + \alpha_2$. We implement constraint applications $T(x_T)$ and $F(x_F)$, that is, we construct formulas $\Phi_T, \Phi_F \in \mathrm{CS}(\Gamma, \mathbb{N})$ over the set of auxiliary variables, such that satisfying α constraint applications in $\Phi_T + \Phi_F$ is only possible when $x_T = 1$ and $x_F = 0$. Let $W = 2 \cdot ||\Phi|| + 1$. We define $\Phi_2 = \Phi_1 + W \cdot \Phi_T + W \cdot \Phi_F$, that is, we copy all the constraint applications from Φ_1 and add the applications from $\Phi_T + \Phi_F$ with weights multiplied by W. Recall that we have $(-||\Phi||) \leq \Phi(x) \leq ||\Phi||$ for all x. By the definition of implementation, any assignment to Φ_2 which does not satisfy $x_T = 1$ or $x_F = 0$ has value at most $(\alpha - 1) \cdot W + ||\Phi|| < \alpha\, W - ||\Phi||$. If the assignment x satisfies $x_T = 1$, $x_F = 0$, it holds that $\Phi_2(x) = \alpha\, W + \Phi(x|_n) \geq \alpha\, W - ||\Phi||$.

Now, if Γ is C-closed, then by Lemma 2.5, point (1), Γ α-implements function XOR for some constant α. We implement $\mathrm{XOR}(x_T, x_F)$, that is, we construct formula $\Phi_{\mathrm{XOR}} \in \mathrm{CS}(\Gamma, \mathbb{N})$ over the set of auxiliary variables, such that satisfying α constraint applications in Φ_{XOR} is only possible when $\mathrm{XOR}(x_T, x_F) = 1$. As before, we define $\Phi_2 = \Phi_1 + W \cdot \Phi_{\mathrm{XOR}}$, where $W = 2 \cdot ||\Phi|| + 1$. Any assignment to Φ_2 which does not satisfy $\mathrm{XOR}(x_T, x_F)$ has value at most $(\alpha - 1) \cdot W + ||\Phi|| < \alpha\, W - ||\Phi||$. For an assignment x satisfying $x_T = 1$, $x_F = 0$, it holds that $\Phi_2(x) = \alpha\, W + \Phi(x|_n) \geq \alpha\, W - ||\Phi||$. It might also be the case that $x_T = 0$, $x_F = 1$. Then, by C-closedness we have $\Phi_2(x) = \Phi_2(\bar{x}) = \alpha\, W + \Phi(\bar{x}|_n) \geq \alpha\, W - ||\Phi||$, where $\bar{x}$ is the bit-wise complement of x.

We summarize the transformation properties for both considered cases: the new number of variables is $n + \mathcal{O}(1)$, $|\Phi_2| = |\Phi| + \mathcal{O}(1)$, and $||\Phi_2|| = ||\Phi|| \cdot \mathcal{O}(1)$. If $t < -||\Phi||$, then we know that all assignments x satisfy $\Phi(x) > t$ and in such case we could return an empty formula over a singleton variable set (so the only possible value is 0) and set threshold $t' = -1$: this is an equivalent instance. To see properties (4, 5) observe that, assuming $t \geq -||\Phi||$, $\Phi(x) = t$ (resp. $\Phi(x) \geq t$) holds for some assignment x iff. $\Phi_2(y) = t'$ (resp. $\Phi_2(y) \geq t'$) holds for some assignment y, where $t' = \alpha\, W + t$. ◀

▶ **Corollary 4.8.** *Let Γ_1, Γ_2 be non-trivial constraint languages such that $\deg(\Gamma_1) \leq \deg(\Gamma_2)$ and Γ_2 is neither 0-valid nor 1-valid. Then $CS(\Gamma_1, \mathbb{Z}) \leq_{ADD} CS(\Gamma_2, \mathbb{Z})$.*

So far we have established a relation between Γ_1 and Γ_2, which allows us to transform one constraint system to another by adding only a constant number of new variables. However, it works only when we allow negative weights. The next two lemmas explain how to get rid of them, so that the hardness results can be applied to the natural setting with only non-negative weights.

▶ **Lemma 4.9** (★). *If* Γ *is a non-trivial constraint language, then* $CS(\Gamma, \mathbb{Z}) \leq_{ADD} CS(\Gamma^{LIT}, \mathbb{N})$.

▶ **Lemma 4.10** (★). *Suppose non-trivial* Γ *is neither 0-valid, 1-valid, nor 2-monotone. Then* $CS(\Gamma^{LIT}, \mathbb{N}) \leq_{LIN} CS(\Gamma, \mathbb{N})$.

In the proof of Lemma 4.9 we increase weights of all the constraint applications at once, in such a way that it changes each value of $\Phi(x)$ by the same quantity. The proof of Lemma 4.10 is similar in spirit to that of Lemma 4.7, but this time the implementation framework is used to implement a negated copy of each variable. As all the transformation above are linear, by transitivity we can summarize them into the following statement connecting constraint languages of the same degree.

▶ **Corollary 4.11.** *Let* Γ_1, Γ_2 *be non-trivial constraint languages such that* $\deg(\Gamma_1) \leq \deg(\Gamma_2)$ *and* Γ_2 *is neither 0-valid, 1-valid, nor 2-monotone. Then* $CS(\Gamma_1, \mathbb{Z}) \leq_{LIN} CS(\Gamma_2, \mathbb{N})$.

5 Consequences for compression

Having an upper bound on $\deg(\Gamma)$ already provides compression for Max CSP$(\Gamma, \mathbb{Z}, c)$, since we can represent all constraint applications as polynomials, sum the coefficients at all $\mathcal{O}\left(n^{\deg(\Gamma)}\right)$ monomials, and store the weights in $\mathcal{O}(\log n)$ bits. Corollary 4.11 transforms the monomial-representation back into a small equivalent instance of Max CSP(Γ).

▶ **Theorem 5.1** (Formalization of Theorem 1.1). *Max CSP*$(\Gamma, \mathbb{N}, c)$ *parameterized by the number of variables* n *admits a compression of size* $\mathcal{O}(n^d \log n)$ *for all* c*, where* $d = \deg(\Gamma)$*. Furthermore, there is a polynomial-time algorithm that reduces any instance of Max CSP*$(\Gamma, \mathbb{N}, c)$ *to an equivalent instance of Max CSP*$(\Gamma, \mathbb{N}, c + \mathcal{O}(1))$ *of size* $\mathcal{O}(n^d \log n)$*. The analogous statements for Max CSP*$(\Gamma, \mathbb{Z}, c)$ *also hold.*

Proof. If Γ is either trivial, 0-valid, 1-valid, or 2-monotone, then Max CSP$(\Gamma, \mathbb{N}, c)$ can be solved in polynomial time, so the compression is trivial. Suppose that it does not have any of these properties. We will prove both claims by compressing a formula $\Phi_1 \in \text{CS}(\Gamma, \mathbb{Z})$ on n variables into a formula $\Phi_2 \in \text{CS}(\Gamma, \mathbb{N})$ satisfying $|\Phi_2| = \mathcal{O}(n^d)$.

First we interpret each constraint application in Φ_1 as a polynomial of degree at most d. After summing these terms, we obtain a polynomial P with $\mathcal{O}(n^d)$ monomials, each associated with an integer weight of absolute value bounded by $||\Phi_1||$. A monomial $\Pi_{i=1}^{k} x_i$ is the characteristic polynomial for the constraint $\text{AND}_k(x_1, \ldots, x_k)$, therefore P can be treated as a formula of $\text{CS}(\Gamma_{d\text{-AND}}, \mathbb{Z})$ for $\Gamma_{d\text{-AND}}$ being the language consisting of functions AND_k for all $k \leq d$. Since $\deg(\Gamma_{d\text{-AND}}) = d$, we can apply Corollary 4.11 to obtain an equivalent formula $\Phi_2 \in \text{CS}(\Gamma, \mathbb{N})$ on $\mathcal{O}(n)$ variables, such that $|\Phi_2| = |\Phi_1| \cdot \mathcal{O}(1) + \mathcal{O}(n) = \mathcal{O}(n^d)$ and $||\Phi_2|| = ||\Phi_1|| \cdot n^{\mathcal{O}(1)}$, so each weight can be stored in $\mathcal{O}(\log n)$ bits. ◀

The self-reduction in Theorem 5.1 is almost, but not quite, a kernelization: the formal decision problem we reduce to is not the same as the original one, due to the increase in weight values. Our lower bounds are based on reducing Max d-CNF-SAT to Max CSP$(\Gamma, \mathbb{N})$ for $\deg(\Gamma) = d$. For $d \geq 3$ it is known that even the non-maximization variant d-CNF-SAT does not admit a compression of size $\mathcal{O}\left(n^{d-\varepsilon}\right)$ [14]. However, the 2-CNF-SAT problem is solvable in polynomial time and only its maximization version becomes NP-hard. We first note that Max 2-CNF-SAT also cannot have any non-trivial compression.

▶ **Lemma 5.2** (★). *Max CSP*$(\Gamma_{2\text{-}SAT}, \mathbb{N}, 3)$ *does not admit a compression of size* $\mathcal{O}\left(n^{2-\varepsilon}\right)$ *for any* $\varepsilon > 0$*, unless NP* $\subseteq$ *co-NP/poly.*

▶ **Theorem 5.3** (Formalization of Theorem 1.2). *Let non-trivial Γ be neither 0-valid, 1-valid, nor 2-monotone, and let $d = \deg(\Gamma)$. Then there is a constant c such that* Max CSP$(\Gamma, \mathbb{N}, c)$ *does not admit a compression of size $\mathcal{O}\left(n^{d-\varepsilon}\right)$ for any $\varepsilon > 0$, unless NP $\subseteq$ co-NP/poly.*

Proof. First observe that a characteristic polynomial of a constraint with $d = 1$ is linear. Since this polynomial is 0/1-valued, it can depend only on one variable, which means that the constraint is 2-monotone. Hence we can assume that $d \geq 2$.

We know that there is a constant c_d so that Max CSP$(\Gamma_{d\text{-SAT}}, \mathbb{N}, c_d)$ does not admit compression of size $\mathcal{O}\left(n^{d-\varepsilon}\right)$ unless NP $\subseteq$ co-NP/poly: for $d = 2$ it is due to Lemma 5.2 and for $d \geq 3$ it follows from the lower bound for the non-maximization variant of d-CNF-SAT [14]. As noted in Proposition 4.2, if we had such a compression for Max CSP$(\Gamma, \mathbb{N}, c)$ with sufficiently large c, then by Corollary 4.11 it would transfer to Max CSP$(\Gamma_{d\text{-SAT}}, \mathbb{N}, c_d)$. ◀

Applications to specific CSPs. Having established both the lower and the upper bound, we can refer to $\deg(\Gamma)$ as the *optimal compression exponent* for Max CSP$(\Gamma, \mathbb{N})$. We are now equipped with a handy but powerful tool for determining the optimal compressibility of Max CSP$(\Gamma, \mathbb{N})$ as this task reduces to computing the degrees of characteristic polynomials in Γ.

As an example, we apply this technique to compute the optimal compression exponent to the following three problems, which are all NP-hard for $k \geq 2$:

- Max k-NAE-SAT = Max CSP$(\{\text{NAE}_k\}^{LIT}, \mathbb{N})$,
- Max Ek-Lin = Max CSP$(\{\text{XOR}\}^{NEG}, \mathbb{N})$,
- Max k-Exact-SAT = Max CSP$(\{\text{EX}_k\}^{LIT}, \mathbb{N})$, where $\text{EX}_k(x_1, \ldots, x_k) = 1$ if and only if there is exactly one 1 in $(x_1, \ldots, x_k)$.

Since $\deg(\Gamma^{LIT}) = \deg(\Gamma^{NEG}) = \deg(\Gamma)$ it suffices to analyze the characteristic polynomials for functions NAE_k, XOR_k, and EX_k. Let $e_i(x_1, \ldots, x_k)$ denote i-th elementary symmetric polynomial, i.e., the sum of all degree-i monomials on k variables.

$$\begin{aligned}
\text{NAE}_k(x_1, \ldots, x_k) &= \textstyle\sum_{i=1}^{k-1} (-1)^{i-1} e_i(x_1, \ldots, x_k) && \text{for odd } k,\\
\text{NAE}_k(x_1, \ldots, x_k) &= \textstyle\sum_{i=1}^{k} (-1)^{i-1} e_i(x_1, \ldots, x_k) && \text{for even } k,\\
\text{XOR}_k(x_1, \ldots, x_k) &= \textstyle\sum_{i=1}^{k} (-2)^{i-1} e_i(x_1, \ldots, x_k) && \text{for all } k,\\
\text{EX}_k(x_1, \ldots, x_k) &= \textstyle\sum_{i=1}^{k} i \cdot (-1)^{i-1} e_i(x_1, \ldots, x_k) && \text{for all } k.
\end{aligned}$$

It is easy to check these formulas using the binomial theorem. We present the argument for XOR_k as an example. Suppose the number of 1s in the vector $(x_1, \ldots, x_k)$ is ℓ. Then $e_i(x_1, \ldots, x_k)$ equals $\binom{\ell}{i}$ for $i \leq \ell$ and 0 for $i > \ell$. The formula for $\text{XOR}_k(x_1, \ldots, x_k)$ becomes $\sum_{i=1}^{\ell} (-2)^{i-1} \binom{\ell}{i} = (-\frac{1}{2}) \cdot \left(\sum_{i=0}^{\ell} (-2)^i \binom{\ell}{i} - 1 \right) = (-\frac{1}{2}) \cdot ((-1)^\ell - 1)$ which is 1 for odd ℓ and 0 for even ℓ, as expected. By these identities we deduce that the optimal compression exponent for Max k-NAE-SAT is k in the even case, $k-1$ in the odd case, and the optimal compression exponent for both Max Ek-Lin and Max k-Exact-SAT is k.

An example of a non-symmetric constraint with a non-trivial upper bound on its degree is f_k, with $\text{AR}(f_k) = 3^k$, defined recursively: $f_0(x) = x$, and

$$f_k(x_1, \ldots x_{3^k}) = \text{NAE}_3\big(f_{k-1}(x_1, \ldots x_{3^{k-1}}), f_{k-1}(x_{3^{k-1}+1}, \ldots x_{2 \cdot 3^{k-1}}), f_{k-1}(x_{2 \cdot 3^{k-1}+1}, \ldots x_{3^k})\big).$$

Because $\deg(\text{NAE}_3) = 2$, we have $\deg(f_k) = 2^k = \text{AR}(f_k)^{\log_3(2)}$ [29].

It is tempting to seek a concise characterization of Γ for which one can obtain a non-trivial bound on $\deg(\Gamma)$ and therefore a non-trivial compression for Max CSP$(\Gamma, \mathbb{N})$, where by non-trivial we mean a bound of the form $\deg(f) \leq \text{AR}(f) - 1$ for functions depending on all the coordinates. By generalizing the argument for NAE_k, it can be shown that $\deg(f) \leq$

$\text{AR}(f) - 1$ when the number of vectors that satisfy f and have an even number of 1s, is equal to the number of satisfying vectors with an odd number of 1s. Unfortunately, as far as we are aware no characterization is known describing all Γ with a non-trivial bound on $\deg(\Gamma)$, not even for symmetric polynomials induced by symmetric constraints. There exist some interesting partial results though, e.g., that if the number of variables k is a prime minus one then the degree is always k, and in general $\deg(f) \geq k - \mathcal{O}(k^{0.548})$ [32]. On the other hand, there are infinitely many symmetric functions for which $\deg(f) = \text{AR}(f) - 3$ [32]. When it comes to non-symmetric functions, there exist infinitely many examples with $\deg(f) \leq \log(\text{AR}(f))$ [30], which is asymptotically the lowest upper bound possible [29].

Compression lower bound for negative weights. For the sake of completeness, we show that Max CSP$(\Gamma, \mathbb{Z})$ admits an analogous classification as Max CSP$(\Gamma_{,}, \mathbb{N})$ that is, whenever Max CSP$(\Gamma, \mathbb{Z})$ is NP-hard, then the upper bound from Theorem 5.1 is essentially tight. The dichotomy theorem for $\mathbb{W} = \mathbb{Z}$ can be stated in a simpler manner, as the problem becomes NP-hard whenever $\deg(\Gamma) \geq 2$ [20] and the case $\deg(\Gamma) = 1$ reduces to linear function maximization. This dichotomy will follow also from the reduction below. First, we show that we can drop the assumption on the language being non 0-valid/1-valid in Corollary 4.8.

▶ **Lemma 5.4.** *Let Γ_1, Γ_2 be non-trivial constraint languages such that $\deg(\Gamma_1) \leq \deg(\Gamma_2)$. Then $CS(\Gamma_1, \mathbb{Z}) \leq_{ADD} CS(\Gamma_2, \mathbb{Z})$.*

Proof. Since f and $\neg f$ cannot be 0-valid (or 1-valid) at the same time, the language Γ_2^{NEG} is neither 0-valid nor 1-valid. As we also have $\deg(\Gamma_2) = \deg(\Gamma_2^{NEG})$, we can apply Corollary 4.8 to Γ_1 and Γ_2^{NEG}, obtaining $\text{CS}(\Gamma_1, \mathbb{Z}) \leq_{ADD} \text{CS}(\Gamma_2^{NEG}, \mathbb{Z})$. By Lemma 4.5, point (1), we get $\text{CS}(\Gamma_2^{NEG}, \mathbb{Z}) \leq_{ADD} \text{CS}(\Gamma_2, \mathbb{Z})$, which proves the claim. ◀

▶ **Theorem 5.5.** *Let non-trivial Γ be such that $d = \deg(\Gamma) \geq 2$. Then there is a constant c such that Max CSP$(\Gamma, \mathbb{Z}, c)$ does not admit a compression of size $\mathcal{O}\left(n^{d-\varepsilon}\right)$ for any $\varepsilon > 0$, unless NP $\subseteq$ co-NP/poly.*

Proof. From Lemma 5.4 we know that $\text{CS}(\Gamma_{d\text{-SAT}}, \mathbb{Z}) \leq_{ADD} \text{CS}(\Gamma, \mathbb{Z})$. Therefore an $\mathcal{O}\left(n^{d-\varepsilon}\right)$-size compression for Max CSP$(\Gamma, \mathbb{Z}, c)$ with sufficiently large c entails the same for Max CSP$(\Gamma_{d\text{-SAT}}, \mathbb{Z}, c - \mathcal{O}(1))$, which implies NP $\subseteq$ co-NP/poly (Lemma 5.2 for $d = 2$ and [14] for $d \geq 3$). ◀

6 Consequences for exponential-time algorithms

As mentioned before, our framework of reductions can be used to preserve the exponential running time as well. Namely, if $CS(\Gamma_1, \mathbb{W}_1) \leq_{ADD} CS(\Gamma_2, \mathbb{W}_2)$, then an algorithm for Max CSP$(\Gamma_2, \mathbb{W}_2, c)$ with running time $T(n)$ entails an algorithm for Max CSP$(\Gamma_2, \mathbb{W}_2, c - \mathcal{O}(1))$ with running time $T(n + \mathcal{O}(1))$. All the constructed transformations, except from $\text{CS}(\Gamma^{LIT}, \mathbb{N}) \leq_{LIN} \text{CS}(\Gamma, \mathbb{N})$ (Lemma 4.10), are additive and in particular they work as long as negative weights are allowed. Alternatively, we can take advantage of other properties of particular constraint languages to remove the negative weights.

▶ **Lemma 6.1.** *Let $d = \deg(\Gamma) \geq 2$. Then $CS(\Gamma_{d\text{-SAT}}, \mathbb{N}) \leq_{ADD} CS(\Gamma, \mathbb{Z}) \leq_{ADD} CS(\Gamma_{d\text{-SAT}}, \mathbb{N})$, that is, these constraint systems are equivalent with respect to the relation $\leq_{ADD}$.*

Proof. We take advantage of the fact that $\Gamma_{d\text{-SAT}}$ can express negated literals, i.e., $(\Gamma_{d\text{-SAT}})^{LIT} = \Gamma_{d\text{-SAT}}$. We have the following cycle of reductions.

$$\begin{aligned} \mathrm{CS}(\Gamma_{d\text{-SAT}}, \mathbb{Z}) &\leq_{ADD} \mathrm{CS}(\Gamma_{d\text{-SAT}}, \mathbb{N}) && \text{Lemma 4.9 for } (\Gamma_{d\text{-SAT}})^{LIT} = \Gamma_{d\text{-SAT}} \\ &\leq_{ADD} \mathrm{CS}(\Gamma, \mathbb{Z}) && \text{Lemma 5.4} \\ &\leq_{ADD} \mathrm{CS}(\Gamma_{d\text{-SAT}}, \mathbb{Z}) && \text{Lemma 5.4} \end{aligned}$$ ◀

▶ **Theorem 6.2.** *For each $d \geq 2$ and any constant $\alpha > 1$ either all the following problems admit an $\alpha^n n^{\mathcal{O}(1)}$ algorithm for all c, or none of them do:*

1. *Max CSP$(\Gamma_{d\text{-SAT}}, \mathbb{N}, c)$,*
2. *Max CSP$(\Gamma, \mathbb{Z}, c)$ for any Γ with $\deg(\Gamma) = d$,*
3. *Max CSP$(\Gamma, \mathbb{N}, c)$ for any Γ with $\deg(\Gamma) = d$ such that $\Gamma^{NEG} = \Gamma$ or $\Gamma^{LIT} = \Gamma$.*

Proof. As noted in Proposition 4.3, if $\mathrm{CS}(\Gamma_1, \mathbb{W}_1) \leq_{ADD} \mathrm{CS}(\Gamma_2, \mathbb{W}_2)$ and Max CSP$(\Gamma_2, \mathbb{W}_2, c)$ admits an algorithm with running time $\alpha^n n^{\mathcal{O}(1)}$, then the same holds for Max CSP$(\Gamma_1, \mathbb{W}_1, c - \mathcal{O}(1))$. The equivalency between (1) and (2) has been proven in Lemma 6.1. Since (2) is more general than (3), it suffices to reduce (2) into (3). Lemma 4.5, point (2), provides the reduction $\mathrm{CS}(\Gamma, \mathbb{Z}) \leq_{ADD} \mathrm{CS}(\Gamma^{NEG}, \mathbb{N})$ for the case $\Gamma^{NEG} = \Gamma$ and Lemma 4.9 provides the reduction $\mathrm{CS}(\Gamma, \mathbb{Z}) \leq_{ADD} \mathrm{CS}(\Gamma^{LIT}, \mathbb{N})$ for the case $\Gamma^{LIT} = \Gamma$. ◀

First corollary of this theorem is that problems of form Max CSP$(\Gamma, \mathbb{Z})$ are divided into equivalence classes with respect to the optimal running time. In particular, solving any Max CSP$(\Gamma, \mathbb{Z})$ with $\deg(\Gamma) \geq 3$ in time $\mathcal{O}(2^{(1-\varepsilon)n})$ for any $\varepsilon > 0$ contradicts the Max 3-SAT Hypothesis. Also, the hypothesis remains equivalent if we replace Max 3-CNF-SAT with Max 3-Lin SAT or Max 3-Exact SAT with only positive weights, because their constraint languages satisfy $\Gamma^{NEG} = \Gamma$ and $\Gamma^{LIT} = \Gamma$, respectively. Another corollary is that improving the running time $\mathcal{O}\big(2^{\frac{\omega}{3} n}\big)$ for Max Cut or Max DiCut with integer weights or Max 3-NAE-SAT with positive weights would imply an analogous breakthrough for Max 2-CNF-SAT.

Alman and Williams [1] have noted that it is not known how to improve the running time for Max 3-CNF-SAT, even for instances with a linear number of clauses. They have therefore formulated a stronger hypothesis. The Sparse Max 3-SAT Hypothesis states that there exists $c > 0$ such that Max 3-CNF-SAT with cn clauses does not admit an $\mathcal{O}(2^{(1-\varepsilon)n})$-time algorithm for any $\varepsilon > 0$. Similarly, their Sparse Max 2-SAT Hypothesis states that one cannot beat running time $\mathcal{O}\big(2^{\frac{\omega}{3} n}\big)$ for Max 2-CNF-SAT with cn clauses. Observe that our reductions preserve the property of having $\mathcal{O}(n)$ different constraint applications (condition (2) in Definition 4.1). Therefore as long as we allow negative weights at constraint applications, we can replace Max 2-CNF-SAT (resp. Max 3-CNF-SAT) in this hypothesis with Max CSP$(\Gamma, \mathbb{Z})$ for any constraint language Γ of degree 2 (resp. 3) to obtain an equivalent statement.

7 Conclusions and open problems

We have provided a complete characterization of the optimal compression for Max CSP(Γ) in the case of a Boolean domain. A natural question arises about larger domains. Our approach does not transfer even to the case with a domain of size 3, since there is no unique way to represent functions $\{0,1,2\}^k \to \{0,1\}$ as polynomials. One may consider, e.g., embedding to a Boolean domain or using non-multilinear polynomials, but it is not clear which approach leads to the optimal degree and how to find accompanying lower bounds.

On the exponential-time front, we have shown that Max d-CNF-SAT is as hard as any Max CSP of degree d as long as negative weights are allowed. Although we were able to get rid of the latter assumption in several cases, there is still a gap in this classification: does improving the running time for any degree-d Max CSP$(\Gamma, \mathbb{N})$ imply an improvement for Max d-CNF-SAT?

Abstract

The graph parameter of *pathwidth* can be seen as a measure of the topological resemblance of a graph to a path. A popular definition of pathwidth is given in terms of *node search* where we are given a system of tunnels (represented by a graph) that is contaminated by some infectious substance and we are looking for a search strategy that, at each step, either places a searcher on a vertex or removes a searcher from a vertex and where an edge is cleaned when both endpoints are simultaneously occupied by searchers. It was proved that the minimum number of searchers required for a successful cleaning strategy is equal to the pathwidth of the graph plus one. Two desired characteristics for a cleaning strategy is to be *monotone* (no recontamination occurs) and *connected* (clean territories always remain connected). Under these two demands, the number of searchers is equivalent to a variant of pathwidth called *connected pathwidth*. We prove that connected pathwidth is fixed parameter tractable, in particular we design a $2^{O(k^2)} \cdot n$ time algorithm that checks whether the connected pathwidth of G is at most k. This resolves an open question by [*Dereniowski, Osula, and Rzążewski, Finding small-width connected path-decompositions in polynomial time. Theor. Comput. Sci., 794:85–100, 2019*]. For our algorithm, we enrich the *typical sequence technique* that is able to deal with the connectivity demand. Typical sequences have been introduced in [*Bodlaender and Kloks. Efficient and constructive algorithms for the pathwidth and treewidth of graphs. J. Algorithms, 21(2):358–402, 1996*] for the design of linear parameterized algorithms for treewidth and pathwidth. While this technique has been later applied to other parameters, none of its advancements was able to deal with the connectivity demand, as it is a "global" demand that concerns an unbounded number of parts of the graph of unbounded size. The proposed extension is based on an encoding of the connectivity property that is quite versatile and may be adapted so to deliver linear parameterized algorithms for the connected variants of other width parameters as well. An immediate consequence of our result is a $2^{O(k^2)} \cdot n$ time algorithm for the monotone and connected version of the edge search number.

1 Introduction

Pathwidth. A *path-decomposition* of a graph $G = (V, E)$ is a sequence $\mathsf{Q} = \langle B_1, \ldots, B_q \rangle$ of vertex sets, called *bags* of Q, such that

1. $\bigcup_{i \in \{1,\ldots,q\}} B_i = V$,
2. every edge $e \in E$ is a subset of some member of Q, and
3. the *trace* of every vertex $v \in V$, that is the set $\{i \mid v \in B_i\}$, is a set of consecutive integers.

The *width* of a path-decomposition is $\max\{|B_i| - 1 \mid i \in \{1, \ldots, q\}\}$ and the *pathwidth* of a graph G, denoted by $\mathsf{pw}(G)$, is the minimum width of a path-decomposition of G.

The above definition appeared for the first time in [36]. Pathwidth can be seen as a measure of the topological resemblance of a graph to a path. Pathwidth, along with its tree-analogue *treewidth*, have been used as key combinatorial tools in the Graph Minors series of Robertson and Seymour [37] and they are omnipresent in both structural and algorithmic graph theory.

Deciding whether the pathwidth of a graph is at most k is an NP-complete problem [2]. This motivated the problem of the existence, or not, of a *parameterized algorithm* for this problem, and algorithm running in $f(k) \cdot n^{O(1)}$ time algorithm. An affirmative answer to this question was directly implied as a consequence of the algorithmic and combinatorial results of the Graph Minors series and the fact that, for every k, the class of graphs with pathwidth at most k is closed under taking of minors[1]. On the negative side, this implication was purely existential. The challenge of *constructing* an $f(k) \cdot n^{O(1)}$ time algorithm for pathwidth (as well as for treewidth) was a consequence of the classic result of Bodlaender and Kloks in [8] (see also [15, 30]). The main result in [8] implies a $2^{O(k^3)} \cdot n$ time algorithm. This was later improved to one running in $2^{O(k^2)} \cdot n$ time by Fürer in [20]).

Graph searching. In a *graph searching* game, the opponents are a group of *searchers* and an evading *fugitive*. The opponents move in turns in a graph. The objective of the searchers is to deploy a strategy of moves that leads to the capture of the fugitive. At each step of the *node searching game*, the searchers may either place a searcher at a vertex or remove a searcher from a vertex. The fugitive resides in the edges of the graph and is lucky, invisible, fast, and agile. The capture of the fugitive occurs when searchers occupy both endpoints of the edge where he currently resides. A *node searching strategy* is a sequence of moves of the searchers that can guarantee the eventual capture of the fugitive.[2] The cost of a searching strategy is the maximum number of searchers simultaneously present in the graph during the deployment of the strategy. The *node search number* of a graph G, denoted by $\mathsf{ns}(G)$, is defined as the minimum cost of a node searching strategy. Node searching was defined by Kirousis and Papadimitriou in [29] who proved that the game is equivalent to its monotone variant where search strategies are *monotone* in the sense that they prevent the fugitive from pervading again areas from where he had been expelled. This result along with the results in [27, 28, 31], imply that, for every graph G, $\mathsf{ns}(G) = \mathsf{pw}(G) + 1$.

The connectivity issue. In several applications of graph searching it is important to guarantee secure communication channels between the searchers so that they can safely exchange information. This issue was treated for the first time in the area of distributed

[1] A graph H is a *minor* of a graph G if H can be obtained by some subgraph of G by contracting edges.

[2] An equivalent setting of graph searching is to see G as a system of pipelines or corridors that is contaminated by some poisonous gas or some highly infectious substance. The searchers can be seen as cleaners that deploy a decontamination strategy [13, 19]. The fact that the fugitive is invisible, fast, lucky, and agile permits us to see him as being omnipresent in any edge that has not yet been cleaned.

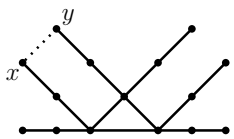

Figure 1 A graph G of connected pathwidth 2 with a subgraph of connected pathwidth 3.

computing, in particular in [4], where the authors considered the problem of capturing an intruder by mobile agents (acting for example as antivirus programs). As agents deploy their cleaning strategy, they must guarantee that, at each moment of the search, the cleaned territories remain connected, so to permit the safe exchange of information between the coordinating agents.

The systematic study of connected graph searching was initiated in [3, 5]. When, in node searching, we demand that the search strategies are monotone and connected, we define *monotone connected node search number*, denoted by $\mathsf{mcns}(G)$. The graph decomposition counterpart of this parameter was introduced by Dereniowski in [16]. He defined the *connected pathwidth* of a connected graph, denoted by $\mathsf{cpw}(G)$, by considering *connected* path-decompositions $\mathsf{Q} = \{B_1, \ldots, B_q\}$ where the following additional property is satisfied:

▶ For every $i \in \{1, \ldots, q\}$, the subgraph of G induced by $\bigcup_{h\in\{1,\ldots,i\}} B_h$ is *connected*.

As noticed in [16], for every connected graph G, $\mathsf{mcns}(G) = \mathsf{cpw}(G) + 1$ (see also [1]). Notice that the above demand results to a break of symmetry: the fact that $\langle B_1, \ldots, B_q\rangle$ is a connected path-decomposition does not imply that the same holds for $\langle B_q, \ldots, B_1\rangle$ (while this is always the case for conventional path-decompositions). This *sense of direction* seems to be the source of all combinatorial particularities (and challenges) of connected pathwidth.

Computing connected pathwidth. It is easy to see that checking whether $\mathsf{cpw}(G) \leq k$ is an NP-complete problem: if we define G^* as the graph obtained from G after adding a new vertex adjacent with all the vertices of G, then observe that $\mathsf{pw}(G) = \mathsf{cpw}(G^*) - 1$. This motivates the question on the parameterized complexity of the problem. The first progress in this direction was done recently in [17] by Dereniowski, Osula, and Rzążewski who gave an $f(k) \cdot n^{O(k^2)}$ time algorithm. In [17, Conjecture 1], they conjectured that there is a fixed parameter algorithm checking whether $\mathsf{cpw}(G) \leq k$. The general question on the parameterized complexity of the connected variants of graph search was raised as an open question by Fedor V. Fomin during the GRASTA 2017 workshop [18].

A somehow dissuasive fact towards a parameterized algorithm for connected pathwidth is that connected pathwdith is not closed under minors and therefore it does not fit in the powerful algorithmic framework of Graph Minors (which is the case with pathwidth). The removal of an edge may increase the parameter. For instance, the connected pathwidth of the graph in Figure 1 has connected pathwidth 2 while if we remove the edge $\{x, y\}$ its connected pathwidth increases to 3. On the positive side, connected pathwidth is closed under contractions (see e.g., [1]), i.e, its value does not increase when we contract edges and, moreover, the yes-instances of the problem have bounded pathwidth, therefore they also have bounded treewidth. Based on these observations, the existence of a parameterized algorithm would be implied if we can prove that, for any k, the set $\mathcal{Z}_k$ of contraction-minimal[3] graphs with connected pathwidth more than k is *finite*: as contraction containment can be expressed

[3] For instance, the graph $G \setminus \{x, y\}$ from Figure 1 belongs in $\mathcal{Z}_2$.

in MSO logic, one should just apply Courcelle's theorem [14] to check whether some graph of $\mathcal{Z}_k$ is a contraction of G. The hurdle in this direction is that we have no idea whether $\mathcal{Z}_k$ is finite or not. The alternative pathway is to try to devise a linear parameterized algorithm by applying the algorithmic techniques that are already known for pathwidth.

The typical sequence technique. The main result of [8] was an algorithm that, given a path-decomposition Q of G of width at most k and an integer w, outputs, if exists, a path-decomposition of G of width at most w, in $2^{O(k(w+\log k))} \cdot n$ time. In this algorithm Bodlaender and Kloks introduced the celebrated *typical sequence technique*, a refined dynamic programming technique that encodes partial path/tree decompositions as a system of suitably compressed sequences of integers, able to encode all possible path-decompositions of width at most w (see also [15, 30]). This technique was later extended/adapted for the design of parametrized algorithms for numerous graph parameters such as branchwidth [9], linear-width [10], cutwidth [39], carving-width [38], modified cutwidth, and others [6,7,40]. In [6] this technique was viewed as a result of *un-nondeterminization*: a stepwise evolution of a trivial hypothetical non-deterministic algorithm towards a deterministic parameterized algorithm. A considerable generalization of the characteristic sequence technique was proposed in the PhD thesis of Soares [32] where this technique was implemented under the powerful meta-algorithmic framework of *q-branched Φ-width*. Non-trivial extensions of the typical sequence technique where proposed for devising parameterized algorithms for parameters on matroids such as matroid pathwidth [23], matroid branchwidth [25], as well as all the parameters on graphs or hypergraphs that can be expressed by them. Very recently Bodlaender, Jaffke, and Telle in [7] suggested refinements of the typical sequence technique that enabled the polynomial time computation of several width parameters on directed graphs. Finally, Bojańczyk and Pilipczuk suggested an alternative approach to the typical sequence technique, based on MSO transductions between decompositions [11].

Unfortunately, the above mentioned state of the art on the typical sequence technique is unable to encompass connected pathwidth. A reason for this is that the connectivity demand is a "global property" applying to *every* prefix of the path-decomposition which correspond to an unbounded number of subgraphs of arbitrary size.

Our result. In this paper we resolve *affirmatively* the conjecture that checking whether $\mathsf{cpw}(G) \leq k$ is fixed parameter tractable. Our main result is the following.

▶ **Theorem 1.** *One may construct an algorithm that given an n-vertex connected graph G, a path-decomposition $\mathsf{Q} = \langle B_1, \ldots, B_q \rangle$ of G of width at most k and an integer w, outputs a connected path-decomposition of G of width at most w or reports correctly that such an algorithm does not exist in $2^{O(k(w+\log k))} \cdot n$ time.*

To design an algorithm checking whether $\mathsf{cpw}(G) \leq k$ we first use the algorithms of [8] and [20], to build, if exists, a path decomposition of G of width at most k, in $2^{O(k^2)} \cdot n$ time. In case of a negative answer we know than $\mathsf{cpw}(G) > k$, otherwise we apply the algorithm of Theorem 1. The overall running time is dominated by the algorithm of Fürer in [20] which is $2^{O(k^2)} \cdot n$.

Our techniques. We now give a brief description of our techniques by focusing on the novel issues that we introduce. This description demands some familiarity with the typical sequence technique. Otherwise, the reader can go directly to the next section.

Let $\mathsf{Q} = \langle B_1, \ldots, B_q \rangle$ be a (nice) path-decomposition of G of width at most k. For every $i \in [q]$, we let $\mathbf{G}_i = (G_i, B_i)$ be the boundaried graph where $G_i = G[\bigcup_{h \in \{1,\ldots,i\}} B_h]$. We follow standard dynamic programming over a path-decomposition that consists in computing a representation of the set of partial solutions associated to $\mathbf{G}_i$, which in our case are *connected* path-decompositions of $\mathbf{G}_i$ of width at most w. The challenge is how to handle in a compact way the connectivity requirement of a path-decomposition of a graph that can be of arbitrarily large size.

A connected path-decomposition $\mathsf{P} = \langle A_1, \ldots, A_\ell \rangle$ of $\mathbf{G}_i$ is represented by means of a $(\mathbf{G}_i, \mathsf{P})$-*encoding sequence* $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$. For every $j \in [\ell]$, the element s_j of the sequence S is a triple $(\mathbf{bd}(\mathsf{s}_j), \mathbf{cc}(\mathsf{s}_j), \mathbf{val}(\mathsf{s}_j))$ where: $\mathbf{bd}(\mathsf{s}_i) = A_j \cap B_i$; $\mathbf{val}(\mathsf{s}_j) = |A_j \setminus B_i|$; and $\mathbf{cc}(\mathsf{s}_j)$ is the projection of the connected components of $G_i^j = G_i[\bigcup_{h \in \{1,\ldots,j\}} A_h]$ onto the subset of boundary vertices $B_i \cap V(G_i^j)$. To compress a $(\mathbf{G}_i, \mathsf{P})$-*encoding sequence* S, we identify a subset $\mathbf{bp}(\mathsf{S})$ of indexes, called *breakpoints*, such that $j \in \mathbf{bp}(\mathsf{S})$ if $\mathbf{bd}(\mathsf{s}_{j-1}) \neq \mathbf{bd}(\mathsf{s}_j)$ (type-1) or $\mathbf{cc}(\mathsf{s}_{j-1}) \neq \mathbf{cc}(\mathsf{s}_j)$ (type-2) or j is an index belonging to a typical sequence of the integer sequence $\langle \mathbf{val}(\mathsf{s}_b), \ldots, \mathbf{val}(\mathsf{s}_{c-1}) \rangle$ where $b, c \in [\ell]$ are consecutive type-1 or 2- breakpoints. We define $\mathsf{rep}(\mathsf{S})$ as the induced subsequence $\mathsf{S}[\mathbf{bp}(\mathsf{S})]$.

The novelty in this representation is the $\mathbf{cc}(\cdot)$ component which is a near-partition of the subset $B_i \cap V(G_i^j)$ of boundary vertices. The critical observation is that for every $j \in [\ell - 1]$, $\mathbf{cc}(\mathsf{s}_{j+1})$ is coarser than $\mathbf{cc}(\mathsf{s}_j)$. This, together with the known results on typical sequences, allows us to prove that the size of $\mathsf{rep}(\mathsf{S})$ is $O(kw)$ and that the number of representative sequences is $2^{O(k(w+\log k))}$. Finally, as in the typical sequence technique, we define a domination relation over the set of representative sequences. The DP algorithm over the path-decomposition Q consists then in computing a domination set $\mathbf{D}_w(G_{i+1})$ of the representative sequences of $\mathbf{G}_{i+1}$ from a domination set $\mathbf{D}_w(G_i)$ of the representative sequences of $\mathbf{G}_i$.

The above scheme extends the current state of the art on typical sequences as it further incorporates the encoding of the connectivity property. While this is indeed a "global property", it appears that its evolution with respect to the bags of the decomposition can be controlled by the second component of our encoding and this is done in terms of a sequence of a gradually coarsening partitions. This establishes a dynamic programming framework that can potentially be applied on the connected versions of most of the parameters where the typical sequence technique was used so far. Moreover, it may be the starting point of the algorithmic study of parameters where other, alternative to connectivity, global properties are imposed to the corresponding decompositions.

Consequences in connected graph searching. The original version of graph searching was the *edge searching* variant, defined [4] by Parsons [33,34], where the only differences with node searching is that a searcher can additionally slide along an edge and sliding is the only way to clean an edge. The corresponding search number is called *edge search number* and is denoted by $\mathsf{es}(G)$. If we additionally demand that the searching strategy is connected and monotone, then we define the *monotone connected edge search number* denoted by $\mathsf{mces}(G)$. As proved

[4] An equivalent model was proposed independently by Petrov [35]. The models of Parsons and Petrov where different but also equivalent, as proved by Golovach in [21,22]. The model of Parsons was inspired by an earlier paper by Breisch [12], titled *"An intuitive approach to speleotopology"*, where the aim was to rescue an (unlucky) speleologist lost in a system of caves. Notice that "unluckiness" cancels the speleologist's will of being rescued as, from the searchers' point of view, it imposes on him/her the status of an "evading entity". As a matter of fact, the connectivity issue appears even in the first inspiring model of the search game. In a more realistic scenario, the searchers cannot "teleport" themselves to non-adjacent territories of the caves while this was indeed permitted in the original setting of Parsons.

in [29], $\mathsf{es}(G) = \mathsf{pw}(G_{\mathsf{v}})$, where G_{v} is the graph obtained if we subdivide twice each edge of G. Applying the same reduction as in [29] for the monotone and connected setting, one can prove that $\mathsf{mces}(G) = \mathsf{cpw}(G_{\mathsf{v}})$. As we already mentioned, $\mathsf{mcns}(G) = \mathsf{cpw}(G_{\mathsf{v}}) + 1$. These two reductions imply that the result of Theorem 1 holds also for mcns and mces, i.e., the search numbers for the monotone and connected versions of both node and edge searching.

2 Preliminaries and definitions

2.1 Basic concepts

Sets and near-partitions. For an integer ℓ, we denote by $[\ell]$ the set $\{1, \ldots, \ell\}$. Let S be a finite set. A *near-partition* Q of S is a family of subsets $\{X_1, \ldots, X_k\}$ (with $k \leq |S| + 1$) of subsets of S, called *blocks*, such that $\bigcup_{i \in [k]} X_i = S$ and for every $1 \leq i < j \leq k$, $X_i \cap X_j = \emptyset$. Observe that a near-partition may contain several copies of the empty set. A *partition* of S is a near-partition with the additional constraint that if it contains the empty set, then this is the unique block. Let Q be a near-partition of a set S and Q' be a near-partition of a set S' such that $S \subseteq S'$. We say that Q is *thinner* than Q', or that Q' is *coarser* than Q, which we denote $\mathsf{Q} \sqsubseteq \mathsf{Q}'$, if for every block X of Q, there exists a block X' of Q' such that $X \subseteq X'$. For a near-partition $\mathsf{Q} = \{X_1, \ldots, X_\ell\}$ of S and a subset $S' \subseteq S$, we define the *projection of* Q *onto* S' as the near-partition $\mathsf{Q}_{|S'} = \{X_1 \cap S', \ldots, X_\ell \cap S'\}$. Observe that if Q is a partition, then $\mathsf{Q}_{|S'}$ may not be a partition: if several blocks of Q are subsets of $S \setminus S'$, then $\mathsf{Q}_{|S'}$ contains several copies of the emptyset.

Sequences. Let S be a set. A *sequence* of elements of S, denoted by $\alpha = \langle a_1, \ldots, a_\ell \rangle$, is a subset of S equipped with a total ordering: for $1 \leqslant i < j \leqslant \ell$, a_i occurs before a_j in the sequence α. The *length* of a sequence is the number of elements that it contains. Let $X \subseteq [\ell]$ be a subset of indexes of α. We define the *subsequence* of α *induced* by X as the sequence $\alpha[X]$ on the subset $\{a_i \mid i \in X\}$ such that, for $i, j \in X$, a_i occurs before a_j in $\alpha[X]$ if and only if $i < j$.

The *duplication* of the element a_j, with $j \in [\ell]$, in the sequence $\alpha = \langle a, \ldots, a_\ell \rangle$ yields the sequence $\alpha' = \langle a_1, \ldots, a_j, a_j, \ldots, a_\ell \rangle$ of length $\ell + 1$. A sequence β is an *extension* of the sequence α if it is either α or it results from a series of duplications on α. We define the set of extensions of α as: $\mathsf{Ext}(\alpha) = \{\alpha^* \mid \alpha^* \text{ is an extension of } \alpha\}$.

Let $\alpha = \langle a_1, \ldots, a_\ell \rangle$ be a sequence and $\alpha^* = \langle a_1, \ldots, a_p \rangle$ be an extension of α. If $p \leq \ell + k$, then α^* results from a series of at most k duplications and we say that α^* is a $(\leq k)$-*extension* of α. With the definition of an extension, every element of α^* is a copy of some element of α. We define the *extension surjection* as a surjective function $\delta_{\alpha^* \to \alpha} : [p] \to [\ell]$ such that if $\delta_{\alpha^* \to \alpha}(j) = i$ then $a^*_j = a_i$. An extension surjection $\delta_{\alpha^* \to \alpha}$ is a certificate that $\alpha^* \in \mathsf{Ext}(\alpha)$. Finally, we observe that if $\alpha^* \in \mathsf{Ext}(\alpha)$, then α is an induced subsequence of α^*. Moreover, if $\alpha^* \in \mathsf{Ext}(\alpha)$ and $\beta \in \mathsf{Ext}(\alpha^*)$, then β is an extension of α.

Graphs and boundaried graphs. Given a graph $G = (V, E)$ and a vertex set $S \subseteq V(G)$, we denote by $G[S]$ the *subgraph* of G that is *induced by the vertices of* S, i.e., the graph $(S, \{e \in E \mid e \subseteq S\})$. Also, if $x \in V$, we define $G \setminus x = G[V \setminus \{x\}]$. The *neighborhood* of a vertex v in G is the set of vertices that are adjacent to v in G and is denoted by $N_G(v)$.

A *boundaried graph* is a pair $\mathbf{G} = (G, B)$ such that G is a graph over a vertex set V and $B \subseteq V$ is a subset of distinguished vertices, called *boundary vertices*. We say that a boundaried graph $\mathbf{G} = (G, B)$ is *connected* if either G is connected and $B = \emptyset$ or, in case $B \neq \emptyset$, every connected component C of G contains some boundary vertex, that is $C \cap B \neq \emptyset$.

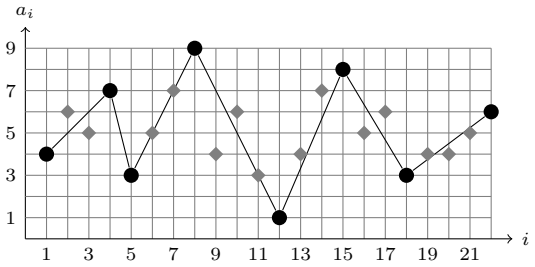

Figure 2 The black bullets forms the typical sequence $\mathsf{Tseq}(\alpha) = \langle 4,7,3,9,1,8,3,6\rangle$ of the sequence $\alpha = \langle 4,6,5,7,3,5,7,9,4,6,3,1,4,7,8,5,6,3,4,4,5,6\rangle$ of black and gray diamonds.

The definition of a connected path-decomposition also naturally extends to boundaried graphs as follows.

▶ **Definition 2.** *Let* $\mathsf{P} = \langle A_1, \ldots, A_\ell\rangle$ *be a path-decomposition of the boundaried graph* $\mathbf{G} = (G, B)$*. Then* P *is* connected *if, for every* $i \in [\ell]$*, the boundaried graph* $(G_i, V_i \cap B)$ *is connected, where* $V_i = \bigcup_{h\in[i]} A_h$ *and* $G_i = G[V_i]$*.*

2.2 Integer sequences

Let us recall the notion of *typical sequences* introduced by Bodlaender and Kloks [8] (see also [15, 30]).

▶ **Definition 3.** *Let* $\alpha = \langle a_1, \ldots, a_\ell\rangle$ *be an integer sequence. The* typical sequence $\mathsf{Tseq}(\alpha)$ *is obtained after iterating the following operations, until none is possible anymore:*

- *if for some* $i \in [\ell - 1]$*,* $a_i = a_{i+1}$*, then remove* a_{i+1} *from* α*;*
- *if there exists* $i, j \in [\ell]$ *such that* $i \leqslant j - 2$ *and* $\forall h$*,* $i < h < j$*,* $a_i \leq a_h \leq a_j$ *or* $\forall h$*,* $i < h < j$*,* $a_i \geq a_h \geq a_j$*, then remove the subsequence* $\langle a_{i+1}, \ldots, a_{j-1}\rangle$ *from* α*.*

As a typical sequence $\mathsf{Tseq}(\alpha) = \langle b_1, \ldots, b_i, \ldots, b_r\rangle$ is a subsequence of α, it follows that, for every $i \in [r]$, there exists $j_i \in [\ell]$ such that $b_i = a_{j_i}$. Herefater every such index j_i is called a *tip* of the sequence α.

If α and β are two integer sequences of same length ℓ, we say that $\alpha \leq \beta$ if for every $j \in [\ell]$, $a_j \leq b_j$.

▶ **Definition 4.** *Let* α *and* β *be two integer sequences. Then* $\alpha \preceq \beta$ *if there are* $\alpha^* \in \mathsf{Ext}(\alpha)$ *and* $\beta^* \in \mathsf{Ext}(\beta)$ *such that* $\alpha^* \leq \beta^*$*. Whenever* $\alpha \preceq \beta$ *and* $\beta \preceq \alpha$*, we say that* α *and* β *are* equivalent *which is denoted by* $\alpha \equiv \beta$*.*

We extend the definition of the $\leq$-relation and $\preceq$-relation on integer sequences to sequences of integer sequences. Let $\mathsf{P} = \langle \mathsf{L}_1, \ldots, , L_r\rangle$ and $\mathsf{Q} = \langle \mathsf{K}_1, \ldots, \mathsf{K}_r\rangle$ be two sequences of integer sequences such that for every $i \in [r]$, L_i and K_i have the same length. We say that $\mathsf{P} \leq \mathsf{Q}$ if for every $i \in [r]$, $\mathsf{L}_i \leq \mathsf{K}_i$. The set of *extensions* of P is $\mathsf{Ext}(\mathsf{P}) = \{\langle \mathsf{L}'_1, \ldots, \mathsf{L}'_r\rangle \mid i \in [r], \mathsf{L}'_i \in \mathsf{Ext}(\mathsf{L}_i)\}$. Finally we say that $\mathsf{P} \preceq \mathsf{Q}$ if there exist $\mathsf{P}' \in \mathsf{Ext}(\mathsf{P})$ and $\mathsf{Q}' \in \mathsf{Ext}(\mathsf{Q})$ such that $\mathsf{P}' \leq \mathsf{Q}'$. If $\mathsf{P} \preceq \mathsf{Q}$ and $\mathsf{Q} \preceq \mathsf{P}$, then we say that $\mathsf{P} \equiv \mathsf{Q}$. The relation $\equiv$ is an equivalence relation.

2.3 Boundaried sequences

We now define the main notion that will allow us to represent and manipulate (connected) path-decompositions of a boundaried graph $\mathbf{G} = (G, B)$ (see Subsection 3.1).

▶ **Definition 5** (B-boundaried sequence). *Let B be a finite set. A* B-boundaried sequence *is a sequence $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$ such that for every $j \in [\ell]$, $\mathsf{s}_j = (\mathbf{bd}(\mathsf{s}_j), \mathbf{cc}(\mathsf{s}_j), \mathbf{val}(\mathsf{s}_j))$ is defined as follows:*

- *$\mathbf{bd}(\mathsf{s}_j) \subseteq B$ with the property that for every $x \in B$, the indices $j \in [l]$ such that $x \in \mathbf{bd}(\mathsf{s}_j)$ are consecutive;*
- *$\mathbf{cc}(\mathsf{s}_j)$ is a near-partition of $\bigcup_{i \leq j} \mathbf{bd}(\mathsf{s}_i) \subseteq B$ with the property that for every $j < \ell$, $\mathbf{cc}(\mathsf{s}_j) \sqsubseteq \mathbf{cc}(\mathsf{s}_{j+1})$;*
- *$\mathbf{val}(\mathsf{s}_j)$ is a positive integer.*

The width *of S is defined as $\mathsf{width}(\mathsf{S}) = \max_{j \in \ell}(|\mathbf{bd}(\mathsf{s}_j)| + \mathbf{val}(\mathsf{s}_j))$.*

▶ **Definition 6** (Connected B-boundaried sequence). *Let $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$ be a B-boundaried sequence for some finite set B. We say that S is* connected *if for every $i \in [\ell]$, $\mathbf{cc}(\mathsf{s}_i)$ is a partition of $\bigcup_{i \leq j} \mathbf{bd}(\mathsf{s}_i) \subseteq B$.*

Observe that if $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$ is a connected B-boundaried sequence and if there exists some $i \in [\ell]$ such that $\mathbf{cc}(\mathsf{s}_i) = \{\emptyset\}$, then, for every $j \leq i$, $\mathbf{bd}(\mathsf{s}_j) = \emptyset$ and $\mathbf{cc}(\mathsf{s}_j) = \{\emptyset\}$.

▶ **Definition 7** (Breakpoints). *Let $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_j, \ldots, \mathsf{s}_\ell \rangle$ be a B-boundaried sequence for some finite set B. Then the index j, with $1 \leq j \leq \ell$, is a* breakpoint *of:*

- type-1 *if $j = 1$ or $\mathbf{bd}(\mathsf{s}_j) \neq \mathbf{bd}(\mathsf{s}_{j-1})$ or $j = \ell$;*
- type-2 *if it is not a type-1 breakpoint and $\mathbf{cc}(\mathsf{s}_j) \neq \mathbf{cc}(\mathsf{s}_{j-1})$;*
- type-3 *if it is not a type-1 nor a type-2 and j is a tip of the integer sequence $\langle \mathbf{val}(\mathsf{s}_{l_j}), \ldots, \mathbf{val}(\mathsf{s}_{r_j - 1}) \rangle$ where l_j and r_j are respectively the largest and smallest type-1 or type-2 breakpoints such that $l_j < j < r_j$.*

Let $\mathbf{bp}(\mathsf{S})$ be the set of breakpoints of S and $\mathbf{bp}_t(\mathsf{S})$ be the set of type-t breakpoints of S, for $t \in \{1, 2, 3\}$. The representative sequence $\mathsf{rep}(\mathsf{S})$ *of S is defined as $\mathsf{S}[\mathbf{bp}(\mathsf{S})]$.*

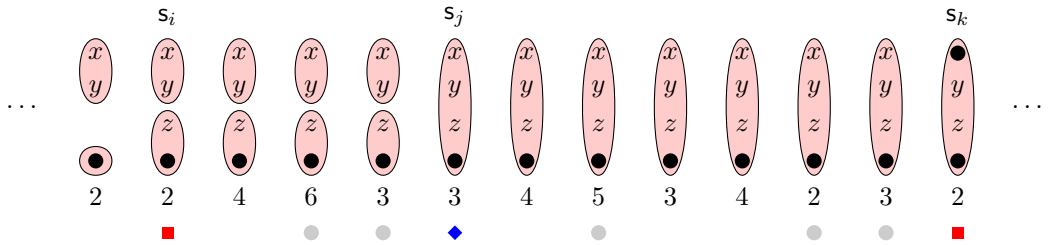

Figure 3 The part $\langle \mathsf{s}_{i-1}, \ldots \mathsf{s}_k \rangle$ of a B-boundaried sequence S for some set $B \supseteq \{x, y, z\}$. A bullet $\bullet$ at some index j represents an element of $\bigcup_{h<j} \mathbf{bd}(\mathsf{s}_h)$. Observe that at index k, x is indeed represented by a black bullet. For the index i, we have $\mathbf{bd}(\mathsf{s}_i) = \{x, y, z\}$, $\mathbf{cc}(\mathsf{s}_i) = \{\{x, y\}, \{z, \bullet\}\}$ and $\mathbf{val}(\mathsf{s}_i) = 2$. At every position j, only named elements belong to $\mathbf{bd}(\mathsf{s}_j)$. The red squares mark the type-1 breakpoints: at position i, element z is new, while at position k, element x is forgotten. The blue diamond at index j marks a type-2 breakpoint which corresponds to the merge of two parts of $\mathbf{cc}(\mathsf{s}_{i+4})$ into a single part. Finally, the grey bullets type-3 breakpoints corresponding to tips of the integer sequences $\langle \mathbf{val}(\mathsf{s}_i), \ldots \mathbf{val}(\mathsf{s}_{j-1}) \rangle$ and $\langle \mathbf{val}(\mathsf{s}_j), \ldots \mathbf{val}(\mathsf{s}_{k-1}) \rangle$.

Figure 3 illustrates the notions of B-boundaried sequence and breakpoints. Observe that $\mathsf{rep}(\mathsf{S})$ can be computed from the B-boundaried sequence S as in Definition 3 and is uniquely defined. The set of representative B-boundaried sequences of width at most w is defined as

$$\mathbf{Rep}_w(B) = \{\mathsf{rep}(\mathsf{S}) \mid \mathsf{S} \text{ is a } B\text{-boundaried sequence of width} \leq w\}.$$

▶ **Definition 8** (B-boundary model). *Let $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_j, \ldots, \mathsf{s}_\ell \rangle$ be a B-boundaried sequence. For every $j \in [\ell]$, we set $\dot{\mathsf{s}}_j = (\mathbf{bd}(\mathsf{s}_j), \mathbf{cc}(\mathsf{s}_j), \mathbf{t}(\mathsf{s}_j))$ with $\mathbf{t}(\mathsf{s}_j) = 1$ if $j \in \mathbf{bp}_1(\mathsf{S})$, $\mathbf{t}(\mathsf{s}_j) = 2$ if $j \in \mathbf{bp}_2(\mathsf{S})$ and $\mathbf{t}(\mathsf{s}_j) = 0$ otherwise. The B-*boundary model *of S, denoted by $\mathsf{model}(\mathsf{S})$, is the subsequence of $\dot{\mathsf{S}} = \langle \dot{\mathsf{s}}_1, \ldots, \dot{\mathsf{s}}_j, \ldots, \dot{\mathsf{s}}_\ell \rangle$ induced by $\mathbf{bp}_1(\mathsf{S}) \cup \mathbf{bp}_2(\mathsf{S})$.*

▶ **Lemma 9.** *Let* S *be a* B*-boundaried sequence. If* $\mathsf{S}^* \in \mathsf{Ext}(\mathsf{S})$*, then* $\mathsf{model}(S^*) = \mathsf{model}(S)$.

As in [8, 24], we will bound the number of representatives of B-boundaried sequences. For doing so, we bound the number of B-boundaried models and then use [8, Lemma 3.5] which gives an upper bound on the number of typical sequences. Taking into account the fact that there are $O(|B|)$ breakpoints and $|B|^{O(k)}$ different coarsening scenarios for the encoded near-partitions, we prove the following bound.

▶ **Lemma 10.** *Let* B *be a set of size* k*. Then,* $|\mathbf{Rep}_w(B)| = 2^{O(k(w+\log k)}$.

Notice that the notion of a B-boundary model corresponds to the one of *interval model* in [8]. Besides the B-boundary model of a sequence S, we introduce the *profile* of S, which corresponds to the concept of *list representation* in [8].

▶ **Definition 11** (Profile)**.** *Let* S *be a* B*-boundaried sequence of length* ℓ *and let* $1 = j_1 < \cdots < j_i < \cdots < j_r = \ell$ *be the subset of indices of* $[\ell]$ *that belong to* $\mathbf{bp}_1(\mathsf{S}) \cup \mathbf{bp}_2(\mathsf{S})$*. Then we set* $\mathsf{profile}(\mathsf{S}) = \langle \mathsf{L}_1, \ldots, \mathsf{L}_r \rangle$ *with, for* $i \in [r]$*,* $\mathsf{L}_j = \langle \mathbf{val}(\mathsf{s}_{j_i}), \ldots, \mathbf{val}(\mathsf{s}_{j_{i+1}-1}) \rangle$.

We introduce the domination relation over B-boundaried sequences. This allows us to compare B-boundaried sequences having the same model by means of their B-profiles.

▶ **Definition 12** (Domination relation)**.** *Let* $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_j, \ldots, \mathsf{s}_\ell \rangle$ *and* $\mathsf{T} = \langle \mathsf{t}_1, \ldots, \mathsf{t}_j, \ldots, \mathsf{t}_\ell \rangle$ *be two* B*-boundaried sequences such that* $\mathsf{model}(\mathsf{S}) = \mathsf{model}(\mathsf{T})$*. If* $\mathsf{profile}(\mathsf{S}) \leq \mathsf{profile}(\mathsf{T})$*, then we write* $\mathsf{S} \leq \mathsf{T}$*. And, we say that* S dominates T*, denoted by* $\mathsf{S} \preceq \mathsf{T}$*, if* $\mathsf{profile}(\mathsf{S}) \preceq \mathsf{profile}(\mathsf{T})$*. If we have* $\mathsf{profile}(\mathsf{S}) \preceq \mathsf{profile}(\mathsf{T})$ *and* $\mathsf{profile}(\mathsf{T}) \preceq \mathsf{profile}(\mathsf{S})$*, then we say that* S *and* T *are equivalent, which is denoted by* $\mathsf{S} \equiv \mathsf{T}$.

▶ **Lemma 13.** *Let* S *be a* B*-boundaried sequence. Then,*

1. $\mathsf{rep}(\mathsf{S}) \equiv \mathsf{S}$*,*
2. *if* $\mathsf{S}^* \in \mathit{Ext}(\mathsf{S})$*, then* $\mathsf{S}^* \equiv \mathsf{S}$*,*
3. $\mathsf{S} \preceq \mathsf{T}$ *if and only if* $\mathsf{rep}(\mathsf{S}) \preceq \mathsf{rep}(\mathsf{T})$*.*
4. *If* T *is a* B*-boundaried sequence such that* $\mathsf{S} \preceq \mathsf{T}$*, then there exist an extension* S^* *of* S *and an extension* T^* *of* T *such that* $\mathsf{S}^* \leq \mathsf{T}^*$*.*
5. *The relation* $\preceq$ *is transitive, and* $\equiv$ *is an equivalence relation (refering to boundary sequences).*

2.4 Operations on B-boundaried sequences

Given a finite set B, we define two operations on B-boundaried sequences that will be later used in the DP algorithm. The *projection* of a B-boundaried sequence S onto $B' \subsetneq B$ aims at changing the status of a boundary element from $B \setminus B'$ to the status of a non-boundary element. The second operation deals with the insertion in a B-boundaried sequence of a new boundary element x with respect to a subset $X \subseteq B$.

2.4.1 Projection of B-boundaried sequences

▶ **Definition 14** (Projection)**.** *Let* $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_i, \ldots, \mathsf{s}_\ell \rangle$ *be a* B*-boundaried sequence. For a subset* $B' \subseteq B$*, the* projection *of* S *onto* B' *is the* B'*-boundaried sequence* $\mathsf{S}_{|B'} = \langle \mathsf{s}_{1|B'}, \ldots, \mathsf{s}_{i|B'}, \ldots, \mathsf{s}_{\ell|B'} \rangle$ *such that for every* $i \in [\ell]$*:*

- $\mathbf{bd}(\mathsf{s}_{i|B'}) = \mathbf{bd}(\mathsf{s}_i) \cap B'$*;*
- $\mathbf{cc}(\mathsf{s}_{i|B'}) = \mathbf{cc}(\mathsf{s}_i)_{|B'}$*;*
- $\mathbf{val}(\mathsf{s}_{i|B'}) = \mathbf{val}(\mathsf{s}_i) + |\mathbf{bd}(\mathsf{s}_i) \setminus B'|$.

We observe that though the B-boundaried sequence S is connected, its projection $\mathsf{S}_{|B'}$ onto $B' \subseteq B$ may not be connected. This is the case if for some $j \in [\ell]$, the partition $\mathbf{cc}(\mathsf{s}_j)$ contains several blocks and at least one of them is a subset of $B \setminus B'$. Notice that the projection operation does not change the width of a sequence.

▶ **Lemma 15.** *Let B be a finite set and $B' \subsetneq B$. If S^* is an extension of a B-boundaried sequence S, then $\mathsf{S}^*_{|B'}$ is an extension of $\mathsf{S}_{|B'}$.*

▶ **Lemma 16.** *Let B be a finite set and $B' \subseteq B$. If S and T are B-boundaried sequences such that $\mathsf{S} \leq \mathsf{T}$, then $\mathsf{S}_{|B'} \leq \mathsf{T}_{|B'}$.*

Using Lemma 15 and Lemma 16, we prove the following:

▶ **Lemma 17.** *Let B be a finite set and $B' \subseteq B$. If S and T are B-boundaried sequences such that and $\mathsf{S} \preceq \mathsf{T}$, then $\mathsf{S}_{|B'} \preceq \mathsf{T}_{|B'}$.*

2.4.2 Insertion into a B-boundaried sequence

Let $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$ be a B-boundaried sequence and let X be a subset of B. An *insertion position* is a pair of indices (f_x, l_x) such that $1 \leq f_x \leq l_x \leq \ell$. An insertion position is *valid with respect to X in S* if $X \subseteq \bigcup_{f_x \leq j \leq l_x} \mathbf{bd}(\mathsf{s}_j)$.

▶ **Definition 18.** *Let $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle$ be a B-boundaried sequence and (f_x, l_x) be a valid insertion position with respect to $X \subseteq B$. Then $\mathsf{S}^x = \mathsf{Ins}(\mathsf{S}, x, X, f_x, l_x) = \langle \mathsf{s}^x_1, \ldots, \mathsf{s}^x_\ell \rangle$ is the $(B \cup \{x\})$-boundaried sequence such that for every $j \in [\ell]$:*

- *if $j < f_x$, then $\mathbf{bd}(\mathsf{s}^x_j) = \mathbf{bd}(\mathsf{s}_j)$; $\mathbf{cc}(\mathsf{s}^x_j) = \mathbf{cc}(\mathsf{s}_j)$ and $\mathbf{val}(\mathsf{s}^x_j) = \mathbf{val}(\mathsf{s}_j)$.*
- *if $f_x \leq j \leq l_x$, then $\mathbf{bd}(\mathsf{s}^x_j) = \mathbf{bd}(\mathsf{s}_j) \cup \{x\}$; $\mathbf{cc}(\mathsf{s}^x_j)$ is obtained by adding a new block $\{x\}$ to $\mathbf{cc}(\mathsf{s}_j)$ and then merging that new block with all the blocks of $\mathbf{cc}(\mathsf{s}_j)$ that contain an element of X (if any); $\mathbf{val}(\mathsf{s}^x_j) = \mathbf{val}(\mathsf{s}_j)$.*
- *and otherwise, $\mathbf{bd}(\mathsf{s}^x_j) = \mathbf{bd}(\mathsf{s}_j)$; $\mathbf{cc}(\mathsf{s}^x_j)$ is obtained by adding a new block $\{x\}$ to $\mathbf{cc}(\mathsf{s}_j)$ and then merging that new block with all the blocks of $\mathbf{cc}(\mathsf{s}_j)$ that contain an element of X (if any); $\mathbf{val}(\mathsf{s}^x_j) = \mathbf{val}(\mathsf{s}_j)$.*

We can show that if T is an extension of S, then, to every valid insertion position (f_x, l_x) with respect to some subset $X \subseteq B$ in S, one can associate a valid insertion position (f^*_x, l^*_x) with respect to X in T. The reverse is not true as illustrated by Figure 4.

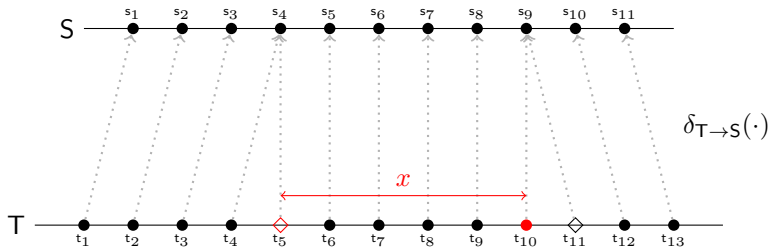

Figure 4 Let T be a 2-extension of the B-boundaried sequence S. Suppose that $(5, 10)$ is a valid insertion position with respect to some set $X \subseteq B$ in T. Observe that as $4 = \delta_{\mathsf{T}\to\mathsf{S}}(5)$ and $9 = \delta_{\mathsf{T}\to\mathsf{S}}(10)$, $(4, 9)$ is also a valid insertion position with respect to some for $X \subseteq B$ in S. However, $\mathsf{Ins}(\mathsf{T}, x, X, 5, 10)$ is not a 2-extension of $\mathsf{Ins}(\mathsf{S}, x, X, 4, 9)$.

However the next two lemmas provides an alternative by means of 2-extensions of S. The idea of the proof of Lemma 20 is illustrated by Figure 5.

▶ **Lemma 19.** *Let B and B' be finite sets with $B = B' \setminus \{x\}$ for some $x \in B'$. Let S and T be B-boundaried sequences such that $\mathsf{S} \leq \mathsf{T}$. If (f_x, l_x) is a valid insertion position with respect to a subset $X \subseteq B$ in T, then (f_x, l_x) is a valid insertion position with respect to X in S and $\mathsf{Ins}(\mathsf{S}, x, X, f_x, l_x) \leq \mathsf{Ins}(\mathsf{T}, x, X, f_x, l_x)$.*

▶ **Lemma 20.** *Let B and B' be finite sets with $B = B' \setminus \{x\}$ for some $x \in B'$. Let S and T be B-boundaried sequences such that $\mathsf{S} \preceq \mathsf{T}$. If (f_x^*, l_x^*) is a valid insertion position with respect to a subset $X \subseteq B$ in T, then there is a valid insertion position (f_x', l_x') in a (≤ 2)-extension R of S such that $\mathsf{Ins}(\mathsf{R}, x, X, f_x', l_x') \preceq \mathsf{Ins}(\mathsf{T}, x, X, f_x^*, l_x^*)$.*

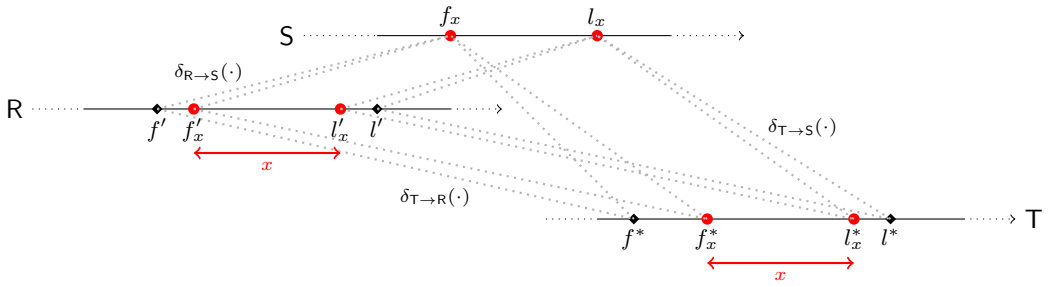

Figure 5 Let the B-boundaried sequence T be an extension of S that is certified by the surjective function $\delta_{\mathsf{T}\to\mathsf{S}}(\cdot)$ such that $f_x^* \neq f^*$, $l_x^* \neq l^*$ and $f^* = \min\{h \in [r] \mid \delta_{\mathsf{T}\to\mathsf{S}}(h) = f_x\}$, $l^* = \max\{h \in [r] \mid \delta_{\mathsf{T}\to\mathsf{S}}(h) = l_x\}$, $\delta_{\mathsf{T}\to\mathsf{S}}(f_x^*) = f_x$ and $\delta_{\mathsf{T}\to\mathsf{S}}(l_x^*) = l_x$. The B-boundaried sequence R is a 2-extension of S certified by the surjective function $\delta_{\mathsf{R}\to\mathsf{S}}(\cdot)$ such that $\delta_{\mathsf{R}\to\mathsf{S}}(f') = f_x$, $\delta_{\mathsf{R}\to\mathsf{S}}(f_x') = f_x$, $\delta_{\mathsf{R}\to\mathsf{S}}(l_x^*) = l_x$ and $\delta_{\mathsf{R}\to\mathsf{S}}(l') = l_x$. The fact that T is an extension of R can be certified by the surjective function $\delta_{\mathsf{T}\to\mathsf{R}}(\cdot)$ such that $\delta_{\mathsf{T}\to\mathsf{R}}(f^*) = f'$, $\delta_{\mathsf{T}\to\mathsf{R}}(f_x^*) = f_x'$, $\delta_{\mathsf{T}\to\mathsf{T}}(l_x^*) = l_x'$ and $\delta_{\mathsf{T}\to\mathsf{R}}(l^*) = l'$.

3 Computing the connected pathwidth

A (connected) path-decomposition $\mathsf{P} = \langle A_1, \ldots, A_\ell \rangle$ of a graph G is *nice* if $|A_1| = 1$ and $\forall i \in [p]$, $|A_{i-1} \vartriangle A_i| = 1$. A bag A_i, for $1 < 1 \leq \ell$, is called an *introduce* bag if $A_i \subsetneq A_{i-1}$ and a *forget* bag otherwise. As we will show, connected B-boundaried sequences are combinatorial objects designed in order to encode connected path-decompositions. Our algorithm is based on two routines. Forget Routine processes the forget bags by performing a projection operation on the B-boundaried sequences associated to those bags, while Insertion Routine handles the insertion bags by performing an insertion operation in the associated boundaried sequences.

3.1 Encoding a connected path-decomposition

▶ **Definition 21** ($(\mathbf{G}, \mathsf{P})$-encoding sequence). *Let $\mathsf{P} = \langle A_1, \ldots, A_\ell \rangle$ be a path-decomposition of the boundaried graph $\mathbf{G} = (G, B)$. A B-boundaried sequence $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_j, \ldots, \mathsf{s}_\ell \rangle$ is a $(\mathbf{G}, \mathsf{P})$-encoding sequence, if for every $j \in [\ell]$:*

- $\mathbf{bd}(\mathsf{s}_j) = A_j \cap B$*: the set of boundary vertices of (G, B) belonging to the bag A_j;*
- $\mathbf{cc}(\mathsf{s}_j) = \{V(C) \cap B \mid C$ *is a connected component of* $G_j\}$*;*
- $\mathbf{val}(\mathsf{s}_j) = |A_j \setminus B|$*: the number of non-boundary vertices in the bag A_j.*

It is worth to observe that $\mathbf{cc}(\mathsf{s}_j)$ is, in general, not a partition of A_j (see Figure 3). Also, notice that if G_j is connected and $B \cap V_j = \emptyset$, then $\mathbf{cc}(\mathsf{s}_j) = \{\emptyset\}$. Notice that if P is a connected path-decomposition, then S is a connected B-boundaried sequence.

▶ **Definition 22.** *Let* $\mathbf{G} = (G, B)$ *be a connected boundaried graph and* S *a* B*-boundaried sequence. We say that* S *is* realizable in $\mathbf{G}$ *if there is an extension* S^* *of* S *that is the* $(\mathbf{G}, \mathsf{P})$*-encoding sequence of some connected path-decomposition* P *of* $\mathbf{G}$.

Let us observe that if a B-boundaried sequence S is realizable, then S is connected. The set of *representative* B*-boundaried sequences of a connected boundaried graph* $\mathbf{G} = (G, B)$ *of width* $\leq w$ is defined as:

$$\mathbf{Rep}_w(\mathbf{G}) = \{\mathsf{rep}(\mathsf{S}) \mid \mathsf{S} \text{ of width} \leq w \text{ is realizable in } \mathbf{G} = (G, B)\}.$$

To compute the connected pathwidth of a graph, rather than computing $\mathbf{Rep}_w(\mathbf{G})$, we compute a subset $\mathbf{D}_w(\mathbf{G}) \subseteq \mathbf{Rep}_w(\mathbf{G})$, called *domination set*, such that for every representative B-boundaried sequence $\mathsf{S} \in \mathbf{Rep}_w(\mathbf{G})$, there exists a representative B-boundaried sequence $\mathsf{R} \in \mathbf{D}_w(\mathbf{G})$ where $\mathsf{R} \preceq \mathsf{S}$. Observe that a connected boundaried graph $\mathbf{G} = (G, B)$ has connected pathwidth at most w if and only if $\mathbf{D}_{w+1}(\mathbf{G}) \neq \emptyset$.

3.2 Forget Routine

Let $\mathbf{G} = (G, B)$ be a boundaried graph. If $x \in B$ is a boundary vertex, we denote by $B^{\overline{x}} = B \setminus \{x\}$. We define $\mathbf{G}^{\overline{x}} = (G, B^{\overline{x}})$, that is, while the graph G is left unchanged, we remove x from the set of boundary vertices. *Forget Routine* is described in Algorithm 1. Its correctness is proved in two steps. We first establish the *completeness* of the algorithm that is: for every connected path-decomposition P of $\mathbf{G}^{\overline{x}}$, there exists some B-boundaried sequence $\mathsf{S} \in \mathbf{D}_w(\mathbf{G})$ such that $\mathsf{rep}(\mathsf{S}_{|B\setminus\{x\}}) \preceq \mathsf{rep}(\mathsf{T})$ where T is the $(\mathbf{G}^{\overline{x}}, \mathsf{P})$-encoding sequence. For the soundness of the routine we prove that for every B-boundaried sequence $\mathsf{S} \in \mathbf{D}_w(\mathbf{G})$, $\mathsf{rep}(\mathsf{S}_{|B\setminus\{x\}}) \in \mathbf{D}_w(\mathbf{G}^{\overline{x}})$ if $\mathsf{S}_{|B\setminus\{x\}}$ is connected. The proofs of completeness and soundness rely both on Lemma 17. The time complexity is dominated by the bound on the number of representatives, given by Lemma 10.

Algorithm 1 Forget Routine.

Input: A boundaried graph $\mathbf{G} = (G, B)$, a vertex $x \in B$, and $\mathbf{D}_w(\mathbf{G})$.
Output: $\mathbf{D}_w(\mathbf{G}^{\overline{x}})$, a domination set of $\mathbf{Rep}_w(\mathbf{G}^{\overline{x}})$.

```
1 D_w(G^x̄) ← ∅;
2 foreach S ∈ D_w(G) do
3 |   if S_{|B\{x}} is connected, then add rep(S_{|B\{x}}) to D_w(G^x̄) ;
4 end
5 return D_w(G^x̄).
```

▶ **Theorem 23.** *Algorithm 1 computes* $\mathbf{D}_w(\mathbf{G}^{\overline{x}})$ *in* $2^{O(k(w+\log k))}$*-time, where* $k = |B|$.

3.3 Insertion Routine

Let $\mathbf{G} = (G, B)$ be a boundaried graph with $G = (V, E)$. For a subset $X \subseteq B$, we set $G^x = (V \cup \{x\}, E \cup \{xy \mid y \in X\})$ and $\mathbf{G}^x = (G^x, B^x)$ where $B^x = B \cup \{x\}$. Algorithm 2 is describing Insertion Routine (notations of Figure 5 are used in the pseudo-code). To prove its correctness, we proceed in two steps. We first establish the *completeness* of the algorithm: for every connected path-decomposition P^x of $\mathbf{G}^x$, the $(\mathbf{G}^x, \mathsf{P}^x)$-encoding sequence T^x is dominated by some B^x-boundaried sequence S^x that can be computed from a B-boundaried sequence S belonging to $\mathbf{D}_w(\mathbf{G})$. Then we argue about the *soundness* of Insertion Routine

Algorithm 2 Insertion Routine.

Input: A boundaried graph $\mathbf{G} = (G, B)$, a subset $X \subsetneq B$, and $\mathbf{D}_w(\mathbf{G})$.
Output: $\mathbf{D}_w(\mathbf{G}^x)$, a domination set of $\mathbf{Rep}_w(\mathbf{G}^x)$.

$\mathbf{D}_w(\mathbf{G}^x) \leftarrow \emptyset$;
foreach $\mathsf{S} = \langle \mathsf{s}_1, \ldots, \mathsf{s}_\ell \rangle \in \mathbf{D}_w(\mathbf{G})$ **do**
  foreach $f_x, l_x \in [\ell]$ *such that* $X \subseteq \bigcup_{f_x \leq j \leq l_x} \mathbf{bd}(\mathsf{s}_j)$ **do**
    foreach (≤ 2)-*extension* R *of* S *duplicating none, one or both of* s_{f_x} *and* s_{l_x} **do**
      let ℓ' be the length of R;
      set $f'_x = \max\{j \in [\ell'] \mid \delta_{\mathsf{R}\to\mathsf{S}}(j) = f_x\}$ and $l'_x = \min\{j \in [\ell'] \mid \delta_{\mathsf{R}\to\mathsf{S}}(j) = l_x\}$;
      set $\mathsf{S}^x = \mathsf{Ins}(\mathsf{R}, x, X, f'_x, l'_x)$;
      (observe that by construction (f'_x, l'_x) is valid with respect to X in R);
      if $\mathsf{width}(\mathsf{S}^x) \leq w$, **then** add $\mathsf{rep}(\mathsf{S}^x)$ to $\mathbf{D}_w(\mathbf{G}^x)$;
    end
  end
end
return $\mathbf{D}_w(\mathbf{G}^x)$.

that is: if S^x is generated from a B-boundaried $\mathsf{S} \in \mathbf{D}_w(\mathbf{G})$, then $\mathsf{rep}(\mathsf{S}^x)$ belongs to $\mathbf{D}_w(\mathbf{G}^x)$. The proofs of completeness and soundness rely both on Lemma 19, and Lemma 20. As for Forget Routine, the time complexity follows from Lemma 10.

▶ **Theorem 24.** *Algorithm 2 computes* $\mathbf{D}_w(\mathbf{G}^x)$ *in* $2^{O(k(w+\log k))}$*-time, where* $k = |B|$.

3.4 The dynamic programming algorithm

We are now in position to prove Theorem 1. We are given a nice path-decompositon $\mathsf{Q} = \langle B_1, \ldots, B_q \rangle$ of G of width at most k and for each $i \in [q]$, we consider the boundaried graphs $\mathbf{G}_i = (G[V_i], B_i)$, where $V_i = \bigcup_{1 \leq h \leq i} B_h$. We have a way to compute $\mathbf{D}_w(G_{i+1})$ from $\mathbf{D}_w(G_i)$, in $2^{O(k^2)} \cdot n$ time, using the algorithms of Theorem 23 or Theorem 24 depending on whether B_i is an insertion or a forget bag. We next describe the set $\mathbf{D}_{w+1}(\mathbf{G}_1)$. For this, we take the representative set $\mathbf{Rep}_{w+1}(\mathbf{G}_1)$ that consists for the following four possible connected B_1-boundaried sequences:

- $\mathsf{S}_1 = \langle (\{x\}, \{\{x\}\}, 0) \rangle$,
- $\mathsf{S}_2 = \langle (\emptyset, \{\emptyset\}, 0), (\{x\}, \{\{x\}\}, 0) \rangle$,
- $\mathsf{S}_3 = \langle (\emptyset, \{\emptyset\}, 0), (\{x\}, \{\{x\}\}, 0), (\emptyset, \{\{x\}\}, 0) \rangle$, and
- $\mathsf{S}_4 = \langle (\{x\}, \{\{x\}\}, 0), (\emptyset, \{\{x\}\}, 0) \rangle$.

As already noticed $\mathsf{cpw}(G) \leq k$ if and only if $\mathbf{D}_{w+1}(\mathbf{G}_q) \neq \emptyset$. This completes proof of the decision version of Theorem 1. In [8, Section 6] Bodlaender and Kloks explained how to turn their decision algorithm for pathwidth and treewidth to one that is able to construct, in case of a positive answer, the corresponding decomposition. It is straightforward to see that the modification of [8, Section 6] that transforms the decision algorithm for pathwidth to one that also constructs the corresponding path-decomposition also applies to our algorithm for connected pathwidth. This completes the proof of Theorem 1.

If we now use the result of Fürer [20] for constructing a path-decomposition of width at most k in $2^{O(k^2)} \cdot n$ time and taking into account that $\mathsf{pw}(G) \leq \mathsf{cpw}(G)$, we have the following.

▶ **Theorem 25.** *One may construct an algorithm that, given an* n*-connected graph* G *and a non-negative integer* k*, either outputs a connected path-decomposition of* G *of width at most* k *or correctly reports that such a decomposition does not exist in* $2^{O(k^2)} \cdot n$ *time.*

Abstract

A graph is c-closed if every pair of vertices with at least c common neighbors is adjacent. The c-closure of a graph G is the smallest number c such that G is c-closed. Fox et al. [SIAM J. Comput. '20] defined c-closure and investigated it in the context of clique enumeration. We show that c-closure can be applied in kernelization algorithms for several classic graph problems. We show that Dominating Set admits a kernel of size $k^{\mathcal{O}(c)}$, that Induced Matching admits a kernel with $\mathcal{O}(c^7k^8)$ vertices, and that Irredundant Set admits a kernel with $\mathcal{O}(c^{5/2}k^3)$ vertices. Our kernelization exploits the fact that c-closed graphs have polynomially-bounded Ramsey numbers, as we show.

1 Introduction

Parameterized complexity [10, 15] aims at understanding which properties of input data can be used in the design of efficient algorithms for problems that are hard in general. The properties of input data are encapsulated in the notion of a *parameter*, a numerical value that can be attributed to each input instance I. For a given hard problem and parameter k, the first aim is to find a *fixed-parameter algorithm*, an algorithm that solves the problem in $f(k) \cdot |I|^{\mathcal{O}(1)}$ time. Such an algorithm is efficient when f grows moderately and k takes on small values. A second aim is to provide a *kernelization*. This is an algorithm that given any instance (I, k) of a parameterized problem computes in polynomial time an equivalent instance of size $g(k)$. If g grows not too much and k takes on small values, then a kernelization

Table 1 A comparison of the c-closure with the number n of vertices, number m of edges, and the maximum degree Δ in social and biological networks.

provably shrinks large input instances and thus gives a guarantee for the efficacy of data reduction rules. A central part of the design of good parameterized algorithms is thus the identification of suitable parameters.

A good parameter should have the following advantageous traits. Ideally, it should be easy to understand and compute.[1] It should take on small values in real-world input data. It should describe input properties that are not captured by other parameters. Finally, many problems should be amenable to parameterization using this parameter. In other words, the parameter should help when designing fixed-parameter algorithms or kernelizations.

Fox et al. [19] recently introduced the graph parameter *c-closure* which describes a structural feature of many real-world graphs: When two vertices have many common neighbors, it is likely that they are adjacent. More precisely, the c-closure of a graph is defined as follows.

▶ **Definition 1.1** ([19]). *A graph $G = (V, E)$ is* c-closed *if every pair of vertices $u \in V$ and $v \in V$ with at least c common neighbors is adjacent. The c-closure of a graph is the smallest number c such that G is c-closed.*

The parameter has many of the desirable traits mentioned above: It is easy to understand and easy to compute. Moreover, social networks are c-closed for relatively small values of c [19] (see also Table 1). In addition, the c-closure of a graph gives a new class of graphs which are not captured by other measures. This follows from the observation that every complete graph is 1-closed. Hence, a graph can have bounded c-closure but, for example, unbounded degeneracy and thus unbounded treewidth. Conversely, the graph consisting of two vertices u and v and many vertex-disjoint u-v-paths of length two is 2-degenerate,

[1] This cannot always be guaranteed. For example, the important parameter treewidth is hard to compute and not as easily understood as simpler parameters.

has treewidth two, and unbounded c-closure. Generally, one may observe that c-closure is different from many common parameterizations which measure, in different ways, the sparseness of the input graph. In this sense, the structure described by the c-closure is novel. The aim of this work is to show that c-closure also has the final, most important trait: it helps when designing fixed-parameter algorithms.

Fox et al. [19] applied c-closure to the enumeration of maximal cliques, showing that a c-closed graph may have at most $3^{(c-1)/3} \cdot n^2$ maximal cliques. In combination with known clique enumeration algorithms this implies that all maximal cliques of a graph can be enumerated in $\mathcal{O}^*(3^{c/3})$ time. We are not aware of any further fixed-parameter algorithms that make use of the c-closure parameter.

An easy example for how parameterization by c-closure helps can be seen for the Independent Set problem. In Independent Set we are given an undirected graph $G = (V, E)$ and an integer k and want to determine whether G contains a set of k vertices that are pairwise nonadjacent. Independent Set is W[1]-hard when parameterized by k [15, 10]. When one uses the maximum degree of G as an additional parameter, then Independent Set has a trivial kernelization: Any graph with at least $(\Delta + 1)k$ vertices has an independent set of size at least k. With the following data reduction rule, we can obtain a kernelization for the combination of c and k.

▶ **Reduction Rule 1.2.** *If G contains a vertex v of degree at least $(c-1)(k-1)+1$, then remove v from G.*

To see that Reduction Rule 1.2 is correct, we need to show that the resulting graph G' has an independent set I of size k if and only if the original graph G has one. The nontrivial direction to show is that if G has an independent set I of size k, then so does G'. Since this clearly holds for $v \notin I$, we assume that $v \in I$. To replace v by some other vertex, we make use of the c-closure: Every vertex u in $I \setminus \{v\}$ has at most $c-1$ neighbors in common with v since u and v are nonadjacent. Thus, at most $(c-1)(k-1)$ neighbors of v are also neighbors of some vertex in $I \setminus \{v\}$. Consequently, some neighbor w of v has no neighbors in $I \setminus \{v\}$ and, therefore, $(I \setminus \{v\}) \cup \{w\}$ is an independent set of size k in G'.

Applying Reduction Rule 1.2 exhaustively results in an instance with maximum degree less than ck which, due to the discussion above, directly gives the following.

▶ **Proposition 1.3.** Independent Set *admits a kernel with at most ck^2 vertices.*

Motivated by this simple result for a famous graph problem, we study how c-closure can be useful for further classic graph problems when they are parameterized by a combination of c and the solution size parameter k. We obtain the following positive results. In Section 4, we show that Dominating Set admits a kernel of size $k^{\mathcal{O}(c)}$ computable in $\mathcal{O}^*(2^c)$ time and show that this kernelization is asymptotically optimal with respect to the dependence of the exponent on c. Our results also hold for the more general Threshold Dominating Set problem where each vertex needs to be dominated r times. In Section 5, we show that Induced Matching admits a kernel with $\mathcal{O}(c^7k^8)$ vertices by means of LP relaxation of Vertex Cover. Finally in Section 6, we show that Irredundant Set admits a kernel with $\mathcal{O}(c^{5/2}k^3)$ vertices. All kernelizations exploit a bound on Ramsey numbers for c-closed graphs, which we prove in Section 3. This bound is – in contrast to Ramsey numbers of general graphs – polynomial in the size of a sought clique and independent set. We believe that this bound on the Ramsey numbers is of independent interest and that it provides a useful tool in the design of fixed-parameter algorithms for more problems on c-closed graphs.

2 Preliminaries

For $m \leq n \in \mathbb{N}$, we write $[m, n]$ to denote the set $\{m, m+1, \ldots, n\}$ and $[n]$ for $[1, n]$. For a graph G, we denote its vertex set and edge set by $V(G)$ and $E(G)$, respectively. Let $X, Y \subseteq V(G)$ be vertex subsets. We use $G[X]$ to denote the subgraph induced by X. We also use $G[X, Y] := (X \cup Y, \{xy \in E(G) \mid x \in X, y \in Y\})$ to denote the bipartite subgraph induced by X, Y for $X \cap Y = \emptyset$. We let $G - X$ denote the graph obtained by removing vertices in X. We denote by $N_G(X) := \{y \in V(G) \setminus X \mid xy \in E(G), x \in X\}$ and $N_G[X] := N_G(X) \cup X$, the open and closed neighborhood of X, respectively. For all these notations, when X is a singleton $\{x\}$ we may write x instead of $\{x\}$. Let $v \in V(G)$. We denote the degree of v by $\deg_G(v)$. We call v *isolated* if $\deg_G(v) = 0$ and *non-isolated* otherwise. We also say that v is a *leaf vertex* if $\deg_G(v) = 1$ and a *non-leaf vertex* if $\deg_G(v) \geq 2$. Moreover, we say that v is *simplicial* if $N_G(v)$ is a clique. The maximum and minimum degree of G are $\Delta_G := \max_{v \in V(G)} \deg_G(v)$ and $\delta_G := \min_{v \in V(G)} \deg_G(v)$, respectively. The degeneracy of G is $d_G := \max_{S \subseteq V(G)} \delta_{G[S]}$. We say that G is c-closed for $c = \max(\{0\} \cup \{|N_G(u) \cap N_G(v)| \mid uv \notin E(G)\}) + 1$. In particular, any cluster graph (a disjoint union of complete graphs) is 1-closed. We drop the subscript $\cdot_G$ when it is clear from context. A graph G has girth g if the shortest cycle in G has length g.

In this paper, we investigate the parameterized complexity of various problems whose input comprises of a graph G and an integer k. A problem is *fixed-parameter tractable* if it can be solved in $f(k) \cdot n^{\mathcal{O}(1)}$ time where $n := |V(G)|$ and f is some computable function. Instances (G, k) and (G', k') are *equivalent* if (G, k) is a Yes-instance if and only if (G', k') is a Yes-instance. A *kernelization algorithm* is a polynomial-time algorithm which transforms an instance (G, k) into an equivalent instance (G', k') such that $|V(G')| + k' \leq g(k)$, where g is some computable function. It is well-known that a problem is fixed-parameter tractable if and only if it admits a kernelization algorithm. Our kernelization algorithms consist of a sequence of *reduction rules*. Given an instance (G, k), a reduction rule computes an instance (G', k'). We will develop kernelization algorithms for c-closed graphs. For our purposes, we say that a reduction rule is *correct* if the input instance (G, k) for a c-closed graph G is equivalent to the resulting instance (G', k') and G' is also c-closed. For more information on parameterized complexity, we refer to the standard monographs [10, 15].

We will make use of the following observations throughout this work.

▶ **Observation 2.1.** *If G is c-closed, then $G - v$ is also c-closed for any $v \in V(G)$.*

▶ **Observation 2.2.** *Let C be a maximal clique in a c-closed graph G. Then $|C \cap N(v)| < c$ for every $v \in V(G) \setminus C$.*

▶ **Observation 2.3.** *Let G be a c-closed graph and let C be a*

- *clique of size at most $c - 1$ in G or*
- *a maximal clique in G.*

Then, the graph G' obtained by attaching a simplicial vertex v to C (that is, $N_{G'}(v) = C$) is c-closed.

Some proofs are deferred to a full version of this work.

3 On Ramsey Numbers of c-Closed Graphs

Ramsey's theorem states that there is a function R such that any graph G with at least $R(a, b)$ vertices contains a clique of size a or an independent set of size b, for any $a, b \in \mathbb{N}$. The numbers $R(a, b)$ are referred to as Ramsey numbers. It is known that $R(t, t) > 2^{t/2}$ for

any $t \geq 3$ [17, 23] and hence $R(t,t)$ grows exponentially with t. Here, we show that the Ramsey number $R(a,b)$ is actually polynomial in a and b in c-closed graphs. Let $R_c(a,b) := (c-1) \cdot \binom{b-1}{2} + (a-1)(b-1) + 1$.

▶ **Lemma 3.1.** *Any c-closed graph G on at least $R_c(a,b)$ vertices contains a clique of size a or an independent set of size b.*

Proof. Assume to the contrary that G has no clique of size a and no independent set of size b. Let $I = \{v_1, \ldots, v_{|I|}\}$ be a maximum independent set of G. Also let C_i be the set of vertices adjacent to v_i (including v_i) and nonadjacent to any other vertex in I (that is, $C_i = N[v_i] \setminus N(I \setminus \{v_i\})$) for each $i \in [|I|]$. Suppose that there exist $u \neq u' \in C_i$ with $uu' \notin E(G)$. Then, $(I \setminus \{v_i\}) \cup \{u, u'\}$ is an independent set of size $|I|+1$, which contradicts the choice of I. Hence, we see that C_i is a clique. Note that every vertex of G is adjacent to some vertex in I due to the maximality of I. It follows that

$$|V(G)| \leq \sum_{i \in [|I|]} |C_i| + \sum_{i<j \in [|I|]} |N(v_i) \cap N(v_j)|.$$

Note that $|C_i| \leq a-1$ for each $i \in [|I|]$ and $|N(v_i) \cap N(v_j)| \leq c-1$ for $i < j \in [|I|]$ by the c-closure of G. Since $|I| < b$, we have a contradiction on $|V(G)|$. ◀

The bound in Lemma 3.1 is essentially tight: Consider a graph G consisting of a disjoint union of $b-1$ complete graphs, each of order $a-1$. Note that G is c-closed for any $c \in \mathbb{N}$ and that G has no clique of size a or independent set of size b. Thus, we have a tight bound for $c = 1$. This example also suggests that the bound in Lemma 3.1 cannot be asymptotically improved for $a \geq cb$.

4 (Threshold) Dominating Set

In this section we show that Threshold Dominating Set admits a kernel with $k^{\mathcal{O}(cr)}$ vertices. The problem is defined as follows.

Threshold Dominating Set
Input: A graph G and $r, k \in \mathbb{N}$.
Question: Is there a vertex set $D \subseteq V(G)$ such that $|D| \leq k$ and each vertex $v \in V(G)$ is dominated by D at least r times, that is, $|N[v] \cap D| \geq r$?

Dominating Set is the special case of Threshold Dominating Set when $r = 1$.

Dominating Set is W[2]-hard when parameterized by k even in bipartite or split graphs [30]. Furthermore, Dominating Set was shown to remain NP-hard on graphs with girth at least t for any constant t [2]. Hence, Dominating Set is NP-hard even on 2-closed graphs.

There are several fixed-parameter tractability results in restricted graph classes: When the graph G contains no induced C_3 or C_4, Dominating Set admits a kernel of $\mathcal{O}(k^3)$ vertices and Threshold Dominating Set is fixed-parameter tractable [30]. Furthermore, Dominating Set in d-degenerate graphs can be solved in $k^{\mathcal{O}(dk)}n$ time [3]. This result was extended to an algorithm with running time $\mathcal{O}^*(k^{\mathcal{O}(dkr)})$ for Threshold Dominating Set in d-degenerate graphs [21].

When the graph G does not contain the complete bipartite graph $K_{i,j}$ for fixed $j \leq i$ as a (not necessarily induced) subgraph, Dominating Set admits a kernel of $\mathcal{O}((j+1)^{i+1}k^{i^2})$ vertices which can be computed in $\mathcal{O}(n^i)$ time [29]. Since d-degenerate graphs do not contain

a $K_{d+1,d+1}$ as a subgraph, Dominating Set admits a kernelization of $\mathcal{O}(k^{(d+1)^2})$ vertices computable in $\mathcal{O}^*(2^d)$ time [29]. This kernel size is essentially optimal since Dominating Set in d-degenerate graphs admits no kernel of size $\mathcal{O}(k^{(d-3)(d-1)-\epsilon})$ for any $\epsilon > 0$ unless NP $\subseteq$ coNP/poly [11]. When G does not contain the complete bipartite graph $K_{t,t}$ as a (not necessarily induced) subgraph, Dominating Set can be solved in $2^{\mathcal{O}(tk^2(4k)^t)}$ time [31]. Since each d-degenerate graph does not contain a $K_{d+1,d+1}$ as a subgraph, this extends the result of [3]. None of the above kernelizations and fixed-parameter algorithms implies a tractability result on c-closed graphs, since the respective structural restrictions on G all exclude cliques of some size. Moreover, since any graph without induced C_3 or C_4 is 2-closed, our results extend the kernelization algorithms for these graphs to a more general class of graphs.

To obtain a kernel for Threshold Dominating Set in c-closed graphs we first provide a kernelization for a more general, colored variant defined as follows. The input graph is a *bw-graph*, where the vertex set $V(G)$ is partitioned into black vertices B and white vertices W. We only require to dominate black vertices r times. The problem is defined as follows.

BW-Threshold Dominating Set
Input: A bw-graph G and $r, k \in \mathbb{N}$.
Question: Does G contain a *bw-threshold dominating set* $D \subseteq V(G)$, that is, a set such that $|N[v] \cap D| \geq r$ for each vertex $v \in B$, of size at most k?

Clearly, each instance (G, k) of Threshold Dominating Set is equivalent to the instance (G, k) of BW-Threshold Dominating Set where each vertex is black.

4.1 Polynomial Kernel in c-closed Graphs

We first develop a kernelization algorithm for BW-Threshold Dominating Set and then we will remove colors at the end. Before we present our reduction rules, we prove the following lemma, which will simplify some proofs later in this section.

▶ **Lemma 4.1.** *Let (G, k) be a Yes-instance of* BW-Threshold Dominating Set *and let v be a simplicial vertex with at least r neighbors. Then, there exists a bw-threshold dominating set D of size at most k such that $v \notin D$.*

Proof. Suppose that G has a bw-threshold dominating set D of size at most k. We are immediately done if $v \notin D$, so we can assume that $v \in D$. If $N[v] \subseteq D$, then $D \setminus \{v\}$ is a bw-threshold dominating set of size at most k. Otherwise, there is a vertex $u \in N(v) \setminus D$ and $(D \setminus \{v\}) \cup \{u\}$ is a bw-threshold dominating set of size at most k not containing v. ◀

We first aim to bound the number of black vertices. Our first reduction rule exploits the fact that any bw-threshold dominating set includes at least r vertices in C, where C is a maximal clique containing sufficiently many black vertices.

▶ **Reduction Rule 4.2.** *Let C be a maximal clique containing at least ck black vertices. Then,*
1. *add a vertex u and add an edge uv for each $v \in C$,*
2. *color u black, and*
3. *color all the vertices in C white.*

Note that Reduction Rule 4.2 does not add new maximal cliques. Hence, Reduction Rule 4.2 can be applied exhaustively in $\mathcal{O}^*(3^{c/3})$ time, because all maximal cliques can be enumerated in $\mathcal{O}^*(3^{c/3})$ time [19].

▶ **Lemma 4.3.** *Reduction Rule 4.2 is correct.*

Proof. Let D be a bw-threshold dominating set of G of size at most k. We claim that $|D \cap C| \geq r$. Assume to the contrary that $|D \cap C| \leq r-1$. By Observation 2.2, each vertex in $D \setminus C$ dominates at most $c-1$ vertices in C. Since C contains at least ck black vertices, there is a black vertex in C that is not dominated r times by D, a contradiction. Thus, $|D \cap C| \geq r$. Let G' be the graph obtained as a result of Reduction Rule 4.2. Since $uv \in E(G)$ for each $v \in C$, we see that $|N_{G'}(u) \cap D| \geq r$ and thus D is also a bw-threshold dominating set of the graph G'. The other direction of the equivalence follows from Lemma 4.1. Finally, note that Reduction Rule 4.2 maintains the c-closure by Observation 2.3. ◀

We will assume henceforth that Reduction Rule 4.2 has been applied exhaustively. Recall that each c-closed graph on at least $R_c(a,b) = (c-1)\binom{b-1}{2} + (a-1)(b-1) + 1$ vertices contains a clique of size a or an independent set of size b by Lemma 3.1. Since G does not contain any black clique of size at least ck, each subgraph of G with at least $\rho := R_c(ck, k+1)$ black vertices contains an independent set of at least $k+1$ black vertices. We take advantage of this observation in the following two reduction rules.

▶ **Reduction Rule 4.4.** *Suppose that $r \leq c-1$. We define Reduction Rule 4.4.i for each $i \in [1, c-r]$ as follows: Let C be a clique of size exactly $c-i$ and let $P := B \cap \{v \in V(G) \mid C \subseteq N(v)\}$ be the set of common black neighbors of C. If $|P| > k^{i-1}\rho$, then*

1. *add a vertex u and add an edge uv for each $v \in C$,*
2. *color u black, and*
3. *color all the vertices in C and P white.*

Apply Reduction Rule 4.4.i in increasing order of i.

Since $|P| > k^{i-1}\rho$, the common black neighbors P of C include an independent set I of size $k+1$. To apply Reduction Rule 4.4.i exhaustively, we consider each pair of vertices v, v' from V and then we consider each clique in the common neighborhood $N(v) \cap N(v')$. Since $|N(v) \cap N(v')| < c$, Reduction Rule 4.4 can be applied exhaustively in $\mathcal{O}^*(2^c)$ time.

▶ **Lemma 4.5.** *Reduction Rule 4.4 is correct.*

Proof. Let C be a clique of size exactly $c-i$ which has more than $k^{i-1}\rho$ common black neighbors P. We prove the following claim for increasing $i \in [1, c-r]$.

▷ Claim. If Reduction Rule 4.4.j has been applied exhaustively for each $j \in [i-1]$, then any bw-threshold dominating set D of size at most k includes at least r vertices of C.

Proof. Suppose that $i = 1$. We assume to the contrary that $|D \cap C| \leq r-1$. Recall that there is no clique of at least ck black vertices by Reduction Rule 4.2. Since $|P| > \rho$, we see from Lemma 3.1 that P contains an independent set I of at least $k+1$ vertices. By pigeon-hole principle, there exists a vertex $w \in D \setminus C$ which is adjacent to at least two vertices x and y in I. Hence, x and y have at least c common neighbors $C \cup \{w\}$, contradicting the c-closure of G. It follows that D contains at least r vertices of C.

Suppose that $i \in [2, c-r]$. Again we assume to the contrary that $|D \cap C| \leq r-1$. Since $|P| > k^{i-1}\rho$, there exists a vertex $w \in D \setminus C$ that dominates at least $k^{i-2}\rho$ vertices of P. Observe that w and each vertex in C have at least $k^{i-2}\rho > c$ common neighbors in P. Hence, we have $vw \in E(G)$ for each $v \in C$. Thus, $C \cup \{w\}$ is a clique of size $c-i+1$ with at least $k^{i-2}\rho$ common black neighbors. However, this contradicts the fact that Reduction Rule 4.4.$(i-1)$ has been applied exhaustively. Therefore, we obtain $|D \cap C| \geq r$. ◁

Let G' be the graph obtained as a result of Reduction Rule 4.4. By the above claim, any bw-threshold dominating set in G is also a bw-threshold dominating set in G'. The other direction follows from Lemma 4.1. Finally, note that G' is c-closed by Observation 2.3. ◀

▶ **Reduction Rule 4.6.** *Suppose that $r \geq c$. Let C be a clique of size exactly $c-1$ and let $P := B \cap \{v \in V(G) \mid C \subseteq N(v)\}$ be the set of common black neighbors of C. If $|P| > \rho$, then return No.*

▶ **Lemma 4.7.** *Reduction Rule 4.6 is correct.*

Proof. Suppose that G has a bw-threshold dominating set D of size at most k. We show that for each clique C of size $c-1$, there are at most ρ common black neighbors. Assume to the contrary that $|P| > \rho$ for $P := B \cap \{v \in V(G) \mid C \subseteq N(v)\}$. Then, there is an independent set $I \subseteq P$ of size $k+1$ by Lemma 3.1. Since $r \geq c$, there are two vertices $x, y \in I$ that are adjacent to a vertex $v \in D \setminus C$. Now, we have a contradiction to the c-closure of G, because x and y have $|C \cup \{v\}| = c$ neighbors. ◀

Note that Reduction Rule 4.6 also can be applied exhaustively in $\mathcal{O}^*(2^c)$ time. Hereafter, we will assume that Reduction Rules 4.4 and 4.6 have been applied exhaustively. In the next lemma, we show that the number of black neighbors is upper-bounded for each vertex.

▶ **Lemma 4.8.** *Each vertex has at most $k^{c-1}\rho$ black neighbors for any Yes-instance (G, k).*

Proof. First, suppose that $r \leq c-1$. To prove the lemma, we prove the following more general claim:

▷ Claim. Let $i \in [r]$ and let C be a clique of size exactly i with the set P of common black neighbors. Then, $|P| \leq k^{c-i}\rho$.

Proof. We prove the claim by induction on decreasing i. By Reduction Rule 4.4, the claim holds for the base case $i = r$. Suppose that $i < r$. Since $|C| = i \leq r-1$, for any bw-threshold dominating set D of size at most k, there is a vertex $v \in D \setminus C$ that dominates at least $|P|/k$ vertices of P. As $|P|/k > c$, the set $C \cup \{v\}$ is a clique with $|P|/k$ common black neighbors. By induction hypothesis, we obtain $|P|/k \leq k^{c-i-1}\rho$ and equivalently, $|P| \leq k^{c-i}\rho$. ◁

Observe that the lemma follows from the above claim for $i = 1$. Using Reduction Rule 4.6, the lemma can be proven analogously for the case $r \geq c$ as well. ◀

By Lemma 4.8, there are at most $k^c\rho$ black vertices for any Yes-instance (G, k):

▶ **Reduction Rule 4.9.** *If G contains more than $k^c\rho$ black vertices, then return No.*

To compute a kernel it remains to upper-bound the number of white vertices in G.

▶ **Reduction Rule 4.10.** *Let w be a white vertex in G. If there exist at least r vertices $v_1, \ldots, v_r$ such that $N(w) \cap B \subseteq N[v_i] \cap B$ for each $i \in [r]$, then remove w.*

It is easy to see that Reduction Rule 4.10 can be applied exhaustively in polynomial time.

▶ **Lemma 4.11.** *Reduction Rule 4.10 is correct.*

Proof. Let $G' := G - w$. Suppose that G has a bw-threshold dominating set D of size at most k. If $w \notin D$, then D is also a bw-threshold dominating set of G'. Hence, we can assume that $w \in D$. If $v_i \in D$ for all $i \in [r]$, then $D \setminus \{w\}$ is a bw-threshold dominating set for G and hence also for G'. Otherwise, there exists some $i \in [r]$ with $v_i \notin D$. Since $N(w) \cap B \subseteq N[v_i] \cap B$, the set $(D \setminus \{w\}) \cup \{v_i\}$ is a bw-threshold dominating set of size at most k of G and G'. The other direction follows trivially. Since Reduction Rule 4.10 only deletes white vertices the c-closure is maintained. ◀

In the following, we will assume that Reduction Rule 4.10 has been applied exhaustively. Now, we obtain a bound on the number of white vertices in G.

▶ **Lemma 4.12.** *The graph G contains $\mathcal{O}(c|B|^2 + |B|^{r-1})$ white vertices.*

Proof. Since Reduction Rule 4.10 has been applied exhaustively, G contains at most r white vertices w such that $N(w) \subseteq W$. Hence, it remains to bound the number of white vertices with at least one black neighbor. Observe that by the c-closure of G, there are $\mathcal{O}(c\,|B|^2)$ white vertices that are neighbors of two nonadjacent vertices $u, v \in B$.

Note that for all remaining white vertices w, the set $B_w := N(w) \cap B$ of black neighbors is a clique. Since Reduction Rule 4.10 has been applied exhaustively, we have $|B_w| < r$. Moreover, for each clique $C \subseteq B$ of size $i \in [r-1]$, there are at most $r - i$ white vertices with $B_w = C$. Thus, the number of white vertices w such that B_w is a clique is

$$\sum_{i=1}^{r-1} i\,|B|^{r-i} = \frac{|B|(|B|^r - 1)}{(|B|-1)^2} - \frac{|B|}{|B|-1} r \in \mathcal{O}(|B|^{r-1}).$$

Overall, there are $\mathcal{O}(c\,|B|^2 + |B|^{r-1})$ white vertices. ◀

Recall that there are $k^c\rho \in \mathcal{O}(ck^{c+2})$ black vertices by Reduction Rule 4.9. Hence, the overall number of vertices is $\mathcal{O}(c^3k^{2c+4} + c^{r-1}k^{(c+2)(r-1)})$, resulting in the following theorem:

▶ **Theorem 4.13.** BW-Threshold Dominating Set *has a kernel with $k^{\mathcal{O}(cr)}$ vertices computable in $\mathcal{O}^*(2^c)$ time.*

To obtain a kernel for Threshold Dominating Set, it remains to show that any BW-Threshold Dominating Set instance can be transformed into an equivalent instance of Threshold Dominating Set.

▶ **Theorem 4.14.** Threshold Dominating Set *has a kernel with $k^{\mathcal{O}(cr)}$ vertices computable in $\mathcal{O}^*(2^c)$ time.*

Proof. To obtain an $k^{\mathcal{O}(cr)}$-vertex kernel for Threshold Dominating Set, we first construct an equivalent instance (G, k) of BW-Threshold Dominating Set using Theorem 4.13. Then, we transform (G, k) into an equivalent instance (G', k') of Threshold Dominating Set in $k^{\mathcal{O}(cr)}$-closed graphs as follows.

We start with a copy of G. We add a clique $Q := \{w_1, \ldots, w_{r+1}\}$ of $r+1$ vertices. Then, for each white vertex w we add edges $ww_1, \ldots, ww_r$. Then, we remove all vertex colors. We call the resulting graph G'. Let $C = \{w_1, \ldots w_r\}$ and let $k' = k + r$. We show that (G, k) is a Yes-instance if and only if (G', k') is a Yes-instance.

Let D be a bw-threshold dominating set of G. By construction, $D \cup C$ is a threshold dominating set of size at most k' of G'. Conversely, suppose that G' has a threshold dominating set D' of size at most k'. By Lemma 4.1, we can assume that $w_{r+1} \notin D'$. Since $\deg_{G'}(w_{r+1}) = r$, it holds that $N_{G'}(w_{r+1}) = C \subseteq D'$. Hence, all white vertices of G are dominated r times by C in G'. Thus, $D := D' \setminus C$ is a bw-threshold dominating set of size at most k for G. ◀

Since the kernelization does not change the parameter r, it also gives a kernelization for Dominating Set.

▶ **Corollary 4.15.** Dominating Set *has a kernel with $k^{\mathcal{O}(c)}$ vertices which is computable in $\mathcal{O}^*(2^c)$ time.*

To complement this result, we show that there is no kernel for Dominating Set significantly smaller than that of Corollary 4.15 under a widely believed assumption.

▶ **Theorem 4.16.** *For $c \geq 3$,* Dominating Set *has no kernel of size $\mathcal{O}(k^{c-1-\epsilon})$ unless* coNP $\subseteq$ NP/poly.

Proof. We will show the theorem by a reduction from λ-Hitting Set.

λ-Hitting Set
Input: A set family $\mathcal{F}$ over an universe U, where each $S \in \mathcal{F}$ has size λ, and $k \in \mathbb{N}$.
Question: Is there a subset $X \subseteq U$ of size at most k such that for each $S \in \mathcal{F}$ we have $X \cap S \neq \emptyset$?

For any $\lambda \geq 2$, λ-Hitting Set does not have a kernel of size $\mathcal{O}(k^{\lambda-\epsilon})$ unless coNP $\subseteq$ NP/poly [13, 14]. Let $(U, \mathcal{F}, k)$ be an instance of λ-Hitting Set. We will construct a $\lambda+1$-closed graph G as follows: The vertex set $V(G)$ is $U \cup \mathcal{F}$. We add edges such that U forms a clique in G. We also add an edge between $u \in U$ and $S \in \mathcal{F}$ if and only if $u \in S$. Finally, we set $k' = k$. Since $\deg_G(S) = \lambda$ for each $S \in \mathcal{F}$ the graph G is $\lambda+1$-closed.

By construction, each hitting set X of size at most k is also a dominating set of size at most k of G. For the converse direction, we may assume by Lemma 4.1 that there is a dominating set D of size at most k for G not containing any vertex from $\mathcal{F}$. Thus, D is also a hitting set of $(U, \mathcal{F}, k)$.

Observe that our reduction preserves the parameter (that is, $k = k'$). Thus, it follows from the result of Hermelin and Wu [22] that if Dominating Set admits a kernel of size $\mathcal{O}(k^{\lambda-1-\epsilon})$ for some $\epsilon > 0$, then λ-Hitting Set admits a kernel of size $\mathcal{O}(k^{\lambda-\epsilon})$, implying that coNP $\subseteq$ NP/poly [13, 14]. ◀

We also obtain an algorithm for Threshold Dominating Set which is faster than brute-force search on the kernel of Theorem 4.14 and an improved kernel on bipartite graphs.

▶ **Theorem 4.17.** Threshold Dominating Set *can be solved in $\mathcal{O}^*(3^{c/3} + (ck)^{\mathcal{O}(rk)})$ time and* Dominating Set *can be solved in $\mathcal{O}^*((ck)^{\mathcal{O}(k)})$ time.*

▶ **Theorem 4.18.** Dominating Set *in bipartite graphs has a kernel with $\mathcal{O}(c^3k^4)$ vertices.*

5 Induced Matching

In this section, we develop kernelizations for Induced Matching in c-closed graphs.

Induced Matching
Input: A graph G and $k \in \mathbb{N}$.
Question: Is there a set M of at least k edges such that endpoints of distinct edges in M are pairwise nonadjacent?

Induced Matching is W[1]-hard when parameterized by k, even in bipartite graphs [26]. In terms of kernelizations, Induced Matching admits a kernel with $\mathcal{O}(\Delta^2 k)$ vertices [26] and $\mathcal{O}(k^d)$ vertices [18, 24]. The latter kernelization result is essentially tight: Unless coNP $\subseteq$ NP/poly, Induced Matching has no kernel of size $\mathcal{O}(k^{d-3-\varepsilon})$ for any $\varepsilon > 0$ [11]. Despite the lower bound in degenerate graphs, we discover in this section that Induced Matching in c-closed graphs has a polynomial kernel when parameterized by $k + c$.

5.1 Ramsey-like Bounds for Induced Matchings

Dabrowski et al. [12] derived fixed-parameter tractability for Induced Matching in $(K_a, K_{b,b})$-free graphs. At the heart of their algorithm lies a Ramsey-type result for induced matchings: For $a, b \in \mathbb{N}$, there exists an integer $Q_{a,b}$ such that any bipartite graph with a matching of size at least $Q_{a,b}$ contains a biclique $K_{a,a}$ or an induced matching of size b. In this subsection, we present analogous results for c-closed graphs where the number $Q_{a,b}$ is polynomial in a and b. We begin with two preliminary lemmas.

▶ **Lemma 5.1.** *Any graph G with a matching M of size at least $2\Delta b$ has an induced matching of size b.*

Proof. We prove by induction on b. The lemma clearly holds for the base case $b = 0$. For $b > 0$, let uv be a matched edge in M and let $G' := G - N[\{u, v\}]$. Since $|N[\{u, v\}]| \leq 2\Delta_G$, there is a matching of size at least $2\Delta_G b - 2\Delta_G \geq 2\Delta_{G'}(b-1)$ in G'. Consequently, there is an induced matching M' of size $b-1$ in G' by induction hypothesis. Thus, G has an induced matching $M' \cup \{uv\}$ of size b. ◀

▶ **Lemma 5.2.** *Suppose that G is a c-closed bipartite graph. If there are at least $2b$ vertices of degree at least cb, then G contains an induced matching of size at least b.*

Proof. Let A, B be a bipartition of G. Without loss of generality, assume that A contains a set A' of exactly b vertices of degree at least cb. Since G is c-closed, $|N(v) \cap N(v')| < c$ for all $v, v' \in A'$. It follows that each $v \in A'$ has a neighbor $u \in N(v)$ such that $u \notin N(v')$ for all $v' \in A' \setminus \{v\}$. Thus, G contains an induced matching of size b. ◀

In the following lemma, we obtain a Ramsey-type result for induced matchings in c-closed bipartite graphs.

▶ **Lemma 5.3.** *Let $Q_c(b) := 2cb^2 + 2b \in \mathcal{O}(cb^2)$. Let G be a c-closed bipartite graph. If G has a matching M of size at least $Q_c(b)$, then G contains an induced matching of size at least b.*

Proof. If there are at least $2b$ vertices of degree at least cb in G, then Lemma 5.2 yields an induced matching of size b. Thus, we can assume that $|S| < 2b$ for the set S of vertices of degree at least cb. Observe that $G - S$ has a matching of size $2cb^2$ and that $\Delta_{G-S} \leq cb$. Thus, $G - S$ has an induced matching of size b by Lemma 5.1. ◀

We extend Lemma 5.3 to non-bipartite c-closed graphs in the subsequent two lemmas. Recall that each c-closed graph G with at least $R_c(a, b) \in \mathcal{O}(cb^2 + ab)$ vertices contains a clique of a vertices or an independent set of b vertices by Lemma 3.1. Our proofs for Lemmas 5.4 and 5.5 put Lemmas 3.1 and 5.3 together.

▶ **Lemma 5.4.** *Let $Q'_c(a, b) := R_c(a, Q_c(b)) \in \mathcal{O}(cab^2 + c^3b^4)$. Any c-closed graph G with an independent set I of size at least $Q'_c(a, b)$ and a matching M saturating I contains a clique of size a or an induced matching of size b.*

Proof. Suppose that G contains no clique of size a. We show that there is an induced matching of size b in G. Let $H := V(M) \setminus I$ be the set of vertices matched to I in M. Since $|H| \geq R_c(a, Q_c(b))$, it follows from Lemma 3.1 that there is an independent set $H' \subseteq H$ of size at least $Q_c(b)$ in G'. Let $I' \subseteq I$ be the set of vertices matched to H' in M. Then, there is an induced matching of size at least b in $G[H' \cup I']$ by Lemma 5.3. Thus, G contains an induced matching of size b. ◀

▶ **Lemma 5.5.** *Let $Q''_c(a,b) := R_c(a, Q'_c(b)) \in \mathcal{O}(c^3a^2b^4 + c^7b^8)$. Any c-closed graph G with a matching M of size at least $Q''_c(a,b)$ contains a clique of size a or an induced matching of size b.*

Proof. Suppose that G contains no clique of size a. We will show that there is an induced matching of size b in G. Let I and H be disjoint vertex sets such that I and H consist of distinct endpoints of each edge in M. Since $|I| \geq R_c(a, Q'_c(b))$, it follows from Lemma 3.1 that there is an independent set $I' \subseteq I$ of size $Q'_c(b)$. Let $H' \subseteq H$ be the set of vertices matched to I' and let $G' := G[H' \cup I']$. Since I is an independent set of size at least $Q'_c(b)$, it follows from Lemma 5.3 that there is an induced matching M' of size at least b in G'. Consequently, G contains an induced matching of size b. ◀

5.2 Polynomial Kernel in c-closed Graphs

In this subsection, we prove that Induced Matching in c-closed graphs admits a kernel with $\mathcal{O}(c^7k^8)$ vertices. Our kernelization is based on Lemmas 5.4 and 5.5. To utilize these lemmas, we start with a reduction rule that destroys large cliques.

▶ **Reduction Rule 5.6.** *Let $v \in V(G)$ and let M_v be a maximum matching in $G[N(v)]$. If $|M_v| \geq 2ck$, then remove v.*

▶ **Lemma 5.7.** *Reduction Rule 5.6 is correct.*

Proof. Let $v \in V(G)$, let M_v be a maximum matching in $G[N_G(v)]$ of size at least $2ck$, and let $G' := G - v$. Suppose that G has an induced matching M of size at least k. We show that G' contains an induced matching of size at least k as well. We are done if M does not use v, because M is also an induced matching in G'. So we can assume that M uses v. Let $v_1v_2, \ldots, v_{2k-1}v_{2k}$ be k edges of M such that $v_{2k} = v$. By the definition of induced matching, $v_i \notin N_G(v)$ holds for each $i \in [2k-2]$. Thus, the c-closure of G yields that $|N_G(v) \cap N_G(v_i)| < c$ for each $i \in [2k-2]$. Since M_v is of size at least $2ck$, there is an edge e in M_v neither whose endpoint is adjacent to any vertex v_i for $i \in [2k-2]$. Hence, the edges $v_1v_2, \ldots, v_{2k-3}v_{2k-2}, e$ form an induced matching of size k in G'. The other direction follows trivially. Note that the c-closure is maintained by Observation 2.1. ◀

Henceforth, we assume that Reduction Rule 5.6 has been applied for each vertex. In the next lemma, we verify that there is no large clique.

▶ **Lemma 5.8.** *There is no clique of size $4ck + 1$ in G.*

Proof. Suppose that G contains a clique C of size at least $4ck + 1$ and let $v \in C$. Note that $C \subseteq N[v]$. Let M_v be a maximum matching in $G[N(v)]$. Also, let $N_v^1 \subseteq N(v)$ be the set of vertices incident with M_v and let $N_v^0 := N(v) \setminus N_v^1$. Since M_v is a maximum matching, N_v^0 is an independent set in $G[N(v)]$. Thus, C includes at most one vertex of N_v^0, that is, $|C \cap N_v^0| \leq 1$. Moreover, it follows from Reduction Rule 5.6 that $|M_v| \leq 2ck - 1$ and hence $|N_v^1| \leq 4ck - 2$. Now, we have a contradiction because $|C| = |C \cap N_v^0| + |C \cap N_v^1| + 1 \leq 4ck$. ◀

Once we show that the graph has a sufficiently large matching, Lemma 5.5 tells us that we can find a sufficiently large induced matching as well. Note, however, that a graph may not have a sufficiently large matching, even if it contains sufficiently many vertices (consider a star $K_{1,n}$ with n leaves). Our way around this obstruction is the LP (Linear Programming) relaxation of Vertex Cover (henceforth, we will abbreviate it as VCLP). It is well-known in the theory of kernelization that VCLP almost trivially yields a linear-vertex kernel for

Vertex Cover [7] due to the Nemhauser-Trotter theorem [28]. Here, we will exploit VCLP to ensure that after we apply some reduction rules, either the size of G is upper-bounded or the minimum vertex cover size (or equivalently the maximum matching size) of G is sufficiently large.

Recall that Vertex Cover can be formulated as an integer linear program as follows, using a variable x_v for each $v \in V(G)$:

$$\min \sum_{v \in V(G)} x_v \qquad \text{subject to} \quad \begin{aligned} x_u + x_v &\geq 1 \quad \forall uv \in E(G), \\ x_v &\in \{0,1\} \quad \forall v \in V(G). \end{aligned}$$

In VCLP, the last integral constraint is relaxed to $0 \leq x_v \leq 1$ for each $v \in V(G)$. It is known that VCLP admits a half-integral optimal solution (that is, $x_v \in \{0, 1/2, 1\}$ for each $v \in V(G)$) and such a solution can be computed in $\mathcal{O}(m\sqrt{n})$ time via a reduction to Maximum Matching (see, for instance, [4] or [10, Section 2.5]). Suppose that we have a half-integral optimal solution $(x_v)_{v \in V(G)}$. Let $V_0 := \{v \in V(G) \mid x_v = 0\}$, $V_1 := \{v \in V(G) \mid x_v = 1\}$, and $V_{1/2} := \{v \in V(G) \mid x_v = 1/2\}$.

We will bound the sizes of V_0, V_1, and $V_{1/2}$ in the upcoming rules. We begin with $V_{1/2}$. We use the bound Q''_c as specified in Lemma 5.5.

▶ **Reduction Rule 5.9.** *If $|V_{1/2}| \geq 3Q''_c(4ck+1, k)$, then return Yes.*

To show the correctness, we will use the fact that $VC + MM \geq 2LP$ for any graph G [20, Lemma 2.1]. Here, VC, MM, and LP refer to the minimum vertex cover size, the maximum matching size, and the optimal VCLP cost of G.

▶ **Lemma 5.10.** *Reduction Rule 5.9 is correct.*

Proof. Observe that the optimal cost of VCLP for $G[V_{1/2}]$ is $|V_{1/2}|/2$. Let X be a minimum vertex cover and M be a maximum matching in $G[V_{1/2}]$. Then, it follows that $|X| + |M| \geq |V_{1/2}|$ [20, Lemma 2.1]. Since $V(M)$ is a vertex cover in $G[V_{1/2}]$, we also have $2|M| \geq |X|$. Thus, $|M| \geq |V_{1/2}|/3 \geq Q''_c(4ck, k)$. Recall that there is no clique of size $4ck+1$ by Lemma 5.8. Hence, Lemma 5.5 yields that G contains an induced matching of size at least k. ◀

We next upper-bound the size of V_1. See Lemma 5.4 for the definition of Q'_c.

▶ **Reduction Rule 5.11.** *If $|V_1| \geq Q'_c(4ck+1, k)$, then return Yes.*

To prove the correctness of Reduction Rule 5.11, let us introduce the notion of *crowns* [9]. For a graph G, a crown is an ordered pair (I, H) of vertex sets of G with the following properties:

1. $I \neq \emptyset$ is an independent set in G,
2. $H = N(I)$, and
3. there is a matching saturating H in $G[H, I]$.

Crowns are closely related to VCLP – in fact, (V_0, V_1) is a crown [1, 8].

▶ **Lemma 5.12.** *Reduction Rule 5.11 is correct.*

Proof. Since (V_0, V_1) is a crown in G, there is a matching M saturating V_1 in $G[V_0, V_1]$. By definition, $I := V_0 \cap V(M)$ is an independent set of size $|V_1| \geq Q'_c(4ck+1, k)$ in G. Now, it follows from Lemma 5.4 that $G[I \cup V_1]$ contains an induced matching of size k. ◀

To deal with V_0, we introduce some additional rules which may add or remove vertices. Let us start with a simple rule. Basically, if there are multiple leaf vertices with the same neighborhood, then only one of them is relevant.

▶ **Reduction Rule 5.13.** *If $v_1 \in V_1$ has more than one leaf neighbor, then remove all but one of them.*

The correctness of Reduction Rule 5.13 is obvious and thus we omit the proof.

▶ **Reduction Rule 5.14.** *Let $v_0 \in V_0$ and let $v_1 \in V_1$. If $N_G[v_0] \subseteq N_G[v_1]$ and there is no leaf vertex attached to v_1, then attach a leaf vertex ℓ to v_1.*

▶ **Lemma 5.15.** *Reduction Rule 5.14 is correct.*

Proof. Let G' be the graph obtained by adding a leaf vertex ℓ to v_1. The forward direction is trivial. For the other direction, note that any induced matching M' in G' is an induced matching in G if M' does not include $v_1\ell$. Hence, it suffices to show that if there is an induced matching M' in G' such that $|M'| \geq k$ and $v_1\ell \in M'$, then there is an induced matching of size k in G as well. By the definition of induced matching, $M' \setminus \{v_1\ell\}$ includes no edge incident with a neighbor of v_1. Since $N_G[v_0] \subseteq N_G[v_1]$, the same holds for v_0. Thus, $(M' \setminus \{v_1\ell\}) \cup \{v_0v_1\}$ is an induced matching of size at least k in G.

For $c > 1$, Reduction Rule 5.14 maintains the c-closure by Observation 2.3. Note that Induced Matching can be solved in linear time when G is 1-closed: Since G is a disjoint union of complete graphs, (G, k) is a Yes-instance if and only if G contains at least k cliques of size at least two. ◀

▶ **Reduction Rule 5.16.** *Let $v_0 \in V_0$ be a non-leaf vertex. If each vertex $v_1 \in N_G(v_0)$ has a leaf neighbor, then remove v_0.*

▶ **Lemma 5.17.** *Reduction Rule 5.16 is correct.*

Proof. Let $G' = G - v_0$. Suppose that G has an induced matching M of size at least k. If M does not use v_0 we are done. So assume that M includes v_0v_1 for $v_1 \in N_G(v_0)$. Since there is a leaf vertex ℓ attached to v_1, the set $(M \setminus \{v_0v_1\}) \cup \{v_1\ell\}$ is an induced matching of size at least k in G'. The other direction follows trivially. The c-closure is maintained by Observation 2.1. ◀

▶ **Theorem 5.18.** Induced Matching *has a kernel with $\mathcal{O}(c^7k^8)$ vertices.*

Proof. We apply Reduction Rules 5.6, 5.9, 5.11, 5.13, 5.14 and 5.16 exhaustively. We also remove all isolated vertices. It is easy to verify that all these rules can be exhaustively applied in polynomial time.

Note that $|V_{1/2}| \in \mathcal{O}(c^7k^8)$ and $|V_1| \in \mathcal{O}(c^3k^4)$ by Reduction Rules 5.9 and 5.11. We show that $|V_0| \in \mathcal{O}(c|V_1|^2) = \mathcal{O}(c^7k^8)$. Note that there are at most $|V_1|$ leaf vertices in V_0 by Reduction Rule 5.13. All other vertices in V_0 are adjacent to at least two nonadjacent vertices in V_1: If there exists a vertex $v_0 \in V_0$ such that $N_G(v_0)$ is a clique of size at least two, then Reduction Rule 5.14 adds a leaf vertex to each vertex in $N_G(v_0)$ and Reduction Rule 5.16 removes v_0. Since G is c-closed, there are $c\binom{|V_1|}{2}$ non-leaf vertices in V_0. It follows that $|V_0| < |V_1| + c\binom{|V_1|}{2} \in \mathcal{O}(c^7k^8)$. ◀

We also obtain smaller kernels in bipartite graphs. Our kernelization is based on the following lemma, proven by a meet-in-the-middle approach on vertex degrees. Interestingly, this lemma will also play a central role in the kernelization for Irredundant Set in Section 6.

▶ **Lemma 5.19.** *Any bipartite graph G with at least $6\Delta^{3/2}b + 2\Delta b$ non-isolated vertices has an induced matching of size b.*

▶ **Theorem 5.20.** Induced Matching *in bipartite graphs has a kernel with $\mathcal{O}(\Delta^{3/2}k)$ vertices and a kernel with $\mathcal{O}(c^{3/2}k^{5/2})$ vertices.*

6 Irredundant Set

A vertex set $S \subseteq V(G)$ is *irredundant* if there is a private neighbor for each vertex v in S. Here, a *private neighbor* of $v \in S$ is a vertex $v' \in N[v]$ (possibly $v' = v$) such that $v' \notin N(u)$ for each $u \in S \setminus \{v\}$.

Irredundant Set
Input: A graph G and $k \in \mathbb{N}$.
Question: Is there an irredundant set S of at least k vertices in G?

Irredundant Set is W[1]-hard in general [16] but it admits a kernel with at most $(d+1)k$ vertices in d-degenerate graphs. This is because any d-degenerate graph on at least $(d+1)k$ vertices contains an independent set and thus an irredundant set of at least k vertices. In this section, we show that Irredundant Set admits a kernel with $\mathcal{O}(c^{5/2}k^3)$ vertices. Our kernelization relies on the Ramsey bound (Lemma 3.1) and the bound on induced matchings (Lemma 5.19). We show that the following reduction rule suffices to obtain a polynomial kernel.

▶ **Reduction Rule 6.1.** *If $u, v \in V(G)$ are simplicial vertices such that $N_G[u] = N_G[v]$, then remove v.*

▶ **Lemma 6.2.** *Reduction Rule 6.1 is correct.*

Proof. Let $u, v \in V(G)$ be vertices such that $N_G[u] = N_G[v]$. Let G' be the graph obtained by removing v as specified in Reduction Rule 6.1. Suppose that (G, k) is a Yes-instance with a solution S. It must hold that $u \notin S$ or $v \notin S$ by the definition of irredundant sets. Without loss of generality, assume that $v \notin S$. If v is a private neighbor of $w \in S$ (possibly $w = u$), then u is also a private neighbor of w. Thus, (G', k) is also a Yes-instance. The other direction follows trivially. The c-closure is maintained by Observation 2.1. ◀

We prove that Reduction Rule 6.1 yields a kernelization of the claimed size.

▶ **Theorem 6.3.** Irredundant Set *in c-closed graphs has a kernel with $\mathcal{O}(c^{5/2}k^3)$ vertices.*

Proof. We assume that Reduction Rule 6.1 has been applied exhaustively.

To simplify notation, let $\alpha' := 6c^{3/2}k + 2ck + 1 \in \mathcal{O}(c^{3/2}k)$ and $\alpha := R_c(\alpha', k) \in \mathcal{O}(c^{3/2}k^2)$. We claim that any instance (G, k) with at least $R_c(c\alpha + 1, k) \in \mathcal{O}(c^{5/2}k^3)$ vertices is a Yes-instance. By Lemma 3.1, G has a clique of size $c\alpha + 1$ or an independent set of size k. Since any independent set is also an irredundant set, (G, k) is a Yes-instance when G contains an independent set of size k. Thus, we assume that there is no independent set of size k in G.

It remains to show that if G has a maximal clique C of size greater than $c\alpha$, then (G, k) is a Yes-instance. Let $C' = \{v \in C \mid N_G(v) \setminus C \neq \emptyset\}$ be the set of vertices in C that have at least one neighbor outside C. There exists at most one vertex v with $N_G[v] = C$ by Reduction Rule 6.1 and thus $|C'| \geq |C| - 1 \geq c\alpha$. Let $G' = G - (C \setminus C')$. That is, G' is a graph obtained by removing a vertex adjacent to all vertices in C, if such a vertex exists. For each $i \in [\alpha]$, we will choose vertices $x_i \in C'$ and $y_i \in N_{G'}(C')$ as follows: Let x_i be an arbitrary vertex in $C' \setminus \bigcup_{j \in [i-1]} N_{G'}(y_j)$ and let y_i be an arbitrary vertex in $N_{G'}(x_i)$. Note that $C' \setminus \bigcup_{j \in [i-1]} N_{G'}(y_j) \neq \emptyset$ for each $i \in [\alpha]$, because $|C'| \geq c\alpha$ and y_j has less than c neighbors in C' for all $j \in [i-1]$ by Observation 2.2.

Since G has no independent set of size k, Lemma 3.1 gives us a clique of size α' among $y_1, \ldots, y_\alpha$. Without loss of generality, let $Y = \{y_1, \ldots, y_{\alpha'}\}$ be a clique of size α' and let $X = \{x_1, \ldots, x_{\alpha'}\}$. For $X' = X \setminus \{x_1\}$ and $Y' = Y \setminus \{y_1\}$, we prove that the bipartite graph $G[X', Y']$ has an induced matching of size k, using Lemma 5.19. First we show that $\Delta_{G[X',Y']} < c$. All vertices in Y' have less than c neighbors in X' by Observation 2.2.

By the choice of x_i and y_i, we have $x_i \notin N_G(y_1)$ for all $i \in [2, \alpha']$. It follows from the c-closure of G that x_i has less than c neighbors in Y' for each $i \in [2, \alpha']$. Thus, we have $\Delta_{G[X',Y']} < c$. Note that we choose x_i and y_i such that there is an edge $x_i y_i \in E(G)$ for each $i \in [2, \alpha']$. So $G[X', Y']$ has no isolated vertices. Therefore, it follows from Lemma 5.19 that there is an induced matching $\{x_{i_1}y_{i_1}, \ldots, x_{i_k}y_{i_k}\}$ of size k in $G[X', Y']$. Now, the set $\{x_{i_1}, \ldots, x_{i_k}\}$ is an irredundant set in G, where y_{i_j} is a private neighbor of x_{i_j} for each $j \in [k]$. ◀

7 Conclusion

We have demonstrated that the c-closure of a graph can be exploited in the design of parameterized algorithms for well-studied graph problems. We believe that the c-closure could become a standard secondary parameter just as the maximum degree Δ or the degeneracy d of the input graph and that studying problems with respect to this parameter may often lead to useful tractability results. In essence, whenever one obtains a fixed-parameter algorithm that uses Δ as one of its parameters, one should ask whether Δ can be replaced by the c-closure of the input graph. As concrete applications of the c-closure parameterization, one could consider further graph problems that are hard with respect to the solution size. For example, is Perfect Code [6] fixed-parameter tractable with respect to $c + k$ where k is the size of the code and does it admit a polynomial kernelization for this parameter? Further problems to investigate could be r-Regular Induced Subgraph which is W[1]-hard when parameterized by the subgraph size [27] or cardinality constrained optimization problems in graphs such as computing a maximum cut where the number of vertices in one part is constrained to be k [5]. These problems are often fixed-parameter tractable for the combination of the cardinality constraint k and the maximum degree Δ [5, 25]. Which of these problems is also fixed-parameter tractable for the combination of k and c? For answering such questions, the Ramsey bound of Lemma 3.1 could prove useful.

Abstract

We study the Many Visits TSP problem, where given a number $k(v)$ for each of n cities and pairwise (possibly asymmetric) integer distances, one has to find an optimal tour that visits each city v exactly $k(v)$ times. The currently fastest algorithm is due to Berger, Kozma, Mnich and Vincze [SODA 2019, TALG 2020] and runs in time and space $\mathcal{O}^*(5^n)$. They also show a polynomial space algorithm running in time $\mathcal{O}(16^{n+o(n)})$. In this work, we show three main results:

- A randomized polynomial space algorithm in time $\mathcal{O}^*(2^n D)$, where D is the maximum distance between two cities. By using standard methods, this results in a $(1+\epsilon)$-approximation in time $\mathcal{O}^*(2^n \epsilon^{-1})$. Improving the constant 2 in these results would be a major breakthrough, as it would result in improving the $\mathcal{O}^*(2^n)$-time algorithm for Directed Hamiltonian Cycle, which is a 50 years old open problem.
- A tight analysis of Berger et al.'s exponential space algorithm, resulting in an $\mathcal{O}^*(4^n)$ running time bound.
- A new polynomial space algorithm, running in time $\mathcal{O}(7.88^n)$.

1 Introduction

In the Many Visits TSP (MVTSP) we are given a set V of n vertices, with pairwise distances (or costs) $d : V^2 \to \mathbb{Z}_{\geq 0} \cup \{\infty\}$. We are also given a function $k : V \to \mathbb{Z}_+$. A valid tour of length ℓ is a sequence of vertices $(x_1, \ldots, x_\ell)$, where $\ell = \sum_{v \in V} k(v)$, such that each $v \in V$ appears in the sequence exactly $k(v)$ times. The cost of the tour is $\sum_{i=1}^{\ell-1} d(x_i, x_{i+1}) + d(x_\ell, x_1)$. Our goal is to find a valid tour with minimum cost.

Many Visits TSP is a natural generalization of the classical (asymmetric) Traveling Salesman Problem (TSP), which corresponds to the case when $k(v) = 1$ for every vertex v. Similarly as its special case, MVTSP arises with a variety of applications, including scheduling [24, 17, 6, 27, 12], computational geometry [20] and parameterized complexity [21].

1.1 Related work

The standard dynamic programming for TSP of Bellman [1], Held and Karp [16] running in time $\mathcal{O}^*(2^n)$ can be easily generalized to MVTSP resulting in an algorithm with the running time of $\mathcal{O}^*(\prod_{v \in V}(k(v)+1))$, as noted by Psaraftis [24]. A breakthrough came in the work of Cosmadakis and Papadimitriou [7] who presented an algorithm running in time $2^{O(n \log n)} + \mathcal{O}(n^3 \log \ell)$ and space $2^{O(n \log n)}$, thus essentially removing the dependence on the function k from the bound (the $\log \ell$ factor can be actually skipped if we support the original algorithm with a today's state-of-the-art minimum cost flow algorithm). This may be surprising since the *length* of the output sequence is ℓ. However, beginning from the work of Cosmadakis and Papadimitriou we consider MVTSP with compressed output, namely the output is a multiplicity function which encodes the number of times every edge is visited by the tour. By using a standard Eulerian tour algorithm we can compute an explicit tour from this output.

The crux of the approach of Cosmadakis and Papadimitriou [7] was an observation that every solution can be decomposed to a minimal connected spanning Eulerian subgraph (which enforces connectivity of the solution) and a subgraph satisfying appropriate degree constraints (which completes the tour so that the numbers of visits agree). Moreover, once we guess the degree sequence δ of the Eulerian subgraph, our task splits into two separate tasks: finding a cheapest minimal connected Eulerian subgraph consistent with δ (which is computationally hard) and finding a cheapest subgraph satisfying the degree constraints (which can by solved in polynomial time by a reduction to minimum cost flow).

Yet another breakthrough came only recently, namely Berger, Kozma, Mnich and Vincze [3, 2] improved the running time to $\mathcal{O}^*(5^n)$. Their main contribution is an idea that it is more convenient to use outbranchings (i.e. spanning trees oriented out of the root) to force connectivity of the solution. The result of Berger et al. is the first algorithm for MVTSP which is optimal assuming Exponential Time Hypothesis (ETH) [18], i.e., there is no algorithm in time $2^{o(n)}$, unless ETH fails. Moreover, by applying the divide and conquer approach of Gurevich and Shelah [15] they design a polynomial space algorithm, running in time $\mathcal{O}(16^{n+o(n)})$.

1.2 Our results

In this work, we take the next step in exploration of the Many Visits TSP problem: we aim at algorithms which are optimal at a more fine grained level, namely with running times of the form $\mathcal{O}(c^n)$, such that an improvement to $\mathcal{O}((c-\epsilon)^n)$ for any $\epsilon > 0$ meets a kind of natural barrier, for example contradicts the Strong Exponential Time Hypothesis (SETH) [19] or the Set Cover Conjecture (SCC) [8]. Our main result is the following theorem.

▶ **Theorem 1.1.** *There is a randomized algorithm that solves* Many Visits TSP *in time* $\mathcal{O}^*(2^n D)$ *and polynomial space, where* $D = \max\{d(u,v) : u,v \in V, d(u,v) \neq \infty\}$. *The algorithm returns a minimum weight solution with constant probability.*

The natural barrier in this case is connected with Directed Hamiltonicity, the problem of determining if a directed graph contains a Hamiltonian cycle. Indeed, this is a special case of Many Visits TSP with $D = 1$, so an improvement to $\mathcal{O}^*(1.99^n D)$ in Theorem 1.1 would result in an algorithm in time $\mathcal{O}^*(1.99^n)$ for Directed Hamiltonicity. While it is not known whether such an algorithm contradicts SETH or SCC, the question about its existence is a major open problem which in the last 58 years has seen some progress only for special graph classes, like bipartite graphs [4, 9].

At the technical level, Theorem 1.1 uses the so-called algebraic approach and relies on two key insights. The first one is to enforce connectivity not by guessing a spanning connected subgraph as in the previous works, but by applying the Cut and Count approach of Cygan et al [10]. The second insight is to satisfy the degree constraints using the Tutte matrix [26, 22].

By using standard rounding techniques, we are able to make the algorithm from Theorem 1.1 somewhat useful even if the maximum distance D is large. Namely, we prove the following.

▶ **Theorem 1.2.** *For any* $\epsilon > 0$ *there is a randomized* $(1+\epsilon)$*-approximation algorithm that solves* Many Visits TSP *in* $\mathcal{O}^*(2^n \epsilon^{-1})$ *time and polynomial space.*

In Theorems 1.1 and 1.2 the better exponential dependence in the running time was achieved at the cost of sacrificing an $\mathcal{O}(D)$ factor in the running time, or the optimality of the solution. What if we do not want to sacrifice anything? While we are not able to get a $\mathcal{O}^*(2^n)$ algorithm yet, we are able to report a progress compared to the algorithm of Berger et al. in time $\mathcal{O}^*(5^n)$. In fact we do not show a new algorithm but we provide a refined analysis of the previous one. The new analysis is tight (up to a polynomial factor).

▶ **Theorem 1.3.** *There is an algorithm that solves* Many Visits TSP *in time and space* $\mathcal{O}^*(4^n)$.

In short, Berger et al.'s polyspace $\mathcal{O}^*(16^{n+o(n)})$ time algorithm iterates through all $O(4^n)$ degree sequences of an outbranching, finds the cheapest outbranching for each sequence in time $O(4^{n+o(n)})$, and completes it to satisfy the degree constraints using a polynomial time flow computation. Note that it is hard to speed up the cheapest outbranching routine, because for the sequence of $n-1$ ones and one zero we get essentially the TSP, for which the best known polynomial space algorithm takes time $O(4^{n+o(n)})$ [15]. However, we are still able to get a significant speed up of their algorithm, roughly, by using a more powerful minimum cost flow network, which allows for computing the cheapest outbranchings in smaller subgraphs.

▶ **Theorem 1.4.** *There is an algorithm that solves* Many Visits TSP *in time* $\mathcal{O}^*(7.88^n)$ *and polynomial space.*

Organization of the paper. In Section 3 we show that, essentially, using a polynomial time preprocessing step we can reduce an instance of Many Visits TSP to an equivalent one but with demands k bounded by $O(n^2)$. This reduction is a crucial prerequisite for Section 4 where we prove Theorem 1.1. Next, in Section 5 we prove Theorem 1.3 and in Section 6 we prove Theorem 1.4. We note that in these two sections we do not need the reduction from Section 3, however, in practice, applying it should speed-up the flow computations used in both algorithms described there. Finally, in Section 7 we show Theorem 1.2 and we discuss further research in Section 8.

2 Preliminaries

We use Iverson bracket, i.e., if α is a logical proposition, then the expression $[\alpha]$ evaluates to 1 when α is true and 0 otherwise.

For two integer-valued functions f, g on the same domain D, we write $f \leq g$ when $f(x) \leq g(x)$ for every $x \in D$. Similarly, $f + g$ (resp. $f - g$) denote the pointwise sum (difference) of f and g. This generalizes to functions on different domains D_f, D_g by extending the functions to $D_f \cup D_g$ so that the values outside the original domain are 0.

For a cost function $d : V^2 \to \mathbb{Z}_{\geq 0} \cup \{\infty\}$, and a multiplicity function $m : V^2 \to \mathbb{Z}_{\geq 0}$ we denote the cost of m as $d(m) = \sum_{u,v \in V^2} d(u, v)m(u, v)$.

Multisets. Recall that a *multiset* A can be identified by its *multiplicity* function $m_A : U \to \mathbb{Z}_{\geq 0}$, where U is a set. We write $e \in A$ when $e \in U$ and $m_A(e) > 0$. Consider two multisets A and B. We write $A \subseteq B$ when for every $e \in A$ we have $e \in B$ and $m_A(e) \leq m_B(e)$. Also, $A = B$ when $A \subseteq B$ and $B \subseteq A$. Assume w.l.o.g. that m_A and m_B have the same domain U. Operations on multisets are defined by the corresponding multiplicities as follows: for every $e \in U$, we have $m_{A \cup B}(e) = \max\{m_A(e), m_B(e)\}$, $m_{A \cap B}(e) = \min\{m_A(e), m_B(e)\}$, $m_{A \setminus B}(e) = \max\{m_A(e) - m_B(e), 0\}$, $m_{A \triangle B}(e) = m_{(A \setminus B) \cup (B \setminus A)} = |m_A(e) - m_B(e)|$. This notation extends to the situation when A or B is a set, by using the indicator function $m_A(e) = [e \in A]$.

Directed graphs. Directed graphs (also called digraphs) in this paper can have multiple edges and multiple loops, so sets $E(G)$ will in fact be multisets. We call a directed graph *simple* if it has no multiple edges or loops. We call it *weakly simple* if it has no multiple edges or multiple loops (but single loops are allowed). For a digraph G by $G^{\downarrow}$ we denote the *support* of G, i.e., the weakly simple digraph on the vertex set $V(G)$ such that $E(G^{\downarrow}) = \{(u, v) \mid G \text{ has an edge from } u \text{ to } v\}$.

Given a digraph $G = (V, E)$ we define its *multiplicity function* $m_G : V^2 \to \mathbb{Z}_{\geq 0}$ as the multiplicity function of its edge multiset, i.e., for any pair $u, v \in V$, we put $m_G(u, v) = m_E((u, v))$. Conversely, for a function $m : V^2 \to \mathbb{Z}_{\geq 0}$ we define the *thick graph* $G_m = (V, E)$ so that $m_G = m$. Abusing notation slightly, we will identify m and G_m, e.g., we can say that m is strongly connected, contains a subgraph, etc.

We call a directed graph *connected* if the underlying undirected graph is connected. Similarly, a *connected component* of a digraph G is a subgraph of G induced by a vertex set of a connected component of the underlying undirected graph.

For a graph G (directed or undirected) and a subset $X \subseteq V(G)$, by $G[X]$ we denote the subgraph induced by X.

Solutions. The following observation follows easily from known properties of Eulerian digraphs.

▶ **Observation 2.1.** *Many Visits TSP has a tour of cost c if and only if there is a multiplicity function $m_G : V^2 \to \mathbb{Z}_{\geq 0}$ of cost c such that (i) for every $v \in V$, $\sum_{w \in V} m(v, w) = \sum_{w \in V} m(w, v) = k(v)$ and (ii) m contains a spanning connected subgraph.*

Thanks to Observation 2.1, in the remainder of this paper we refer to multiplicity functions as solutions of MVTSP (and some related problems which we are going to define). By standard arguments, the multiplicity function can be transformed to a tour in time $\mathcal{O}(\ell)$. Moreover, Grigoriev and Van de Klundert [14] describe an algorithm which transforms it to a compressed representation of the tour in time $O(n^4 \log \ell)$.

Out-trees. An *out-tree* is the digraph obtained from a rooted tree by orienting all edges away from the root. If an out-tree T is a subgraph of a directed graph G and additionally T spans the whole vertex set $V(G)$ we call T an *outbranching*. The sequence $\{\mathsf{outdeg}_T(v)\}_{v\in V(T)}$ is called the *outdegree sequence* of T. Consider a set of vertices $X \subseteq V$, $|X| \geq 2$.

▶ **Lemma 2.2** (Berger et al. [3], Lemma 2.4). *A sequence of nonnegative integers $\{d_v\}_{v\in X}$ is an outdegree sequence of an out-tree spanning X and rooted at $r \in X$ if and only if (i) $d_r \geq 1$ and (ii) $\sum_{v\in X} d_v = |X| - 1$.*

A sequence $\{d_v\}_{v\in X}$ that satisfies (i) and (ii) will be called an *out-tree sequence rooted at r*, or *outbranching sequence rooted at r* when additionally $X = V$. A δ-out-tree means any subtree spanning X with outdegree sequence δ.

3 Reduction to small demands

Consider the following problem, for a family of simple digraphs $\mathcal{F}$.

Fixed Degree $\mathcal{F}$-Subgraph
Input: $d : V^2 \to \mathbb{Z}_{\geq 0} \cup \{\infty\}$, $\mathsf{in}, \mathsf{out} : V \to \mathbb{Z}_{\geq 0}$
Question: Find a function $m : V^2 \to \mathbb{Z}_{\geq 0}$ such that
(i) G_m contains a member of $\mathcal{F}$ as a spanning subgraph,
(ii) for every $v \in V$ we have $\mathsf{in}(v) = \mathsf{indeg}_{G_m}(v)$ and $\mathsf{out}(v) = \mathsf{outdeg}_{G_m}(v)$, and
so as to minimize the value of $d(m) = \sum_{v,w\in V} d(v,w)m(v,w)$.

In this paper, we will consider two versions of the problem: when $\mathcal{F}$ is the family of all oriented trees, called Fixed Degree Connected Subgraph, and when $\mathcal{F}$ is the family of all out-trees with a fixed root r, called Fixed Degree Subgraph With Outbranching. The role of $\mathcal{F}$ is to force connectivity of the instance. Other choices for $\mathcal{F}$ can also be interesting, for example Cosmadakis and Papadimitriou [7] consider the family of minimal Eulerian digraphs.

The goal of this section is to show that, essentially, using a polynomial time preprocessing step we can reduce an instance of Fixed Degree $\mathcal{F}$-Subgraph to an equivalent one but with demands in, out bounded by $O(n^2)$.

When considering the instance of Fixed Degree $\mathcal{F}$-Subgraph we will use the notation $n = |V|$ and $\ell = \sum_{v\in V} \mathsf{in}(v)$. (Clearly, we can assume that also $\ell = \sum_{v\in V} \mathsf{out}(v)$, for otherwise there is no solution.)

Observe that if the image of d is $\{0, +\infty\}$ we get the natural unweighted version, where we are given a graph with edge set $d^{-1}(0)$ and the goal is to decide if one can choose multiplicities of the edges so that the resulting digraph contains a member of $\mathcal{F}$ and its in- and outdegrees match the demands of in and out.

The following observation follows by standard properties of Eulerian cycles in digraphs and the fact that every strongly connected graph contains an outbranching rooted at arbitrary vertex.

▶ **Observation 3.1.** *Many Visits TSP is a special case of both Fixed Degree Connected Subgraph and Fixed Degree Subgraph With Outbranching with $\mathsf{in}(v) = \mathsf{out}(v) = k(v)$ for every vertex $v \in V$.*

In the following lemma, we consider the relaxed problem Fixed Degree Subgraph, defined exactly as Fixed Degree $\mathcal{F}$-Subgraph, but dropping the constraint that solutions must contain a member of $\mathcal{F}$. In what follows, $s_n(\mathcal{F}) = \max_{G\in\mathcal{F},|V(G)|=n} |E(G)|$. (Note that in applications we consider in this work $\mathcal{F}$ is a family of oriented spanning trees, so $s_n(\mathcal{F}) = n - 1$.)

▶ **Lemma 3.2.** *Fix an input instance $d : V^2 \to \mathbb{Z}_{\geq 0} \cup \{\infty\}$, $\mathsf{in}, \mathsf{out} : V^2 \to \mathbb{Z}_{\geq 0}$. For every optimal solution r of* Fixed Degree Subgraph *there is an optimal solution c' of* Fixed Degree $\mathcal{F}$-Subgraph *such that for every $u, v \in V$*

$$|r(u,v) - c'(u,v)| \leq s_{|V|}(\mathcal{F}).$$

Before we proceed to a formal proof of Lemma 3.2, let us sketch an intuition behind it. We pick an optimal solution c of Fixed Degree $\mathcal{F}$-Subgraph and let $B \in \mathcal{F}$ be a spanning subgraph in G_c. The symmetric difference between $E(G_r)$ and $E(G_c)$ can be decomposed into "alternating" cycles. It suffices to alternate $|E(B) \setminus E(G_r)| \leq s_n(\mathcal{F})$ of them to enforce containing B. If we alternated *all* the cycles, we would get the cost of exactly $d(c)$, but because of the optimality of r, alternating any of the cycles does not decrease the cost of the solution. Hence alternating a subset of them cannot make the cost bigger than $d(c)$.

Proof. Let c be an arbitrary optimal solution of Fixed Degree $\mathcal{F}$-Subgraph and let B be an arbitrary graph from $\mathcal{F}$ which is a spanning subgraph of G_c. Our plan is to build an optimal solution c' of Fixed Degree $\mathcal{F}$-Subgraph which contains B and does not differ too much from r.

Define multisets $A_c = E(G_c) \setminus E(G_r)$, $A_r = E(G_r) \setminus E(G_c)$ and $A = A_c \cup A_r = E(G_c) \triangle E(G_r)$. In what follows, by an *alternating cycle* we mean an even cardinality set of edges

$$\{(v_0, v_1), (v_2, v_1), (v_2, v_3), (v_4, v_3) \ldots, (v_{2\ell-2}, v_{2\ell-1}), (v_0, v_{2\ell-1})\},$$

where edges come alternately from A_c and A_r. Note that an alternating cycle is not really a directed cycle, it is just an orientation of a simple undirected cycle.

Note that for every vertex $v \in V$, among the edges in A that enter (resp. leave) v the number of edges from A_c is the same as the number of edges from A_r (counted with corresponding multiplicities), since both c and r satisfy the degree constraints for the same instance. It follows that A can be decomposed into a multiset $\mathcal{C}$ of alternating simple cycles, i.e.,

$$m_A = \sum_{C \in \mathcal{C}} m_C,$$

where $m_C : V^2 \to \mathbb{Z}_{\geq 0}$ and for each pair $u, v \in V$ we have $m_C(u,v) = [(u,v) \in C] \cdot m_{\mathcal{C}}(C)$. To clarify, we note that the sum above is over all cycles in $\mathcal{C}$, and not over all copies of cycles.

Denote $B^+ = E(B) \setminus E(G_r)$. Since $B^+ \subseteq A_c$, for each $e \in B^+$, there is at least one cycle in $\mathcal{C}$ that contains e. We choose an arbitrary such cycle and we denote it by C_e. (Note that it may happen that $C_e = C_{e'}$ for two different edges $e, e' \in B^+$.) Let $\mathcal{C}^+ = \{C_e \mid e \in B^+\}$. Then we define c', by putting for every $u, v \in V$

$$c'(u,v) = r(u,v) + (-1)^{[(u,v) \in A_r]} \sum_{C \in \mathcal{C}^+} [(u,v) \in C]. \tag{1}$$

In other words, c' is obtained from r by iterating over all cycles in $C \in \mathcal{C}^+$, and adding one copy of each edge of $C \cap A_c$ and removing one copy of each edge of $C \cap A_r$.

Let us show that $G_{c'}$ contains B. This is trivial for every $e \in B^+$. When $e \in E(B) \cap E(G_r)$, consider two cases. If $e \notin A_r$, then $c'(e) \geq r(e)$, so $e \in G_{c'}$. If $e \in A_r$, $m_A(e) = r(e) - c(e)$. Then $c'(e) = r(e) - \sum_{C \in \mathcal{C}^+} [(u,v) \in C] \geq r(e) - m_A(e) = c(e) \geq 1$, where the last inequality follows since $B \subseteq G_c$.

To see that c' satisfies the degree constraints, recall that r does so, and note that if in (1) we consider only the summands corresponding to a single cycle $C \in \mathcal{C}^+$, then for every vertex we either add one outgoing edge and remove one outgoing edge, or add one ingoing edge and remove one ingoing edge, or we do not change the set of edges incident to it.

For a cycle $C \in \mathcal{C}$ let $\delta(C) = d(A_c \cap C) - d(A_r \cap C)$. Observe that for every cycle $C \in \mathcal{C}$ we have $\delta(C) \geq 0$, for otherwise $E(G_r) \setminus (C \cap A_r) \cup (C \cap A_c)$ contradicts the optimality of r. It follows that

$$d(c') = d(r) + \sum_{C \in \mathcal{C}^+} \delta(C) \leq d(r) + \sum_{C \in \mathcal{C}} \delta(C) = d(c). \tag{2}$$

Hence, since c is optimal solution of Fixed Degree $\mathcal{F}$-Subgraph, we get that c' is optimal solution of Fixed Degree $\mathcal{F}$-Subgraph as well. Moreover, by (1), for every $u, v \in V$,

$$|c'(u,v) - r(u,v)| \leq |\mathcal{C}^+| \leq |B| \leq s_{|V|}(\mathcal{F}). \tag{3}$$

This ends the proof. ◀

As noted in [7, 2], Fixed Degree Subgraph can be solved by a reduction to minimum cost flow. By applying Orlin's algorithm [23] we get the following.

▶ **Observation 3.3** (Folklore, [7, 2]). *Fixed Degree Subgraph can be solved in time* $O(n^3 \log n)$.

▶ **Theorem 3.4** (Kernelization). *There is a polynomial time algorithm which, given an instance* $I = (d, \mathsf{in}, \mathsf{out})$ *of Fixed Degree* $\mathcal{F}$*-Subgraph, outputs an instance* $I' = (d, \mathsf{in}', \mathsf{out}')$ *of the same problem and a function* $f : V^2 \to \mathbb{Z}_{\geq 0}$ *such that*

(i) $\mathsf{in}'(v), \mathsf{out}'(v) = \mathcal{O}(n \cdot s_n(\mathcal{F}))$ *for every vertex* v,

(ii) *if* m^* *is an optimal solution for* I'*, then* $f + m^*$ *is an optimal solution for* I.

The algorithm does not need to know $\mathcal{F}$*, just the value of* $s_n(\mathcal{F})$.

Proof. Our algorithm begins by finding an optimal solution r of Fixed Degree Subgraph using Observation 3.3.

Define $f_0 : V^2 \to \mathbb{Z}_{\geq 0}$, where for every $v, w \in V$ we put $f_0(v,w) = \max\{r(v,w) - s_n(\mathcal{F}), 0\}$. By Lemma 3.2, there exists an optimal solution c' for instance I such that $c' \geq f_0$. Now define $f : V^2 \to \mathbb{Z}_{\geq 0}$, where for every $v, w \in V$ we put $f(v,w) = \max\{f_0(v,w) - 1, 0\}$. Finally, we put $\mathsf{in}'(v) = \mathsf{in}(v) - \sum_{w \in V} f(w,v)$ and $\mathsf{out}'(v) = \mathsf{out}(v) - \sum_{w \in V} f(v,w)$. The algorithm outputs $I' = (d, \mathsf{in}', \mathsf{out}')$ and f. In what follows, we show that the output has the desired properties.

For the property (i), consider any vertex $v \in V$ and observe that $\sum_{w \in V} f(v,w) \geq \sum_{w \in V}(f_0(v,w) - 1) \geq \sum_{w \in V}(r(v,w) - s_n(\mathcal{F}) - 1)$. Since r is a feasible solution of I, we have $\mathsf{out}(v) = \sum_{w \in V} r(v,w)$. It follows that $\mathsf{out}'(v) \leq n(1 + s_n(\mathcal{F})) = O(n \cdot s_n(\mathcal{F}))$ as required. The argument for $\mathsf{in}'(v)$ is symmetric.

Now we focus on (ii). Let m^* be an optimal solution for I'. It is easy to check that $f + m^*$ satisfies the degree constraints for the instance I. Also, since m^* contains a subgraph from $\mathcal{F}$, then $f + m^*$ contains the same subgraph. It follows that $f + m^*$ is a feasible solution of I. It suffices to show that $f + m^*$ is an optimal solution for I.

Denote $r = c' - f$. Consider any pair $v, w \in V$ such that $c'(v,w) \geq 1$. We claim that $f(v,w) \leq c'(v,w) - 1$. Indeed, if $f_0(v,w) = 0$ then $f(v,w) = 0 \leq c'(v,w) - 1$, and if $f_0(v,w) \geq 1$ then $f(v,w) = f_0(v,w) - 1 \leq c'(v,w) - 1$. It follows that $r(v,w) \geq 1$. In particular, since c' contains a subgraph from $\mathcal{F}$, then also r contains the same subgraph. It follows that r is a feasible solution for I' (the degree constraints are easy to check). Hence, $d(m^*) \leq d(r)$. It follows that $d(f + m^*) \leq d(r + f) = d(c')$, so $f + m^*$ is indeed an optimal solution for I. ◀

4 The small costs case in time $\mathcal{O}^*(2^n D)$

In this section we establish Theorem 1.1. We do it in a bottom-up fashion, starting with a simplified core problem, and next generalizing the solution in a few steps.

4.1 Unweighted decision version with small degree demands

Consider the following problem.

Decision Unweighted Fixed Degree Connected Subgraph
Input: a digraph $G = (V, E)$, $\mathsf{in}, \mathsf{out} : V \to \mathbb{Z}_{\geq 0}$
Question: Is there a function $m : V^2 \to \mathbb{Z}_{\geq 0}$ such that $G_m^{\downarrow}$ is a connected subgraph of G and for every $v \in V$ we have $\mathsf{in}(v) = \mathsf{indeg}_{G_m}(v)$ and $\mathsf{out}(v) = \mathsf{outdeg}_{G_m}(v)$?

Note that Decision Unweighted Fixed Degree Connected Subgraph generalizes the directed Hamiltonian cycle problem, which is known to be solvable in $\mathcal{O}^*(2^n)$ time and polynomial space. In this section we show that this running time can be obtained for the more general problem as well, though we need to allow some randomization.

▶ **Theorem 4.1.** *There is a randomized algorithm which solves an instance $I = (\mathsf{in}, \mathsf{out})$ of Decision Unweighted Fixed Degree Connected Subgraph in time $\mathcal{O}^*(2^n \operatorname{poly}(M))$ and polynomial space, where $M = \max_v \max\{\mathsf{in}(v), \mathsf{out}(v)\}$. The algorithm is Monte Carlo with one-sided error, i.e., the positive answer is always correct and the negative answer is correct with probability at least p, for any constant $p < 1$.*

Our strategy will be to reduce our problem to detecting a perfect matching in a bipartite graph with an additional connectivity constraint.

We define a bipartite graph $B_G = (O, I, E(B_G))$ as follows. Let $I = \{v_1^I, \ldots, v_{\mathsf{in}(v)}^I \mid v \in V(H)\}$, $O = \{v_1^O, \ldots, v_{\mathsf{out}(v)}^O \mid v \in V(H)\}$, and $E(B_G) = \{u_i^O v_j^I \mid (u, v) \in E(G)\}$.

▶ **Observation 4.2.** *$|I| = |O| = \mathcal{O}(nM)$ and $|E(B_G)| \leq E(G)M^2 = \mathcal{O}(n^2M^2)$.*

For an undirected graph H by $\mathcal{PM}(H)$ we denote the set of perfect matchings in H. We say that a matching M in B_G is *connected* when for every cut $(X, V \setminus X)$ with $\emptyset \neq X \subsetneq V$ the matching M contains an edge $u_i^O v_j^I$ such that $u \in X$ and $v \in V \setminus X$ or $v \in X$ and $u \in V \setminus X$.

For a matching M in B_G we define a *contraction* of M as function $m : V^2 \to \mathbb{Z}_{\geq 0}$ such that $m(u, v) = |\{u_i^O v_j^I \in M \mid i \in [\mathsf{out}(u)], j \in [\mathsf{in}(v)]\}|$. In other words G_m is obtained from M by (1) orienting every edge from O to I and (2) identifying all vertices in $\{v_1^I, \ldots, v_{\mathsf{in}(v)}^I\} \cup \{v_1^O, \ldots, v_{\mathsf{out}(v)}^O\}$ for every $v \in V$, and keeping the multiple edges and loops.

▶ **Lemma 4.3.** *$(G, \mathsf{in}, \mathsf{out})$ is a yes-instance of Decision Unweighted Fixed Degree Connected Subgraph iff graph B_G contains a connected perfect matching.*

Proof. Let M be a connected perfect matching in B_G and let m be its contraction. We claim that m is a solution of $(G, \mathsf{in}, \mathsf{out})$. By the definition of B_G, $G_m^{\downarrow}$ is a subgraph of G. Since M is connected, G_m is connected as well, and so is $G_m^{\downarrow}$. Moreover, since M is a perfect matching $\mathsf{in}(v) = \mathsf{indeg}_{G_m}(v)$ and $\mathsf{out}(v) = \mathsf{outdeg}_{G_m}(v)$ for every vertex v.

For the other direction, let m be a solution for $(G, \mathsf{in}, \mathsf{out})$. For every $v \in V$, there are exactly $\mathsf{out}(v)$ edges leaving v in G_m. Let us denote them $e_{v,1}^O, \ldots, e_{v,\mathsf{out}(v)}^O$. Similarly, let us denote all the edges entering v by $e_{v,1}^I, \ldots, e_{v,\mathsf{in}(v)}^I$. Then we define M as the set of edges of the form $u_i^O v_j^I$ such that G_m contains an edge $e = e_{u,i}^O = e_{v,j}^I$. The fact that M is a perfect matching is clear from the construction. Also, M is connected, for otherwise G_m is not connected. ◀

From now on, let $B = (O, I, E(B))$ be an arbitrary subgraph of B_G. Define the following multivariate polynomial over $\mathrm{GF}(2^t)$, for an integer t to be specified later.

$$R = \sum_{\substack{M \in \mathcal{PM}(B) \\ M \text{ is connected}}} \prod_{e \in M} x_e \tag{4}$$

▶ **Lemma 4.4.** *R is not the zero polynomial if and only if B contains a connected perfect matching.*

Proof. It is clear that if R is non-zero then B contains a connected perfect matching. For the reverse implication it suffices to notice that every summand in R has a different set of variables, so it does not cancel out with other summands over $\mathrm{GF}(2^t)$. ◀

Our strategy is to test whether R is non-zero by means of DeMillo–Lipton–Schwartz–Zippel Lemma, which we recall below.

▶ **Lemma 4.5** (DeMillo and Lipton [11], Schwartz [25], Zippel [28])**.** *Let $P(x_1, x_2, \ldots, x_m)$ be a nonzero polynomial of degree at most d over a field $\mathbb{F}$ and let S be a finite subset of $\mathbb{F}$. Then, the probability that P evaluates to zero on a random element $(a_1, a_2, \ldots, a_m) \in S^m$ is bounded by $d/|S|$.*

By Lemmas 4.4 and 4.5, the task reduces to *evaluating* R fast. To this end, we will define a different polynomial P which is easier to evaluate and turns out to be equal to R over $\mathrm{GF}(2^t)$.

Consider a subset $X \subseteq V$. Let $I_X = \{v_i^I \in I \mid v \in X, i = 1, \ldots, \mathsf{in}(v)\}$ and $O_X = \{v_i^O \in O \mid v \in X, i = 1, \ldots, \mathsf{out}(v)\}$. Abusing the notation slightly, we will denote $B[X] = B[I_X \cup O_X]$. Define the following polynomial.

$$P_X = \sum_{M \in \mathcal{PM}(B[X])} \prod_{e \in M} x_e \tag{5}$$

In what follows, v^* is an arbitrary but fixed vertex of V. Define yet another polynomial.

$$P = \sum_{\substack{X \subseteq V \\ v^* \in X}} P_X P_{V \setminus X}. \tag{6}$$

▶ **Lemma 4.6.** *$P = R$.*

Proof. For a matching M in B we say that a set $X \subseteq V$ is *consistent* with M when M does not contain an edge $u_i^O v_j^I$ such that $u \in X$ and $v \in V \setminus X$ or $v \in X$ and $u \in V \setminus X$. The family of all subsets of V that are consistent with M will be denoted by $\mathcal{C}(M)$. Then we can rewrite P as follows.

$$\begin{aligned}
P &= \sum_{\substack{X \subseteq V \\ v^* \in X}} \sum_{M_1 \in \mathcal{PM}(B[X])} \sum_{M_2 \in \mathcal{PM}(B[V \setminus X])} \prod_{e \in M_1 \cup M_2} x_e && \text{[definition]} \\
&= \sum_{M \in \mathcal{PM}(B)} \sum_{\substack{X \in \mathcal{C}(M) \\ v^* \in X}} \prod_{e \in M} x_e && \text{[group by } M = M_1 \uplus M_2\text{]} \\
&= \sum_{M \in \mathcal{PM}(B)} |\{X \in \mathcal{C}(M) \mid v^* \in X\}| \prod_{e \in M} x_e && \text{[trivial]}
\end{aligned}$$

Let us consider a perfect matching $M \in \mathcal{PM}(B)$ and the corresponding contraction m. Observe that the number of sets that are consistent with M and contain a vertex v^* is equal to $2^{\mathrm{cc}(M)-1}$, where $\mathrm{cc}(M)$ is the number of connected components of G_m. Indeed, when X is consistent with M, then for every connected component Q of G_m, either $V(Q) \subseteq X$ or $V(Q) \subseteq V \setminus X$. For the component that contains v^* the choice is fixed, while every choice for the remaining components defines a set consistent with M. It follows that when M is not connected $\mathrm{cc}(M) \geq 2$, and the value of $2^{\mathrm{cc}(M)-1}$ is equal to 0 in $\mathrm{GF}(2^t)$, so the corresponding summand vanishes. On the other hand, if M is connected, the corresponding summand equals just $\prod_{e \in M} x_e$ and it does not cancel out with another summand because the monomial has a unique set of variables. It follows that $P = R$. ◀

▶ **Lemma 4.7** (Tutte, Lovász [26, 22])**.** *For an arbitrary set $X \subseteq V$, the polynomial P_X can be evaluated using $\mathrm{poly}(n+M)$ field operations.*

Proof. Compute the determinant of the corresponding Tutte matrix of dimension $|O| \times |I|$. ◀

Let us now fix our field, namely $t = \lceil 1 + \log n + \log M \rceil$. Since arithmetic operations in $\mathrm{GF}(2^t)$ can be performed in time $\mathcal{O}(t \log^2 t) = \mathcal{O}(\log(n+M) \log^2 \log(n+m))$, by the definition of P and Lemma 4.7 we get the following corollary.

▶ **Corollary 4.8.** *P can be evaluated in time $2^n \,\mathrm{poly}(n+M)$.*

▶ **Lemma 4.9.** *There is a randomized algorithm which decides if B contains a connected perfect matching in time $\mathcal{O}^*(2^n \,\mathrm{poly}(M))$ and polynomial space, where $M = \max_v \max\{\mathsf{in}(v), \mathsf{out}(v)\}$. The algorithm is Monte Carlo with one-sided error, i.e., the positive answer is always correct and the negative answer is correct with probability at least p, for any constant $p < 1$.*

Proof. The algorithm evaluates polynomial P using Corollary 4.8 substituting a random element of $\mathrm{GF}(2^t)$ for each variable, and reports "yes" when the evaluation is nonzero and "no" otherwise. If it reported "yes", then P was a non-zero polynomial and by Lemma 4.4 the answer is correct. Assume it reported 'no' for a yes-instance. By Lemma 4.4 P is non-zero. Since $\deg P = |I| \leq nM$, by Lemma 4.5 the probability that P evaluated to 0 is bounded by $\deg P / 2^t \leq 1/2$ and we can make this probability arbitrarily small by repeating the whole algorithm a number of times, and reporting "yes" if at least one evaluation was nonzero. The claim follows. ◀

Theorem 4.1 follows immediately from Lemma 4.3 and Lemma 4.9 applied to B_G.

4.2 Finding the solution

▶ **Lemma 4.10.** *There is a randomized algorithm which, given a yes-instance of* Decision Unweighted Fixed Degree Connected Subgraph*, always returns the corresponding solution m in expected time $\mathcal{O}^*(2^n \,\mathrm{poly}(M))$. The time can be made deterministic at the cost of introducing arbitrarily small probability of failure.*

In order to prove Lemma 4.10 we cast the problem in the setting of *inclusion oracles* from the work of Björklund et al. [5]. Consider a universe U and an (unknown) family of *witnesses* $\mathcal{F} \subseteq 2^U$. An *inclusion oracle* is a procedure which, given a query set $Y \subseteq U$, answers (either YES or NO) whether there exists at least one witness $W \in \mathcal{F}$ such that $W \subseteq Y$. Björklund et al. prove the following.

▶ **Theorem 4.11** ([5]). *There exists an algorithm that extracts a witness of size k in $\mathcal{F}$ using in expectation at most $O(k \log |U|)$ queries to a randomized inclusion oracle that has no false positives but may output a false negative with probability at most $p \leq \frac{1}{4}$.*

Proof of Lemma 4.10. Let $U = E(B_G)$ and let $\mathcal{F}$ be the family of all connected perfect matchings in B_G. Note that $|U| = O(n^2M^2)$ and witnesses in $\mathcal{F}$ have all size $|I| = O(nM)$. Then, Lemma 4.9 provides a randomized inclusion oracle and we can apply Theorem 4.11. (If one insists on deterministic, and not expected, running time, it suffices to chose a sufficiently large constant r and stop the algorithm if it exceeds the expected running time at least r times – by Markov's inequality, this happens with probability at most $1/r$.) ◀

4.3 Proof of Theorem 1.1

In the lemma below we will adapt the construction from Section 4.1 to the weighted case in a standard way, by introducing a new variable tracking the weight.

▶ **Lemma 4.12.** *There is a randomized algorithm which solves an instance $I = (d, \mathsf{in}, \mathsf{out}, w)$ of Fixed Degree Connected Subgraph in time $\mathcal{O}^*(2^n D \operatorname{poly}(M))$ and polynomial space, where $M = \max_v \max\{\mathsf{in}(v), \mathsf{out}(v)\}$ and D is the maximum integer value of d. The algorithm returns a minimum weight solution with probability at least p, for any constant $p < 1$.*

Proof. Define $G = (V, E)$ where $E = \{(u, v) \in V^2 \mid d(u, v) \in \mathbb{Z}_{\geq 0}\}$. Let R' be the polynomial obtained from R by replacing every variable x_e for $e = u_i^O v_j^I \in E(B_G)$ by the product $x_e \cdot y^{d(u,v)}$, where y is a new variable. Proceed similarly with P, obtaining P'. By Lemma 4.4, $P' = R'$. Decompose R' as $R' = \sum_{i=0}^{|I|\cdot D} R'_i y^i$, where R'_i, for every $i = 0, \ldots, |I| \cdot D$, is a polynomial in variables $\{x_e\}_{e \in E(B_G)}$. The monomials in R'_i enumerate all matchings M such that the contraction m of M has weight $d(m) = i$. By the construction in the proof of Lemma 4.3 R'_i is non-zero if and only if instance I has a solution of weight i. Using Lagrange interpolation, we can recover the value of each R'_i for random values of the variables $\{x_e\}_{e \in E(B_G)}$ (the values are the same for all the polynomials). The interpolation algorithm requires $|I| \cdot D = \mathcal{O}(nMD)$ evaluations of R'. Since $R' = P'$, by Lemma 4.8 each of them takes $2^n \operatorname{poly}(n + M))$ time. Our algorithm reports the minimum w such that R'_w evaluated to a non-zero element of $\mathrm{GF}(2^t)$, or $+\infty$ if no such w exists. The solution of weight w is then found using Lemma 4.10. The event that the optimum value w^* is not reported means that R'_{w^*} is a non-zero polynomial that evaluated to 0 at the randomly chosen values. By Lemma 4.5 this happens with probability at most $\deg P / 2^t \leq 1/2$, and one can make this probability arbitrarily small by standard methods. ◀

Theorem 1.1 follows now immediately by applying Theorem 3.4 which reduces the general problem to the $M = \mathcal{O}(n^2)$ case and solving the resulting instance by Lemma 4.12. Theorem 1.1 says in particular that if finite weights are bounded by a polynomial in n then we can solve Many Visits TSP in time $\mathcal{O}^*(2^n)$ and polynomial space by a randomized algorithm with no false positives and with false negatives with arbitrarily small constant probability.

5 The general case

In this section we prove Theorem 1.3, i.e., we show an algorithm solving Many Visits TSP in time $\mathcal{O}^*(4^n)$. In fact, we do not introduce a new algorithm, but we consider an algorithm by Berger et al. (Algorithm 5 in [3]) and we provide a refined analysis, resulting in an improved running time bound $\mathcal{O}^*(4^n)$, which is tight up to a polynomial factor.

Let us recall the algorithm of Berger et al., in a slightly changed notation. In fact, they solve a slightly more general problem, namely Fixed Degree Subgraph With Outbranching. Let $I = (d, \mathsf{in}, \mathsf{out}, r)$ be an instance of this problem, i.e., we want to find a solution $m : V^2 \to \mathbb{Z}_{\geq 0}$ that satisfies the degree constraints specified by in and out and contains an outbranching rooted at r. In what follows we assume $V = \{1, \ldots, n\}$ and $r = 1$.

Consider an outbranching sequence $\{\delta_v\}_{v \in V}$ rooted at $r = 1$. In what follows, all outbranching sequences will be rooted at 1, so we skip specifying the root. Let T_δ be a minimum cost outbranching among all outbranchings with outdegree sequence δ and let r_δ be an optimum solution of Fixed Degree Subgraph for instance $(d, \mathsf{in}', \mathsf{out}')$ where $\mathsf{out}' = \mathsf{out} - \mathsf{outdeg}_T$ and $\mathsf{in}' = \mathsf{in} - \mathsf{indeg}_T$. Berger et al. note that then $m_\delta = m_{T_\delta} + r_\delta$ is a feasible solution for instance I of Fixed Degree Subgraph With Outbranching, and moreover it has minimum cost among all solutions that contain an outbranching with outdegree sequence δ. Since r_δ can be found in polynomial time by Observation 3.3, in order to solve instance I it suffices to find outbranchings T_δ for all outbranching sequences δ and return the solution m_δ of minimum cost. Hence, Theorem 1.3 boils down to proving the following lemma.

▶ **Lemma 5.1.** *There is an algorithm which, for every outbranching sequence δ, finds a minimum cost outbranching among all outbranchings with outdegree sequence δ and runs in time $\mathcal{O}^*(4^n)$.*

We prove Lemma 5.1 by using dynamic programming (DP). However, it will be convenient to present the DP as a recursive function BestOutbranching with two parameters, $S \subseteq V$ and $\{\delta_v\}_{v \in S}$ (see Algorithm 1). It is assumed that $1 \in S$. We will show that BestOutbranching(S, δ) returns a minimum cost out-tree among all out-trees with outdegree sequence δ that are rooted at 1 and span S. Our algorithm runs BestOutbranching for $S = V$ and all outbranching sequences $\delta : V \to \mathbb{Z}_{\geq 0}$. Whenever BestOutbranching returns a solution for an input (S, δ), it is memoized (say, in an efficient dictionary), so that when BestOutbranching is called with parameters (S, δ) again, the output can be retrieved in polynomial time.

Algorithm 1 A pseudocode of the algorithm from Lemma 5.1.

```
function BestOutbranching(S, δ)
    v_first ← min{v ∈ S | δ_v = 0}
    if |S| = 2 then return {(1, v_first)}.
    else
        minCost ← ∞
        for w ∈ S do
            if (δ_w ≥ 1 ∧ w ≠ 1) ∨ (δ_w ≥ 2 ∧ w = 1) then
                S' ← S \ {v_first}
                δ' ← δ|_{S'}
                δ'_w ← δ'_w − 1
                R_w ← BestOutbranching(S', δ') ∪ {(w, v_first)}
                if d(R_w) < minCost then
                    minCost ← d(R_w)
                    best ← R_w
        return best
```

Let us define $\mathsf{lastRmvd}(S) := \max(\{0, 1, 2, \ldots, n\} \setminus S)$ and $\mathsf{bad}(S, \delta) := \{v \in S \mid v < \mathsf{lastRmvd}(S) \wedge \delta_v = 0\}$. Let us call (S, δ) a *reachable state* if it meets the following conditions:

(i) $\delta_1 \geq 1$
(ii) $\sum_{v \in S} \delta_v = |S| - 1$
(iii) $|\mathsf{bad}(S, \delta)| \leq 1$

▶ **Lemma 5.2.** *If function* BestOutbranching *is given a reachable state as input then all recursively called* BestOutbranching *will also be given only reachable states.*

Proof. Let us fix a reachable state (S, δ) for $|S| > 2$ and consider the associated value v_{first} from the algorithm. Denote $S' = S \setminus \{v_{\mathsf{first}}\}$. Clearly, it suffices to show that all pairs (S', δ') created in the **for** loop are reachable states. First, let us argue that $\mathsf{bad}(S', \delta) = \emptyset$. There are two cases:

- Assume $|\mathsf{bad}(S, \delta)| = 0$. In this case $v_{\mathsf{first}} > \mathsf{lastRmvd}(S)$ so $\mathsf{lastRmvd}(S') = v_{\mathsf{first}}$. Then, $\mathsf{bad}(S', \delta) = \{v \in S' \mid v < \mathsf{lastRmvd}(S') \wedge \delta_v = 0\} = \{v \in S \mid v < v_{\mathsf{first}} \wedge \delta_v = 0\} = \emptyset$.
- Assume $|\mathsf{bad}(S, \delta)| = 1$. Then, (1) $\mathsf{lastRmvd}(S') = \mathsf{lastRmvd}(S)$ because $\mathsf{lastRmvd}(S) > v_{\mathsf{first}}$ and (2) $\mathsf{bad}(S, \delta) = \{v_{\mathsf{first}}\}$. It follows that $\mathsf{bad}(S', \delta) \overset{(1)}{=} \{v \in S' \mid v < \mathsf{lastRmvd}(S) \wedge \delta_v = 0\} = \mathsf{bad}(S, \delta) \setminus \{v_{\mathsf{first}}\} \overset{(2)}{=} \emptyset$.

Let us consider the recursive call of BestOutbranching for a particular w. The sequence $\delta'|_{S'}$ differs from δ only at w, so $\mathsf{bad}(S', \delta') \subseteq \{w\} \cup \mathsf{bad}(S', \delta) = \{w\}$. This means that condition (iii) from the definition of a reachable state holds for (S', δ'). Since (S, δ) is reachable, $\delta_1 \geq 1$. Then either $w \neq 1$ and $\delta'_1 = \delta_1 \geq 1$ or $w = 1$ and $\delta'_1 = \delta_1 - 1 \geq 1$, where the last inequality holds thanks to the condition in the **if** statement in Algorithm 1. In both cases, (i) holds for (S', δ'). Finally, (ii) is immediate by the definition of δ'. It follows that (S', δ') is a reachable state, as required. ◀

▶ **Lemma 5.3.** *If the function* BestOutbranching *is given a reachable state (S, δ), it returns a cheapest out-tree T rooted at vertex 1, spanning S and with outdegree sequence δ.*

Proof. We will use induction on $|S|$.

In the base case $|S| = 2$, there is only one outbranching spanning S rooted at 1, namely $\{(1, v_{\mathsf{first}})\}$ and it is indeed returned by the algorithm.

In the inductive step assume $|S| > 2$. By conditions (i) and (ii) in the definition of a reachable state and Lemma 2.2, there is at least one out-tree rooted at 1, spanning S, and with outdegree sequence δ. Let T be a cheapest out-tree among all such out-trees. Vertex v_{first} is a leaf of T, since $\delta_{v_{\mathsf{first}}} = 0$. At some point w in the **for** loop in Algorithm 1 is equal to the parent w^* of v_{first} in T. Then, $T \setminus \{(w^*, v_{\mathsf{first}})\}$ is an out-tree rooted at 1, spanning S', and with outdegree sequence δ'. Since (S', δ') is a reachable state by Lemma 5.2, by the inductive hypothesis we know that a cheapest such out-tree T' will be returned by BestOutbranching(S', δ'). In particular, it means that $d(T') \leq d(T \setminus \{(w^*, v_{\mathsf{first}})\})$. Denote $R_{w^*} = T' \cup \{(w^*, v_{\mathsf{first}})\}$. Then, $d(R_{w^*}) = d(T') + d(w^*, v_{\mathsf{first}}) \leq d(T \setminus \{(w^*, v_{\mathsf{first}})\}) + d(w^*, v_{\mathsf{first}}) = d(T)$. It follows that BestOutbranching returns a set of edges best of cost at most $d(T)$. However $\mathsf{best} = R_w$ for a vertex w and by applying the induction hypothesis it is easy to see that R_w is an out-tree rooted at 1, spanning S with outdegree sequence δ. The claim follows. ◀

▶ **Lemma 5.4.** *There are $\mathcal{O}^*(4^n)$ reachable states.*

Proof. Any sequence of n nonnegative integers that sums up to at most $n-1$ will be called an *extended sequence*. It is well known that there are exactly $\binom{2n-1}{n} < 2^{2n-1} = \mathcal{O}(4^n)$ such sequences. To see this consider sequences of $n-1$ balls and n barriers and bijectively map them to the sequences of n numbers by counting balls between barriers and discarding the balls after the last barrier.

Let us fix an extended sequence $\bar{\delta} = \{\bar{\delta}_v\}_{v \in V}$, and denote $\bar{s} := n - (1 + \sum_{i=1}^{n} \bar{\delta}_i)$. We claim that there are only $\mathcal{O}(n)$ reachable states (S, δ) such that $\bar{\delta}|_S = \delta$ and $\bar{\delta}|_{V \setminus S} = 0$. Consider any such pair (S, δ). Let $(v_1, v_2, \ldots, v_k)$ be the vertices of $\{v \in V \mid \bar{\delta}_v = 0\}$ sorted

in increasing order. By the definition of a reachable state we know that $|S| = 1 + \sum_{i=1}^{n} \bar{\delta}_i$, so $\bar{s} = |\{1, 2, \ldots, n\} \setminus S|$. By (ii), for at least one vertex $v \in S$ we have $\bar{\delta}_v = \delta_v = 0$, so $k \geq \bar{s} + 1$. Let us assume that $k \geq \bar{s} + 2$ and $\mathsf{lastRmvd}(S) \geq v_{\bar{s}+2}$. Then, $\{v_1, v_2, \ldots, v_{\bar{s}+1}\} \cap S \subseteq \mathsf{bad}(S, \delta)$. Since $v_{\bar{s}+2} \leq \mathsf{lastRmvd}(S) \notin S$, at most $\bar{s} - 1$ elements from $\{v_1, v_2, \ldots, v_{\bar{s}+1}\}$ are outside S, so $|\mathsf{bad}(S, \delta)| \geq (\bar{s} + 1) - (\bar{s} - 1) = 2$. This is a contradiction with (S, δ) being a reachable state, which proves that $k \leq \bar{s} + 1$ or $\mathsf{lastRmvd}(S) < v_{\bar{s}+2}$. In any case, $\{1, 2, \ldots, n\} \setminus S \subseteq \{v_1, \ldots, v_{\bar{s}+1}\}$. There are $\bar{s} + 1 = \mathcal{O}(n)$ ways to choose $\bar{s}$ elements to the set $\{1, 2, \ldots, n\} \setminus S$ from $\{v_1, \ldots, v_{\bar{s}+1}\}$, so equivalently there are $\mathcal{O}(n)$ sets S such that (S, δ) is a reachable state, $\bar{\delta}|_S = \delta$ and $\bar{\delta}|_{V \setminus S} = 0$.

Every reachable state (S, δ) has the corresponding extended sequence $\{\bar{\delta}\}_{v \in V}$ defined by $\bar{\delta}|_S = \delta$ and $\bar{\delta}|_{V \setminus S} = 0$. Since there are $\mathcal{O}(4^n)$ extended sequences, and each of them has $O(n)$ corresponding reachable states there are $\mathcal{O}(4^n) \cdot \mathcal{O}(n) = \mathcal{O}^*(4^n)$ reachable states in total. ◀

We are ready to prove Lemma 5.1. Recall that our algorithm runs BestOutbranching(V, δ) for all outbranching sequences δ and uses memoization to avoid repeated computation. We claim that for any outbranching sequence δ, the pair (V, δ) is a reachable state. Indeed, conditions (i) and (ii) hold since δ is an outbranching sequence. By definition, $\mathsf{lastRmvd}(V) = 0$, so $\mathsf{bad}(V, \delta) = \emptyset$ which implies (iii). Hence by Lemma 5.3 the algorithm is correct. By Lemma 5.2 the running time can be bounded by the number of reachable states times a polynomial, which is $\mathcal{O}^*(4^n)$ by Lemma 5.4. This ends the proof of Lemma 5.1 and hence also Theorem 1.3, as discussed in the beginning of this section.

6 Polynomial space

In this section we show Theorem 1.4, that is, we solve Many Visits TSP in $\mathcal{O}^*(7.88^n)$ time and polynomial space. Berger et al. [2] solved this problem in $\mathcal{O}(16^{n+o(n)})$ time and polynomial space, with the key ingredient being the following.

▶ **Lemma 6.1** (Berger et al. [2]). *There is a polynomial space algorithm running in time $\mathcal{O}(4^{n+o(n)})$ which, given an outdegree sequence $\{\delta_v\}_{v \in V}$, a cost function $d : V^2 \to \mathbb{Z}_{\geq 0}$, and a root $r \in V$ computes the cheapest outbranching rooted at r with the required outdegrees.*

More precisely, the $\mathcal{O}(16^{n+o(n)})$-time algorithm consists of the following steps:

- **(i)** Enumerate all $\mathcal{O}(4^n)$ outbranching sequences
- **(ii)** For each outbranching sequence compute the cheapest outbranching with required degrees using Lemma 6.1 in time $\mathcal{O}(4^{n+o(n)})$
- **(iii)** For each of these outbranchings complete it to a solution of the original Many Visits TSP instance with an optimal solution of Fixed Degree Subgraph on the residual degree sequences (in polynomial time, by Observation 3.3).

The intuition behind our approach is as follows. We iterate over all subsets of vertices R. Here, R represents our guess of the set of inner vertices of an outbranching in an optimal solution. Then we perform (i) and (ii) in the smaller subgraph induced by R. Finally, we replace (iii) by a more powerful flow-based algorithm which connects the vertices in $V \setminus R$ to R, and at the same time computes a feasible solution of Fixed Degree Subgraph on the residual degree sequences, so that the total cost is minimized. Let $r = |R|$. Clearly, when r is a small fraction of n, we get significant savings in the running time. The closer r/n is to 1 the smaller are the savings, but also the smaller is the number $\binom{n}{r}$ of sets R to examine.

In fact, the real algorithm is slightly more complicated. Namely, we fix an integer parameter K, and then R corresponds to the set of vertices left from an outbranching in an optimal solution after K iterations of removing all leaves. The running time of our algorithm depends on K, because the algorithm actually guesses the layers of leaves in each iteration. The space complexity is polynomial and does not depend on K. In the end of this section, we show that our running time bound is minimized when $K = 4$.

6.1 Our algorithm

Similarly as in Section 5, we solve the more general Fixed Degree Subgraph With Outbranching: for a given instance $I = (d, \mathsf{in}, \mathsf{out}, \mathsf{root})$ we want to find a solution $m : V^2 \to \mathbb{Z}_{\geq 0}$ that satisfies the degree constraints specified by in and out and contains an outbranching rooted at root.

Let T be an arbitrary outbranching. We define a sequence $L_1(T), L_2(T), \ldots$ of subsets of $V(T)$ as follows. For $i \geq 1$ let $L_i(T)$ be the set of leaves of $T \setminus (L_1(T) \cup L_2(T) \cup \ldots \cup L_{i-1}(T))$ if $|V(T) \setminus (L_1(T) \cup \ldots \cup L_{i-1}(T))| > 1$, and otherwise $L_i = \emptyset$. The sets $L_i(T)$ will be called *leaf layers*. Denote $R_i(T) = V \setminus (L_1(T) \cup \cdots \cup L_i(T))$ for any $i \geq 1$.

▶ **Lemma 6.2.** *For every $i \geq 1$ we have $\mathsf{root} \in R_i(T) \setminus L_{i+1}(T)$, $|L_i(T)| \geq |L_{i+1}(T)|$ and $|L_{i+1}| \leq \frac{n-|R_i(T)|}{i}$.*

Proof. In this proof we skip the "(T)" in L_i and R_i because there is no ambiguity. Assume $\mathsf{root} \in L_i$ for some $i \geq 1$. It means that root is a leaf in $T \setminus (L_1 \cup L_2 \cup \ldots \cup L_{i-1})$. Then $V \setminus (L_1 \cup L_2 \cup \ldots \cup L_{i-1}) = \{\mathsf{root}\}$ and $L_i = \emptyset$, a contradiction. Hence $\mathsf{root} \notin L_i$ for all $i \geq 1$, and in consequence $\mathsf{root} \in R_i$ for all $i \geq 1$. However, $\mathsf{root} \in R_{i+1}(T)$ implies that $\mathsf{root} \notin L_{i+1}(T)$, hence $\mathsf{root} \in R_i \setminus L_{i+1}$.

If $|V \setminus (L_1 \cup \ldots \cup L_i)| > 1$, then L_{i+1} is the set of leaves of the out-tree $T \setminus (L_1 \cup \ldots \cup L_i)$, which is contained in the set of parents of vertices in L_i. Since every vertex in L_i has exactly one parent, $|L_i| \geq |L_{i+1}|$. If $|V \setminus (L_1 \cup \ldots \cup L_i)| \leq 1$ then $L_{i+1} = \emptyset$ and clearly $|L_i| \geq |L_{i+1}| = 0$.

Finally, since for every $j < i$ we have $|L_j| \geq |L_i|$ we get $n - |R_i| = |L_1| + \ldots + |L_i| \geq i|L_i|$. It follows that $|L_{i+1}| \leq |L_i| \leq \frac{n-|R_i|}{i}$, as required. ◀

Pseudocode of our algorithm is presented as Algorithm 2.

Algorithm 2 A pseudocode of the algorithm from Section 6.1.

```
1:  function Solve(G, out, in, d, root)
2:      best ← ∞
3:      for R, L_{K+1}, δ do
4:          T_R ← cheapest δ-out-tree spanning R rooted at root (Lemma 6.1)
5:          out' ← out − outdeg_{T_R}
6:          in' ← in − indeg_{T_R}
7:          for L_1, ..., L_K do
8:              F ← CreateNetwork(G, R, out', in', d, L_1, ..., L_K)
9:              f ← MinCostMaxFlow(F)
10:             if |f| = Σ_{v∈V(G)} out'(v) and cost(f) + d(T_R) < best then
11:                 best ← cost(f) + d(T_R)
        return best
```

For clarity, in the pseudocode we skipped some constraints that we enforce on the sets L_i and sequence δ. We state them below.

(C1) $L_{K+1} \subseteq R \subseteq V, \mathsf{root} \in R \setminus L_{K+1}, |L_{K+1}| \leq \frac{n-|R|}{K}$

(C2) $\{\delta_v\}_{v \in R}$ is a rooted out-tree sequence, i.e., for all $v \in R$ we have $\delta_v \in \mathbb{Z}_{\geq 0}, \sum_{v \in R} \delta(v) = |R| - 1$; also $\delta_{\mathsf{root}} \geq 1$ if $|R| \geq 2$ and $\delta_{\mathsf{root}} = 0$ if $|R| = 1$.

(C3) for every $v \in L_{K+1}$ we have $\delta_v = 0$ and for every $v \in R \setminus (L_{K+1} \cup \{\mathsf{root}\})$ we have $\delta_v \geq 1$

(C4) $L_1 \uplus L_2 \uplus \cdots \uplus L_K = V \setminus R$

(C5) $|L_i| \geq |L_{i+1}|$ for $i = 1, \ldots, K$.

It is clear that all these possibilities can be enumerated in time proportional to their total number times $O(n)$.

Let us provide some further intuition about Algorithm 2. Consider an optimum solution m of I and any outbranching B in m rooted at root. In Algorithm 2, for any $i = 1, \ldots K+1$, the set L_i is a guess of the leaf layer $L_i(B)$, while R is a guess of $V \setminus (L_1(B) \cup \cdots \cup L_K(B))$. Finally, δ is a guess of the outdegree sequence of the out-tree $B[R]$.

In Line 8 we create a flow network, and in line 9 a minimum cost maximum flow is found in polynomial time. In the next section we discuss the flow network and properties of the flow.

6.2 The flow

In this section we consider a run of Algorithm 2, and in particular we assume that the variables $R, \delta, L_1, \ldots, L_{K+1}$ have been assigned accordingly. The function CreateNetwork in our algorithm builds a flow network $F = (V(F), E(F), \mathsf{cap}, \mathsf{cost})$, where $E(F)$ is a set of directed edges and cap and cost are functions from edges to integers denoting capacities and costs of corresponding edges. As usual, the function cost extends to flow functions in a natural way, i.e., $\mathsf{cost}(f) = \sum_{e \in E(F)} f(e)\mathsf{cost}(e)$. We let $V(F) = \{s, t\} \cup \{v^I, v^O \mid v \in V(G)\} \cup \{v^C \mid v \in V \setminus R\}$, where s and t denote the source and the sink of F.

We put following edges into $E(F)$:

- (s, v^O), where $\mathsf{cap}(s, v^O) = \mathsf{out}'(v), \mathsf{cost}(s, v^O) = 0$ for every $v \in V(G)$
- (v^I, t), where $\mathsf{cap}(v^I, t) = \mathsf{in}'(v), \mathsf{cost}(v^I, t) = 0$ for every $v \in R$
- (v^I, t), where $\mathsf{cap}(v^I, t) = \mathsf{in}'(v) - 1, \mathsf{cost}(v^I, t) = 0$ for every $v \notin R$
- (v^C, t), where $\mathsf{cap}(v^C, t) = 1, \mathsf{cost}(v^C, t) = 0$ for every $v \notin R$
- (u^O, v^I), where $\mathsf{cap}(u^O, v^I) = \infty, \mathsf{cost}(u^O, v^I) = d(u, v)$ for every $(u, v) \in E(G)$
- (u^O, v^C), where $\mathsf{cap}(u^O, v^C) = \infty, \mathsf{cost}(u^O, v^C) = d(u, v)$ for every $v \in L_i, u \in R \cup L_{i+1} \cup \ldots \cup L_K, (u, v) \in E(G)$.

We will say that F has a *full flow* if it has a flow f with value $|f| = \sum_{v \in V} \mathsf{out}'(v)$. By the construction of F, then all edges leaving source are saturated, i.e., carry flow equal to their capacity. Since $\sum_{v \in V} \mathsf{out}'(v) = \sum_{v \in V} \mathsf{in}'(v)$, also all edges that enter the sink are saturated.

Essentially, the network above results from extending the standard network used to get Observation 3.3 by vertices v^C. The flow between $\{v^O \mid v \in V\}$ and $\{v^I \mid v \in V\} \cup \{v^C \mid v \in V \setminus R\}$ represents the resulting solution. In a full flow the edges leaving v^C are saturated, so a unit of flow enters every vertex v^C, which results in connecting v in the solution to a higher layer or to R. Thanks to that the solution resulting from adding the out-tree T_R to the solution extracted from f contains an outbranching.

▶ **Lemma 6.3.** *If f is a full flow of minimum cost in F then there exists a solution of I with cost $\mathsf{cost}(f) + d(T_R)$. Moreover, the solution can be extracted from f in polynomial time.*

Proof. By standard arguments, since all capacities in F are integer, we infer that there is an integral flow of minimum cost (and it can be found in polynomial time), so we assume w.l.o.g. that f is integral.

Let $b : V^2 \to \{0, 1\}$ denote a function such that $b(u, v) = [(u, v) \in T_R]$. Now we construct a solution $m : V^2 \to \mathbb{Z}_{\geq 0}$ of I.

$$m(u,v) = \begin{cases} f(u^O, v^I) + b(u,v) & \text{if } v \in R \\ f(u^O, v^I) + f(u^O, v^C) & \text{if } v \notin R. \end{cases}$$

In other words, m describes how many times edge (u, v) was used by the out-tree T_R and flow f in total. Let us verify that m is a feasible solution for I. The degree constraints are easy to verify, so we are left with showing that m contains an outbranching rooted at root. To this end it suffices to show that every vertex v is reachable from root in G_m. Clearly, this holds for vertices in R, thanks to the out-tree T_R. Pick an arbitrary vertex $v \notin R$. Then $v \in L_i$ for some $i = 1, \ldots, K$. We know that $f(v^C, t) = 1$, so there exists u such that $f(u^O, v^C) = 1$. Therefore, v is connected in G_m to a vertex from $R \cup L_{i+1} \cup \ldots L_K$. Since v in G_m has an in-neighbor either in R or in a layer with a higher index, we can conclude that there is a path in G_m from R to v. Hence m indeed contains the required outbranching.

Finally, it can be easily checked that $d(m) = \mathsf{cost}(f) + d(T_R)$, what concludes this proof. ◀

Let m be a feasible solution for I. Let R, L_i for $i = 1, \ldots, K + 1$ be sets of vertices and δ an out-tree sequence on R, as in Algorithm 2. We say that m is *compliant* with R, $L_1, \ldots, L_{K+1}$ and δ when m contains an outbranching T rooted at root such that $R_K(T) = R$, $L_i(T) = L_i$ for $i = 1, \ldots, K + 1$ and δ is equal to the outdegree sequence of $T[R]$.

▶ **Lemma 6.4.** *Assume that there exists a solution m of I that is compliant with R, $L_1, \ldots, L_{K+1}$ and δ. Then F has a full flow f such that $\mathsf{cost}(f) + d(T_R) \leq d(m)$.*

Proof. Let T be an outbranching in m which certifies that m is compliant with $R, L_1, \ldots, L_{K+1}$ and δ. Let $p : V^2 \to \{0, 1\}$ be a function such that for every $u, v \in V$ we have $p(u, v) = [(u, v) \in T]$.

We set $f(s, u) = \mathsf{cap}(s, u)$ for all edges $(s, u) \in E(F)$ and $f(u, t) = \mathsf{cap}(u, t)$ for all edges $(u, t) \in E(F)$. If $v \in V \setminus R$ then we set $f(u^O, v^C) = p(u, v)$. For all $u, v \in V(G)$ we set $f(u^O, v^I) = m(u, v) - p(u, v)$. It can be easily checked that such function f is a full flow and $\mathsf{cost}(f) = d(m) - d(T[R])$. However, since $T[R]$ is a δ-out-tree rooted at root and T_R is a cheapest such out-tree, $d(T_R) \leq d(T[R])$. It follows that $\mathsf{cost}(f) \leq d(m) - d(T_R)$, so $\mathsf{cost}(f) + d(T_R) \leq d(m)$ as required. ◀

Consider a *minimum cost* full flow f' in F that is found by Algorithm 2 for a choice of $R, L_1, \ldots, L_{K+1}, \delta$. The claim above implies that $\mathsf{cost}(f') + d(T_R) \leq d(m)$. However, notice that we do not claim that $\mathsf{cost}(f')$ is the cost of optimal completion of T_R consistent with all guesses, as the intuitions we described earlier might suggest. It could be the case that in the solution resulting from f', a vertex which was guessed to belong to L_i does not have any out-neighbor that was guessed to belong to L_{i-1}, which would mean that this vertex should be in an earlier layer. However, that is not an issue for the extraction of the global optimum solution of I, because we may get only better solutions than the optimum completion for that particular guess.

6.3 Correctness

▶ **Lemma 6.5.** *Function* Solve *returns the cost of an optimal solution of* I.

Proof. From Lemma 6.3 we infer that Solve returns the cost of a feasible solution of I. It remains to show that it returns a value that is smaller or equal to the cost of an optimal solution of I. To this end, let m be an arbitrary optimal solution of I and let T be an arbitrary outbranching rooted at root in G_m. Let $R = R_K(T)$, $L_i = L_i(T)$ for $i = 1, \ldots, K+1$ and let δ be the outdegree sequence of $T[R]$.

Let us verify that $R, L_1, \ldots, L_{K+1}$ and δ satisfy constraints (C1)–(C5). We get (C1) and (C5) by Lemma 6.2. (C2) follows from the definition of δ. For (C3), consider two cases. If $|R| > 1$, then L_{K+1} is the set of leaves in R and hence indeed for every $v \in L_{K+1}$ we have $\delta_v = 0$ and for every $v \in R \setminus (L_{K+1} \cup \{\mathsf{root}\})$ we have $\delta_v \geq 1$. When $|R| \leq 1$, we have $L_{K+1} = \emptyset$ and since $\mathsf{root} \in R$ by Lemma 6.2, $R = \{\mathsf{root}\}$. Then both sets L_{K+1} and $R \setminus (L_{K+1} \cup \{\mathsf{root}\})$ are empty, so (C3) trivially holds. Finally, (C4) follows by the definition of leaf layers.

Since $R, L_1, \ldots, L_{K+1}$ and δ satisfy constraints (C1)–(C5), then Solve reaches this particular evaluation of the variables $R, L_1, \ldots, L_{K+1}$ and δ. Then, based on Lemma 6.4, the network F has a full flow f such that $\mathsf{cost}(f) + d(T_R) \leq d(m)$, and it follows that Solve returns a value $\mathsf{best} \leq \mathsf{cost}(f) + d(T_R) \leq d(m)$, as required. ◀

Obviously, Solve can be easily adapted to return a solution of I with the cost it returns, but we have not taken this into account in Algorithm 2 for the sake of its readability.

6.4 Running time

Having a correct algorithm solving Fixed Degree Subgraph With Outbranching in polynomial space, let us analyze its complexity depending on K.

Let us denote $r = |R|$ and $c = |L_{K+1}|$. Recall that $1 \leq r \leq n$ and $0 \leq c \leq \lfloor \frac{n-r}{K} \rfloor$.

If we fix r and c, then there are $\binom{n-1}{r-1}$ guesses for R (it has to contain root) and at most $\binom{r-1}{c}$ guesses for L_{K+1}. Let us bound the number of guesses for δ. By (C2) and (C3), $\sum_{v \in R} \delta_v = r - 1$, and $\delta_v = 0$ iff $v \in L_{K+1}$ so essentially we put $r-1$ balls into $r-c$ bins that must be nonempty, which is $\binom{r-2}{c-1}$ by standard combinatorics. In the special case $c = 0$ there is one choice for δ, where $\delta_{\mathsf{root}} = 0$.

In total, there are at most $\binom{n}{r}\binom{r}{c}^2$ guesses for all R, L_{K+1}, δ simultaneously. For each of these guesses, using Lemma 6.1 function Solve calculates an optimal δ-out-tree spanning R, which takes time $\mathcal{O}(4^{n+o(n)})$. It follows that that part takes time $\mathcal{O}^*(\sum_r \binom{n}{r} 4^{r+o(r)} \sum_c \binom{r}{c}^2)$. Then, Solve guesses a partition of $V \setminus R$ into $L_1, \ldots, L_K$ in at most K^{n-r} ways. For each such guess, Solve spends polynomial time, so that part takes $\mathcal{O}^*(\sum_r \binom{n}{r} K^{n-r} \sum_c \binom{r}{c}^2)$ time. Hence the total running time can be bounded by

$$\mathcal{O}^*\left(2^{o(n)} \sum_{r=1}^{n} \sum_{c=0}^{\lfloor \frac{n-r}{K} \rfloor} \underbrace{\binom{n}{r}(K^{n-r} + 4^r)\binom{r}{c}^2}_{\xi(r,c)}\right).$$

Since there are polynomially many guesses for r and c, we can actually replace sums with maxima in the expression above and focus on the expression $\xi(r,c) = \binom{n}{r}(K^{n-r} + 4^r)\binom{r}{c}^2$.

We will heavily use the well-known bound $\binom{n}{\alpha n} < 2^{h(\alpha)n}$, where $h(\alpha) = -\alpha \log_2 \alpha - (1-\alpha)\log_2(1-\alpha)$ is the binary entropy function (see e.g. [13]). For readability, let us denote $f(\alpha) = 2^{h(\alpha)}$ and let us point out that f is increasing on the interval $[0, \frac{1}{2}]$ and decreasing on the interval $[\frac{1}{2}, 1]$. Let us denote $\beta \coloneqq \frac{r}{n}$. We are going to distinguish two cases here.

1. $\frac{n-r}{K} \geq \frac{r}{2}$
   This inequality can be rephrased as $r \leq \frac{2}{K+2}n$, which is equivalent to $\beta \leq \frac{2}{K+2}$. We will use here a trivial bound $\binom{r}{c} \leq 2^r$. Then, $\xi(r,c) \leq f(\beta)^n((K^{1-\beta})^n + 4^{\beta n})4^{\beta n} = (f(\beta)K^{1-\beta}4^{\beta})^n + (f(\beta)4^{2\beta})^n$
2. $\frac{n-r}{K} < \frac{r}{2}$
   In that case we know that $\max_{c=0}^{\lfloor \frac{n-r}{K} \rfloor} \binom{r}{c}^2$ is attained when $c = \lfloor \frac{n-r}{K} \rfloor$ and for that particular value of c we can use the following bound.

$$\binom{r}{c}^2 = \left(\frac{r}{\lfloor \frac{n-r}{K} \rfloor} \cdot r\right)^2 = \mathcal{O}^*\left(f\left(\frac{\lfloor \frac{n-r}{K} \rfloor}{r}\right)^{2r}\right) = \mathcal{O}^*\left(f\left(\frac{\frac{n-r}{K}}{r}\right)^{2r}\right) =$$

$$= \mathcal{O}^*\left(f\left(\frac{1-\beta}{K\beta}\right)^{2\beta n}\right)$$

   In the third equality above we used fact that f is increasing on the interval $[0, \frac{1}{2}]$. To sum up, in this case,

$$\xi(r,c) = \mathcal{O}^*\left(\left(f(\beta)K^{1-\beta}f\left(\frac{1-\beta}{K\beta}\right)^{2\beta}\right)^n + \left(f(\beta)4^{\beta}f\left(\frac{1-\beta}{K\beta}\right)^{2\beta}\right)^n\right).$$

Our numerical analysis shows that it is optimal to choose $K = 4$. For that particular value of K, the first case applies if and only if $\beta \leq \frac{1}{3}$. Then,

$$\xi(r,c) = (4f(\beta))^n + (4^{2\beta}f(\beta))^n = \mathcal{O}((4f(\beta))^n) = \mathcal{O}((4f(\tfrac{1}{3}))^n) = \mathcal{O}(7.56^n).$$

Let us now investigate the second case, when $\beta > \frac{1}{3}$. For $\frac{1}{3} < \beta < \frac{1}{2}$ the summand $\left(f(\beta)4^{1-\beta}f\left(\frac{1-\beta}{4\beta}\right)^{2\beta}\right)^n$ dominates, and for $\beta \geq \frac{1}{2}$ the summand $\left(f(\beta)4^{\beta}f\left(\frac{1-\beta}{4\beta}\right)^{2\beta}\right)^n$ dominates. We have numerically verified that

$$f(\beta)4^{1-\beta}f\left(\frac{1-\beta}{4\beta}\right)^{2\beta} \leq 7.68 \text{ for } \beta \in (\tfrac{1}{3}, \tfrac{1}{2})$$

and

$$f(\beta)4^{\beta}f\left(\frac{1-\beta}{4\beta}\right)^{2\beta} \leq 7.871 \text{ for } \beta \in [\tfrac{1}{2}, 1].$$

Hence, we can conclude that for $K = 4$ and our algorithm runs in time $\mathcal{O}^*(7.871^{n+o(n)}) = \mathcal{O}(7.88^n)$ and in polynomial space. This concludes the proof of Theorem 1.4.

7 $(1+\epsilon)$-approximation

In this section we show theorem 1.2, i.e. we present an algorithm for Many Visits TSP which finds a $(1+\epsilon)$-approximation in $\mathcal{O}^*\left(\frac{2^n}{\epsilon}\right)$ time and polynomial space.

To achieve this we consider a more general problem, namely Fixed Degree Connected Subgraph. The main idea is to round weights of edges of the given instance, so that we can use the algorithm for polynomially bounded weights from Lemma 4.12 which is an analog of theorem 1.1 for Fixed Degree Connected Subgraph.

Let us first consider the case with degrees bounded by a polynomial.

▶ **Lemma 7.1.** *For given $\epsilon > 0$ and an instance $I = (d, \mathsf{in}, \mathsf{out})$ of* Fixed Degree Connected Subgraph *such that $\mathsf{in}(v), \mathsf{out}(v) \leq \mathcal{O}(n^2)$ for every vertex v there exists an algorithm finding a $(1+\epsilon)$-approximate solution in $\mathcal{O}^*\left(\frac{2^n}{\epsilon}\right)$ time and polynomial space.*

Proof. Let us denote the optimal solution for I by OPT. First, our algorithm guesses the most expensive edge used by OPT. Let us denote its cost by E, in particular

$$E \leq d(\mathrm{OPT}). \tag{1}$$

Let us denote by C the universal constant such that $\mathsf{in}(v), \mathsf{out}(v) \leq Cn^2$ for every vertex v and let us round d in the following way

$$d'(u,v) := \begin{cases} \left\lceil \frac{Cn^3}{\epsilon E} d(u,v) \right\rceil & \text{if } d(u,v) \leq E \\ \infty & \text{if } d(u,v) > E \end{cases} \tag{2}$$

If $d'(u,v)$ is finite then it is bounded by $\left\lceil \frac{Cn^3}{\epsilon E} E \right\rceil = \left\lceil \frac{Cn^3}{\epsilon} \right\rceil$. Our algorithm simply returns the optimal solution for instance $I' = (d', \mathsf{in}, \mathsf{out})$ which can be found in $\mathcal{O}^*\left(\frac{2^n}{\epsilon}\right)$ time using the algorithm from Lemma 4.12 with $D = \left\lceil \frac{Cn^3}{\epsilon} \right\rceil$. Let us denote this solution by ALG. Now we only need to prove that ALG is a $(1+\epsilon)$-approximation for the original instance I. We know that ALG is an optimal solution for I', in particular

$$d'(\mathrm{ALG}) \leq d'(\mathrm{OPT}). \tag{3}$$

For every v we have $\mathsf{out}(v) \leq Cn^2$, so

$$\sum_{(u,v) \in V^2} \mathrm{OPT}(u,v) = \sum_{u \in V} \mathsf{out}(u) \leq n \cdot Cn^2. \tag{4}$$

The following chain of inequalities finishes the proof.

$$d(\mathrm{ALG}) \overset{(2)}{\leq} \frac{\epsilon E}{Cn^3} d'(\mathrm{ALG}) \overset{(3)}{\leq} \frac{\epsilon E}{Cn^3} d'(\mathrm{OPT}) \overset{(2)}{\leq} \frac{\epsilon E}{Cn^3} \sum_{(u,v) \in V^2} \mathrm{OPT}(u,v) \left(\frac{d(u,v) Cn^3}{\epsilon E} + 1 \right) =$$

$$= d(\mathrm{OPT}) + \frac{\epsilon E}{Cn^3} \sum_{(u,v) \in V^2} \mathrm{OPT}(u,v) \overset{(4)}{\leq} d(\mathrm{OPT}) + \frac{\epsilon E}{Cn^3} Cn^3 \overset{(1)}{\leq} (1+\epsilon) d(\mathrm{OPT}) \qquad \blacktriangleleft$$

Now we can generalize the algorithm from Lemma 7.1 by using it as a black box for the general case.

▶ **Lemma 7.2.** *For a given $\epsilon > 0$ and an instance $I = (d, \mathsf{in}, \mathsf{out})$ of* Fixed Degree Connected Subgraph *there exists an algorithm finding a $(1+\epsilon)$-approximate solution in $\mathcal{O}^*\left(\frac{2^n}{\epsilon}\right)$ time and polynomial space.*

Proof. First let us use the algorithm from Theorem 3.4 which outputs an instance $I' = (d, \mathsf{in}', \mathsf{out}')$ of Fixed Degree Connected Subgraph and a function $f : V^2 \to \mathbb{Z}_{\geq 0}$. Let us denote the optimal solution for I' by OPT'. By Theorem 3.4 the optimal solution for I equals $\mathrm{OPT}' + f$. Moreover, we know that $\mathsf{in}', \mathsf{out}'(v) \leq \mathcal{O}(n^2)$ for every vertex v. In particular we can use algorithm from Lemma 7.1 to get a solution ALG' for instance I' such that $d(\mathrm{ALG}') \leq (1+\epsilon) d(\mathrm{OPT}')$. Our algorithm simply returns solution $\mathrm{ALG}' + f$, which is a solution for I because ALG is connected and f increases degrees exactly by difference between I and I'. To prove $\mathrm{ALG}' + f$ is $(1+\epsilon)$-approximation we just need to observe that

$$d(\mathrm{ALG}' + f) \leq (1+\epsilon) d(\mathrm{OPT}') + d(f) \leq (1+\epsilon) d(\mathrm{OPT}' + f). \qquad \blacktriangleleft$$

Fixed Degree Connected Subgraph is a generalization of Many Visits TSP so the algorithm from Lemma 7.2 proves Theorem 1.2.

8 Further Research

Since TSP is solvable in time $\mathcal{O}^*(2^n)$ and exponential space [1, 16] and time $\mathcal{O}(4^{n+o(n)})$ and polynomial space [15], the main remaining question is whether these bounds can be achieved for Many Visits TSP avoiding in the running time bound the linear dependence on maximum distance D. Another interesting goal is a deterministic version of Theorem 4.1.

Abstract

The FOCS'19 paper of Le and Solomon [59], culminating a long line of research on Euclidean spanners, proves that the lightness (normalized weight) of the greedy $(1+\epsilon)$-spanner in $\mathbb{R}^d$ is $\tilde{O}(\epsilon^{-d})$ for any $d = O(1)$ and any $\epsilon = \Omega(n^{-\frac{1}{d-1}})$ (where $\tilde{O}$ hides polylogarithmic factors of $\frac{1}{\epsilon}$), and also shows the existence of point sets in $\mathbb{R}^d$ for which any $(1+\epsilon)$-spanner must have lightness $\Omega(\epsilon^{-d})$.[1] Given this tight bound on the lightness, a natural arising question is whether a better lightness bound can be achieved using *Steiner points*.

Our first result is a construction of Steiner spanners in $\mathbb{R}^2$ with lightness $O(\epsilon^{-1}\log\Delta)$, where Δ is the spread of the point set.[2] In the regime of $\Delta \ll 2^{1/\epsilon}$, this provides an improvement over the lightness bound of [59]; this regime of parameters is of practical interest, as point sets arising in real-life applications (e.g., for various random distributions) have polynomially bounded spread, while in spanner applications ϵ often controls the precision, and it sometimes needs to be much smaller than $O(1/\log n)$. Moreover, for spread polynomially bounded in $1/\epsilon$, this upper bound provides a quadratic improvement over the non-Steiner bound of [59], We then demonstrate that such a light spanner can be constructed in $O_\epsilon(n)$ time for polynomially bounded spread, where O_ϵ hides a factor of $\text{poly}(\frac{1}{\epsilon})$. Finally, we extend the construction to higher dimensions, proving a lightness upper bound of $\tilde{O}(\epsilon^{-(d+1)/2} + \epsilon^{-2}\log\Delta)$ for any $3 \le d = O(1)$ and any $\epsilon = \Omega(n^{-\frac{1}{d-1}})$.

1 Introduction

A *t-spanner* for a set P of points in the d-dimensional Euclidean space $\mathbb{R}^d$ is a *geometric graph* that preserves all the pairwise Euclidean distances between points in P to within a factor of t, called the *stretch factor*; by geometric graph we mean a weighted graph in which the vertices correspond to points in $\mathbb{R}^d$ and the edge weights are the Euclidean distances between the corresponding points. The study of Euclidean spanners dates back to the seminal work of Chew [27, 28] from 1986, which presented a spanner with constant stretch and $O(n)$ edges for any set of n points in $\mathbb{R}^2$. In the three following decades, Euclidean spanners

[1] The lightness of a spanner is the ratio of its weight and the MST weight.
[2] The spread $\Delta = \Delta(P)$ of a point set P in $\mathbb{R}^d$ is the ratio of the largest to the smallest pairwise distance.

have evolved into an important subarea of Discrete and Computational Geometry, having found applications in many different areas, such as approximation algorithms [65], geometric distance oracles [42, 45, 44, 43], and network design [52, 60]; see the book by Narasimhan and Smid "Geometric Spanner Networks" [61] for an excellent account on Euclidean spanners and some of their applications. Numerous constructions of Euclidean spanners in two and higher dimensions were introduced over the years, such as Yao graphs [70], Θ-graphs [29, 54, 55, 66], the (path-)greedy spanner [4, 23, 61] and the gap-greedy spanner [67, 6] – unveiling an abundance of techniques, tools and insights along the way; refer to the book of [61] for more spanner constructions.

In addition to low stretch, many applications require that the spanner would be *sparse*, in the unweighted and/or weighted sense. The *sparsity* (respectively, *lightness*) of a spanner is the ratio of its size (respectively, weight) to the size (resp., weight) of a spanning tree (resp., MST), providing a normalized notion of size (resp., weight), which should ideally be $O(1)$. For any dimension $d = O(1)$, spanners with constant sparsity are known since the 80s [70, 29, 54, 55, 66, 4, 67, 6]; also, it is known since the early 90s that the greedy spanner has constant lightness [4]. The constant bounds on the sparsity and lightness depend on both ϵ and d. In some applications, ϵ must be a very small sub-constant parameter, so as to achieve the highest possible precision and minimize potential errors, and in some situations ϵ may be as small as n^{-c} for some constant $0 < c < 1$. Consequently, besides the theoretical appeal, achieving the precise dependencies on ϵ and d in the sparsity and lightness bounds is of practical importance.

Culminating a long line of work, in FOCS'19 Le and Solomon [59] showed that the precise dependencies on ϵ in the sparsity and lightness bounds are $\Theta(\epsilon^{1-d})$ and $\tilde{\Theta}(\epsilon^{-d})$, respectively, for any $d = O(1)$ and any $\epsilon = \Omega(n^{-\frac{1}{d-1}})$; throughout we shall use $\tilde{O}, \tilde{\Omega}, \tilde{\Theta}$ to hide polylogarithmic factors of $\frac{1}{\epsilon}$. The lower bounds of [59] are proved for the d-dimensional sphere, for $d = O(1)$. On the upper bound side, sparsity $O(\epsilon^{1-d})$ is achieved by a number of classic constructions such as Yao graphs [70], Θ-graphs [29, 54, 55, 66], the (path-)greedy spanner [4, 23, 61] and the gap-greedy spanner [67, 6], and the argument underlying all these upper bounds is basic and simple. On the other hand, constant lightness upper bound (regardless of the dependency on ϵ and d) is achieved only by the greedy algorithm [4, 31, 32, 65, 61, 41, 13, 59], and all known arguments for constant lightness are highly nontrivial, even for $d = 2$; in fact, the proofs in [4, 31, 32, 65] have missing details. The first complete proof was given in the book of [61], in a 60-page chapter, where it is shown that the greedy $(1+\epsilon)$-spanner has lightness $O(\epsilon^{-2d})$, which improved the dependencies on ϵ and d given in all previous work. In SODA'19, Borradaile, Le and Wulff-Nilsen [13] presented a shorter and arguably simpler alternative proof that applies to the wider family of *doubling metrics*, which improves the ϵ dependency provided in FOCS'15 by Gottlieb [41] for doubling metrics, but is inferior to the lightness bound of $O(\epsilon^{-2d})$ by [61].[3] Finally, the lightness bound of $\tilde{O}(\epsilon^{-d})$ of [59] was proved via a tour-de-force argument; interestingly, the proof for $d = 2$ is much more intricate than for higher dimensions $d \geq 3$.

Le and Solomon [59] showed that, counter-intuitively, one can use Steiner points to bypass the sparsity lower bound of Euclidean spanners. Specifically, in this way they reduced the sparsity upper bound almost quadratically to $\tilde{O}(\epsilon^{(1-d)/2})$, and also provided a matching

[3] The *doubling dimension* of a metric space (X, δ) is the smallest value d such that every ball B in the metric space can be covered by at most 2^d balls of half the radius of B. This notion generalizes the Euclidean dimension, since the doubling dimension of the Euclidean space $\mathbb{R}^d$ is $\Theta(d)$. A metric space is called *doubling* if its doubling dimension is constant.

lower bound for $d = 2$. Their lower bound for sparsity is derived from a lightness lower bound; specifically, they first prove that, for a set of points evenly spaced on the boundary of the unit square, with distances $\Theta(\sqrt{\epsilon})$ between neighboring points, any Steiner $(1+\epsilon)$-spanner must incur lightness $\tilde{\Omega}(\frac{1}{\epsilon})$, and then they translated the lightness lower bound into a sparsity lower bound of $\tilde{\Omega}(\sqrt{1/\epsilon})$. Whether or not Steiner points can be used to reduce the lightness remained open in [59], but this should not come as a surprise.[4] First, bounding the lightness of spanners is inherently more difficult than bounding their sparsity – this is true for both Euclidean spaces and doubling metrics, as well as other graph families including general weighted graphs [4, 31, 32, 65, 61, 41, 13, 59, 26, 39, 33]. Second, constructing Steiner trees and spanners *with asymptotically improved bounds* is inherently more difficult than constructing their non-Steiner counterparts [34, 35, 68, 57, 11, 58]. In our particular case, while the classic sparsity upper bound for non-Steiner Euclidean spanners is simple, its improved counterpart for Steiner spanners by [59] requires a number of nontrivial insights and is rather intricate. On the other hand, the lightness upper bound of [59] uses a tour-de-force argument, and as mentioned already this is true even for $d = 2$. Consequently, obtaining an improved lightness bound using Steiner points seems currently out of reach, at least until an inherently simpler proof to [59] for non-Steiner lightness is found (if one exists).

1.1 Our Contribution

In this paper, we explore the power of Steiner points in reducing lightness for Euclidean spaces of bounded spread Δ.[5] Point sets of bounded spread have been studied extensively for Euclidean spanners and related geometric objects [9, 53, 30, 51, 17, 16, 36, 64, 1, 2, 5, 49, 50, 19, 62, 63, 18, 69, 21]. The motivation for studying point sets of bounded spread is three-fold.

1. Such point sets arise naturally in practice, and are thus important in their own right; indeed, for many random distributions, the spread is polynomial in the number of points – in expectation and with high probability. In particular, it is known that for n-point sets drawn uniformly at random from the unit square, the expected spread is $\Theta(n)$, and the expected spread in the unit d-dimensional hypercube is $n^{2/d}$ for any $d = O(1)$. Researchers have studied random distributions of point sets, in part to explain the success of solving various geometric optimization problems in practice [9, 53, 30], and there are many results on spanners for random point sets [24, 7, 37, 10, 38, 14, 61, 69, 15, 21, 8, 56]. Of course, the family of bounded spread point sets is much wider than that of random point sets.
2. Euclidean spanners can be constructed in (deterministic) $O(n)$ time in such point sets [20], while there is no $o(n \log n)$-time algorithm for constructing Euclidean spanners in arbitrary point sets. (The result of [20] extends to other geometric objects, such as WSPD and compressed quadtrees, and some of the aforementioned references (e.g., [50, 17]) build on this result to achieve faster algorithms for other geometric problems for point sets of polynomially bounded spread.)
3. The case of bounded spread is sometimes used as a stepping stone towards the general case; see, e.g., [40, 47, 46, 21, 22, 3, 59].

[4] The lightness of Steiner spanners can be defined with respect to the SMT (Steiner minimum tree) weight, but we can also stick to the original definition, since the SMT and MST weights differ by a constant factor smaller than 2.

[5] The *spread* of a Euclidean space is the ratio of the maximum to minimum pairwise distances in it.

As mentioned above, Le and Solomon [59] showed that for a set of points evenly spaced on the boundary of the unit square, with distances $\Theta(\sqrt{\epsilon})$ between neighboring points, any Steiner $(1+\epsilon)$-spanner must incur lightness $\tilde{\Omega}(\frac{1}{\epsilon})$. Note that the spread of this point set is $\frac{1}{\sqrt{\epsilon}}$. The non-Steiner upper bound for $d=2$ by [59] is $\tilde{O}(\epsilon^{-2})$. A natural arising question is whether one can improve the lightness upper bound of $\tilde{O}(\epsilon^{-2})$ using Steiner points, ideally quaratically, for point sets of bounded spread. We answer this question in the affirmative.

▶ **Theorem 1.** *Any point set P in $\mathbb{R}^2$ of spread Δ admits a Steiner $(1+\epsilon)$-spanner of lightness $O(\frac{\log\Delta}{\epsilon})$.*

Recalling that the lower bound of $\tilde{\Omega}(\frac{1}{\epsilon})$ by [59] applies to a point set of spread $\frac{1}{\sqrt{\epsilon}}$, the lightness upper bound provided by Theorem 1 is therefore tight (up to polylogarithmic factors in $\frac{1}{\epsilon}$) for point sets of spread $\text{poly}(\frac{1}{\epsilon})$. Moreover, this upper bound improves the general upper bound of $\tilde{O}(\epsilon^{-2})$ from [59] in the regime $\log\Delta \ll \epsilon^{-1}$, i.e., when $\Delta \ll 2^{1/\epsilon}$. For spread polynomial in n, we get an improvement over [59] as long as $\epsilon \ll \frac{1}{\log n}$. Of course, the improvement gets more significant as ϵ decays – in the most extreme situation ϵ is inverse polynomial in n, and then the improvement over [59] is polynomial in n even when Δ is exponential in n.

Our second result is that a Steiner spanner with near-optimal lightness can be constructed in linear time, when the spread Δ is polynomial in n.

▶ **Theorem 2.** *For any point set P in $\mathbb{R}^2$ of spread $\Delta = O(n^c)$, for any $c = O(1)$, a Steiner $(1+\epsilon)$-spanner of lightness $O(\frac{\log\Delta}{\epsilon})$ can be constructed in $O_\epsilon(n)$ time, where $O_\epsilon(.)$ hides a factor of $\text{poly}(\frac{1}{\epsilon})$.*

Higher dimensions

The lower bound of [58] states that any (non-Steiner) $(1+\epsilon)$-spanner must incur lightness $\Omega(\epsilon^{-d})$, for any $d = O(1)$. We show that, similarly to the 2-dimensional case, one can improve the lightness almost quadratically using Steiner points, for point sets of bounded spread.

▶ **Theorem 3.** *For any $d \geq 3$, any point set P in $\mathbb{R}^d$ of spread Δ admits a Steiner $(1+\epsilon)$-spanner of lightness $\tilde{O}(\epsilon^{-(d+1)/2} + \epsilon^{-2}\log\Delta)$.*

Interestingly, the dependence on the spread in the lightness bound provided by Theorem 3 does not grow with the dimension, hence the improvement over the non-Steiner bound gets more significant as the dimension grows, provided of course that the spread is not too large.

1.2 Proof Overview

Proof of Theorem 1

We partition the set of pairs of points into $m = O(\log\Delta)$ subsets $\{\mathcal{P}_1, \ldots, \mathcal{P}_m\}$ where $\mathcal{P}_i$ contains pairs of distances in $[2^{i-1}, 2^i)$. The objective is to show that one can preserve distances between all pairs in $\mathcal{P}_i$ to within a factor of $(1+\epsilon)$ using a Steiner spanner S_i of weight $O(\frac{w(\mathsf{MST})}{\epsilon})$; by taking the union of all such spanners, we obtain a Steiner spanner with the required lightness.

Let $L_i = 2^i$. A natural idea to preserve distances in $\mathcal{P}_i$ is to (a) find an (ϵL_i)-net N_i[6] of P and (b) add to the spanner edges between any two net points p and q such that $(u,v) \in \mathcal{P}_i$ and there is a pair (u,v) in $\mathcal{P}_i$ such that u and v are covered by (i.e., within distance ϵL_i

[6] A subset of points $N \subseteq P$ is an r-net if every point in P is within distance r from (or *covered* by) some point in N and pairwise distances between points in N are larger than r.

from) p and q, respectively. The stretch will be in check because u and v are at distance roughly $O(\epsilon)||u,v||$ from their net points and thus, the *additive* stretch between u and v is $O(\epsilon)||u,v||$. For lightness, we can show that the number of net points $|N_i| = O(\frac{w(\mathsf{MST})}{\epsilon L_i})$, and using a (nontrivial) packing argument, there are about $\frac{N_i}{\epsilon}$ edges of length $O(L_i)$ added in step (b). Thus, the total weight of the spanner is $O(\frac{w(\mathsf{MST})}{\epsilon^2})$, which is bigger than our aimed lightness bound by a factor of $\frac{1}{\epsilon}$.

To shave the factor of $\frac{1}{\epsilon}$, we employ two ideas. First, we take N_i to be a $\sqrt{\epsilon}L_i$-net of P. In this way $|N_i| = O(\frac{w(\mathsf{MST})}{\sqrt{\epsilon}})$. By applying the 2-dimensional Steiner spanner construction of [59] as a blackbox, we obtain a Steiner spanner with only $\frac{|N_i|}{\sqrt{\epsilon}}$ edges of length $O(L_i)$ that approximates distances between points in N_i; we have thus reduced the weight bound to $O(\frac{w(\mathsf{MST})}{\epsilon})$, as required. The problem now is with the stretch guarantee: Preserving distances between the points in N_i is no longer sufficient. Indeed, for every pair $(u,v) \in \mathcal{P}_i$, the distance between u and v to the nearest net points is $O(\sqrt{\epsilon})||u,v||$, hence the resulting stretch is $(1+O(\sqrt{\epsilon}))||u,v||$. We overcome this hurdle by introducing a novel construction of *single-source spanners*, which generalize Steiner shallow-light trees of Solomon [68]. Specifically, we open the black-box of [59] and observe that every time we want to preserve the distance from (some) Steiner point s to a net-point $p \in N_i$, instead of connecting s to p by a straight line of weight $O(L_i)$, we can use a single-source spanner (rooted at s) of *weight* $O(L_i)$ to preserve distances (up to a $(1+\epsilon)$ factor) from s to *every point* within distances $O(\sqrt{\epsilon}L_i)$ from p. As a result, our Steiner spanner can preserve distances between any two points $(u,v) \in \mathcal{P}_i$ to within a factor of $(1+\epsilon)$, where $u \in B(p, O(\sqrt{\epsilon}L_i))$, $v \in B(q, O(\sqrt{\epsilon}L_i))$, and p, q are their nearest net points.

Proof of Theorem 3

By extending the construction in Theorem 1, we can construct a Steiner spanner with lightness $\tilde{O}(\epsilon^{-(d+1)/2}\log\Delta)$ as follows: for each $\mathcal{P}_i$, we construct an ϵL_i-net N_i and then apply the construction of [59] as a black box to obtain a Steiner spanner S_i for N_i with weight $\tilde{O}(\epsilon^{-(d-1)/2}|N_i|L_i)$. The stretch will be in check since N_i is an ϵL_i-net. Since $|N_i| = O(\frac{w(\mathsf{MST})}{\epsilon L_i})$, $w(S_i) = \tilde{O}(\epsilon^{-(d+1)/2}w(\mathsf{MST}))$. The union of Steiner spanners S_i for all $i \in [1,m]$ has weight $\tilde{O}(\epsilon^{-(d+1)/2}\log\Delta)w(\mathsf{MST})$. Note when $d \geq 3$, we can not take N_i as a $\sqrt{\epsilon}L_i$-net since the construction of single-source spanners with $O(L_i)$ weight in the proof of Theorem 1 only works when $d = 2$.

Most of our effort is to further refine the result in a way that $\log\Delta$ term is multiplied only by ϵ^{-2} and not by the term that depends on d. We first reduce to the problem of approximating distances between pairs (of endpoints) in a family of edge sets $\mathcal{E} = \{E_1, \ldots, E_m\}$ with $m = O(\log\Delta)$, where edges of E_i have length (roughly) in the interval $(\frac{1}{2\epsilon^i}, \frac{1}{\epsilon^i}]$ and edges in E_1 have length in $[1, \frac{1}{\epsilon})$. Let $L_i = \frac{1}{\epsilon^i}$. For a technical reason, we will subdivide edges of MST by using a set of Steiner points K so that each new edge has length in $(1/2, 1]$.

We construct a Steiner spanner for edges in $\mathcal{E}$ using a *charging cover tree* T: T has depth $m+1$, level i of T is associated with an ϵL_i-*cover*[7] of $P \cup K$, and leaves (at level 0) of T are points in $P \cup K$. For each cover N_i at level i of T, we construct a graph H_i where $V(H_i) = N_i$ and there is an edge (u,v) between $u, v \in N_i$ if there is a corresponding edge in E_i whose endpoints are covered by u and v, respectively. Graph H_i is used to distinguish between *low degree points*, whose degree in H_i is $O(\frac{1}{\epsilon})$, and *high degree points*, whose degree

[7] A subset of points $N \subseteq P$ is an r-cover if every point in P is within distance r from some point in N.

in H_i is $\Omega(\frac{1}{\epsilon})$. T will have two *charging properties*: (1) every point $p \in N_i$ has at least ϵL_i *uncharged descendants* and (2) at every level i, one can charge up to $\frac{\epsilon L_i}{2}$ uncharged descendants of high degree points. Note that, once an uncharged point is *charged* at level i, it will be marked as charged at higher levels; initially at level 0, every point is *uncharged*.

We then use a charging cover tree T to guide the Steiner spanner construction. Specifically, at level i, we add all edges incident to low degree points to the spanner and we can show that the total weight of all these edges over all levels is at most $O(\frac{w(\mathsf{MST})\log\Delta}{\epsilon^2})$. For high degree points, we apply the construction of Le and Solomon [59] to obtain a Steiner spanner S_i, and we charge the weight of S_i to $\frac{L_i\epsilon}{2}$ uncharged descendants of each high degree point. This charging is possible by the charging property (2) of T. We then show that each point in $K \cup P$ is charged a weight at most $\tilde{O}(\epsilon^{-(d+1)/2})$. Thus, the total weight of the Steiner spanners (for high degree points) at all levels is $\tilde{O}(\epsilon^{-(d+1)/2})w(\mathsf{MST})$.

Our construction of a charging cover tree is inspired by the construction of a hierarchy of clusters in the iterative clustering technique. The technique was initially developed by Chechick and Wulff-Nilsen [25] to construct light spanners for general graphs, and then was adapted to many other different settings [25, 12, 13, 59, 58]. Our construction is directly inspired by the construction of Borradaile et al. [13] in the doubling dimension setting. However, our construction is much simpler. Specifically, we are able to decouple the Steiner spanner construction from the charging cover tree construction. We refer readers to Section 5 for more details.

2 Preliminaries

Let P be a point set of n points in $\mathbb{R}^d$. We denote by $||p,q||$ the Euclidean distance between two points $p, q \in \mathbb{R}^d$. Let $B(p,r) = \{x \in \mathbb{R}^d, ||p,x|| \leq r\}$ be the ball of radius r centered at p. Given a point p and a set of point Q on the plane, we define the distance between p and Q, denoted by $d(p,Q)$, to be $\inf_{x\in Q} ||p,x||$.

An *r-cover* of P is a subset of points $N \subseteq P$ such that for every point $x \in P$, there is at least one point $p \in N$ such that $||p,x|| \leq r$; we say x is *covered* by p. When the value of r is clear from the context, we simply call N a cover of P. A subset of point $N \subseteq P$ is called an *r-net* if N is an r-cover of P and also an *r-packing* of P, i.e., for every two points $p \neq q \in N$, $||p,q|| > r$.

Let G be a graph with weight function w on the edges. We denote the vertex set and edge set of G by $V(G)$ and $E(G)$, respectively. Let $d_G(p,q)$ be the distance between two vertices p, q of G. We denote by $G[X]$ the subgraph induced by a subset of vertices X.

G is *geometric* in $\mathbb{R}^d$ if each vertex of G corresponds to a point $p \in \mathbb{R}^d$ and for every edge (p,q), $w(p,q) = ||p,q||$. In this case, we use points to refer to vertices of G. We say that a geometric graph G is a $(1+\epsilon)$-*spanner* of P if $V(G) = P$ and for every two points $p \neq q \in P$, $d_G(p,q) \leq (1+\epsilon)||p,q||$. We say that G is a Steiner $(1+\epsilon)$-*spanner* for P if $P \subseteq V(G)$ and for every two points $p \neq q \in P$, $d_G(p,q) \leq (1+\epsilon)||p,q||$. Points in $V(G) \setminus P$ are called *Steiner points*. Note that distances between Steiner points may not be preserved in a Steiner $(1+\epsilon)$-spanner.

3 Steiner Spanners on the Plane

We focus on constructing a Steiner spanner with good lightness; the fast construction is in Section 4. We will use the following geometric Steiner *shallow-light tree* (SLT) construction by Solomon [68].

▶ **Lemma 4.** *Let L be a line segment of length $\sqrt{\epsilon}$ and p be a point on the plane such that $d(p, L) = 1$. For any point set $X \in L$, there is a geometric graph H of weight $\Theta(1)$ such that $d_H(p, x) \leq (1 + \epsilon)||p, x||$ for any point $x \in X$.*

We will use *single-source spanners* (defined below) as a black box in our construction.

▶ **Definition 5** (Single-source spanners). *Given a point p (source), a set of points X on the plane and a connected geometric graph S_X spanning X, a* single source $(1 + \epsilon)$-spanner *w.r.t. (p, X, S_X) is a graph H such that for every $x \in X$: $||p, x|| \leq d_{H \cup S_X}(p, x) \leq (1 + \epsilon)||p, x||$.*

Our starting point is the construction of a single source spanner from a point p to point set X enclosed in a circle C of radius $\sqrt{\epsilon}$ such that $d(p, C) = 1$. We show that, if S_X approximately preserves the distances between pairs of points in X up to a $(1 + g\epsilon)$ factor for any constant g, it is possible to construct a single-source spanner with weight $O(1)$. It is not so hard to see that if Steiner points are not allowed, a lower bound of weight $\Omega(\frac{1}{\sqrt{\epsilon}})$ holds here.

▶ **Lemma 6.** *Let X be a set of points in a circle C of radius $\sqrt{\epsilon}$ on the plane and a point p of distance 1 from C. Let S_X be a $(1 + g\epsilon)$-spanner of X for any constant g. Then there is a single-source $(1 + 13\epsilon)$-spanner H w.r.t. (p, X, S_X) of weight $O(1)$ when $g \ll \frac{1}{\epsilon}$.*

Proof. Let c be a center of C. W.l.o.g, we assume that pc is parallel to y-axis. Let Q be the axis-aligned smallest square bounding C. Observe that the side length of Q is at mos $2\sqrt{\epsilon}$. Place a $\frac{2}{\sqrt{\epsilon}} \times \frac{2}{\sqrt{\epsilon}}$ grid W on Q, so that every cell of W is a square of side length ϵ. Observe that:

$$w(W) \leq \epsilon \cdot \frac{4}{\epsilon} = O(1)$$

We extend W to W_1 by connecting an (arbitrary) corner of each grid cell to an arbitrary point of X in the cell. Observe that: $w(W_1) = O(W) = O(1)$. Let P be the set of grid points on the side, say L, of Q that is closer to p (than the opposite side). We apply the construction in Lemma 4 to p and L to obtain a geometric graph K. Let $H = W_1 \cup K$. Since $w(K) = O(1)$ by Lemma 4, it holds that $w(H) = O(1)$.

It remains to show the stretch bound. Let x be any point of X and v be the point in the same cell with x that is connected to a corner, say z of grid W. We will show below that:

$$d_{W \cup K}(z, p) \leq (1 + 3\epsilon)||p, z|| \tag{1}$$

If Equation 1 holds, it would imply:

$$\begin{aligned} d_{S_X \cup H}(x, p) &\leq d_{S_X}(x, v) + d_H(v, p) \leq (1 + g\epsilon)\sqrt{2}\epsilon + d_H(v, p) \\ &\leq (1 + g\epsilon)\sqrt{2}\epsilon + d_H(z, v) + d_H(z, p) \overset{g \ll 1/\epsilon}{\leq} 2\sqrt{2}\epsilon + \sqrt{2}\epsilon + d_{W \cup K}(z, p) \\ &\overset{\text{Eq. 1}}{\leq} (1 + 3\epsilon)||p, z|| + 3\sqrt{2}\epsilon \overset{||x,z|| \leq \sqrt{2}\epsilon}{\leq} (1 + 3\epsilon)(||p, x|| + \sqrt{2}\epsilon) + 3\sqrt{2}\epsilon \\ &\leq (1 + 3\epsilon)||p, x|| + 7\sqrt{2}\epsilon \leq (1 + 13\epsilon)||p, x|| \qquad \text{since } ||p, x|| \geq 1 \end{aligned}$$

Thus, it remains to prove Equation 1. To this end, let y be the projection of z on L. (Point y is also a grid point; see Figure 1) Let y', z' be projections of y and z on the line containing pc, respectively. Let u be the intersection of pz and yy'. Observe that $||p, y|| \leq (1 + \epsilon) \leq (1 + \epsilon)||p, u||$. Thus,

$$||p, y|| + ||y, z|| \ \leq \ (1 + \epsilon)||p, u|| + ||y, z|| \leq (1 + \epsilon)||p, u|| + ||u, z|| \leq (1 + \epsilon)||p, z|| \tag{2}$$

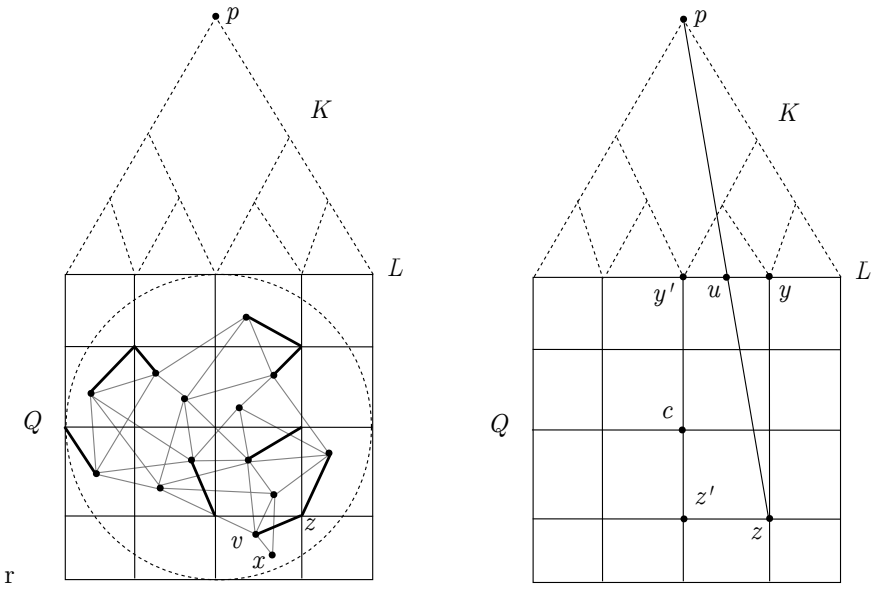

Figure 1 *(Left) A single source spanner from p to a set of points enclosed by a circle of radius $\sqrt{\epsilon}$. One point in each non-empty cell is connected to a corner by a thick edge. (Right) An illustration for analyzing the stretch of pz.*

Since $d_W(z,y) = ||z,y||$ and $d_K(y,p) = (1+\epsilon)||p,y||$ by Lemma 4, we have:

$$d_{W\cup K}(z,p) \;\leq\; (1+\epsilon)(||z,y|| + ||p,y||) \overset{Eq.\ 2}{\leq} (1+\epsilon)(1+\epsilon)||p,z|| \;\leq\; (1+3\epsilon)||p,z|| \quad (3)$$

which implies Equation 1. ◀

We obtain the following corollary of Lemma 6.

▶ **Corollary 7.** *Let X be a set of points in a circle C of radius $\sqrt{\epsilon}L$ on the plane and a point p of distance L/h from C for some constant $h \geq 1$. Let S_X be a $(1+g\epsilon)$-spanner of X for any constant g. Then there is a single-source $(1+13\epsilon)$-spanner H w.r.t. (p, X, S_X) of weight $O(hL)$ when $g \ll \frac{1}{\epsilon}$.*

Proof. We scale the space by L/h. In the scaled space, C has radius $h\sqrt{\epsilon}$ and $d(p,C) = 1$. Let $C_1, C_2, \ldots, C_m$, where $m = O(h^2)$, be circles of radius $\sqrt{\epsilon}$ covering C; such a set of circles can be constructed greedily. We apply Lemma 6 to p and each C_i to construct a single-source $(1+13\epsilon)$-spanner H_i from p to each C_i. The final spanner is $H = \cup_{i=1}^{m} H_i$ that has total weight $O(h^2)$ in the scaled metric. Thus, in the original metric, $w(H) = O(h^2 L/h) = O(hL)$. ◀

We are now ready to prove Theorem 1.

Proof of Theorem 1. Assume that the minimum pairwise distance is 1. Let $\mathcal{P} = \binom{P}{2}$ be all pairs of points. Partition $\mathcal{P}$ into $O(\log \Delta)$ sets $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_{\lceil \log \Delta \rceil}$ where $\mathcal{P}_i$ is the set of pairs (x,y) such that $||x,y|| \in [2^{i-1}, 2^i)$.

For a fixed i, we claim that there is a geometric graph H_i such that for every two distinct points $(x,y) \in \mathcal{P}_i$, $d_{H_1 \cup \ldots \cup H_i}(x,y) \leq (1+\epsilon)||x,y||$ and that $w(H_i) = O(\frac{1}{\epsilon})w(\mathsf{MST})$. Thus, $H_1 \cup \ldots \cup H_{\lceil \log \Delta \rceil}$ is a Steiner spanner with weight $O(\frac{\log \Delta}{\epsilon})w(\mathsf{MST})$.

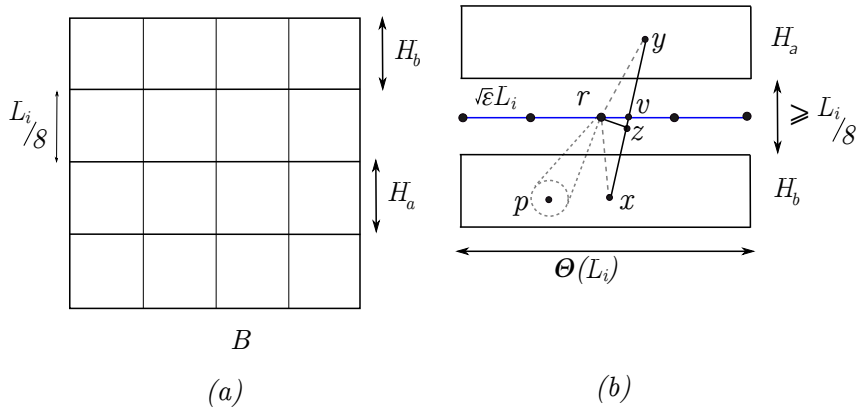

Figure 2 *(a) Square B is divided into $O(1)$ horizontal and vertical bands of width $L_i/8$ each. (b) The Steiner spanner construction for two non-adjacent horizontal bands H_a and H_b. The dashed cone represents a single-source spanner from r to circle $B(p, \sqrt{\epsilon}L_i)$.*

We now focus on constructing H_i. Let $S_{i-1} = H_1 \cup H_2 \ldots \cup H_{i-1}$. We will construct a spanner with stretch $(1 + c\epsilon)$ for some constant c. By induction, we can assume that:

$$d_{S_{i-1}}(p, q) \leq (1 + c\epsilon)||p, q|| \tag{4}$$

for any pair $(p, q) \in \mathcal{P}_1 \cup \ldots \cup \mathcal{P}_{i-1}$.

Let $L_i = 2^i$ and N_i be a $(\sqrt{\epsilon}L_i)$-net of P. For each point x, let $N_i(x)$ be the net point that *covers* x: the distance from x to $N_i(x)$ is at most $\sqrt{\epsilon}L_i$.

▷ Claim 8. $|N_i| = O(\frac{w(\mathsf{MST})}{L_i\sqrt{\epsilon}})$.

Proof. Consider the circle $B(p, \sqrt{\epsilon}L_i)$ centered at p; $B(p, \sqrt{\epsilon}L_i)$ contains a segment of length $\Omega(\sqrt{\epsilon}L_i)$ of the MST, which is not contained in any other circle. Thus, the claim holds. ◁

Next, we consider the smallest axis-aligned square Q bounding the point set. In the following, we divide Q into a set of (overlapping) sub-squares $\mathcal{B}$ of side length $\Theta(L_i)$ each. This way, for any pair $(x, y) \in \mathcal{P}_i$ (of distance at most L_i), there is a sub-square entirely containing $N_i(x), N_i(y)$, and the balls of radius $O(\sqrt{\epsilon}L_i)$ around the two net points.

Constructing $\mathcal{B}$. We first divide Q into subsquares of side length $5L_i$ each[8]. For each subsquare B, we extend its borders equally to four directions by an amount of $2L_i$ in each direction. After this extension, B has side length $9L_i$.

▷ Claim 9. Every point in Q belongs to at most 4 subsquares in $\mathcal{B}$. Furthermore, for each pair $(x, y) \in \mathcal{P}_i$, there is a subsquare $B \in \mathcal{B}$ such that $B(N_i(x), \sqrt{\epsilon}L_i), B(N_i(y), \sqrt{\epsilon}L_i)$ are entirely contained in B.

Proof. Let B be a subsquare in $\mathcal{B}$ containing one of the endpoints of (x, y), say x, before extension. Then, after extension, B will contain both x, y since $||x, y|| \leq L_i$, and furthermore, x and y are at least L_i away from the boundary since we extended B by $2L_i$ in each direction. Thus, points in $B(N_i(x), \sqrt{\epsilon}L_i)$ $(B(N_i(y), \sqrt{\epsilon}L_i))$ will be at most $2\sqrt{\epsilon}L_i < L_i$ from x (y) when $\epsilon \ll 1$. ◁

[8] We assume that the side length of Q is divisible by $5L_i$; otherwise, we can extend Q in such a way.

Consider a subsquare $B \in \mathcal{B}$. Let $N_B = N_i \cap B$. By abusing notation, we denote by $\mathcal{P}_i \cap B$ all the pairs in B of $\mathcal{P}_i$. We will show that:

▷ Claim 10. There is a Steiner spanner S_B of weight at most $O(|N_B|L_i/\sqrt{\epsilon})$ such that for any pair of points $(x, y) \in \mathcal{P}_i \cap B$, it holds that:

$$d_{S_B \cup S_{i-1}}(x, y) \leq (1 + c\epsilon)||x, y||$$

for some big enough constant c.

Proof. We divide B into $O(1)$ horizontal (vertical) *bands* of length (width) $L_i/8$ so that for any two points $x, y \in \mathcal{P}_i \cap B$, $N_i(x)$ and $N_i(y)$ are in two non-adjacent horizontal bands and/or vertical bands (see Figure 2). These bands exist since

$$||N_i(x), N_i(y)|| \ \geq \ ||x, y|| - 2\sqrt{\epsilon}L_i \ \geq \ L_i/2 - 2\sqrt{\epsilon}L_i \ \geq \ L_i/4$$

Now for each pair of non-adjacent horizontal bands H_a and H_b, $d(H_a, H_b) \geq \frac{L_i}{8}$. Draw a bisecting segment (touching two sides of B) between H_a and H_b and place $O(\frac{1}{\sqrt{\epsilon}})$ equally-spaced Steiner points, say R, on the bisecting line in a way that the distance between any two nearby Steiner points is $L_i\sqrt{\epsilon}$ (see Figure 2(a)). For each point $r \in R$, and each net point $p_i \in N_B \cap (H_a \cup H_b)$, we apply the construction of Corollary 7 to r, the set of endpoints of $\mathcal{P}_i$ inclosed in circle $B(p_i, \sqrt{\epsilon}L_i)$ and S_{i-1}; let $S_{a,b}(p_i)$ be the obtained geometric graph (see Figure 2(b)). Note that $d(r, B(p_i, \sqrt{\epsilon}L_i)) = \Omega(L_i)$. Thus, by Corollary 7, $w(S_{a,b}(p_i)) = O(L_i)$ and that:

$$d_{S_{i-1} \cup S_{a,b}(p_i)}(r, q) \leq (1 + 13\epsilon)||r, q|| \tag{5}$$

for any $q \in B(p_i, \sqrt{\epsilon}L_i) \cap P$. Let $S_{a,b}(r) = \cup_{p_i \in N_B \cap (H_a \cup H_b)} S_{a,b}(p_i)$. It holds that

$$w(S_{a,b}(r)) \leq O(L_i)|N_B \cap (H_a \cup H_b)|.$$

Let $S_{a,b} = \cup_{r \in R} S_{a,b}(r)$. Then, we have:

$$w(S_{a,b}) \leq O(L_i \cdot |R| \cdot |N_B \cap (H_a \cup H_b)|) = O(\frac{L_i}{\sqrt{\epsilon}}|N_B \cap (H_a \cup H_b)|) \tag{6}$$

We apply the same construction for every pair of non-adjacent vertical bands. We then let S_B be the union of all $S_{a,b}$ for every pair of non-adjacent horizontal/vertical bands H_a, H_b. It holds that:

$$w(S_B) = O(L_i \cdot |R| \cdot |N_B|) = O(\frac{L_i|N_B|}{\sqrt{\epsilon}}) \tag{7}$$

since there are only $O(1)$ pairs of bands. To bound the stretch, let (x, y) be a pair in $\mathcal{P}_i$ whose endpoints are in B. W.l.o.g, assume that H_a, H_b are two non-adjacent horizontal bands that contain $N_i(x)$ and $N_i(y)$, respectively. Let v be the intersection of segment xy and the bisecting line L of H_a, H_b (see Figure 2(b)). Let $r \in R$ be the closest Steiner point to v in L and z be the projection of r on xy. Observe that $||z, x||, ||z, y|| \geq \frac{L_i}{16} - ||z, v|| \geq L_i/16 - \sqrt{\epsilon}L_i \geq L_i/32$ when $\epsilon \ll 1$. We have:

$$\begin{aligned}
||r, x|| + ||r, y|| &= \sqrt{||x, z||^2 + ||r, z||^2} + \sqrt{||y, z||^2 + ||r, z||^2} \\
&\leq ||x, z||\sqrt{1 + \frac{\epsilon L_i^2}{||x, z||^2}} + ||y, z||\sqrt{1 + \frac{\epsilon L_i^2}{||y, z||^2}} \qquad \text{since } ||r, z|| \leq \sqrt{\epsilon}L_i \\
&\leq ||x, z||\sqrt{1 + 1024\epsilon} + ||y, z||\sqrt{1 + 1024\epsilon} \qquad \text{since } ||x, z||, ||y, z|| \geq L_i/32 \\
&\leq ||x, z||(1 + 512\epsilon) + ||y, z||(1 + 512\epsilon) = (1 + 512\epsilon)||x, y||
\end{aligned}$$

Thus, by Equation 5, we have:

$$d_{S_B \cup S_{i-1}}(x,y) \leq (1+13\epsilon)(||r,x||+||r,y||) = (1+13\epsilon)(1+512\epsilon)||x,y|| = (1+O(\epsilon))||x,y||$$

Thus, the stretch is $(1+c\epsilon)$ for a sufficiently big constant c. ◁

Let $H_i = \cup_{B\in\mathcal{B}} S_B$. Since each net point belongs to at most 4 subsquares in $\mathcal{B}$ by Claim 9, and $w(H_i) \leq O(\frac{|N_i|L_i}{\sqrt{\epsilon}})$ by Claim 10, it holds that:

$$w(H_i) = O(\frac{L_i}{\sqrt{\epsilon}}\frac{w(\mathsf{MST})}{L_i\sqrt{\epsilon}}) = O(\frac{w(\mathsf{MST})}{\epsilon}) \tag{8}$$

by Claim 8 as desired. ◀

4 A Linear Time Construction

In this section, we assume that $\Delta = O(n^c)$ for some constant c, and ϵ is a constant. We use the same model of computation used by Chan [20]: the real-RAM model with $\Theta(\log n)$ word size and floor function. We will use O_ϵ notation to hide a polynomial factor of $\frac{1}{\epsilon}$. Chan [20] showed that:

▶ **Theorem 11** (Step 4 in [20]). *Given a poin set $P \in \mathbb{R}^d$ with spread $\Delta = O(n^c)$ for* constant *d and c, a $(1+\epsilon)$-spanner of P can be constructed in $O_\epsilon(P)$ time.*

We will use a construction of an r-net for a point set P for any r in time $O(n)$. Such a construction was implicit in the work of Har-Peled [48] which was made explicit by Har-Peled and Raichel (Lemma 2.3 [50]).

▶ **Lemma 12** (Lemma 2.3 and Corollary 2.4 [50]). *Given $r \geq 1$ and an n-point set P in $\mathbb{R}^d$, an r-net N of P can be constructed in $O(n)$ time. Furthermore, for each net point p, one can compute all the points covered by p in total $O(n)$ time.*

We first show that the spanner in Corollary 7 can be implemented in $O_\epsilon(|X|)$ time.

▷ Claim 13. The single-source spanner H in Corollary 7 can be found in $O_\epsilon(|X|)$ time.

Proof. First, we observe that the single source spanner in Lemma 6 can be constructed in time $O_\epsilon(|X|)$. This is because the grid W has size $O_\epsilon(1)$ and the SLT tree from p to (a set of $O(\frac{1}{\sqrt{\epsilon}})$ grid points on) L can be constructed in $O_\epsilon(1)$ time. The single-source spanner in Corollary 7 uses a constant number of constructions construction in Lemma 6. Thus, the total running time is $O_\epsilon(|X|)$. ◁

Proof of Theorem 2. Our implementation will follow the construction in Section 3 ; we will reuse notation in that section as well. Let K be a $(1+\epsilon)$-spanner H for P constructed in time $O(n)$ by Theorem 11. In our fast construction algorithm, instead of considering all pairs of points $\mathcal{P} = \binom{P}{2}$, we only consider the pairs corresponding to edges of H; there are $O(n)$ such pairs. Our algorithm has four steps:

- **Step 1.** Partition pairs of endpoints in $E(H)$ into at most $O(\log(\Delta))$ sets $\mathcal{P}_1, \ldots, \mathcal{P}_{\lceil \log \Delta \rceil}$ where $\mathcal{P}_i$ is the set of pairs (x,y) such that $||x,y|| \in [2^{i-1}, 2^i)$. Let $L_i = 2^i$. This step can be implemented in time $O(|E(H)|) = O_\epsilon(n)$. The following steps are applied to each $i \in [1, \lceil \log \Delta \rceil]$. Let P_i be the set of endpoints of $\mathcal{P}_i$. We observe that:

$$\sum_{i=1}^{n} |P_i| \;\leq\; 2\sum_{i=1}^{n} |\mathcal{P}_i| \;=\; 2|E(H)| \;=\; O(n) \tag{9}$$

- **Step 2.** Construct a $(\sqrt{\epsilon}L_i)$-net N_i for P_i in $O(|P_i|)$ time using the algorithm in Lemma 12.
- **Step 3.** Compute a bounding square Q and divide it into (overlapping) subsquares of length $\Theta(L_i)$ each. Let $\mathcal{B}$ be the set of subsquares that contain at least one point participating in the pairs $\mathcal{P}_i$. Since there are only $O(|P_i|)$ non-empty subsquares, $\mathcal{B}$ can be computed in time $O(|P_i|)$ by iterating over each point and check (in $O(1)$ time) which subsquare the point falls into. Here we use the fact that each floor operation takes $O(1)$ time.
- **Step 4.** For each subsquare $B \in \mathcal{B}$, we divide it into $O(1)$ horizontal bands and vertical bands of length $L_i/8$. For each pair of non-adjacent (horizontal) bands H_a, H_b, construct a set of $O(\frac{1}{\sqrt{\epsilon}})$ Steiner points on the bisecting line between H_a and H_b as in Section 3. For each Steiner point r and each net point $p \in N_i \cap (H_a \cap H_b)$, we apply Corollary 7 to construct a single source spanner from r to a set of points $B(p, \sqrt{\epsilon}L_i) \cap P_i$; this step can be implemented in time $O_\epsilon(|B(p, \sqrt{\epsilon}L_i) \cap P_i|)$ by Claim 13. By Claim 9, the construction in this step can be implemented in $O_\epsilon(|P_i|)$ time. Our final spanner is the union of all single source spanners in all subsquares in $\mathcal{B}$.

The running time needed to implement Steps 2 to 4 is $O_\epsilon(\sum_{i=1} |P_i|) = O_\epsilon(n)$ by Equation 9. The same analysis in Section 3 gives $O(\frac{\log \Delta}{\epsilon})$ lightness. For stretch, we observe that the stretch of the spanner for each edge of H is $(1 + O(\epsilon))$. Thus, the stretch for every pair of points in P is $(1 + \epsilon)(1 + O(\epsilon)) = (1 + O(\epsilon))$. We can recover stretch $(1 + \epsilon')$ by setting $\epsilon' = \frac{\epsilon}{c}$ where c is the constant behind big-O. ◀

5 Steiner Spanners in High Dimension

In this section, we a light Steiner spanner for a point set $P \in \mathbb{R}^d$ with spread Δ as in Theorem 3. We rescale the metric so that every edge in $\binom{P}{2}$ has weight at least $\frac{1}{\epsilon}$. Let MST be the minimum spanning tree of P. We subdivide each MST edge of length > 1, by placing Steiner points greedily, in a way that each new edge has length *at least* $1/2$ *and at most* 1. Let K be the set of Steiner points. We observe that:

$$w(\mathsf{MST}) = \Theta(|P| + |K|) \tag{10}$$

Let $\delta > 1$ be some parameter and $L_i = \frac{\delta}{\epsilon^i}$. Let $\mathcal{E}_\delta = \{E_1, \ldots, E_m\}$ be the set of edges such that

$$E_i = \{e | e \in \binom{P}{2} \wedge w(e) \in (L_i/2, L_i]\} \tag{11}$$

where $m = \lceil \log_{\frac{1}{\epsilon}}(\Delta/(\epsilon\delta)) \rceil \leq \lceil \log_{\frac{1}{\epsilon}} \Delta \rceil + 1$. If an edge $e \in E_i$ for some $E_i \in \mathcal{E}_\delta$, we will abuse notation by saying that $e \in \mathcal{E}_\delta$. The main focus of this section is to show that:

▶ **Lemma 14.** *There is a Steiner spanner that preserves distances between the endpoints of edges in $\mathcal{E}_\delta$ with weight $\tilde{O}(\epsilon^{-(d+1)/2} + (\delta + \epsilon^{-2}) \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST})$.*

We will show below that Lemma 14 implies Theorem 3.

Proof of Theorem 3. We assume that $\frac{1}{\epsilon}$ is a power of 2. We partition the interval $[1, \epsilon)$ into $J = \log_2(\frac{1}{\epsilon})$ intervals $[1, 2), \ldots, [2^{J-1}, 2^J)$. For each fixed $j \in [1, J]$, let $\delta_i = 2^j$, and $\mathcal{E}_{\delta_j}$ be the set of edges with $\delta = \delta_j$ in the definition of $\mathcal{E}_\delta$. Recall that we scale the metric so that every edge in $\binom{P}{2}$ has weight at least $\frac{1}{\epsilon}$. Thus, $\binom{P}{2} = \cup_{j=1}^{J} \mathcal{E}_{\delta_j}$

Observe that $\delta_j \leq \frac{1}{\epsilon}$ for all $j \in [1, J]$. By Lemma 14, there exists a Steiner spanner S_j with weight $\tilde{O}(\epsilon^{-(d+1)/2} + (\epsilon^{-2} \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST})$ preseving distances between endpoints of edges in $\mathcal{E}_{\delta_j}$ up to a $(1 + \epsilon)$ factor. Then $S = \cup_{i=1}^{J} S_j$ is a Steiner $(1 + \epsilon)$-spanner with weight $\tilde{O}(\epsilon^{-(d+1)/2} + \epsilon^{-2} \log \Delta) w(\mathsf{MST})$. ◀

We now focus on constructing a Steiner spanner in Lemma 14. We will use the following Steiner spanner construction as a black box.

▶ **Theorem 15** (Theorem 1.3 [59]). *For a given point set P, there is a Steiner $(1+\epsilon)$-spanner, denoted by $\mathsf{STP}(P)$, with $\tilde{O}(\epsilon^{-(d-1)/2})|P|$ edges that preserves pairwise distances of points in P up to a $(1+\epsilon)$ factor.*

We will rely on a *cover tree* to construct a Steiner spanner. Let c be a sufficiently big constant chosen later ($c = 20$).

▶ **Definition 16** (Cover tree). *A cover T for point set $P \cup K$ with $(m+1)$ levels has each node associated with a point of P such that (a) level-0 of T is the point set $P \cup K$, (b) level-i of T is associated with a $(c\epsilon L_i)$-cover N_i of P and (c) $N_m \subseteq N_{m-1} \subseteq \ldots \subseteq N_0$.*

A point p may appear in many levels of a cover tree T. To avoid confusion, we denote by (p,i) the copy of p at level i, and we still call (p,i) a *point* of $P \cup K$. For each point (p,i), we denote by $\mathsf{child}(p,i)$ and $\mathsf{desc}(p,i)$ the set of children and descendants of (p,i) in T, respectively. Note that $\mathsf{desc}(p,i)$ includes (p,i).

We will construct the Steiner spanner level by level, starting from level 1. At every level, we will add a certain set of edges to E_{sp}. We then charge the weight of a subset of the edges to a subset of *uncharged points* of $P \cup K$; initially, every point of $P \cup K$ is *uncharged*. To decide which uncharged points we will charge to at level i, we consider a geometric graph H_i where $V(H_i) = N_i$ and there is an edge between two points $(p,i) \neq (q,i)$ (of weight $||p,q||$) in H_i if there exists at least one $e \in E_i$ between two descendants of (p,i) and (q,i), respectively. We say a cover point (p,i) has *high degree* if its degree in H_i is at least $\frac{4c}{\epsilon}$. At level i, we only charge to uncharged points which are descendants of high degree cover points. The intuition is that high cover points have many descendants. This leads to a notion of a *charging cover tree*. We call a cover tree a charging cover tree for $\mathcal{E}_\delta$ if for all level $i \geq 1$,

(1) Each point (p,i) has at least ϵL_i descendants that are uncharged at level less than i.

(2) Up to $\epsilon L_i/2$ uncharged descendant of each high-degree cover point (p,i) can be charged at level i. No descendant of low-degree points is charged at level i.

We show how to construct a charging cover tree in Appendix 5.4. We now show that given a charging cover tree, we can construct a Steiner spanner with the lightness bound in Lemma 14. Let T be such a charging cover tree. We define a set of edges E_T as follows:

$$E_T = \{(p,q) | (p \in \mathsf{child}(q,i) \vee q \in \mathsf{child}(p,i)) \text{ for some } i\} \tag{12}$$

We abuse notation by denoting E_T the graph induced by the set of edges in E_T.

▷ Claim 17. $w(E_T) = O(\delta + \epsilon^{-1} \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST}))$ and for any p and every $x \neq y \in \mathsf{desc}(p,i)$, $d_{E_T}(x,y) \leq 4c\epsilon L_i$.

Proof. Edges in E_T can be partitioned according to levels where an edge is at level i if it connects a point (p,i) and its parent. Observe that at level 0, the total edge weight is at most $c\delta$ times the number of points and hence, the total weight is $O(\delta|K \cup P|) = O(\delta w(\mathsf{MST}))$ by Equation 10. At higher level, we observe that the total weight of edges of E_T at level $i \geq 1$ is at most $L_i|N_i|$, and that $N_i \leq \frac{|K \cup P|}{|\epsilon L_i|}$ since each point (p,i) has $|\mathsf{desc}(p,i)| \geq \epsilon L_i$ by property (1) of the charging tree. Thus, the total weight of edges E_t at level at least 1 is at most:

$$\sum_{i=1}^{m} \frac{|K \cup P|}{\epsilon} = m \frac{|K \cup P|}{\epsilon} = O(\epsilon^{-1} \log_{\frac{1}{\epsilon}} \Delta |K \cup P|) = O(\epsilon^{-1} \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST})$$

This implies the weight bound of E_T. We now bound the distance between $x \neq y \in \mathsf{desc}(p,i)$. Let $x = v_0, v_1, \ldots, v_k = p$ be the (unique) path from x to p. By construction, $||v_{i-1}, v_i|| \leq \frac{v_i v_{i+1}}{\epsilon}$ for $i \in [1, k-1]$. This implies:

$$d_{E_T}(x,p) = ||p, v_{k-1}|| \sum_{i=0}^{k-1} \epsilon^i \leq \frac{||p, v_{k-1}||}{1-\epsilon} \leq 2||p, v_{k-1}|| = 2c\epsilon L_i$$

when $\epsilon \leq \frac{1}{2}$. Similarly, $d_{E_T}(y,p) \leq 2c\epsilon L_i$ and hence $d_{E_T}(x,y) \leq 4c\epsilon L_i$. ◁

Claim 17 implies that the descendants of any level i node in a charging cover tree form a subgraph of diameter at most $O(c\epsilon L_i)$. Let E_{sp} be the set of edges that will be our final spanner. Initially, $E_{sp} = E_T \cup \mathsf{MST}$. We will abuse notation by denoting E_{sp} the graph induced by edge set E_{sp}.

5.1 Spanner construction at level i

Recall that H_i is a geometric graph where $V(H_i) = N_i$ and there is an edge between two points $(p,i) \neq (q,i)$ in H_i if there exists at least one $e \in E_i$ between two descendants of (p,i) and (q,i), respectively. Recall that a high degree point (p,i) has at least $\frac{4c}{\epsilon}$ neighbors in H_i. We proceed in two steps.

- **Step 1.** For every low degee point (p,i), we add all incident edges of (p,i) in H_i to E_{sp}.
- **Step 2.** Let Q be the set of high degree points in N_i. We add to E_{sp} the set of edges of $\mathsf{STP}(Q)$. We take from each high degree cover point (p,i) exactly $\epsilon L_i/2$ uncharged descendants and let X be the set of these uncharged points. We charge the cost of $\mathsf{STP}(Q)$ equally to all points in X and mark them *charged*. This charging is possible by property (2) of T.

5.2 Bounding the stretch

We will show that the stretch is $(1 + (48c+1)\epsilon)$. We can recover stretch $(1+\epsilon')$ by setting $\epsilon' = \frac{\epsilon}{48c+1}$.

Observe by construction that for every edge $e \in H_i$, the stretch of e in E_{sp} is at most $(1+\epsilon)$. Recall that for every edge $(u,v) \in E_i$, there is an edge $(p,q) \in E(H_i)$ such that $u \in \mathsf{desc}(p,i), v \in \mathsf{desc}(q,i)$. By Claim 17, there is a path between u and v in E_{sp} of length at most $d_{E_{sp}}(p,q) + 8c\epsilon L_i$. By triangle inequality, $||p,q|| - 2c\epsilon L_i \leq ||u,v|| \leq ||p,q|| + 2c\epsilon L_i$. Thus, we have:

$$\begin{aligned}
\frac{d_{E_{sp}}(u,v)}{||u,v||} &\leq \frac{d_{E_{sp}}(p,q) + 8c\epsilon L_2}{||p,q|| - 2c\epsilon L_i} = \frac{d_{E_{sp}}(p,q)}{||p,q||} + \frac{(d_{E_{sp}}(p,q) + 4||p,q||)2c\epsilon L_i}{||p,q||(||p,q|| - 2c\epsilon L_i)} \\
&\leq \frac{d_{E_{sp}}(p,q)}{||p,q||} + \frac{12c\epsilon L_i}{||p,q|| - 2c\epsilon L_i} \qquad \text{since } d_{E_{sp}}(p,q) \leq 2||p,q|| \\
&\leq \frac{d_{E_{sp}}(p,q)}{||p,q||} + 48c\epsilon \leq 1 + (48c+1)\epsilon
\end{aligned}$$

The penultimate inequality follows from the fact that

$$||p,q|| - 2c\epsilon L_i \;\geq\; ||u,v|| - 4c\epsilon L_i \;\geq\; L_i/2 - 4c\epsilon L_i \;\geq\; L_i/4$$

when $\epsilon \ll \frac{1}{c}$.

5.3 Bounding $w(E_{sp})$

Observe that the total number of low degree points in N_i is at most $\frac{|K \cup P|}{\epsilon L_i}$ since each low degree point has at least ϵL_i (uncharged) descendants by property (1) of charging tree T. By triangle inequality, each edge of H_i has weight at most $L_i + 2c\epsilon L_i \leq 3L_i$ when $\epsilon < \frac{1}{c}$. Thus, the total weight of edges added to E_{sp} in Step 1 is bounded by:

$$\frac{3L_i \cdot 4c}{\epsilon} |\{p | p \in N_i \text{ and } p \text{ has low degree}\}| = O(\frac{L_i}{\epsilon} \frac{|K \cup P|}{\epsilon L_i}) = O(\frac{1}{\epsilon^2}) w(\mathsf{MST})$$

by Equation 10. Thus, the total weight of the edges added to E_{sp} in Step 1 over m levels is $O(\epsilon^{-2} \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST})$. Note here that $m \leq \lceil \log_{\frac{1}{\epsilon}} \Delta \rceil + 1$.

We now bound the total weight of the edges added to E_{sp} in Step 2 *over m levels*. Since each edge of H_i has weight at most $3L_i$, each edge of $\mathsf{STP}(Q)$ has weight a most $(1+\epsilon)3L_i \leq 6L_i$. By Theorem 15,

$$w(\mathsf{STP}(Q)) = \tilde{O}(\epsilon^{-(d-1)/2})|Q|6L_i = \tilde{O}(\epsilon^{-(d-1)/2+o(1)})|Q|L_i$$

Thus, in Step 2, each uncharged point is charged at most:

$$\frac{\tilde{O}(\epsilon^{-(d-1)/2})|Q|L_i}{|Q|\epsilon L_i/2} = \tilde{O}(\epsilon^{-(d+1)/2}) \tag{13}$$

This implies the total weight of the edges added to E_{sp} in Step 2 *over all levels* is $\tilde{O}(\epsilon^{-(d+1)/2})(|P \cup K|) = \tilde{O}(\epsilon^{-(d+1)/2}) w(\mathsf{MST})$. Together with Claim 17, we conclude that:

$$w(E_{sp}) = \tilde{O}(\epsilon^{-(d+1)/2} + (\delta + \epsilon^{-2}) \log_{\frac{1}{\epsilon}} \Delta) w(\mathsf{MST})$$

This completes the proof of Lemma 14.

5.4 Constructing a Charging Cover Tree

The main difficulty is to guarantee property (1) in constructing a charging cover tree; for property (2) at each level i, we simply charge to exactly $\epsilon L_i/2$ uncharged descendants of each high degree cover point.

A natural idea is to guarantee that each cover point has $\frac{1}{\epsilon}$ children. Then inductively, if each child of a cover point (p, i) has at least $\epsilon L_{i-1}/2$ uncharged descendants after the charging at level $i-1$, we can hope that p has at least $\frac{1}{\epsilon}\epsilon L_{i-1} = \epsilon L_i$ uncharged descendants. There are two issues with this idea: (a) if at least one child, say $(q, i-1)$, of (p, i) has high degree in the graph H_{i-1}, up to $\epsilon L_{i-1}/2$ uncharged points in $\mathsf{desc}(q, i-1)$ were charged at level $i-1$ by property (2), and thus, $(q, i-1)$ only contributes $\frac{\epsilon L_{i-1}}{2}$ uncharged descendants to (p, i); and (b) there may not be enough cover points at level $i-1$ close to p as these points and their descendants must be within distance $c\epsilon L_i$ from p.

In our construction, we resolve both issues by picking a cover point in a way that the total number of uncharged descendants of its children is at least ϵL_i. We do so by having a more accurate way to track the number of uncharged descendants of a cover point, instead of simply relying on the lower bound ϵL_i of uncharged descendants. Specifically, denote by $\mathsf{D}(X)$ the diameter of a point set X. We will construct a charging cover tree in a way that the following invariant is maintained *at all levels*.

Strong Charging Invariant: (SCI)
Each point (p, i) has at least $\max(\epsilon L_i, \mathsf{D}(\mathsf{desc}(p, i)) + 1)$ uncharged descendants (before the charging happened at level i).

Clearly, SCI implies property (1) of T. We begin by constructing the level-1 cover. Recall that MST edges have weight at most 1 and at least $\frac{1}{2}$, and that $\delta \geq 1$.

Level 1

We construct level-1 cover points N_1 by greedily breaking MST edges into subtrees of diameter at least δ and at most $3\delta + 2 \leq 5\delta$. Let X be such a subtree of MST with diameter d_X; X will have at least δ points since MST edge has weight at most 1. We pick any point, say $p \in X$, to be a level-1 cover point, and make other points in X become p's children; p will have at least δ children (uncharged at level 0). Recall that $\epsilon L_1 = \delta$. Since each MST edge has weight at most 1, the number of descendants of $(p, 1)$ is at least:

$$d_X + 1 \geq \max(\epsilon L_1, \mathsf{D}(\mathsf{desc}(p, 1)) + 1)$$

Thus, SCI holds for this level.

Level $i + 1$

Recall H_i is a graph with vertex set N_i. We construct a cover N_{i+1} in three steps A, B and C.

- **Step A.** For each high degree point p (with at least $\frac{4c}{\epsilon}$ unmarked neighbors in H_i), we pick p to N_{i+1} andmake its unmarked neighbors become its children. We then mark p and all of its neighbors. For each remaining unmarked high degree point x in H_i, at least one of its neighbors, say q, must be marked before. We make x become a child of q's parent.

The intuition of the construction in Step A is that $(p, i+1)$ picked at this step has at least $\frac{4c}{\epsilon}$ children. Since at least $(\epsilon L_i)/2$ descendants of each child of (p, i) remain uncharged after level i, the total number of uncharged descendants of $(p, i+1)$ is $\frac{4c}{\epsilon}\frac{\epsilon L_i}{2} = 2cL_i = 2c\epsilon L_{i+1} > \epsilon L_{i+1}$. Furthermore, since every high degree point is marked in this step, points in subsequent steps have low degree and hence no uncharged descendant of these points is charged at level i by property (2) of charging cover trees.

Let W be the set of remaining points in N_i. We construct a forest F from W as follows. The vertex set of F is W, and there is an edge between two vertices p, q of F if there is an MST edge, called the source of the edge, connecting a point in $\mathsf{desc}(p)$ and a point in $\mathsf{desc}(q)$. We set the weight of each edge in F to be the weight of the source edge. Note that F is not a geometric graph. We observe that:

▶ **Observation 18.** *For every connected component $C \in F$, there must be a point $p \in C$ and a point q marked in Step A such that there is an MST edge between a descendant of (p, i) and a descendant of (p, i), except when there is no point marked in Step A (and F is a tree in this case).*

Proof. The observation follows from the fact that MST spans $P \cup K$. ◀

We define the weight on each vertex p of F to be $w(p) = D(\mathsf{desc}(p, i))$, and the *vertex-weight* of a path P, denoted by $\mathsf{vw}(P)$, of F to be the total weight of vertices on the path. We define the *absolute weight* of P, denoted by $\mathsf{aw}(P)$, to be the total vertex and edge weight of P. Since each MST edge has weight at most 1 and each vertex has weight at least 1,

$$\mathsf{aw}(P) \leq 2\mathsf{vw}(P) \tag{14}$$

The *vertex-diameter* of a subtree C, denoted by $\mathsf{VD}(C)$, of F is defined to be the vertex-weight of the path of maximum vertex-weight in the subtree. The *absolute diameter* of C, denoted by $\mathsf{AD}(C)$, is defined similarly but w.r.t absolute weight.

- **Step B.** For each component C of F of vertex-diameter at least L_i, we greedily break C into sub-trees of vertex-diameter at least L_i and at most $3L_i$. For each subtree of C, choose an arbitrary point p to be a level-$(i+1)$ cover point and make other points become p's children.
- **Step C.** For each component C of F of vertex-diameter at most L_i, by Observation 18, there must be at least one MST connecting a point in $\mathsf{desc}(u,i)$ for some $u \in C$ to a point in $\mathsf{desc}(v,i)$ for some point v marked in Step 1. We make all points in C become children of v's parent.

The following claim implies that N_{i+1} is a $(c\epsilon L_{i+1})$-cover.

▷ Claim 19. For each point $(p, i+1)$, $\mathsf{D}(\mathsf{desc}(p,i+1)) \leq c\epsilon L_{i+1}$ for $c = 20$.

Proof. Note that for each point (q,i), $1 \leq \mathsf{D}(\mathsf{desc}(q,i)) \leq 2c\epsilon L_i$ since every point in $\mathsf{desc}(q,i)$ is within distance $c\epsilon L_i$ from q.

First, consider the case that $(p,i+1)$ is chosen in Step B. Then p and its children belong to a subtree C of F of vertex-diameter at most $3L_i$. by Equation 14, $\mathsf{AD}(C) \leq 2 \cdot 3L_i = 6L_i$. Thus, for a point $p \in N_{i+1}$ selected in Step B, $D(\mathsf{desc}(p,i+1)) \leq \mathsf{AD}(C) \leq 6L_i$.

We now consider the case where $(p,i+1)$ is chosen in Step A. (There is no cover point at level $(i+1)$ selected in Step C.) Recall that each edge of H_i has length at most $L_i + 2c\epsilon L_i$ by the triangle inequality. Observe that after Step 1, for any $(q,i) \in \mathsf{child}(p,i+1)$, the hop distance in H_i between (p,i) and (q,i) is at most 2, hence $||p,q|| \leq 2(L_i + 2c\epsilon L_i) = 2L_i + 4c\epsilon L_i$. That implies, after Step A,

$$||p,x|| \leq (2L_i + 4c\epsilon L_i) + c\epsilon L_i = 2L_i + 5c\epsilon L_i \quad \text{for any } x \in \mathsf{desc}(p,i+1) \tag{15}$$

In Step C, we add more points belonging to subtrees of F to $\mathsf{child}(p,i+1)$. Let C be any of these subtrees. Since $\mathsf{VD}(C) \leq L_i$, $\mathsf{AD}(C) \leq 2L_i$. By construction, there exists a point $(v,i) \in C$ and a point $(u,i) \in \mathsf{child}(p,i+1)$ such that there is an MST edge e connecting a point in $\mathsf{desc}(v,i)$ and a point in $\mathsf{desc}(u,i)$. Thus, the augmentation in Step C increases the distance from p to the furthest point of $\mathsf{desc}(p,i+1)$ by at most $w(e) + \mathsf{AD}(C) \leq 1 + 2L_i \leq 3L_i$. This implies:

$$\mathsf{D}(\mathsf{desc}(p,i+1)) \leq 2(2L_i + 5c\epsilon L_i + 3L_i) \leq 20L_i$$

when $\epsilon < \frac{1}{c}$. ◁

To complete the proof of Lemma 14, it remains to show SCI for level $(i+1)$.

▷ Claim 20. Each point $(p,i+1)$ has at least $\max(\epsilon L_{i+1}, \mathsf{D}(\mathsf{desc}(p,i+1)+1)$ uncharged descendants.

Proof. We first consider the case $(p,i+1)$ is picked in Step B. Let X be the subtree of F that p belongs to. Let P be a path of X of maximum absolute weight. By definition on absolute weight, $\mathsf{aw}(P) \geq \mathsf{D}(\mathsf{desc}(p,i+1))$. Since MST has length at most 1, we have:

$$\sum_{q \in P} \mathsf{D}(\mathsf{desc}(q,i)) + |E(P)| \geq \mathsf{aw}(P) \geq \mathsf{D}(\mathsf{desc}(p,i+1))$$

By SCI for level i, we conclude that the number of uncharged descendants of $(p,i+1)$ is at least:

$$\sum_{q \in P} (\mathsf{D}(\mathsf{desc}(q,i)) + 1) \geq (\sum_{q \in P} \mathsf{D}(\mathsf{desc}(q,i)) + |E(P)|) + 1 \geq \mathsf{D}(\mathsf{desc}(p,i+1))) + 1$$

To show that X has at least ϵL_{i+1} uncharged descendants, we observe by construction that X has a path Q with $\mathsf{vw}(Q) \geq L_i$. By definition of vertex-weight, $\mathsf{vw}(Q) = \sum_{q \in Q} \mathsf{D}(\mathsf{desc}(q, i))$. Thus, the total number of uncharged descendants of all $q \in Q$ by SCI is at least:

$$\sum_{q \in Q} (\mathsf{D}(\mathsf{desc}(q, i)) + 1) > \sum_{q \in Q} \mathsf{D}(\mathsf{desc}(q, i)) \geq L_i = \epsilon L_{i+1}$$

Thus, $(p, i+1)$ has at least $\max(\epsilon L_{i+1}, \mathsf{D}(\mathsf{desc}(p, i+1)) + 1)$ uncharged descendants.

It remains to consider the case $(p, i+1)$ is picked in Step A. By construction, $(p, i+1)$ has at least $\frac{4c}{\epsilon}$ children, and each has at least $\epsilon L_{i-1}/2$ uncharged descendants by property (2) of a charging cover tree. Note that $\mathsf{D}(\mathsf{desc}(p, i+1)) \leq c\epsilon L_{i+1} = cL_i$ by Claim 19. Thus, $(p, i+1)$ has at least:

$$\frac{4c}{\epsilon} \frac{\epsilon L_i}{2} = 2cL_i \geq \max(\epsilon L_{i+1}, \mathsf{D}(\mathsf{desc}(p, i+1))) + cL_i > \max(\epsilon L_{i+1}, \mathsf{D}(\mathsf{desc}(p, i+1)) + 1)$$

uncharged descendants as desired. ◁

Settling the Relationship Between Wilber's Bounds for Dynamic Optimality

Abstract

In FOCS 1986, Wilber proposed two combinatorial lower bounds on the operational cost of any binary search tree (BST) for a given access sequence $X \in [n]^m$. Both bounds play a central role in the ongoing pursuit of the *dynamic optimality conjecture* (Sleator and Tarjan, 1985), but their relationship remained unknown for more than three decades. We show that Wilber's *Funnel bound* dominates his *Alternation bound* for all X, and give a tight $\Theta(\lg \lg n)$ separation for some X, answering Wilber's conjecture and an open problem of Iacono, Demaine et. al. The main ingredient of the proof is a new *symmetric* characterization of Wilber's Funnel bound, which proves that it is invariant under *rotations* of X. We use this characterization to provide initial indication that the Funnel bound matches the Independent Rectangle bound (Demaine et al., 2009), by proving that when the Funnel bound is constant, $\mathsf{IRB}_{\nearrow}$ is linear. To the best of our knowledge, our results provide the first progress on Wilber's conjecture that the Funnel bound is dynamically optimal (1986).

1 Introduction

The *dynamic optimality conjecture* of Sleator and Tarjan [14] postulates the existence of an *instance optimal* binary search tree algorithm (BST), namely, an online self-adjusting BST whose running time[1] matches the best possible running time *in hindsight* for any fixed sequence of queries. More formally, letting $\mathcal{T}(X)$ denote the operational time of a BST algorithm $\mathcal{T}$ on a sequence $X = (x_1, \ldots, x_m) \in [n]^m$ of keys to be searched, the conjecture says that there is an online BST $\mathcal{T}$ such that $\forall X$, $\mathcal{T}(X) \leq O(\mathsf{OPT}(X))$, where $\mathsf{OPT}(X) := \min_{\mathcal{T}'} \mathcal{T}'(X)$ denotes the optimal offline cost for X. Such instance optimal algorithms are generally impossible, as an offline algorithm that sees the input X in advance

[1] i.e. the number of pointer movements and tree rotations performed by the BST

can simply "store the answers" and output them in $O(1)$ per operation, which is why worst-case analysis is the typical benchmark for online algorithms. Nevertheless, in the BST model, where the competing class of algorithms are self-adjusting binary search trees, instance optimality is an intriguing possibility. After 35 years of active research, two BST algorithms are still conjectured to be constant-competitive: The first one is the celebrated *splay tree* of [14], the second one is the more recent *GreedyFuture* algorithm [12, 5, 13]. However, optimality of both splay trees and GreedyFuture was proven only in special cases, and they are not known to be $o(\lg n)$-competitive for general access sequences X (note that every balanced BST is trivially $O(\lg n)$-competitive). The best provable result to date on the algorithmic side is an $O(\lg \lg n)$-competitive BST, the *Tango Tree* ([5] and its subsequent variants [15, 2]).

The ongoing pursuit of dynamically-optimal BSTs motivated the development of lower bounds on the cost of the offline solution $\mathsf{OPT}(X)$, attempting to capture the "correct" complexity measure of a fixed access sequence X in the BST model, and thereby providing a concrete benchmark for competitive analysis. Indeed, one defining feature of the dynamic optimality problem (and the reason why it is a viable possibility) is the existence of nontrivial lower bounds on $\mathsf{OPT}(X)$ for individual *fixed* access sequences X, as opposed to distributional lower bounds. [2] These lower bounds are all derived from a natural geometric interpretation of the access sequence $X = x_1, \ldots, x_m$ as a point set on the plane, mapping the i^{th} access x_i to point (x_i, i) ([5, 8], see Figure 1). The earliest lower bounds on $\mathsf{OPT}(X)$ were proposed in an influential paper of Wilber [16], and are the main subject of this paper.

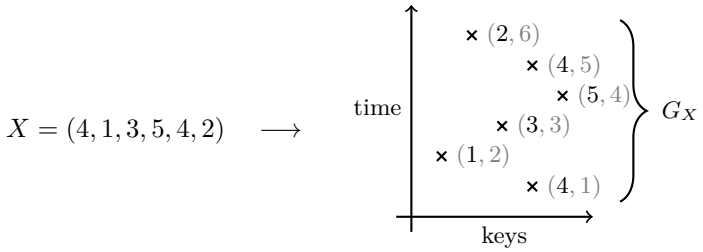

Figure 1 Transforming X into its geometric view G_X.

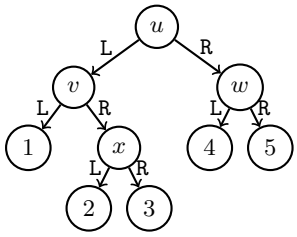
The Alternation bound

Wilber's first lower bound, the *Alternation bound* $\mathsf{Alt}_{\mathcal{T}}(X)$, counts the total number of left/right alternations obtained by searching the keys $X = (x_1, \ldots, x_m)$ on a *fixed* (static) binary search tree $\mathcal{T}$, where alternations are summed up over all nodes $v \in \mathcal{T}$ of the "reference tree" $\mathcal{T}$ (see Figure 2 and the formal definition in Section 2). Thus, the Alternation bound is actually a family of lower bounds, optimized by the choice of the reference tree $\mathcal{T}$, and we henceforth define $\mathsf{Alt}(X) \coloneqq \max_{\mathcal{T}} \mathsf{Alt}_{\mathcal{T}}(X)$. This lower bound played a key role in the design and analysis of Tango trees and their variants [6, 15], whose operational cost is in fact shown to be $O(\lg \lg n) \cdot \mathsf{Alt}_{\mathcal{T}}(X) \leq O(\lg \lg n) \cdot \mathsf{OPT}(X)$ (when setting the reference tree $\mathcal{T}$ to be the canonical balanced BST on $[n]$). Unfortunately, this bound is not tight, as we show that there are access sequences $\tilde{X}$ for which $\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) \leq O(\mathsf{OPT}(\tilde{X})/\lg \lg n)$ *simultaneously* for all

[2] For example, Wilber's Alternation bound can be used to show that the "bit-reversal" access sequence obtained by reversing the binary representation of the monotone sequence $\{1, 2, 3, \ldots, n\}$ has cost $\Omega(\lg n)$ per operation [16].

choices of reference trees $\mathcal{T}$ (previously, this was known only for any *fixed* $\mathcal{T}$ [8]), and hence the combined bound $\mathsf{Alt}(X)$ does not capture dynamic optimality in general. Nevertheless, the algorithmic interpretation of the Alternation bound is an interesting proof-of-concept of how lower bounds can lead to new and interesting online BST algorithms.



reference tree $\mathcal{T}$

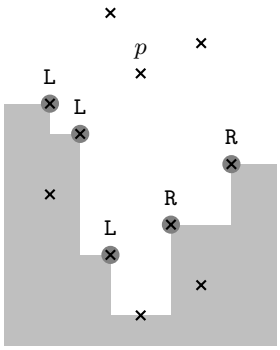
Node	Link used by each access	Group by letter	#
u	R, L, L, R, R, L	[R], [L, L], [R, R], [L]	4
v	L, R, R	[L], [R, R]	2
w	L, R, L	[L], [R], [L]	3
x	R, L	[R], [L]	2
Total			11

Figure 2 For access sequence $X = (4, 1, 3, 5, 4, 2)$ and reference tree $\mathcal{T}$, $\mathsf{Alt}_{\mathcal{T}}(X) = 11$.

The Funnel bound

The definition of Wilber's second bound, the *Funnel bound*, is less intuitive (and as such, was much less understood prior to this work). Let G_X be the set of m points in the plane given by the map $x_i \mapsto (x_i, i)$. The *funnel* of a point $p \in G_X$ is the set of "orthogonally visible" points below p, i.e. points q such that the axis-aligned rectangle with corners at p and q contains no other points (see Figure 3). For each p, look at the points in the funnel of p sorted by y coordinate, and count the number of alternations from the left to the right of P that occur. Call this $f(p)$; this is p's contribution to the lower bound. Summing this value for all $p \in G_X$ gives the lower bound $\mathsf{Funnel}(X) := \sum_{p \in G_X} f(p)$. An algorithmic view of this bound is as follows: consider the algorithm that simply brings each x_i to the root by a series of single rotations. Then $f(p)$ for $p = (x_i, i)$ is exactly the number of *turns* on the path from the root to x_i right before it is accessed [1, 8]. This view emphasizes the amortized nature of the funnel bound: at any point, there could be linearly many keys in the tree that are only *one* turn away from the root, so one can only hope to achieve this bound in some amortized fashion. This partially explains why Wilber's second bound has been so elusive to analyze (more on this interpretation can be found in the recent work of [11]).

Wilber conjectured that $\mathsf{Funnel}(X) \geq \Omega(\mathsf{Alt}(X))$ for every access sequence X, and that the Funnel bound is in fact *dynamically optimal*, i.e., that $\mathsf{Funnel}(X) = \Theta(\mathsf{OPT}(X))\ \forall X$. These conjectures were echoed multiple times in the long line of research spanning dynamic optimality (see e.g., [5, 8, 4, 9]). Very recently, Levy and Tarjan [11] gave a compelling intuitive explanation for why $\mathsf{Funnel}(X)$ is related to the amortized analysis of splay trees (see Section 4). Despite all this, the Funnel bound remained elusive and no progress was made on Wilber's conjectures for nearly 40 years (To the best of our knowledge, the only properties that were previously known about the Funnel bound is that it is optimal in the "key-independent" setting [7] and "approximately monotone" [11], both are prerequisites for dynamic optimality.)



the funnel of p has 5 points (highlighted)
Sorted by increasing y-coordinate: L, R, R, L, L.
This forms 3 groups [L], [R, R], [L, L], so $f(p) = 3$.

Figure 3 Computing $f(p)$ for $p = (4, 9)$ in the geometric view of $X = (4, 6, 3, 5, 1, 7, 2, 4, 6, 3)$. Notice how the funnel points form a staircase-like front on either side of p.

Our main contribution affirmatively answers Wilber's first question, and settles the relationship between the Alternation bound and the Funnel bound:

▶ **Theorem 1** (Funnel dominates Alt). *For every access sequence X without repeats*[3] *and for every tree $\mathcal{T}$, $\mathsf{Alt}_{\mathcal{T}}(X) \le O(\mathsf{Funnel}(X) + m)$.*

▶ **Theorem 2** (Tight separation). *There is an access sequence $\tilde{X}$ for which $\mathsf{Funnel}(\tilde{X}) \ge \Omega(\lg\lg n) \cdot (\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) + m)$ simultaneously for all trees $\mathcal{T}$.*

The latter separation is tight up to constant factors, since Tango trees imply that $\mathsf{OPT}(X) \le O(\lg\lg n) \cdot \mathsf{Alt}(X)$. An interesting corollary of Theorem 2 is that the analysis of Tango trees cannot be improved by choosing *any* reference tree, answering an open question of Iacono [8]. (One attractive idea is to choose a *random* reference tree instead of the canonical balanced BST, but Theorem 2 shows that this will not help in general.)

A symmetric characterization of the Funnel bound

The geometric equivalence of dynamic optimality (through "arborally satisfied" rectangles [5]) makes it clear that $\mathsf{OPT}(X)$ is *invariant* under geometric transformations of the access sequence X. Indeed, a fundamental barrier in understanding the Funnel bound and its claim to optimality is that it was unclear whether Wilber's bounds were invariant under *rotations* of the access sequence X. Demaine et al. explicitly pointed out this challenge:

> "It is also unclear how [Wilber's] bounds are affected by 90-degree rotations of the point set representing the access sequence and, for the Funnel bound, by *flips*. Computer search reveals many examples where the bounds change slightly, and proving that they change by only a constant factor seems daunting." [5]

This shows that *exact* symmetry of $\mathsf{Funnel}(X)$ is hopeless, and can only hold in some "amortized" sense. Indeed, the heart of our paper, which is also a key ingredient in the proof of Theorem 1, is a new *symmetric* characterization of the Funnel bound, which proves

[3] As explained at the beginning of Section 2, it is fine for our purposes to focus on access sequences where each value appears only once.

that, up to a $\pm O(m)$ additive term, it is indeed invariant to rotations. More formally, we show that for any access sequence X, $\mathsf{Funnel}(X)$ is asymptotically equal to the number of occurrences in G_X of a configuration of 4 points that we call a **z-rectangle**[4] (see Figure 4).

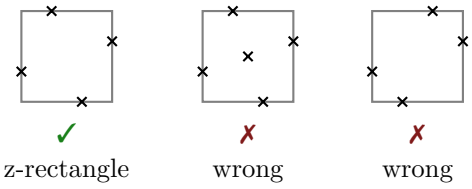


Figure 4 A z-rectangle is a configuration of 4 points. Its interior must be empty, and the relative order of the four points matters.

A crucial difference between z-rectangles and the notion of *independent rectangles* [5] is that the latter have to satisfy additional *independence* constaints across several rectangles, whereas z-rectangles have no "global" constraints whatsoever. In other words, z-rectangles are a *local* feature of the access sequence, in the sense that their existence and contribution to the lower bound are unaffected by other z-rectangles and by points outside of it. We believe this key property will make the analysis of online BST algorithms more tractable, as it gives a simpler competitive benchmark. We next describe an initial step in this direction.

Towards dynamic optimality of the Funnel Bound

One consequence of the simplicity of the z-rectangle characterization of the Funnel bound is that it makes it easier to compare it both to other BST lower bounds and to candidate algorithms for dynamic optimality. As a proof of concept, we show that when there is only a constant number of z-rectangle in G_X, then $\mathsf{IRB}_{\nearrow}(X)$ is linear, where $\mathsf{IRB}_{\nearrow}$ is one of the terms in the *Independent Rectangle* bound $\mathsf{IRB}(X) := \mathsf{IRB}_{\nearrow}(X) + \mathsf{IRB}_{\nwarrow}(X)$, which is known to dominate both of Wilber's bounds [5] (we define $\mathsf{IRB}_{\nearrow}(X)$ in the last section of the full version [10]). More formally,

▶ **Theorem 3.** *If G_X contains $O(1)$ z-rectangles, then $\mathsf{IRB}_{\nearrow}(X) \leq O(m)$.*

We remark that the proof of this theorem already introduces a nontrivial charging argument that could (hopefully) be generalized to prove that Funnel matches IRB, as conjectured by previous works [8].

Techniques

At a very high level, the main ideas in Theorem 1 are to use the self-reducible structure of the Alternation bound, and to show that interleaving two access sequences $X_{\mathtt{L}}$ and $X_{\mathtt{R}}$ on *disjoint ranges* is a super-additive operation, i.e., it increases the overall value of $\mathsf{Funnel}(X)$ to more than the sum of its parts $\mathsf{Funnel}(X_{\mathtt{L}}) + \mathsf{Funnel}(X_{\mathtt{R}})$. This argument involves both X and its *reverse* (flip), hence our new symmetric characterization of the Funnel bound (through z-rectangles) is key to the proof. The main idea behind Theorem 2 is to form hard sequences over geometrically-spaced sets of keys $\{i+1, i+2, i+4, i+8, \ldots\}$, each of which can "force" $\mathsf{Alt}_{\mathcal{T}}$ to pick a very lopsided reference tree $\mathcal{T}$. Those sequences can then be

[4] We thank an anonymous reviewer for informing us that z-rectangles have been discussed in the past under the name "pinwheel configuration", though (to the best of their knowledge) never in writing.

concatenated together so that the average value of $\mathsf{Alt}_{\mathcal{T}}$ is provably low whichever $\mathcal{T}$ was picked. Finally, the key idea in Theorem 3 is to study the consequences of the *absence* of z-rectangles on the combinatorial structure of point set G_X, and use this to bound the value of $\mathsf{IRB}_{\not\square}(X)$ by a charging argument.

Remark on independent work

In a concurrent and independent work, Chalermsook, Chuzhoy and Saranurak [3] obtain a (weaker) $\Theta(\lg\lg n/\lg\lg\lg n)$ separation between Alt and Funnel, in the same spirit as the tight separation we give in Theorem 2. Our works are otherwise unrelated.

2 Preliminaries

To make our definitions and proofs easier, we will work directly in the geometric representation of access sequences as (finite) sets of points in the plane $\mathbb{R}^2$.

▶ **Definition 4** (geometric view). *Any access sequence $X = (x_1, \ldots, x_m) \in [n]^m$ can be represented as the set of points $G_X = \{(x_i, i) \mid i \in [n]\}$, where the x-axis represents the key and the y-axis represents time (see Figure 1).*

By construction, in G_X, no two points share the same y-coordinate. We will say such a set has "distinct y-coordinates". In addition, we note that it is fine to restrict our attention to sequences X without repeated values.[5] The geometric view G_X of such sequences also has no two points with the same x-coordinate. We will say that such a set has "distinct x- and y-coordinates".

▶ **Definition 5** (x- and y-coordinates). *For a point $p \in \mathbb{R}^2$, we will denote its x- and y-coordinates as $p.x$ and $p.y$. Similarly, we define $P.x = \{p.x \mid p \in P\}$ and $P.y = \{p.y \mid p \in P\}$.*

We start by defining the *mixing value* of two sets: a notion of how much two sets of numbers are interleaved. It will be useful in defining both the Alternation bound and the Funnel bound. We define it in a few steps.

▶ **Definition 6** (mixing string). *Given two disjoint finite sets of real numbers L, R, let $\mathrm{mix}(L, R)$ be the string in $\{\mathtt{L}, \mathtt{R}\}^*$ that is obtained by taking the union $L \cup R$ in increasing order and replacing each element from L by $\mathtt{L}$ and each element from R by $\mathtt{R}$. For example, $\mathrm{mix}(\{2, 3, 8\}, \{1, 5\}) = \mathtt{RLLRL}$.*

▶ **Definition 7** (number of blocks). *Given a string $s \in \{\mathtt{L}, \mathtt{R}\}^*$, we define $\mathrm{blocks}(s)$ as the number of contiguous blocks of the same symbol in s. Formally,*

$$\mathrm{blocks}(s) := \begin{cases} 0 & \text{if } s \text{ is empty} \\ 1 + \#\{i \mid s_i \neq s_{i+1}\} & \text{otherwise.} \end{cases}$$

For example, $\mathrm{blocks}(\mathtt{LLLRLL}) = 3$. Note that if we insert characters into s, $\mathrm{blocks}(s)$ can only increase.

▶ **Definition 8** (mixing value). *Let $\mathrm{mixValue}(L, R) := \mathrm{blocks}(\mathrm{mix}(L, R))$ (see Figure 5).*

The mixing value has some convenient properties, which we will use later:

[5] Indeed, Appendix E in [4] gives a simple operation that transforms any sequence X into a sequence $\mathrm{split}(X)$ without repeats such that $\mathsf{OPT}(\mathrm{split}(X)) = \Theta(\mathsf{OPT}(X))$. Thus if we found a tight lower bound $L(X)$ for sequences without repeats, a tight lower bound for general X could be obtained as $L(\mathrm{split}(X))$.

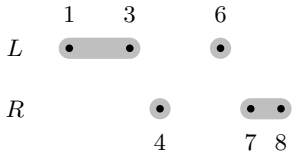

Figure 5 A visualization of $\text{mixValue}(\{1,3,6\},\{4,7,8\}) = 4$.

▶ **Fact 9** (properties of mixValue). *Function* $\text{mixValue}(L,R)$ *is:*

(a) *symmetric:* $\text{mixValue}(L,R) = \text{mixValue}(R,L)$*;*

(b) *monotone: if* $L_1 \subseteq L_2$ *and* $R_1 \subseteq R_2$*, then* $\text{mixValue}(L_1,R_1) \leq \text{mixValue}(L_2,R_2)$*;*

(c) *subadditive under concatenation: if* $L_1, R_1 \subseteq (-\infty, x]$ *and* $L_2, R_2 \subseteq [x, +\infty)$*, then* $\text{mixValue}(L_1 \cup L_2, R_1 \cup R_2) \leq \text{mixValue}(L_1,R_1) + \text{mixValue}(L_2,R_2)$.

Finally, $\text{mixValue}(L,R) \leq 2 \cdot \min(|L|,|R|) + 1$.

We now give precise definitions of Wilber's two bounds.[6]

▶ **Definition 10** (Alternation bound). *Let* P *be a point set with distinct* y*-coordinates, and let* $\mathcal{T}$ *be a binary tree in which leaves are labeled with elements of* $P.x$ *in increasing order, and each non-leaf node has two children.*

We define $\mathsf{Alt}_{\mathcal{T}}(P)$ *using the recursive structure of* $\mathcal{T}$*. If* $\mathcal{T}$ *is a single node, let* $\mathsf{Alt}_{\mathcal{T}}(P) := 0$*. Otherwise, let* $\mathcal{T}_{\mathtt{L}}$ *and* $\mathcal{T}_{\mathtt{R}}$ *be the left and right subtrees at the root. Partition* P *into two sets* $P_{\mathtt{L}} := \{p \in P \mid p.x \in \mathcal{T}_{\mathtt{L}}\}$ *and* $P_{\mathtt{R}} := \{p \in P \mid p.x \in \mathcal{T}_{\mathtt{R}}\}$*. Define quantity*

$$a(P,\mathcal{T}) := \text{mixValue}(P_{\mathtt{L}}.y, P_{\mathtt{R}}.y),$$

which describes how much $P_{\mathtt{L}}$ *and* $P_{\mathtt{R}}$ *are interleaved in time. Then*

$$\mathsf{Alt}_{\mathcal{T}}(P) := a(P,\mathcal{T}) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{L}}}(P_{\mathtt{L}}) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{R}}}(P_{\mathtt{R}}). \tag{1}$$

In addition, for an access sequence X*, let* $\mathsf{Alt}_{\mathcal{T}}(X) := \mathsf{Alt}_{\mathcal{T}}(G_X)$.

▶ **Definition 11** (axis-aligned rectangle delimited two points). *Given two points* p *and* q *with distinct* x*- and* y*- coordinates, let* $\square pq$ *be the smallest axis-aligned rectangle that contains both* p *and* q*. Formally,*

$$\square pq := [\min(p.x,q.x), \max(p.x,q.x)] \times [\min(p.y,q.y), \max(p.y,q.y)].$$

▶ **Definition 12** (empty rectangles). *Let* P *be a point set. Given* $p,q \in P$*, we say* $\square pq$ *is empty*[7] *in* P *if* $P \cap \square pq = \{p,q\}$ *(see Figure 6).*

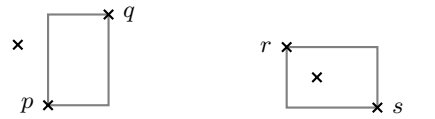
For the next definitions, it is helpful to refer back to Figure 3. In particular, $F_{\mathtt{L}}(P,p)$ and $F_{\mathtt{R}}(P,p)$ (the left and right funnel) correspond to the points marked with `L` and `R`.

▶ **Definition 13** (left and right funnel). *Let* P *be a point set. For each* $p \in P$*, we say that access* $q \in P$ *is in the left (resp. right) funnel of* p *within* P *if* q *is to the lower left (resp. lower right) of* p *and* $\square pq$ *is empty. Formally, let*

$$F_{\mathtt{L}}(P,p) := \{q \in P \mid q.y < p.y \wedge q.x < p.x \wedge P \cap \square pq = \{p,q\}\}$$

[6] These definitions may differ by a constant factor or an additive $\pm O(m)$ from the definitions the reader has seen before. We will ignore such differences, because the cost of a BST also varies by $\pm O(m)$ depending on the definition, and the interesting regime is when $\mathsf{OPT}(X) = \omega(m)$.

[7] This corresponds to the notion of "unsatisfied rectangle" in [5].



$\square pq$ is empty $\square rs$ is *not* empty

Figure 6 Some axis-aligned rectangles.

and

$$F_{\mathtt{R}}(P,p) \coloneqq \{q \in P \mid q.y < p.y \wedge q.x > p.x \wedge P \cap \square pq = \{p,q\}\}.$$

We will collectively call $F_{\mathtt{L}}(P,p) \cup F_{\mathtt{R}}(P,p)$ *the funnel of* p *within* P*.*

▶ **Definition 14** (Funnel bound)**.** *Let* P *be a point set with distinct* y*-coordinates. For each* $p \in P$*, define quantity*

$$f(P,p) \coloneqq \text{mixValue}(F_{\mathtt{L}}(P,p).y, F_{\mathtt{R}}(P,p).y),$$

which describes how much the left and right funnel of p *are interleaved in time. Then*

$$\mathsf{Funnel}(P) \coloneqq \sum_{p \in P} f(P,p).$$

In addition, for an access sequence X*, let* $\mathsf{Funnel}(X) \coloneqq \mathsf{Funnel}(G_X)$*.*

3 The Funnel bound dominates the Alternation bound

We prove that Funnel dominates Alt in two parts: in Section 3.1 we show that $\mathsf{Alt}(X)$ is dominated by the sum $\mathsf{Funnel}(X) + \mathsf{Funnel}(\overline{X})$, where $\overline{X}$ is the reverse of X, then in Section 3.2 we prove that $\mathsf{Funnel}(\overline{X}) \approx \mathsf{Funnel}(X)$ using our new characterization of Funnel by z-rectangles.

3.1 Upper-bounding the Alternation bound by a sum of two Funnel bounds

▶ **Definition 15** (time reversal)**.** *The time reversal of a point* $p \in \mathbb{R}^2$ *is* $\overline{p} \coloneqq (p.x, -p.y)$.[8] *The time reversal of a point set* P *is* $\overline{P} \coloneqq \{\overline{p} \mid p \in P\}$ *(see Figure 7).*

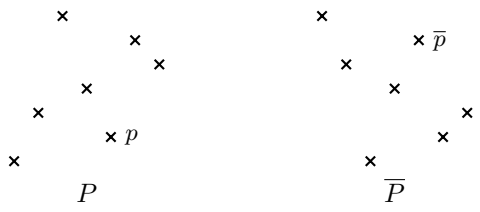


Figure 7 A point set and its time reversal.

We first prove the following lemma.

[8] The notation is inspired from the notion of complex conjugate, which is also a vertical flip.

▶ **Lemma 16.** *Let P be a point set with distinct y-coordinates, and let $\mathcal{T}$ be a tree that satisfies the conditions of Definition 10. Then* $\mathsf{Funnel}(P) + \mathsf{Funnel}(\overline{P}) \geq \mathsf{Alt}_{\mathcal{T}}(P)$.

Even though the formal proof of this lemma is a relatively involved case analysis, it is easy to understand geometrically. The key observation is the following. Consider two sequences $X_{\mathtt{L}}$ and $X_{\mathtt{R}}$ on disjoint ranges, and interleave to form a single sequence X. Then the more times we switch from elements of $X_{\mathtt{L}}$ to elements of $X_{\mathtt{R}}$, the bigger $\mathsf{Funnel}(X) + \mathsf{Funnel}(\overline{X})$ is going to be.

To see this, let's look at the geometric view of X (see Figure 8). Let p and q be two consecutive points on the $X_{\mathtt{L}}$ side that are separated by a streak of points from $X_{\mathtt{R}}$ (i.e. all accesses between p and q vertically are from $X_{\mathtt{R}}$). First, assume $p.x > q.x$. Then q is in the left funnel of p, and at least of the points on the $X_{\mathtt{R}}$ between p and q must be in the right funnel of p, which forms a completely new group of funnel points compared to what p had in $X_{\mathtt{L}}$. This means that the contribution of p to $\mathsf{Funnel}(X)$ is at least one higher than its contribution to $\mathsf{Funnel}(X_{\mathtt{L}})$.

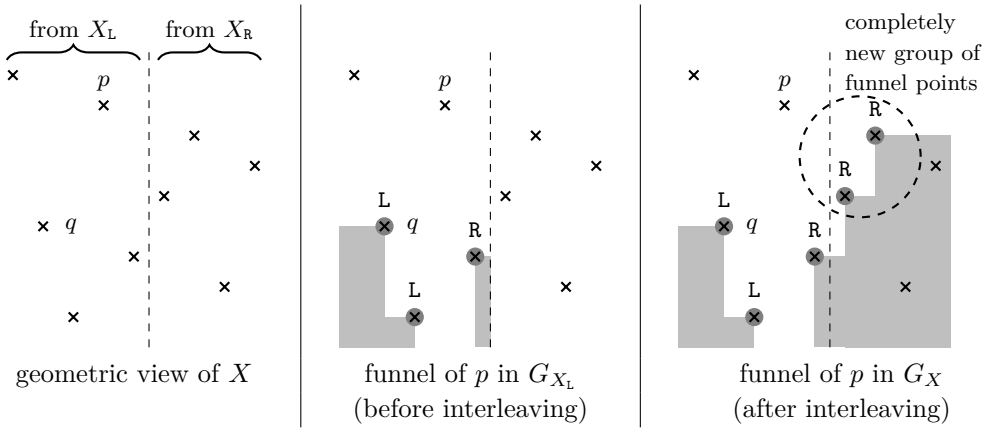

Figure 8 Interleaving sequences $X_{\mathtt{L}} = (3, 5, 2, 4, 1)$ and $X_{\mathtt{R}} = (8, 6, 9, 7)$ into $X = (3, 8, 5, 2, 6, 9, 7, 4, 1)$. The contribution of p to $\mathsf{Funnel}(X_{\mathtt{L}})$ is 3, while the contribution of p to $\mathsf{Funnel}(X)$ is 4.

What if $p.x < q.x$ instead? Then it turns out that an analogous argument can be made on q if we take the time reversal of X. That is, the contribution of $\overline{q}$ to $\mathsf{Funnel}(\overline{X})$ is at least one higher than its contribution to $\mathsf{Funnel}(\overline{X_{\mathtt{L}}})$. Indeed, if we flip the point set vertically, then p and q exchange roles, which means $p.x > q.x$ once again.

To conclude, it remains to observe that the $a(P, p)$ term in the recursive definition of $\mathsf{Alt}_{\mathcal{T}}(X)$ is precisely a measure of how much the subsequences $X_{\mathtt{L}}$ and $X_{\mathtt{R}}$ corresponding to the left and right subtree at the root of $\mathcal{T}$ are interleaved. So we can apply the argument above by induction to show that $\mathsf{Funnel}(X) + \mathsf{Funnel}(\overline{X}) \geq \mathsf{Alt}_{\mathcal{T}}(X)$. We now reluctantly move to the formal proof.

Proof of Lemma 16. We prove this by induction on $\mathcal{T}$. The base case is $\mathcal{T}$ made of a single node. In this case, $\mathsf{Alt}_{\mathcal{T}}(P) = 0$ by definition, so the inequality trivially holds.

Now consider a general tree $\mathcal{T}$, and define $\mathcal{T}_{\mathtt{L}}$, $\mathcal{T}_{\mathtt{R}}$, $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ as in Definition 10. Note that each leaf of $\mathcal{T}$ has a label in $P.x$ and $\mathcal{T}_{\mathtt{L}}$ and $\mathcal{T}_{\mathtt{R}}$ must each have at least one leaf, so $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ are not empty. Let's apply the induction hypothesis on $(P_{\mathtt{L}}, \mathcal{T}_{\mathtt{L}})$ and $(P_{\mathtt{R}}, \mathcal{T}_{\mathtt{R}})$. This means that

$$\mathsf{Funnel}(P_{\mathtt{L}}) + \mathsf{Funnel}(\overline{P_{\mathtt{L}}}) \geq \mathsf{Alt}_{\mathcal{T}_{\mathtt{L}}}(P_{\mathtt{L}})$$
$$\mathsf{Funnel}(P_{\mathtt{R}}) + \mathsf{Funnel}(\overline{P_{\mathtt{R}}}) \geq \mathsf{Alt}_{\mathcal{T}_{\mathtt{R}}}(P_{\mathtt{R}}).$$

Thus we find that

$$\begin{aligned}\mathsf{Alt}_{\mathcal{T}}(P) &= a(P,\mathcal{T}) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{L}}}(P_{\mathtt{L}}) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{R}}}(P_{\mathtt{R}}) && \text{(by definition)}\\ &\leq a(P,\mathcal{T}) + \mathsf{Funnel}(P_{\mathtt{L}}) + \mathsf{Funnel}(\overline{P_{\mathtt{L}}}) + \mathsf{Funnel}(P_{\mathtt{R}}) + \mathsf{Funnel}(\overline{P_{\mathtt{R}}}) && (2)\end{aligned}$$

▷ Claim 17. If $p \in P_{\mathtt{L}}$, then

$$f(P,p) \geq f(P_{\mathtt{L}},p) \quad \text{and} \quad f(\overline{P},\overline{p}) \geq f(\overline{P_{\mathtt{L}}},\overline{p});$$

and if $p \in P_{\mathtt{R}}$, then

$$f(P,p) \geq f(P_{\mathtt{R}},p) \quad \text{and} \quad f(\overline{P},\overline{p}) \geq f(\overline{P_{\mathtt{R}}},\overline{p}).$$

Proof. We will deal with the first case (the other three cases are symmetric). The key is that $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ operate on disjoint ranges of x-coordinates.

- The left funnel of p within $P_{\mathtt{L}}$ is identical to its left funnel within P, since all elements of $P_{\mathtt{R}}$ are to the right of p. Formally, $F_{\mathtt{L}}(P_{\mathtt{L}},p) = F_{\mathtt{L}}(P,p)$.
- All points q that were in the right funnel of p within $P_{\mathtt{L}}$ will still be part of the right funnel of p within P. Indeed, the only way for them to stop being funnel points would be to add accesses inside the rectangle delimited by p and q. This doesn't happen because all points in $P_{\mathtt{R}}$ are strictly to the right of all points in $P_{\mathtt{L}}$. Formally, $F_{\mathtt{R}}(P_{\mathtt{L}},p) \subseteq F_{\mathtt{R}}(P,p)$.

Therefore, $\mathrm{mix}(F_{\mathtt{L}}(P_{\mathtt{L}},p).y, F_{\mathtt{R}}(P_{\mathtt{L}},p).y)$ is a subsequence of $\mathrm{mix}(F_{\mathtt{L}}(P,p).y, F_{\mathtt{R}}(P,p).y)$, which means that

$$f(P_{\mathtt{L}},p) = \mathrm{blocks}(\mathrm{mix}(F_{\mathtt{L}}(P_{\mathtt{L}},p), F_{\mathtt{R}}(P_{\mathtt{L}},p))) \leq \mathrm{blocks}(\mathrm{mix}(F_{\mathtt{L}}(P,p), F_{\mathtt{R}}(P,p))) = f(P,p).$$

◁

Summing up $f(P,p)$ and $f(\overline{P},\overline{p})$ over all points $p \in P$, we obtain

$$\begin{aligned}\mathsf{Funnel}(P) &= \sum_{p\in P} f(P,p) \geq \sum_{p\in P_{\mathtt{L}}} f(P_{\mathtt{L}},p) + \sum_{p\in P_{\mathtt{R}}} f(P_{\mathtt{R}},p) = \mathsf{Funnel}(P_{\mathtt{L}}) + \mathsf{Funnel}(P_{\mathtt{R}})\\ \mathsf{Funnel}(\overline{P}) &= \sum_{p\in P} f(\overline{P},\overline{p}) \geq \sum_{p\in P_{\mathtt{L}}} f(\overline{P_{\mathtt{L}}},\overline{p}) + \sum_{p\in P_{\mathtt{R}}} f(\overline{P_{\mathtt{R}}},\overline{p}) = \mathsf{Funnel}(\overline{P_{\mathtt{L}}}) + \mathsf{Funnel}(\overline{P_{\mathtt{R}}}).\end{aligned} \tag{3}$$

This, combined with (2), gives

$$\begin{aligned}\mathsf{Funnel}(P) + \mathsf{Funnel}(\overline{P}) &\geq \mathsf{Funnel}(P_{\mathtt{L}}) + \mathsf{Funnel}(P_{\mathtt{R}}) + \mathsf{Funnel}(\overline{P_{\mathtt{L}}}) + \mathsf{Funnel}(\overline{P_{\mathtt{R}}})\\ &\geq \mathsf{Alt}_{\mathcal{T}}(P) - a(P,\mathcal{T})\end{aligned}$$

This falls $a(P,\mathcal{T})$ short of our goal (which makes sense, since we haven't used the interleaving of $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ yet). To fix this, we will show the following claim.

▷ Claim 18. Consider the following properties defined over a point $p \in P$:

(a) $p \in \mathcal{T}_{\mathtt{L}}$ and $f(P,p) \geq f(P_{\mathtt{L}},p) + 1$;
(b) $p \in \mathcal{T}_{\mathtt{L}}$ and $f(\overline{P},\overline{p}) \geq f(\overline{P_{\mathtt{L}}},\overline{p}) + 1$;
(c) $p \in \mathcal{T}_{\mathtt{R}}$ and $f(P,p) \geq f(P_{\mathtt{R}},p) + 1$;
(d) $p \in \mathcal{T}_{\mathtt{R}}$ and $f(\overline{P},\overline{p}) \geq f(\overline{P_{\mathtt{R}}},\overline{p}) + 1$.

The sum of the number of points in P having each property (a)–(d) is at least $a(P, \mathcal{T})$.

Proof. Let's number the points of P by increasing y-coordinate (i.e. in chronological order) as $p_1, \dots, p_m$. Recall that $a(P, \mathcal{T}) = \text{mixValue}(P_{\mathtt{L}}.y, P_{\mathtt{R}}.y)$. Also, $P_{\mathtt{L}}$ and $P_{\mathtt{R}}$ are non-empty, so $a(P, \mathcal{T}) \geq 2$. This means that as we go through the points $p_1, \dots, p_m$, we switch $a(P, \mathcal{T}) - 1 \geq 1$ times between points of $P_{\mathtt{L}}$ and points of $P_{\mathtt{R}}$.

Therefore, there are exactly $a(P, \mathcal{T}) - 2$ pairs of indices (i, j) with $i + 1 < j$ such that

- case 1: $p_i, p_j \in P_{\mathtt{L}}$ but $p_{i+1}, \dots, p_{j-1} \in P_{\mathtt{R}}$, or
- case 2: $p_i, p_j \in P_{\mathtt{R}}$ but $p_{i+1}, \dots, p_{j-1} \in P_{\mathtt{L}}$,

which "straddle accesses of the opposite side". Also, there is an index $i^* > 1$ (the "first element of the side that starts appearing later") such that

- case 3: $p_{i^*} \in P_{\mathtt{L}}$ but $p_1, \dots, p_{i^*-1} \in P_{\mathtt{R}}$, or
- case 4: $p_{i^*} \in P_{\mathtt{R}}$ but $p_1, \dots, p_{i^*-1} \in P_{\mathtt{L}}$

and similarly, there is an index $j^* < m$ (the "last element of the side that finishes appearing earlier") such that

- case 5: $p_{j^*} \in P_{\mathtt{L}}$ but $p_{j^*+1}, \dots, p_m \in P_{\mathtt{R}}$, or
- case 6: $p_{j^*} \in P_{\mathtt{R}}$ but $p_{j^*+1}, \dots, p_m \in P_{\mathtt{L}}$.

This makes for a total of $a(P, \mathcal{T}) - 2 + 1 + 1 = a(P, \mathcal{T})$ occurrences of one of the six cases. We will show that each of them leads to a point p satisfying one of the properties (a)–(d). More precisely, we claim that:

- case 1 implies p_j has property (a) or p_i has property (b);
- case 2 implies p_j has property (c) or p_i has property (d);
- case 3 implies p_{i^*} has property (a);
- case 4 implies p_{i^*} has property (c);
- case 5 implies p_{j^*} has property (b);
- case 6 implies p_{j^*} has property (d).

We will show this for case 1 and case 3. The other four cases are analogous. To treat case 1, let's separate into more cases.[9]

- If $p_i.x < p_j.x$, then p_i is in the left funnel of p_j within both P and $P_{\mathtt{L}}$. But within P, p_{j-1} would be an additional right funnel point. Since it has a higher index than p_i, this would add at least 1 to $f(P, p_j)$ compared to $f(P_{\mathtt{L}}, p_j)$. In other words, $f(P, p_j) \geq f(P_{\mathtt{L}}, p_j) + 1$ (scenario (a)).
- If $p_i.x > p_j.x$, then we can use the same argument as above on $\overline{P}$ and $\overline{P_{\mathtt{L}}}$ by swapping i and j, obtaining $f(\overline{P}, \overline{p_i}) \geq f(P_{\mathtt{L}}, \overline{p_i}) + 1$ (scenario (b)).
- If $p_i.x = p_j.x$, then both funnels of p_j within $P_{\mathtt{L}}$ are completely empty, which means that $f(P_{\mathtt{L}}, p_j) = 0$, while the right funnel of p_j in P would contain at least p_{j-1}. Therefore, $f(P, p_j) = 1 \geq f(P_{\mathtt{L}}, p_j) + 1$ (scenario (a)).

To treat case 3, it suffices to observe that both funnels of p_{i^*} within $P_{\mathtt{L}}$ would be completely empty (for lack of lower points), so $f(P_{\mathtt{L}}, p_{i^*}) = 0$, while in P the right funnel of x_{i^*} would contain at least p_{i^*-1}. Therefore, $f(P, p_{i^*}) \geq 1 = f(P_{\mathtt{L}}, p_{i^*}) + 1$ (scenario (a)). ◁

Now, if we sum up $f(P, p)$ and $f(\overline{P}, \overline{p})$ over all points p as we did in (3), but this time also apply Claim 18, we obtain that

$$\mathsf{Funnel}(P) + \mathsf{Funnel}(\overline{P}) \geq \mathsf{Funnel}(P_{\mathtt{L}}) + \mathsf{Funnel}(P_{\mathtt{R}}) + \mathsf{Funnel}(\overline{P_{\mathtt{L}}}) + \mathsf{Funnel}(\overline{P_{\mathtt{R}}}) + a(P, \mathcal{T}).$$

Combined with (2), this gives the desired result and concludes the inductive step. ◀

[9] We wish we were joking.

3.2 Characterizing the Funnel bound using z-rectangles

Lemma 16 asserts that all possible Alternation bounds for all choices of reference trees $\mathcal{T}$, are simultaneously upper-bounded by the sum of two specific Funnel bounds. While this is already a nontrivial bound, $\mathsf{Funnel}(P)$ and $\mathsf{Funnel}(\overline{P})$ could in principle be wildly different, and it is therefore more compelling to show that the *single* quantity $\mathsf{Funnel}(P)$ already provides an upper bound. (It is curious that the symmetry properties of the Funnel bound, which are a necessary precondition for dynamic optimality, already enter the picture in determining the relationship between Wilber's bounds.)

To achieve this, we need to think about how geometric transformations affect the value of the Funnel bound. It is clear from the definition that $\mathsf{Funnel}(P)$ is unaffected by a horizontal flip. Indeed, the left funnel would become the right funnel and vice versa, so this wouldn't affect the number of times we switch between the two: the quantity $f(P, p)$ would remain the same for each p (see Figure 9).

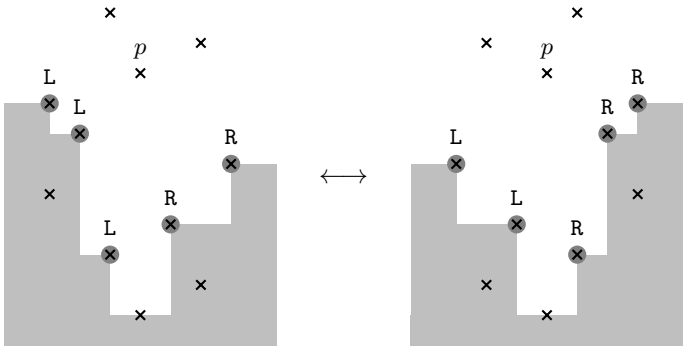

Figure 9 Flipping the geometric view horizontally conserves the contribution $f(P, p)$ of each point: the only change is that the labels of the funnel points flip between `L` and `R`.

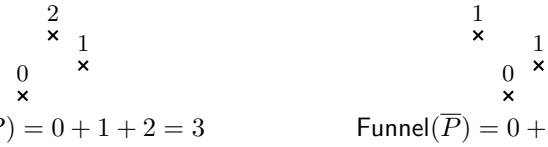
On the other hand, it is far from obvious that the Funnel bound is unaffected by a vertical flip. Because of the time reversal, the notion of funnel changes completely. And indeed, the precise value will change, as is shown in Figure 10.



$\mathsf{Funnel}(P) = 0 + 1 + 2 = 3$ $\quad$ $\mathsf{Funnel}(\overline{P}) = 0 + 1 + 1 = 2$

Figure 10 A minimal example such that $\mathsf{Funnel}(P) \neq \mathsf{Funnel}(\overline{P})$ is $P = \{(1, 1), (3, 2), (2, 3)\}$. Each access p is labeled with its contribution $f(P, p)$ (left) or $f(\overline{P}, p)$ (right).

Nevertheless, we will show that for any point set P with distinct x- and y-coordinates, $\mathsf{Funnel}(P)$ and $\mathsf{Funnel}(\overline{P})$ are equal up to an additive $O(m)$. We do this by introducing a new characterization of the Funnel bound that is naturally invariant under *90° rotations* of the point set. This new characterization is the number of *z-rectangles*.

▶ **Definition 19** (z-rectangle). *Let P be a point set. We call tuple $(p, q, r, s) \in P^4$ a z-rectangle of P if the following conditions hold:*

(a) $q.x < p.x < r.x < s.x$;

(b) $r.y < q.y < s.y < p.y$;

(c) $P \cap [q.x, s.x] \times [r.y, p.y] = \{p, q, r, s\}$.

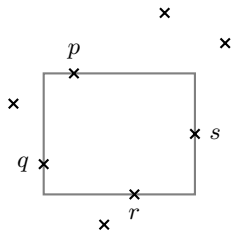


Figure 11 A z-rectangle. The relative order of points p, q, r, s horizontally and vertically matters.

In other words, a z-rectangle is a subsequence of 4 accesses with key values in relative order $3, 1, 4, 2$ and such that the axis-aligned rectangle that they span is empty (see Figure 11 for an example). We define the corresponding quantity, which we will prove is equivalent to the Funnel bound.

▶ **Definition 20** (z-rectangle bound). *For any point set P with distinct x- and y-coordinates,*[10] *let*

$$\mathsf{zRects}(P) := |\{(p, q, r, s) \mid (p, q, r, s) \text{ is a z-rectangle of } P\}|.$$

First, we formally state the rotation-invariance of z-rectangles.

▶ **Definition 21** (counter-clockwise 90° rotation). *For a point $p \in \mathbb{R}^2$, let $p^\perp := (-p.y, p.x)$. Analogously, for a point set P, let $P^\perp := \{p^\perp \mid p \in P\}$.*

▶ **Lemma 22.** *For any point set P, $\mathsf{zRects}(P) = \mathsf{zRects}(P^\perp)$.*

Proof. Each z-rectangle of P induces a z-rectangle in $P^\perp$ and vice-versa: z-rectangle (p, q, r, s) in P becomes z-rectangle $(s^\perp, p^\perp, q^\perp, r^\perp)$ in $P^\perp$ (the reader is encouraged to physically rotate the page containing figure 11 in order to convince themselves of this fact). Therefore, P and $P^\perp$ have the same number of z-rectangles. ◀

The relation between $\mathsf{Funnel}(P)$ and $\mathsf{zRects}(P)$ is proved in the following two lemmas.

▶ **Lemma 23.** $\mathsf{zRects}(P) \geq \mathsf{Funnel}(P)/2 - O(m)$.

▶ **Lemma 24.** $\mathsf{Funnel}(P) \geq 2 \cdot \mathsf{zRects}(P)$.

We will use the fact that P has distinct x- and y- coordinates.

Proof of Lemma 23. We will show that for each $p \in P$, the funnel of p induces at least $\lfloor f(P, p)/2 \rfloor - 1$ different z-rectangles of the form $(p, \cdot, \cdot, \cdot)$. Summing this up for each p then completes the proof.

Let's assume $f(P, p) \geq 4$; otherwise the claim holds vacuously. Let's number the points in $F_{\mathtt{L}}(P, p) \cup F_{\mathtt{R}}(P, p)$ (the funnel of p) by increasing y-coordinate as $a_1, a_2, \ldots, a_l$. Note that l may be greater than $f(P, p)$, because a sequence of funnel points that are all on the same side of p counts only for 1 in $f(P, p)$.

[10] If the x- and y-coordinates are not distinct, $\mathsf{zRects}(P)$ may give absurd results. For example, if we start with any P and add a duplicate point $(x, y + \epsilon)$ for every point (x, y) of P (with ϵ small enough), then $\mathsf{zRects}(P)$ will drop to 0.

We will call $(i, j) \in [l]^2$ a *left-straddling pair* if $i + 1 < j$, $a_i.x > p.x$ and $a_j.x > p.x$, but for all $i < k < j$, $a_k.x < p.x$. That is, a_i and a_j are to the right of p but all funnel points between them in order of height are to the left of p. Because funnel points alternate $f(P, p) - 1$ times between the left and the right of p, there must be at least $\lfloor f(P, p)/2 \rfloor - 1$ left-straddling pairs.

We claim that if (i, j) is a left-straddling pair, then (p, a_{i+1}, a_i, a_j) is a z-rectangle. Since all left-straddling pairs have distinct i, this produces $\lfloor f(P, p)/2 \rfloor - 1$ distinct z-rectangles.

First, we verify that p, a_{i+1}, a_i, a_j have the correct relative positions. The order in y-coordinate is correct by definition of the numbering $a_1, \ldots, a_k$. For the order in x-coordinates, we know that a_{i+1} is to the left of p and a_i, a_j are to its right, so we only need to verify that $a_i.x < a_j.x$. This is true because a_i is in the funnel of p, so $\square pa_i$ must be empty. If $a_i.x > a_j.x$, then a_j would be in $\square pa_i$.

What we still need to prove is that rectangle $[a_{i+1}.x, a_j.x] \times [a_i.y, p.y]$ is empty (except for points p, a_{i+1}, a_i, a_j themselves). First, since a_i, a_{i+1} and a_j in the funnel of p, we know that $\square pa_i$, $\square pa_{i+1}$ and $\square pa_j$ are empty. This covers the zones pictured in Figure 12.

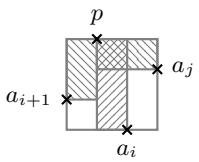

Figure 12 Proposed z-rectangle (p, a_{i+1}, a_i, a_j) with empty rectangles $\square pa_i$, $\square pa_{i+1}$ and $\square pa_j$ highlighted. If in addition we can prove that $\square a_i a_{i+1}$ and $\square a_i a_j$ are empty, then this is a valid z-rectangle.

Finally, we will prove that $\square a_i a_{i+1}$ and $\square a_i a_j$ are empty, which covers the missing parts.

- Assume $\square a_i a_{i+1}$ is not empty, and let b be the highest point of P in it (except for a_{i+1}). We have already shown that $\square pa_i$ and $\square pa_{i+1}$ are empty, so $\square pb$ must be empty. This means that b must be in the funnel of p. But $a_i.y < b.y < a_{i+1}.y$, so this contradicts the numbering by increasing y-coordinate.
- Assume $\square a_i a_j$ is not empty, and let b be the highest point of P in it (except for a_j). We have already shown that $\square pa_i$ and $\square pa_j$ are empty, so $\square pb$ must be empty. This means that b must be in the (right) funnel of p. But this contradicts our assumption that all funnel points between a_i and a_j in y-coordinate must be to the left of p.

Since points p, a_{i+1}, a_i, a_j and $[a_{i+1}.x, a_j.x] \times [a_i.y, p.y]$ is empty, (p, a_{i+1}, a_i, a_j) is a z-rectangle. This completes the proof of Lemma 23. ◀

Proof of Lemma 24. Essentially, the reason why this is true is because all z-rectangles must be exactly of the form described in the previous proof. We will prove something slightly weaker which still reaches the desired result. We will group the z-rectangles by their top point and show that if P has k rectangles of the form $(p, \cdot, \cdot, \cdot)$, then $f(P, p) \geq 2k$.

Fix p, and sort the k z-rectangles by the increasing y-coordinate of their bottom point r. Name their points (p, q_1, r_1, s_1) to (p, q_k, r_k, s_k). First, we will show that there can be no ties. Indeed, if $r_i.y = r_j.y$ then $r_i = r_j$. Also, when the p and r (top and bottom) points of a z-rectangle are fixed, then the other two points q and s are uniquely determined as the rightmost point in $(-\infty, p.x] \times [r.x, p.x]$ and the leftmost point in $[r.x, \infty) \times [r.x, p.x]$, respectively.

We will now prove that

$$q_1.y < s_1.y < q_2.y < s_2.y < \cdots < q_k.y < s_k.y. \tag{4}$$

The $q_i.y < s_i.y$ inequalities are true by the definition of a z-rectangle, so we only need to prove $s_i.y < q_{i+1}.y$. To do this, consider two consecutive z-rectangles (p, q_i, r_i, s_i) and $(p, q_{i+1}, r_{i+1}, s_{i+1})$ (see Figure 13). Since $r_i.y < r_{i+1}.y$, s_i can't be strictly to the right of r_{i+1}, because otherwise r_{i+1} would be inside z-rectangle (p, q_i, r_i, s_i). In turn, this means that s_i can't be strictly higher than r_{i+1} because otherwise it would be inside $\square pr_{i+1}$. Therefore, we have $s_i.y \leq r_{i+1}.y < q_{i+1}.y$.

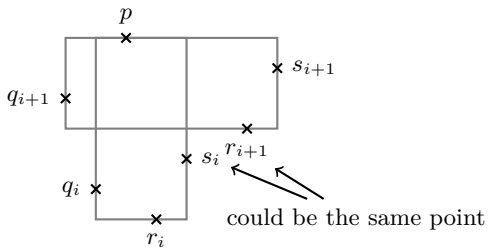

Figure 13 The only possible relative position of two z-rectangle with the same top point p.

Points $q_1, s_1, \ldots, q_k, s_k$ are all in the funnel of p by the definition of z-rectangle. Therefore, Equation (4) reveals $2k$ funnel points that alternate from the left to the right side of p with increasing y-coordinates. Thus $\mathrm{mix}(F_{\mathtt{L}}(P,p).y, F_{\mathtt{R}}(P,p).y)$ contains a subsequence $\mathtt{LRLR}\cdots\mathtt{LR}$ of length $2k$, and

$$f(P,p) = \mathrm{blocks}(\mathrm{mix}(F_{\mathtt{L}}(P,p).y, F_{\mathtt{R}}(P,p).y)) \geq \mathrm{blocks}(\underbrace{\mathtt{LRLR}\cdots\mathtt{LR}}_{\text{length } 2k}) = 2k.$$

Summing this up for each p completes the proof. ◀

▶ **Corollary 25.** $\mathsf{Funnel}(P) \geq \mathsf{Funnel}(\overline{P}) - O(m)$.

Proof. By the left-right symmetry of $\mathsf{Funnel}(\cdot)$, we know that $\mathsf{Funnel}(\overline{P}) = \mathsf{Funnel}(P^{\perp\perp})$, where $P^{\perp\perp}$ is P rotated by 180°. Therefore,

$$\begin{aligned}
\mathsf{Funnel}(P) &\geq 2 \cdot \mathsf{zRects}(P) && \text{(Lemma 24)}\\
&= 2 \cdot \mathsf{zRects}(P^{\perp\perp}) && \text{(Lemma 22)}\\
&\geq \mathsf{Funnel}(P^{\perp\perp}) - O(m) && \text{(Lemma 23)}\\
&= \mathsf{Funnel}(\overline{P}) - O(m). && \blacktriangleleft
\end{aligned}$$

We can now finally prove Theorem 1.

Proof of Theorem 1. By Lemma 16, $\mathsf{Alt}_{\mathcal{T}}(P) \leq \mathsf{Funnel}(P) + \mathsf{Funnel}(\overline{P})$. Combining this with Corollary 25, we obtain $\mathsf{Alt}_{\mathcal{T}}(P) \leq \mathsf{Funnel}(P) + (\mathsf{Funnel}(P) + O(m)) \leq O(\mathsf{Funnel}(P) + m)$. ◀

4 Separation between the Alternation bound and the Funnel bound

We will now define an access sequence $\tilde{X}$ such that the Alternation bound is too low for all reference trees $\mathcal{T}$ simultaneously. More precisely, we will define an access sequence $\tilde{X} \in [n]^m$ such that $\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) = O(m)$ for all trees $\mathcal{T}$ while on the other hand $\mathsf{OPT}(\tilde{X})$ and $\mathsf{Funnel}(\tilde{X})$ are $\Theta(m \lg\lg n)$. This $\lg\lg n$ factor is the biggest possible separation: indeed, Tango trees show that for a balanced tree $\mathcal{T}$, $\mathsf{Alt}_{\mathcal{T}}(X)$ is always within $O(\lg\lg n)$ of $\mathsf{OPT}(X)$.

To define $\tilde{X}$, we will need the notion of a *bit-reversal* sequence. This is a permutation that in a sense looks "maximally shuffled" to a binary search tree.

▶ **Definition 26.** *Let k be a positive integer and let $K = 2^k$. Then let* $\text{bitReversal}^k \in \{0, \cdots, K-1\}^K$ *be the sequence where* bitReversal^k_i *is the number obtained by taking the binary representation of $i-1$, padding it with leading zeroes to reach length k, flipping it, then converting this back to a number.*

It is easiest to understand through an example. Take $k = 2$, then bitReversal^2 is obtained this way:

$$(0,1,2,3) \xrightarrow{\text{to binary}} (00,01,10,11) \xrightarrow{\text{flip}} (00,10,01,11) \xrightarrow{\text{from binary}} (0,2,1,3).$$

The reason why we use this sequence is the following well-known fact.

▶ **Fact 27.** *Let $\mathcal{T}$ be the complete binary tree of height k which has K leaves labeled 0 through $K-1$. Then $\mathsf{Alt}_{\mathcal{T}}(\text{bitReversal}^k) = kK = K \lg K$.*

Proof. Because of the way bitReversal^k is defined, for each node $u \in \mathcal{T}$, the keys that are accessed below u as the sequence is processed constantly alternate from u's left subtree to u's right subtree. So the contribution of u is exactly the number of keys of its subtree. This way, every key is counted once at each of the $k = \lg K$ levels, so the total is $K \lg K$. ◀

We can now define our access sequence as follows. Let $n \coloneqq 2^K = 2^{2^k}$, and let

$$S_i \coloneqq (i + 2^{\text{bitReversal}^k_1}, i + 2^{\text{bitReversal}^k_2}, \ldots, i + 2^{\text{bitReversal}^k_K}).$$

Then, denoting concatenation by $\circ$, we define

$$\tilde{X} \coloneqq \underbrace{S_0 \circ \cdots \circ S_0}_{n \text{ times}} \circ \underbrace{S_1 \circ \cdots \circ S_1}_{n \text{ times}} \circ \cdots \circ \underbrace{S_{n/2} \circ \cdots \circ S_{n/2}}_{n \text{ times}}.$$

The range of $\tilde{X}$ is $[n]$ and its length is $m = (\frac{n}{2}+1) \cdot n \cdot K = \Theta(n^2 \lg n)$. See Figure 14 for an example with $k = 2$. We will prove that for all $\mathcal{T}$, $\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) \le O(m)$ while on the other hand $\mathsf{Funnel}(\tilde{X}) \ge \Omega(m \lg \lg n)$.

▶ **Lemma 28.** *For any $\mathcal{T}$, $\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) \le O(m)$.*

▶ **Lemma 29.** $\mathsf{Funnel}(\tilde{X}) \ge \Omega(m \lg \lg n)$.

The combination of Lemma 28 and Lemma 29 shows the separation claimed in Theorem 2. Before we move to the proofs of those lemmas, let's go over some intuition for the proof of Lemma 28, which is the more complicated one.

First, note that the only reason we use bitReversal^k in $\tilde{X}$ is to make $\mathsf{Funnel}(\tilde{X})$ large. Replacing bitReversal^k by any other permutation of $\{0, \ldots, K-1\}$ would not affect the proof of Lemma 28 in any way because that proof only looks at the *set* of keys that are hit by each of the parts $S_0, \ldots, S_{n/2}$.

The general intuition of the proof of Lemma 28 is that while one tree could give a high lower bound for *one* of the sequences S_i, no tree can give a high lower bound *on average* over all S_i. The reason is that, given the geometric spacing of each S_i, any way to split an interval of keys into two will typically (on average over i) leave almost all the keys of S_i in either the left or the right part (Claim 31). Therefore, it is impossible to split the keys into subtrees in a way that would ensure a high number of alternations.

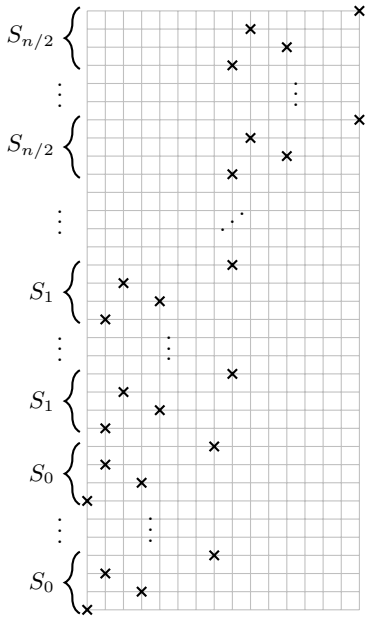

Figure 14 A schematic view of sequence $\tilde{X}$ for $k = 2$. Each part S_i is made of $K = 2^k = 4$ accesses. There are $n = 2^K = 16$ distinct keys and the length of $\tilde{X}$ is $m = (16/2 + 1)nK = 576$.

Proof of Lemma 28. The first step of the proof is to decompose $\tilde{X}$ into substrings $S_0 \circ \cdots \circ S_0$ through $S_{n/2} \circ \cdots \circ S_{n/2}$, and then bound the sum of their Alternation bounds. Let's denote those substrings as $S_0 * n$, $S_1 * n$, …, $S_{n/2} * n$. Because of the subadditivity of mixValue under concatenation (Fact 9), we have

$$\mathsf{Alt}_{\mathcal{T}}(\tilde{X}) \leq \sum_{i=0}^{n/2} \mathsf{Alt}_{\mathcal{T}}(S_i * n). \tag{5}$$

Note that we don't want to decompose $\tilde{X}$ down to the S_i's themselves: every time we split it, our analysis loses up to an additive $O(n)$ in precision. Intuitively, this $O(n)$ is due to a "warmup" cost which we might or might not incur at the beginning of each substring, depending on which parts of the tree were last visited. With our decomposition into n substrings, that's an extra $O(n^2)$ cost, which is okay since it is small compared to the total length of the sequence $\Theta(n^2 \log n)$. In fact, this is precisely why we repeated each S_i several times: if we had defined $\tilde{X}$ as $S_0 \circ S_1 \circ \cdots \circ S_{n/2}$ instead, this $O(n^2)$ would have been large compared to the length of the sequence $\Theta(n \log n)$.[11]

We will upper-bound the sum $\sum_i \mathsf{Alt}_{\mathcal{T}}(S_i * n)$ by induction on the recursive definition of $\mathsf{Alt}_{\mathcal{T}}(\cdot)$. Concretely, let $\mathcal{T}^*$ be a subtree of $\mathcal{T}$, and let $\mathcal{T}_{\mathtt{L}}{}^*, \mathcal{T}_{\mathtt{R}}{}^*$ be the left and right subtrees of $\mathcal{T}^*$. Let s, $s_{\mathtt{L}}$ and $s_{\mathtt{R}}$ be the number of keys in $\mathcal{T}^*$, $\mathcal{T}_{\mathtt{L}}{}^*$ and $\mathcal{T}_{\mathtt{R}}{}^*$ (note that $s = s_{\mathtt{L}} + s_{\mathtt{R}}$). For each i, let P_i^* be the subset of $P(S_i * n)$ corresponding to keys in $\mathcal{T}^*$, and let $P_{i,\mathtt{L}}^*, P_{i,\mathtt{R}}^*$ be the same for $\mathcal{T}_{\mathtt{L}}{}^*$ and $\mathcal{T}_{\mathtt{R}}{}^*$. We will prove the following claim by induction:

[11] The astute reader will notice that we could have repeated each S_i only $\Theta(n/\log n)$ times instead of n times. But we are not limited in terms of the length of $\tilde{X}$, so it was (notationally) simpler to repeat them n times.

▷ Claim 30. For some constant $C > 0$,

$$\sum_{i=0}^{n/2} \mathsf{Alt}_{\mathcal{T}^*}(P_i^*) \leq (s-1)(n/2+1) + 2Cns \lg s.$$

The base case is when $\mathcal{T}^*$ is a single node. Then $\mathsf{Alt}_{\mathcal{T}^*}(S_i * n) = 0$ for all i, while $s = 1$, so the result holds. To deal with the inductive step, we will need make a few tools first. By definition of the Alternation bound (Definition 10), for each i we have

$$\mathsf{Alt}_{\mathcal{T}^*}(P_i^*) = a(P_i^*, \mathcal{T}^*) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{L}}{}^*}(P_{i,\mathtt{L}}^*) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{R}}{}^*}(P_{i,\mathtt{R}}^*). \tag{6}$$

The challenging part is how to deal with $a(P_i^*, \mathcal{T}^*)$. By Fact 9, we have

$$a(P_i^*, \mathcal{T}^*) = \text{mixValue}(P_{i,\mathtt{L}}^*.y, P_{i,\mathtt{R}}^*.y) \leq 2 \cdot \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|) + 1.$$

Summing this up over all i, we get

$$\sum_{i=0}^{n/2} a(P_i^*, \mathcal{T}^*) \leq \sum_{i=0}^{n/2} (2 \cdot \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|) + 1) = (n/2+1) + 2 \cdot \sum_{i=0}^{n/2} \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|). \tag{7}$$

▷ Claim 31. For some constant $C > 0$,

$$\sum_{i=0}^{n/2} \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|) \leq Cn \cdot \begin{cases} s_{\mathtt{L}} \lg \frac{s}{s_{\mathtt{L}}} \text{ if } s_{\mathtt{L}} \leq s_{\mathtt{R}}, \text{ and} \\ s_{\mathtt{R}} \lg \frac{s}{s_{\mathtt{R}}} \text{ if } s_{\mathtt{R}} \leq s_{\mathtt{L}}. \end{cases}$$

This left-right symmetry is very surprising given that the sequences S_i themselves are *not* left-right symmetric. But it will be very convenient.

Proof. To simplify the notation, let's say that the keys in $\mathcal{T}_{\mathtt{L}}{}^*$ are in range $[a, b]$ and the keys in $\mathcal{T}_{\mathtt{R}}{}^*$ are in range $[b, c]$, for some real numbers a, b, c with $b - a = s_{\mathtt{L}}$ and $c - b = s_{\mathtt{R}}$.[12]

For each i, let $V_i = \{i + 2^0, \ldots, i + 2^{K-1}\}$ be the set of values that are hit by sequence S_i. Then $|P_{i,\mathtt{L}}^*|$ (resp. $|P_{i,\mathtt{L}}^*|$) is exactly n times the number of elements of V_i that are in $[a, b]$ (resp. $[b, c]$). Let's name this number of keys l_i (resp. r_i). We will instead prove that

$$\sum_{i=0}^{n/2} \min(l_i, r_i) \leq O\left(s_{\mathtt{L}} \lg \frac{s}{s_{\mathtt{L}}}\right) \text{ if } s_{\mathtt{L}} \leq s_{\mathtt{R}}, \text{ and} \tag{8}$$

$$\sum_{i=0}^{n/2} \min(l_i, r_i) \leq O\left(s_{\mathtt{R}} \lg \frac{s}{s_{\mathtt{R}}}\right) \text{ if } s_{\mathtt{R}} \leq s_{\mathtt{L}}. \tag{9}$$

Once this is proved, C can be set to the maximum of the two constants hidden inside the $O(\cdot)$s. Those constants might be different since the reasonings leading to (8) and (9) are completely different.

We first make a general observation. Look at set $V_i = \{i + 2^0, \ldots, i + 2^j, \ldots, \}$ in increasing order. Note that after $i + 2^j$, all further elements are spaced by at least 2^j. In order for $\min(l_i, r_i)$ to be non-zero, we need to have at least two elements of S_i in $[a, c]$: specifically, one in $[a, b]$ and one in $[b, c]$. But this means that $i + 2^{j+1} \in [a, c]$ isn't acceptable for $j > \lg s$:

[12] We can for example fix a to the first key of $\mathcal{T}_{\mathtt{L}}{}^*$ minus $\frac{1}{2}$, b to the last key of $\mathcal{T}_{\mathtt{L}}{}^*$ plus $\frac{1}{2}$, and c to the last key of $\mathcal{T}_{\mathtt{R}}{}^*$ plus $\frac{1}{2}$.

indeed, the closest other point in S_i is more than s away, so it must be outside of $[a,c]$. Therefore, in bounding $\sum \min(l_i, r_i)$, it is fine to imagine that the elements $i + 2^{j+1}$ for $j > \lg s$ simply do not exist.

Let us now prove (8). Assume $s_{\mathtt{L}} \leq s_{\mathtt{R}}$. We split into two cases:

- "Far" case: $i < a - s_{\mathtt{L}}$. Since i is further from $[a,b]$ than its size $s_{\mathtt{L}}$, this means that $[a,b]$ can only contain at most one point from S_i. So $l_i \leq 1$. Besides, that (potential) single point must have $j \leq 1 + \lg s$ (see above) and $j \geq \lg s_{\mathtt{L}}$ (because we have $i + 2^j \geq a$). And of course, we have in addition that $i + 2^j \in [a,b]$. Therefore, this limits the number of possible values of i to at most $s_{\mathtt{L}}(2 + \lg s - \lg s_{\mathtt{L}})$, and since $l_i \leq 1$, this also limits the total contribution to $\sum \min(l_i, r_i)$.
- "Close to right" case: $i \geq a - s_{\mathtt{L}}$. Then we also have $i \geq b - 2s_{\mathtt{L}}$. Since we need $l_i \neq 0$ to have some contribution, we must have $i < b$, so the total number of possible values of i is limited to $2s_{\mathtt{L}}$. Let's consider the values of j such that $i + 2^j$ can lie in $[b,c]$, the right part. We already know that $j \leq 1 + \lg s$, but we have no lower limit, as i could be very close to b. However, values of j much smaller than $\lg s_{\mathtt{L}}$ will be only for the few values of i close enough to b.

  More precisely, we study the contribution of each j to $\sum r_i$ into two groups:
  - $j \geq \lg s_{\mathtt{L}}$: there are $2 + \lg s - \lg s_{\mathtt{L}}$ such values j, and there are $2s_{\mathtt{L}}$ possible values of i, so the total contribution is at most $2s_{\mathtt{L}}(2 + \lg s - \lg s_{\mathtt{L}})$.
  - $j < \lg s_{\mathtt{L}}$: as j decreases, the number of acceptable values of i decreases exponentially. The number of values of i for which $i + 2^j \in [b,c]$ for $j \leq \lg s_{\mathtt{L}} - l$ is at most $s_{\mathtt{L}}/2^l$. Therefore, the overal contribution is at most $s_{\mathtt{L}} + s_{\mathtt{L}}/2 + \cdots \leq 2s_{\mathtt{L}}$.

All those quantities are upper bounded by $O(s_{\mathtt{L}}(1 + \lg(s/s_{\mathtt{L}})))$, which under the assumption $s_{\mathtt{L}} \leq s_{\mathtt{R}}$, is also bounded by $O(s_{\mathtt{L}} \lg(s/s_{\mathtt{L}}))$.

We now prove (9) in a very similar way. Assume $s_{\mathtt{L}} \leq s_{\mathtt{R}}$.

- "Far" case: $i < b - s_{\mathtt{R}}$. The argument is analogous to the "far" case for (8), but considering r_i this time. We obtain a contribution of at most $s_{\mathtt{R}}(2 + \lg s - \lg s_{\mathtt{R}})$.
- "Close to right" case: $i \geq b - s_{\mathtt{R}}$. The argument is analogous to the "close to right" case for (8), but with a distance of $s_{\mathtt{R}}$ instead of $2s_{\mathtt{L}}$ this time. We obtain contributions of at most $s_{\mathtt{R}}(2 + \lg s - \lg s_{\mathtt{R}})$ and $2s_{\mathtt{R}}$ for the two subcases.

All those quantities are upper bounded by $O(s_{\mathtt{R}}(1 + \lg(s/s_{\mathtt{R}})))$, which under the assumption $s_{\mathtt{R}} \leq s_{\mathtt{L}}$, is also bounded by $O(s_{\mathtt{R}} \lg(s/s_{\mathtt{R}}))$. ◁

We are now ready to finish the induction step.

Proof of Claim 30. We define C to be the same as in Claim 31. We have

$$\begin{aligned}
\sum_{i=0}^{n/2} \mathsf{Alt}_{\mathcal{T}^*}(P_i^*) &= \sum_{i=0}^{n/2} \left(a(P_i^*, \mathcal{T}^*) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{L}}^*}(P_{i,\mathtt{L}}^*) + \mathsf{Alt}_{\mathcal{T}_{\mathtt{R}}^*}(P_{i,\mathtt{R}}^*)\right) && \text{(by (6))} \\
&\leq \left(\sum_{i=0}^{n/2} a(P_i^*, \mathcal{T}^*)\right) + (s_{\mathtt{L}} - 1)(n/2+1) + 2Cns_{\mathtt{L}} \lg s_{\mathtt{L}} + (s_{\mathtt{R}} - 1)(n/2+1) + 2Cns_{\mathtt{R}} \lg s_{\mathtt{R}} \\
& && \text{(inductive hypothesis)} \\
&\leq (n/2+1) + 2 \cdot \sum_{i=0}^{n/2} \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|) \\
&\quad + (s_{\mathtt{L}} - 1)(n/2+1) + 2Cns_{\mathtt{L}} \lg s_{\mathtt{L}} + (s_{\mathtt{R}} - 1)(n/2+1) + 2Cns_{\mathtt{R}} \lg s_{\mathtt{R}} && \text{(by (7))} \\
&\leq (s-1)(n/2+1) + 2Cn(s_{\mathtt{L}} \lg s_{\mathtt{L}} + s_{\mathtt{R}} \lg s_{\mathtt{R}}) + 2 \cdot \sum_{i=0}^{n/2} \min(|P_{i,\mathtt{L}}^*|, |P_{i,\mathtt{R}}^*|) && (s = s_{\mathtt{L}} + s_{\mathtt{R}})
\end{aligned}$$

All we need to show is that

$$Cn(s_{\mathtt{L}} \lg s_{\mathtt{L}} + s_{\mathtt{R}} \lg s_{\mathtt{R}}) + \sum_{i=0}^{n/2} \min(|P^*_{i,\mathtt{L}}|, |P^*_{i,\mathtt{R}}|) \leq Cn(s \lg s).$$

Let's assume that $s_{\mathtt{L}} \leq s_{\mathtt{R}}$ (the other case is identical). Then by Claim 31,

$$\begin{aligned} Cn(s_{\mathtt{L}} \lg s_{\mathtt{L}} + s_{\mathtt{R}} \lg s_{\mathtt{R}}) + \sum_{i=0}^{n/2} \min(|P^*_{i,\mathtt{L}}|, |P^*_{i,\mathtt{R}}|) &\leq Cn(s_{\mathtt{L}} \lg s_{\mathtt{L}} + s_{\mathtt{R}} \lg s_{\mathtt{R}}) + Cns_{\mathtt{L}} \lg \frac{s}{s_{\mathtt{L}}} \\ &\leq Cn(s_{\mathtt{L}} \lg s + s_{\mathtt{R}} \lg s_{\mathtt{R}}) \\ &\leq Cn(s_{\mathtt{L}} \lg s + s_{\mathtt{R}} \lg s) \\ &= Cns \lg s. \end{aligned}$$

This completes the proof of Claim 30. ◁

Applying Claim 30 to the full tree $\mathcal{T}$, which has n keys, we get

$$\begin{aligned} \mathsf{Alt}_{\mathcal{T}}(\tilde{X}) &\leq \sum_{i=0}^{n/2} \mathsf{Alt}_{\mathcal{T}^*}(S_i * n) && \text{(by (5))} \\ &\leq (n-1)(n/2+1) + 2Cn^2 \lg n && \text{(Claim 30)} \\ &\leq O(n^2 \lg n) \\ &= O(m). \end{aligned}$$ ◀

We now move to the proof of Lemma 29, which is much simpler.

Proof of Lemma 29. From the definition of $\mathsf{Funnel}(\cdot)$ (Definition 14), it is easy to see that for any two sequences S and T, $\mathsf{Funnel}(S \circ T) \geq \mathsf{Funnel}(S) + \mathsf{Funnel}(T)$. Indeed concatenating S and T does not affect the funnel of each point in S, and can only add points to the funnel of each point in T. Therefore,

$$\mathsf{Funnel}(\tilde{X}) \geq n \sum_{i=0}^{n/2} \mathsf{Funnel}(S_i). \tag{10}$$

Since $\mathsf{Funnel}(\cdot)$ only depends on the relative order of the keys in the access sequence, not on their exact value, we have $\mathsf{Funnel}(S_i) = \mathsf{Funnel}(\text{bitReversal}^k)$ for each i. Besides, defining $\mathcal{T}$ to be the complete binary search tree of height k as in Fact 27, we have

$$\begin{aligned} \mathsf{Funnel}(\text{bitReversal}^k) &\geq \Omega(\mathsf{Alt}_{\mathcal{T}}(\text{bitReversal}^k)) - K && \text{(by Theorem 1)} \\ &\geq \Omega(K \lg K) - K && \text{(by Fact 27)} \\ &\geq \Omega(K \lg K). \end{aligned}$$

Combined with (10), this gives $\mathsf{Funnel}(\tilde{X}) \geq n \cdot (n/2+1) \cdot \Omega(K \lg K) \geq \Omega(m \lg K) = \Omega(m \lg \lg n)$. ◀

Due to space constraints, the last (short) section, which relates the Funnel bound to the Independent Rectangle bound, is deferred to the full version.

Abstract

Many problems in computer science and applied mathematics require rounding a vector $\mathbf{w}$ of fractional values lying in the interval $[0, 1]$ to a binary vector $\mathbf{x}$ so that, for a given matrix $\mathbf{A}$, $\mathbf{Ax}$ is as close to $\mathbf{Aw}$ as possible. For example, this problem arises in LP rounding algorithms used to approximate NP-hard optimization problems and in the design of uniformly distributed point sets for numerical integration. For a given matrix $\mathbf{A}$, the worst-case error over all choices of $\mathbf{w}$ incurred by the best possible rounding is measured by the linear discrepancy of $\mathbf{A}$, a quantity studied in discrepancy theory, and introduced by Lovasz, Spencer, and Vesztergombi (EJC, 1986).

We initiate the study of the computational complexity of linear discrepancy. Our investigation proceeds in two directions: (1) proving hardness results and (2) finding both exact and approximate algorithms to evaluate the linear discrepancy of certain matrices. For (1), we show that linear discrepancy is NP-hard. Thus we do not expect to find an efficient exact algorithm for the general case. Restricting our attention to matrices with a constant number of rows, we present a poly-time exact algorithm for matrices consisting of a single row and matrices with a constant number of rows and entries of bounded magnitude. We also present an exponential-time approximation algorithm for general matrices, and an algorithm that approximates linear discrepancy to within an exponential factor.

1 Notation

Below bold-face capital letters such as $\mathbf{A}$ denote matrices; $A_{i,j}$ is the entry in the i^{th} row and j^{th} column of the matrix $\mathbf{A}$. Bold-face lowercase letters such as $\mathbf{x}$ denote vectors; x_i is the i^{th} entry of the vector $\mathbf{x}$. We denote the all ones vector by $\mathbb{1}$. Whenever we write $i \in [n]$, we mean $i \in \{1, 2, ..., n\}$. For simplicity of exposition, assume that $\mathbf{A} \in \mathbb{Q}^{m \times n}$ in the following sections. We will explicitly indicate other uses of $\mathbf{A}$.

2 Introduction

A number of questions in mathematics and computer science can be reduced to the following basic rounding question: given a vector $\mathbf{w} \in [0, 1]^n$, and an $m \times n$ matrix $\mathbf{A}$, find an integer vector $\mathbf{x} \in [0, 1]^n$ such that $\mathbf{Ax}$ is as close as possible to $\mathbf{Aw}$. For example, many NP-hard optimization problems can be modeled as an integer program

$$\begin{aligned} \min \quad & \mathbf{c}^\top \mathbf{x} \\ \text{s.t.} \quad & \mathbf{A}\mathbf{x} \geq \mathbf{b} \\ & \mathbf{x} \in \{0,1\}^n \end{aligned}$$

This integer program can be relaxed to a linear program by replacing the integer variables $\mathbf{x} \in \{0,1\}^n$ with real-valued variables $\mathbf{w} \in [0,1]^n$. A powerful method in approximation algorithms is to solve this linear programming relaxation to get an optimal $\mathbf{w}$, and then round $\mathbf{w}$ to an integer solution $\mathbf{x}$ which is feasible (i.e., $\mathbf{A}\mathbf{x} \geq \mathbf{b}$), and has objective value not much bigger than $\mathbf{c}^\top \mathbf{w}$. Often, a useful intermediate step is to guarantee that $\mathbf{x}$ is approximately optimal, i.e., that the coordinates of $\mathbf{b} - \mathbf{A}\mathbf{x}$ are bounded from above. This approximately feasible solution can then, hopefully, be turned into a truly feasible one with a small loss in the objective value. This method was used, for example, by Rothvoss [18], and Rothvoss and Hoberg [12] to give the best known approximation algorithm for the bin packing problem.

Another example is provided by the problem of constructing uniformly distributed points, or, more generally, points that are well-distributed with respect to some measure. Variants of this problem date back to work by Weyl, van der Corput, van Aardenne-Ehrenfest, and Roth, and have important applications to such fields as numerical integration; see the book of Matoušek [15] for references and an introduction to the area. In the classical setting, the problem is to find, for any positive integer n, a set of n points P in $[0,1]^d$, so as to minimize the quantity

$$\sup_{R \in \mathcal{R}_d} ||R \cap P| - n\lambda_d(R)|,$$

where $\mathcal{R}_d$ is the set of all axis-aligned boxes contained in $[0,1]^d$, and λ_d is the Lebesgue measure on $\mathbb{R}^d$. The quantity above is known as the (unnormalized) discrepancy of P. Note that if we sample a random point uniformly from P, then it would land in R with probability $\frac{|R \cap P|}{n}$; on the other hand, if we sample a random point uniformly from $[0,1]^d$, then it would land in R with probability $\lambda_d(R)$. The problem of minimizing the discrepancy of P is then equivalent to finding a distribution that is uniform over n points that "looks the same" as the continuous uniform distribution to all boxes R.

The discrepancy minimization problem can be modeled by the rounding problem with which we started our discussion. To that end, we can discretize the domain $[0,1]^d$ to a finite set X of size N, and let $\mathbf{A}$ be the incidence matrix of sets induced by axis-aligned boxes, i.e., each row of $\mathbf{A}$ is associated with a box R, and equals the indicator vector of $R \cap X$. If we also let $\mathbf{w} = \frac{n}{N}\mathbb{1}$, where $\mathbb{1}$ is the all-ones vector, then, for a sufficiently fine discretization, each coordinate of $\mathbf{A}\mathbf{w}$ is a close approximation of $n\lambda_d(R)$. The problem of finding an n-point set P of minimum discrepancy then becomes essentially equivalent to minimizing $\|\mathbf{A}\mathbf{x} - \mathbf{A}\mathbf{w}\|_\infty$ over $\mathbf{x} \in \{0,1\}^N$, where $\|\cdot\|_\infty$ is the standard ℓ_∞ norm. In particular, given $\mathbf{x}$, we can take P to consist of the points in X for which the corresponding coordinate in $\mathbf{x}$ is set to 1. Then, since $[0,1]^d \in \mathcal{R}_d$, we have $||P| - n| \leq \|\mathbf{A}\mathbf{x} - \mathbf{A}\mathbf{w}\|_\infty$, and we can remove or add at most $\|\mathbf{A}\mathbf{x} - \mathbf{A}\mathbf{w}\|_\infty$ to P to make it exactly of size n. The discrepancy of P is then bounded by $2\|\mathbf{A}\mathbf{x} - \mathbf{A}\mathbf{w}\|_\infty$ plus the additional error incurred by the discretization of $[0,1]^d$.

These two examples motivate the definition of *linear discrepancy*, initially introduced by Lovász, Spencer, and Vesztergombi [14]. The smallest possible error for rounding $\mathbf{w}$ with respect to $\mathbf{A}$ is

$$\operatorname{lindisc}(\mathbf{A}, \mathbf{w}) = \min_{\mathbf{x} \in \{0,1\}^n} \|\mathbf{A}(\mathbf{w} - \mathbf{x})\|_\infty.$$

This is the linear discrepancy of $\mathbf{A}$ with respect to $\mathbf{w}$. The linear discrepancy of $\mathbf{A}$ is defined as as the worse case over all $\mathbf{w} \in [0,1]^n$, i.e.,

$$\operatorname{lindisc}(\mathbf{A}) = \max_{\mathbf{w}\in[0,1]^n} \operatorname{lindisc}(\mathbf{A}, \mathbf{w}). \tag{1}$$

It will be useful to consider a maximizer of equation (1) i.e. $\mathbf{w}^* \in [0,1]^n$ such that $\operatorname{lindisc}(\mathbf{A}, \mathbf{w}^*) = \operatorname{lindisc}(\mathbf{A})$. We call $\mathbf{w}^*$ a *deep-hole* of $\mathbf{A}$. Every $\mathbf{A}$ has at least one deep-hole, since linear discrepancy is a continuous function over the compact set $[0,1]^n$.

The special case of $\operatorname{lindisc}(\mathbf{A}, \mathbf{w})$ when $\mathbf{w} = \frac{1}{2}\mathbb{1}$ is especially well studied. When $\mathbf{A}$ is the indicator matrix of a collection $\mathcal{S}$ of m subsets of a universe X, $\operatorname{lindisc}(\mathbf{A}, \frac{1}{2}\mathbb{1})$ measures to what extent it is possible to choose a subset S of X that contains approximately half the elements of each set. This is a rescaling of the well-known combinatorial discrepancy of $\mathcal{S}$, defined as

$$\operatorname{disc}(\mathcal{S}) = \min_{\chi: X\to\{-1,+1\}} \max_{S\in\mathcal{S}} \left|\sum_{s\in S} \chi(s)\right|$$

It is straightforward to check that, by a change of variables, $\operatorname{disc}(\mathcal{S}) = 2\cdot\operatorname{lindisc}(\mathbf{A}, \frac{1}{2}\mathbb{1})$ where, again, $\mathbf{A}$ is the incidence matrix of $\mathcal{S}$. This definition can be extended to arbitrary matrices $\mathbf{A}$ as $\operatorname{disc}(\mathbf{A}) = 2\cdot\operatorname{lindisc}(\mathbf{A}, \frac{1}{2}\mathbb{1})$. Combinatorial discrepancy has been widely studied in combinatorics and computer science, see [4, 8, 15].

Sometimes $\operatorname{disc}(\mathbf{A})$ can be small "by accident", thus it is useful to define a more robust discrepancy variant.[1] The hereditary discrepancy of $\mathbf{A}$ is the maximum discrepancy over all sub-matrices, i.e.,

$$\operatorname{herdisc}(\mathbf{A}) = \max_{\mathbf{B}} \operatorname{disc}(\mathbf{B}), \tag{2}$$

where $\mathbf{B}$ ranges over submatrices of $\mathbf{A}$.

A fundamental theorem by Lovász, Spencer, and Vesztergombi shows that linear discrepancy can be bounded above by twice the hereditary discrepancy.

▶ **Theorem 1** (Lovász et al. 1986, [14]). $\operatorname{lindisc}(\mathbf{A}) \le 2\cdot\operatorname{herdisc}(\mathbf{A})$.

A number of the applications of combinatorial discrepancy use this basic theorem. In particular, it is common to give an upper bound on the hereditary discrepancy, and from that deduce an upper bound on the linear discrepancy. For example, this strategy was used to give approximation algorithms for bin packing [18, 12], and broadcast scheduling [3], and to design point sets well distributed with respect to arbitrary Borel measures [17, 1]. However, linear discrepancy can be much smaller (by a factor of at least 2^n) than hereditary discrepancy,[2] so hereditary discrepancy lower bounds do not translate to linear discrepancy, and, in general, linear discrepancy lower bounds appear to be challenging. Arguably, a better understanding of linear discrepancy itself would allow proving more and tighter results, in comparison with going through hereditary discrepancy. For example, it is likely that new

[1] Consider any matrix $\mathbf{B} \in \mathbb{R}^{m\times n}$ and let $\mathbf{A} \in \mathbb{R}^{m\times 2n}$ be the concatenation of two copies of $\mathbf{B}$ side by side. Regardless of the discrepancy of $\mathbf{B}$, $\operatorname{disc}(\mathbf{A}) = 0$ since there exists $\mathbf{x} \in \{-1,1\}^n$ such that $\|\mathbf{Ax}\|_\infty = 0$, namely

$$\mathbf{x}^\intercal = [\underbrace{-1,\ldots,-1}_{n},\underbrace{1,\ldots,1}_{n}].$$

[2] Whether this remains true if the matrix $\mathbf{A}$ has bounded entries is a tantalizing open question.

analytic tools to estimate linear discrepancy would allow progress on questions in geometric discrepancy theory, as well as questions about the integrality gaps of linear programming relaxations of important optimization problems, such as the bin packing problem.

A sequence of recent works has shed light on the computational complexity of combinatorial and hereditary discrepancy. It is now known that combinatorial discrepancy does not allow efficient approximation algorithms, even in a weak sense (assuming $\mathsf{P} \neq \mathsf{NP}$)[6], while hereditary discrepancy is NP-hard to approximate better than a factor of 2 [2], and can be approximated within poly-logarithmic factors [16]. Despite being the tool most directly relevant to many applications of discrepancy, however, essentially nothing is known about the computational complexity of linear discrepancy itself. In this paper, we initiate the study of linear discrepancy from a computational viewpoint, and give both the first hardness results, as well as the first exact and approximate algorithms for it.

Before stating our results, it is worth mentioning that linear discrepancy can also be seen as an analogue of the covering radius in lattice theory. Let $\Lambda \subset \mathbb{R}^n$ be a lattice, i.e. discrete additive subgroup of $\mathbb{R}^n$, and let us choose $\mathbf{b}_1, \ldots, \mathbf{b}_n$ to be a basis of Λ. Let $\mathbf{B}$ be a matrix with the $\mathbf{b_i}$ as its columns. The covering radius of Λ in the ℓ_p-norm is defined as

$$\rho(\Lambda) = \max_{\mathbf{y}\in\mathbb{R}^n} \min_{\mathbf{z}\in\Lambda} \|\mathbf{y}-\mathbf{z}\|_p = \max_{\mathbf{w}\in\mathbb{R}^n} \min_{\mathbf{x}\in\mathbb{Z}^n} \|\mathbf{B}\cdot(\mathbf{w}-\mathbf{x})\|_p = \max_{\mathbf{w}\in[0,1]^n} \min_{\mathbf{x}\in\mathbb{Z}^n} \|\mathbf{B}\cdot(\mathbf{w}-\mathbf{x})\|_p, \quad (3)$$

and is independent of the basis. This definition is equivalent to the the definition of $\mathrm{lindisc}(\mathbf{A})$, except that the minimum is over $\mathbb{Z}^n$ rather than $\{0,1\}^n$. Haviv and Regev showed that the covering radius problem (CRP) in the ℓ_p-norm is Π_2-hard to approximate within some fixed constant for all large enough p [11], and Guruswami, Micciancio, and Regev showed it can be approximated within a factor of $2^{O(n \log n/\log\log n)}$ for the case of $p = 2$ [10].

2.1 Our Results

Let us start with the simple observation that, when $\mathbf{A}$ is a single row matrix, deciding $\mathrm{lindisc}(\mathbf{A}, t\mathbb{1}) = 0$ is the NP-hard Subset Sum problem with target sum $t\sum_{j=1}^{n} A_{1,j}$, and is, therefore, NP-hard. This does not show, however, that computing $\mathrm{lindisc}(\mathbf{A})$ is NP-hard. In this work we show the following hardness result for linear discrepancy.

▶ **Theorem 2.** *The Linear Discrepancy problem of deciding, given an $m \times n$ matrix $\mathbf{A}$ with rational entries, and a rational number t, whether* $\mathrm{lindisc}(\mathbf{A}) \leq t$, *is NP-hard and is contained in the class Π_2.*

We present algorithms for computing linear discrepancy exactly when the matrix $\mathbf{A}$ has a constant number of rows. We start with a result for a single row matrix.

▶ **Theorem 3.** *For any matrix $\mathbf{A} \in \mathbb{Q}^{1\times n}$,* $\mathrm{lindisc}(\mathbf{A})$ *can be computed in time $O(n \log n)$.*

Note that this stands in contrast to the observation above that computing $\mathrm{lindisc}(\mathbf{A}, \mathbf{w})$ is hard even for a single-row matrix $\mathbf{A}$. In addition to the theorem above, we also give a corresponding rounding result, showing that any $\mathbf{w} \in \mathbb{Q}^n$ can be efficiently rounded to within error bounded by the linear discrepancy in the case of single row matrices.

▶ **Theorem 4.** *For any matrix $\mathbf{A} \in \mathbb{Q}^{1\times n}$ and any $\mathbf{w} \in ([0,1] \cap \mathbb{Q})^n$, we can find an $\mathbf{x} \in \{0,1\}^n$ such that $\|\mathbf{A}(\mathbf{w}-\mathbf{x})\|_\infty \leq \mathrm{lindisc}(\mathbf{A})$ in time $O(n \log n)$.*

This result stands in contrast with the hardness of the subset sum problem, which easily implies that it is NP-hard to round $\mathbf{w}$ to within error $\mathrm{lindisc}(\mathbf{A}, \mathbf{w})$ even when $\mathbf{A}$ is a single row matrix.

We can extend Theorem 3 to the case of matrices with a bounded number of rows, with the additional assumption that the entries of $\mathbf{A}$ are bounded. Removing this additional assumption is a fascinating open question.

▶ **Theorem 5.** *For any matrix* $\mathbf{A} \in \mathbb{Z}^{d\times n}$ *where* d *is some fixed constant and* $\max_{i,j} |A_{i,j}| \leq \delta$, $\text{lindisc}(\mathbf{A})$ *can be computed in time* $O\left(d(n\delta)^{d^2+d}\right)$.

We further present an approximation algorithm for linear discrepancy.

▶ **Theorem 6.** *For any matrix* $\mathbf{A} \in \mathbb{Q}^{m\times n}$, $\text{lindisc}(\mathbf{A})$ *can be approximated in polynomial time within a factor of* 2^{n+1}.

3 Hardness Result

In this section, we show that linear discrepancy (LDS) is NP-Hard by reducing from monotone not-all-equal 3-SAT (MNAE3SAT) [9] to each. The decision problem version of linear discrepancy we consider is defined below.

[MNAE3SAT] **Monotone Not-All-Equal 3-SAT**
Let U be a collection of variables $\{u_1, ..., u_n\}$ and $\mathcal{C}$ be a 3-CNF with clauses $\{C_1, ..., C_m\}$ such that $C_i = t_{i,1} \vee t_{i,2} \vee t_{i,3}$ for positive literals $t_{i,j}$.
Question: Does there exist a truth assignment $\tau : U \to \{\mathsf{T}, \mathsf{F}\}$ such that $\mathcal{C}$ is satisfied and each clause has at least one true and one false literal?

[LDS] **Linear Discrepancy**
Let $\mathbf{A} \in \mathbb{Q}^{m\times n}$ be a matrix and $t \geq 0$ a rational value.
Question: Is $\text{lindisc}(\mathbf{A}) \leq t$?

3.1 Linear Discrepancy

Before we show that linear discrepancy is hard, we will show that the value of $\text{lindisc}(\mathbf{A})$ can be expressed using a polynomial number of bits in the bit complexity of a matrix for rational matrices. Due to space constraints, the proof can be found in Section A.1.

▶ **Lemma 7.** *For any matrix* $\mathbf{A} \in \mathbb{Q}^{m\times n}$, *there exists a deep hole for* $\mathbf{A}$ *with bit complexity polynomial in* n *and the bit complexity of* $\mathbf{A}$, *and, therefore,* $\text{lindisc}(\mathbf{A})$ *can be written in number of bits polynimial in* n *and the bit complexity of* $\mathbf{A}$.

Proof of Theorem 2. Note first that the fact that LDS is contained in Π_2 is a straightforward consequence of Lemma 7: the "for-all" quantifier is over potential deep holes $\mathbf{w} \in [0, 1]^n$ of the appropriate polynomially bounded bit complexity, and the "exists" quantifier is over $\mathbf{x} \in \{0, 1\}^n$.

Next we prove hardness. Let 3-CNF $\mathcal{C}$ be a MNAE3SAT instance as described above. The corresponding LDS instance will be the incidence matrix $\mathbf{A} \in \{0, 1\}^{m\times n}$ of $\mathcal{C}$: column $\mathbf{a}_j$ of $\mathbf{A}$ corresponds to variable u_j and row $\mathbf{r}_i$ of $\mathbf{A}$ corresponds to clause C_i, and $A_{i,j} = 1$ if and only if variable u_j appears in clause C_i. Let the target t in the LDS problem be $\frac{3}{2} - \epsilon$ for $\epsilon > 0$ to be determined later.

Consider first that case that $\mathcal{C}$ is a NO-instance of MNAE3SAT i.e. for every truth assignments τ, there exists a clause C_i whose literals all get the same truth assignment. Each $\mathbf{x} \in \{0,1\}^n$ corresponds to a truth assignment. If $x_i = 1$ (resp. $x_i = 0$) then u_i is true (resp. u_i is false). Let C_j be the clause whose literals have the same truth value. Then

$$\text{lindisc}(\mathbf{A}) \geq \text{lindisc}(\mathbf{A}, (1/2) \cdot \mathbb{1}) \geq \left| \mathbf{r}_j \left(\frac{1}{2} \cdot \mathbb{1} - \mathbf{x} \right) \right| = \frac{3}{2} > \frac{3}{2} - \epsilon,$$

so $\mathbf{A}$ is a NO-instance of LDS.

Consider next the case that $\mathcal{C}$ is a YES-instance of MNAE3SAT, and let τ be a satisfying assignment. Suppose $\mathbf{w}^* \in [0,1]^n$ is a deep-hole of $\mathbf{A}$. If $w_i^* = \frac{1}{2}$ for all $i \in [n]$ then

$$\text{lindisc}(\mathbf{A}) = \text{lindisc}(\mathbf{A}, (1/2) \cdot \mathbb{1}) = \text{disc}(\mathbf{A}) \leq \left\| \mathbf{A} \left(\frac{1}{2} \cdot \mathbb{1} - \mathbf{x}^* \right) \right\|_\infty = \frac{1}{2}$$

since every clause has exactly two elements with the same truth value. Thus $\mathbf{A}$ is a YES-instance of LDS as long as we choose $\epsilon \leq 1$. Suppose then that $\mathbf{w}^* \neq \frac{1}{2}\mathbb{1}$, and let ϵ be a lower bound on the smallest non-zero gap between w_i^* and $1/2$ i.e. for all $w_i^* \neq \frac{1}{2}$,

$$\left| w_i^* - \frac{1}{2} \right| \geq \epsilon.$$

By Lemma 7, which implies that $\mathbf{w}^*$ has polynomial bit complexity, we know that we can choose such an ϵ of polynomial bit complexity. We will show that $\text{lindisc}(\mathbf{A}, \mathbf{w}^*) \leq \frac{3}{2} - \epsilon$ by constructing a colouring $\mathbf{x}^*$. Let

$$x_i^* = \begin{cases} \text{rd}(w_i^*) & \text{if } w_i^* \neq \frac{1}{2} \\ \tau(u_i) & \text{otherwise} \end{cases}$$

where $\text{rd}(w_i^*)$ is w_i^* rounded to the closest integer and u_i is the variable corresponding to column i. Let $\mathbf{r}$ be a row of matrix $\mathbf{A}$ with non-zero entries in columns i, j, and k. We bound the discrepancy of row $\mathbf{r}$ based on the number of rounded variables R_v among $\{x_i, x_j, x_k\}$.

$R_v = 0$: Since none of the variables are rounded, $w_i^* = w_j^* = w_k^* = \frac{1}{2}$ and

$$|\mathbf{r}(\mathbf{x}^* - \mathbf{w}^*)| = \left| \left(x_i^* - \frac{1}{2} \right) + \left(x_j^* - \frac{1}{2} \right) + \left(x_k^* - \frac{1}{2} \right) \right| = \frac{1}{2}$$

since τ is a satisfying assignment.

$R_v = 1$: W.l.o.g assume that that x_i^* is the rounded value and $w_j^* = w_k^* = \frac{1}{2}$. Then

$$|\mathbf{r}(\mathbf{x}^* - \mathbf{w}^*)| = \left| (x_i^* - w_i^*) + \left(x_j^* - \frac{1}{2} \right) + \left(x_k^* - \frac{1}{2} \right) \right| \leq \left(\frac{1}{2} - \epsilon \right) + 1 = \frac{3}{2} - \epsilon.$$

$R_v = 2$: W.l.o.g assume that x_i^* and x_j^* are the rounded values and $w_k^* = \frac{1}{2}$. Then

$$|\mathbf{r}(\mathbf{x}^* - \mathbf{w}^*)| = \left| (x_i^* - w_i^*) + (x_j^* - w_j^*) + \left(x_k^* - \frac{1}{2} \right) \right| \leq 2 \cdot \left(\frac{1}{2} - \epsilon \right) + \frac{1}{2} = \frac{3}{2} - 2\epsilon.$$

$R_v = 3$: All three values are rounded so

$$|\mathbf{r}(\mathbf{x}^* - \mathbf{w}^*)| = \left| (x_i^* - w_i^*) + (x_j^* - w_j^*) + (x_k^* - w_k^*) \right| \leq 3 \cdot \left(\frac{1}{2} - \epsilon \right) = \frac{3}{2} - 3\epsilon.$$

Since $\mathbf{r}$ was an arbitrary row of $\mathbf{A}$, $\text{lindisc}(\mathbf{A}) = \text{lindisc}(\mathbf{A}, \mathbf{w}^*) \leq \frac{3}{2} - \epsilon$ as required. This completes the reduction. ◀

4 Algorithms for Linear Discrepancy

In the following we consider restrictions and variants of linear discrepancy for which we are able to give poly-time algorithms. The first subsection considers matrices with a single row. The second subsection considers matrices $\mathbf{A} \in \mathbb{Z}^{d \times n}$ with constant d and entry of largest magnitude δ. In that case, we compute $\text{lindisc}(\mathbf{A})$ in time $O\left(d(2n\delta)^{d^2}\right)$. The third subsection presents a poly-time 2^n approximation to $\text{lindisc}(\mathbf{A})$ for $\mathbf{A} \in \mathbb{Q}^{m \times n}$.

4.1 Linear Discrepancy of a Row Matrix

We begin by developing some intuition for the linear discrepancy of a one-row matrix, $\mathbf{A} = [a_1, ..., a_n]$. For now, let us make the simplifying assumption that the entries of $\mathbf{A}$ are non-negative and sorted in decreasing order. Define the *subset sums* of $\mathbf{A}$ to be the multi-set $\mathcal{S}(\mathbf{A}) = \{s_1, ..., s_{2^n}\}$ where each $s_i = \mathbf{Ax}$ for exactly one $\mathbf{x} \in \{0,1\}^n$. Enumerate the element of $\mathcal{S}(\mathbf{A})$ in non-decreasing order, i.e. $s_i \leq s_{i+1}$. If $\ell_A = 2 \cdot \text{lindisc}(\mathbf{A})$, then ℓ_A is the width of the largest gap between consecutive entries in $\mathcal{S}(\mathbf{A})$.

Suppose $\mathbf{A}_i = [a_1, ..., a_i]$. Let us consider how $\mathcal{S}(\mathbf{A}_i)$ and $\text{lindisc}(A_i)$ change for the first couple of values of i. Clearly, $\mathcal{S}(\mathbf{A}_1) = [0, a_1]$ and $\text{lindisc}(\mathbf{A}_1) = \frac{a_1}{2}$. $\mathcal{S}(\mathbf{A}_2)$ is the disjoint union of $\mathcal{S}(\mathbf{A}_1)$ and $\mathcal{S}(\mathbf{A}_1)$ shifted to the right by a_2. Since $a_1 \geq a_2$, $\mathcal{S}(\mathbf{A}_2) = [0, a_2, a_1, a_1 + a_2]$ where the largest gap is of size $\max(a_2, a_1 - a_2)$. See Figure 1. In general, the entries of $\mathcal{S}(\mathbf{A}_i)$ consists of two copies of $\mathcal{S}(\mathbf{A}_{i-1})$ with one shifted to the right by a_i. The gaps in $\mathcal{S}(\mathbf{A}_i)$ are gaps previously in $\mathcal{S}(\mathbf{A}_{i-1})$ or between an element of $\mathcal{S}(\mathbf{A}_{i-1})$ and one in $\{a_i + s : s \in \mathcal{S}(\mathbf{A}_{i-1})\}$.

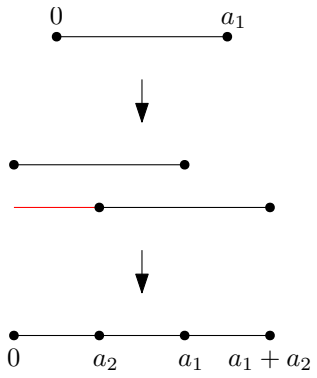

Figure 1 Obtaining $\mathcal{S}(\mathbf{A}_2)$ from $\mathcal{S}(\mathbf{A}_1)$ when $a_1 \geq a_2$.

A similar structure occurs for general matrices with real valued entries with two caveats: (1) the previous interval is shifted left or right depending on the sign of the current entry (negative and positive respectively) and (2) the smallest entry of $\mathcal{S}(\mathbf{A})$ is not zero but the sum of the negative entries in $\mathbf{A}$.

▶ **Lemma 8.** *Suppose $\mathbf{A}_{k-1} = [a_1, ..., a_{k-1}]$ with entries in $\mathbb{R}$ and $|a_i| \geq |a_{i+1}|$. Let the largest gap in $\mathcal{S}(\mathbf{A}_{k-1})$ be of size ℓ_{k-1}. Then, for $\mathbf{A}_k = [a_1, ..., a_{k-1}, a_k]$ where $|a_k| \leq |a_i|$ for all $i \in [k-1]$, the largest gap in $\mathcal{S}(\mathbf{A}_k)$ is of size $\max(|a_k|, \ell_{k-1} - |a_k|)$.*

Proof. Again, it is important to remember that the entries of $\mathcal{S}(\mathbf{A}_k)$ are exactly those in $\mathcal{S}(\mathbf{A}_{k-1})$ along with those in $\{a_k + s : s \in \mathcal{S}(\mathbf{A}_{k-1})\}$. Let $\ell = \max(|a_k|, \ell_{k-1} - |a_k|)$.

We first show that $2 \cdot \text{lindisc}(\mathbf{A}_k) \leq \ell$ by showing that gaps between consecutive entries in $\mathcal{S}(\mathbf{A}_k)$ have size at most ℓ. If (s_j, s_{j+1}) is a consecutive pair in $\mathcal{S}(\mathbf{A}_{k-1})$ such that $s_{j+1} - s_j > \ell$, then s_j and s_{j+1} are no longer consecutive in $\mathcal{S}(\mathbf{A}_k)$, since $s_j \leq s_j + a_k \leq s_{j+1}$

if $a_k > 0$ and $s_j \leq s_{j+1} + a_k \leq s_{j+1}$ if $a_k < 0$. See Figure 2. Then, the gap given by any such pair gets split into gaps of size at most $\max\{|a_k|, s_{j+1} - s_j - |a_k|\} \leq \ell$, where the inequality holds because $s_{j+1} - s_j \leq \ell_{k-1}$. It follows that the size of each gap in $\mathcal{S}(\mathbf{A}_k)$ is at most ℓ.

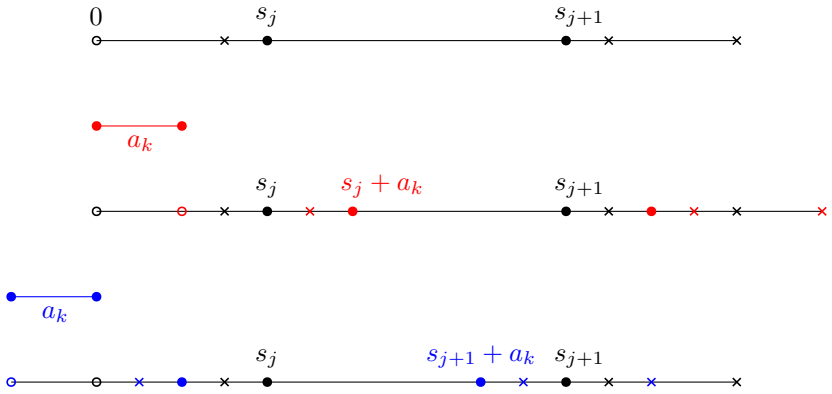

Figure 2 All consecutive pairs in $\mathcal{S}(\mathbf{A}_{k-1})$ of size greater than $|a_k|$ will be divided into two or more consecutive pairs in $\mathcal{S}(\mathbf{A}_k)$. The red interval indicates what happens when $a_k > 0$. The blue interval indicates what happens when $a_k < 0$.

Next we will show that $2 \cdot \text{lindisc}(\mathbf{A}_k) \geq \ell$ by producing a pair of consecutive entries in $\mathcal{S}(\mathbf{A}_k)$ which achieves gap ℓ. Suppose $\ell = |a_k|$. Recall that s_0 is the smallest subset sum of all entries in $\mathbf{A}_k$, which equals the sum of all negative entries in $\mathbf{A_k}$. Then it is easy to check that s_1 equals $s_0 + |a_k|$, where we recall that a_k is the entry in $\mathbf{A}_k$ with minimum absolute value. Therefore, $(s_0, s_0 + |a_k|)$ is a consecutive pair in $\mathcal{S}(\mathbf{A}_k)$. This means that if $\ell = |a_k|$, then we are done, as we have produced a pair with gap ℓ.

When $\ell = \ell_{k-1} - |a_k| > |a_k|$, we split our analysis into two cases: (1) $a_k > 0$ and (2) $a_k < 0$.

In the former case, let (s_{j^*}, s_{j^*+1}) be a consecutive pair in $\mathcal{S}(\mathbf{A}_{k-1})$ that achieves gap ℓ_{k-1} and suppose, towards a contradiction, that $s_{j^*} + a_k$ and s_{j^*+1} do not appear consecutively in $\mathcal{S}(\mathbf{A}_k)$. Then there must be some $s \in \mathcal{S}(\mathbf{A}_k)$ such that $s_{j^*} + a_k < s < s_{j^*+1}$. Note that s cannot be an element of $\mathcal{S}(\mathbf{A}_{k-1})$ since s_{j^*} and s_{j^*+1} are consecutive in $\mathcal{S}(\mathbf{A}_{k-1})$, so $s - a_k$ must be an element of $\mathcal{S}(\mathbf{A}_{k-1})$. However, since $s > s_{j^*} + a_k$, we have $s - a_k > s_{j^*}$. This is a contradiction since s_{j^*} and s_{j^*+1} are consecutive entries in $\mathcal{S}(\mathbf{A}_{k-1})$. See Figure 3. Thus $(s_{j^*} + a_k, s_{j^*+1})$ must be a consecutive pair in $\mathcal{S}(\mathbf{A}_k)$.

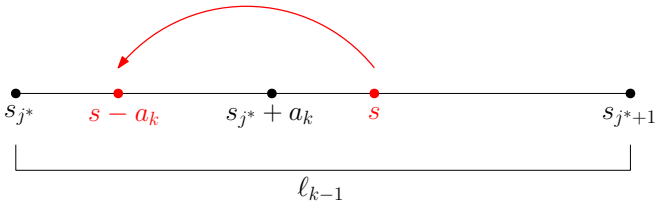

Figure 3 Suppose $a_k < \ell_{k-1} - a_k$ and there exists $s \in \mathcal{S}(\mathbf{A}_k)$ such that $s_{j^*} + a_k < s < s_{j^*+1}$.

The latter case, when $a_k < 0$, is similar. Again there exists a pair of consecutive entries (s_{j^*}, s_{j^*+1}) in $\mathcal{S}(\mathbf{A}_{k-1})$ which achieves gap ℓ_{k-1}. Suppose, towards contradiction, that s_{j^*} and $s_{j^*+1} - |a_k|$ do not appear consecutively in $\mathcal{S}(\mathbf{A}_k)$. Then there must be some $s \in \mathcal{S}(\mathbf{A}_k)$ such that $s_{j^*} < s < s_{j^*+1} - |a_k|$. Again, s cannot be an element of $\mathcal{S}(\mathbf{A}_{k-1})$ since s_{j^*} and s_{j^*+1} are consecutive in $\mathcal{S}(\mathbf{A}_{k-1})$, so $s + |a_k|$ must be an element of $\mathcal{S}(\mathbf{A}_{k-1})$. However since $s < s_{j^*+1} - |a_k|$, we have $s + |a_k| < s_{j^*+1}$. This is a contradiction since s_{j^*} and s_{j^*+1} are consecutive entries in $\mathcal{S}(\mathbf{A}_{k-1})$. ◀

Lemma 8 has the following curious corollary.

▶ **Corollary 9.** *Let* $\mathbf{A} = [a_1, ..., a_n]$ *and* $\mathbf{A}' = [|a_1|, ..., |a_n|]$. *Then* $\text{lindisc}(\mathbf{A}) = \text{lindisc}(\mathbf{A}')$.

Lemma 8 and Corollary 9 suggest an algorithm: replace the entries of $\mathbf{A}$ by their magnitudes. Sort $\mathbf{A}$. Consider each entry in turn and update the largest gap accordingly. See Algorithm 1.

Proof of Theorem 3. By Corollary 9 it is sufficient to consider row matrices with non-negative entries. Suppose that $\mathbf{A} = [a_1, ..., a_n]$ is such a matrix with entries sorted in decreasing order. Algorithm 1 correctly outputs the linear discrepancy for matrices with a single entry. Let $\mathbf{A}_i = [a_1, ..., a_i]$. Lemma 8 gives us a recursive method for computing the largest gap in $\mathcal{S}(\mathbf{A}_{i+1})$ from the largest gap in $\mathcal{S}(\mathbf{A}_i)$. Since $\text{lindisc}(\mathbf{A})$ is half the size of the largest gap in $\mathcal{S}(\mathbf{A})$, Algorithm 8 output $\text{lindisc}(\mathbf{A})$ as required. ◀

Algorithm 1 Linear discrepancy of row matrix.

Input: Matrix $\mathbf{A} \in \mathbb{Q}^{1\times n}$.
Output: $\text{lindisc}(\mathbf{A})$.
for i *from* 1 *to* n **do**
  $\mathbf{A}[i] \leftarrow |a_i|$
sort $\mathbf{A}$ in decreasing order
$\ell \leftarrow a_1$
for i *from* 2 *to* n **do**
  $\ell \leftarrow \max(a_i, \ell - a_i)$
return $\frac{\ell}{2}$

Thus, for any row matrix $\mathbf{A}$ with n elements, we can find $\text{lindisc}(\mathbf{A})$ in time $O(n \log n)$.

4.1.1 One Row Linear Discrepancy Rounding

Let $\text{lindisc}(\mathbf{A}) = \ell$. By the definition of linear discrepancy, for every $\mathbf{w} \in [0,1]^n$ there exists an $\mathbf{x} \in \{0,1\}^n$ such that $\|\mathbf{A}(\mathbf{w} - \mathbf{x})\|_\infty \leq \ell$. In-fact, if $\mathbf{w}$ is not a deep-hole, there exists an $\mathbf{x}$ which satisfies $\|\mathbf{A}(\mathbf{w} - \mathbf{x})\|_\infty < \ell$. However it is not obvious that finding such an $\mathbf{x}$ can be done efficiently i.e. in polynomial time with respect to the bit complexity of $\mathbf{A}$ and n. By reducing from the subset-sum problem, we observe that it is difficult to compute $\text{lindisc}(\mathbf{A}, \mathbf{w})$ let alone find an $\mathbf{x}$ which minimizes $\|\mathbf{A}(\mathbf{w} - \mathbf{x})\|_\infty \leq \ell$.

Proof of Theorem 4. To begin, let $\mathbf{A} = [a_1, ..., a_n]$ for positive a_i in non-increasing order. We will consider $\mathbf{A}$ with arbitrary entries at the end. Let $w = \mathbf{A}\mathbf{w}$. As before, let $\mathcal{S}(\mathbf{A}) = [s_0, ..., s_{2^n-1}]$ be the subset-sums of $\mathbf{A}$ where each $s_i = \mathbf{A}\mathbf{x}$ for an $\mathbf{x} \in \{0,1\}^n$ and $s_i \leq s_{i+1}$ for all i. Recall that $2 \cdot \text{lindisc}(\mathbf{A})$ is the largest gap between any two consecutive entries in $\mathcal{S}(\mathbf{A})$. Our algorithm will find a pair of subset sums containing w. If we can show that the size of the interval between these two subset sums is no more than the gap between some two consecutive entries in $\mathcal{S}(\mathbf{A})$, then the closest subset sum to w among these two will be within $\text{lindisc}(\mathbf{A})$ of w.

Just as in Algorithm 1, we refine the interval between two subset sums containing w by incrementally adding the entries of $\mathbf{A}$ in decreasing order. Initially our interval is $g_0 = [0, \sum_{i=1}^n a_i]$. We maintain the invariants: (1) $w \in g_i$ for all i, and (2) the end-points of g_i are subset sums.

Suppose $w \in g_i = [u, v]$ and we are considering a_i. If $u+a_i > w$ then set $v \leftarrow \min(v, u+a_i)$. Otherwise let $u \leftarrow u + a_i$. Algorithm 2 computes this interval and the associated vectors $\mathbf{u}$ and $\mathbf{v}$ representing its endpoints.

Consider the values of u and v at the end of the algorithm. We claim that the final interval $[u, v]$ is at most the width of some gap between two consecutive terms in $\mathcal{S}(\mathbf{A})$, the array of all subset sums of $\mathbf{A}$. Notice $u = a_1u_1 + \cdots + a_nu_n$ where $\mathbf{u} = [u_1, ..., u_n]$ is an endpoint of the interval once Algorithm 2 completes.

We partition $\mathbf{u}$ into maximal blocks where all entries in the same block have the same value i.e. $[u_1, u_2, ..., u_{\ell_1}], ..., [u_{\ell_r+1}, u_{\ell_r+2}, ..., u_n]$ such that $u_{\ell_i+1} = u_{\ell_i+2} = \cdots = u_{\ell_{i+1}}$ for $i = 0, 1, ..., r-1$ where $\ell_0 = 0$.

We claim that Algorithm 2 outputs an interval containing w whose width is at most the distance between some two consecutive entries in $\mathcal{S}(\mathbf{A})$. The proof is by induction on r, the number of blocks. In the base case, $r = 1$ and there is only one block. Thus $u = 0$ or $u = \sum a_i$. In the case where $u = 0$, we must have $a_i > w$ for all $i \in [n]$, and $v = a_n$. Thus $w \in [0, a_n]$ with consecutive elements 0 and a_n of $\mathcal{S}(\mathbf{A})$. In the latter case when $u = \sum a_i$, we can output $\mathbf{w}$ since it is already a subset sum.

Suppose next that the claim holds for all matrices where the algorithm outputs a vector $\mathbf{u}$ with k blocks, and we will show that it still holds for a matrix $\mathbf{A}$ whose output $\mathbf{u}$ has $k+1$ blocks. Let $\mathbf{u}' = [u_1, ..., u_{\ell_{k+1}}]$ and $\mathbf{v}' = [v_1, ..., v_{\ell_{k+1}}]$ be the final vectors after running the algorithm on $\mathbf{A}' = [a_1, ..., a_{\ell_{k+1}}]$. Further let $u' = \sum_{i=1}^{\ell_{k+1}} a_iu_i$ and $v' = \sum_{i=1}^{\ell_{k+1}} a_iv_i$. By the induction hypothesis, the width of $[u', v']$ is at most the distance between some two consecutive elements in the list of subset sums of $\mathbf{A}'$. The last block of $\mathbf{u}$ is $[u_{\ell_{k+1}+1}, ..., u_n]$. The entries of this block are either all zeros or all ones. Consider each case in-turn.

First suppose $u_{\ell_{k+1}+1} = \cdots = u_n = 0$. Since none of the a_i for $i = \ell_{k+1} + 1, ..., n$ were added to u, it must be the case that $u' + a_i > w$ for all such i. Thus the interval $[u, v] = [u', \min(v', u' + a_n)]$ has width at most a_n. Since 0 and a_n are consecutive in $\mathcal{S}(\mathbf{A})$, as $|a_n|$ is the entry with the smallest magnitude in $\mathbf{A}$, the output interval satisfies our requirements.

Next suppose $u_{\ell_{k+1}+1} = \cdots = u_n = 1$. It must be the case that $u = u' + a_{\ell_{k+1}+1} + \cdots + a_n \leq w$. Observe that $a_{\ell_{k+1}}$ is in the k^{th} block and so $u_{\ell_{k+1}} = 0$. Let $[u'', v'']$ be our interval after processing the $k-1^{\text{st}}$ block i.e. $u'' = \sum_{i=1}^{\ell_k} a_iu_i$ and $v'' = \sum_{i=1}^{\ell_k} a_iv_i$. Notice that since none of the entries in the k^{th} block were added to u'', we must have $u'' + a_i > w$ for all $i = \ell_k + 1, ..., \ell_{k+1}$. In such cases, we always update $v'' \leftarrow \min(v'', u'' + a_i)$ after each such i, thus the interval $[u', v']$ has width at most $a_{\ell_{k+1}}$. Thus it suffices to show that $a_{\ell_{k+1}+1} + \cdots + a_n$ and $a_{\ell_{k+1}}$ are consecutive in $\mathcal{S}(\mathbf{A})$. First note that $a_{\ell_{k+1}+1} + \cdots + a_n \leq a_{\ell_{k+1}}$ since $u' + a_{\ell_{k+1}+1} + \cdots + a_n \leq w \leq v' \leq u' + a_{\ell_{k+1}}$. The two subset sums then are also consecutive, since $a_i > a_{\ell_{k+1}}$ for all $i < \ell_{k+1}$.

Now consider the case where $\mathbf{A}$ can have both positive and negative entries. Without loss of generality we can assume that none of the entries are zero. Let $A_- = \{a_i \in \mathbf{A} : a_i < 0\}$ and $A_+ = \{a_i \in \mathbf{A} : a_i > 0\}$. It suffices to set $u_0 = \sum_{a \in A_-} a$ and $v_0 = \sum_{a \in A_+} a$ and let $\mathbf{u}$ and $\mathbf{v}$ be the indicator vectors of $\mathbf{A}_-$ and $\mathbf{A}_+$ respectively. The remainder of the algorithm is identical except that the matrix should be sorted in decreasing order of *magnitude* and every time an element $a_i \in \mathbf{A}_-$ is added to u, its entry in $\mathbf{u}$ should be set to zero. ◀

4.2 Constant Rows with Bounded Matrix Entries

Let $\mathbf{A} \in \mathbb{Z}^{d \times n}$ with $\max_{i,j} |A_{i,j}| \leq \delta$. Let $Z = \mathbf{A}[0, 1]^d$ be the zonotope of $\mathbf{A}$ and let $T = [-n\delta, n\delta]^d \cap \mathbb{Z}^d$ be the set of all integer lattice points of Z. The following algorithm computes lindisc($\mathbf{A}$) in polynomial time with respect to n for fixed d and δ. The algorithm makes use of Lemma 11, which is proved in the Appendix.

Algorithm 2 Finding a close subset sum to $\mathbf{Aw}$.

Input: A vector $\mathbf{w} \in [0,1]^n$ and a row matrix $\mathbf{A} = [a_1, ..., a_n]$ of positive integers sorted in increasing order.

Output: A vector $\mathbf{x} \in \{0,1\}^n$ such that $\|\mathbf{A}(\mathbf{w}-\mathbf{x})\|_\infty \leq \text{lindisc}(\mathbf{A})$.

```
A ← SORT-DECREASING(A)
u ← ZEROS(n)
v ← ONES(n)
w ← Aw, u ← Au, v ← Av
return v if w == v
for k = 1..n do
    if u + a_k > w then
        v ← min(v, u + a_k)
        if v == u + a_k then
            v ← COPY(u)
            v[k] ← 1
    else
        u ← u + a_k
        u[k] ← 1
return u if u is closer to w else v
```

Proof of Theorem 5. For every one of the $(2n\delta+1)^d$ integral points $\mathbf{b} \in T$, compute whether $\mathbf{Ax} = \mathbf{b}$ for some $\mathbf{x} \in \{0,1\}^n$ using dynamic programming. This procedure generalizes dynamic programming algorithms for knapsack and subset sum and will be outlined in the following. Let $\mathbf{a}_1, ..., \mathbf{a}_n$ be the columns of $\mathbf{A}$. Construct a matrix $\mathbf{M}$ with dimensions $[-n\delta, n\delta]^d \times n$. Cell $(\mathbf{v}, i)$ of $\mathbf{M}$ contains the indicator $[\mathbf{M}(\mathbf{v}-\mathbf{a}_i, i-1) \vee \mathbf{M}(\mathbf{v}, i-1)]$; this corresponds to a linear combination of the first $i-1$ columns of $\mathbf{A}$ which adds up to $\mathbf{v}-\mathbf{a}_i$ or a linear combination of the first $i-1$ columns which adds up to $\mathbf{v}$. The first column of $\mathbf{M}$ is the indicator vector for $\{\mathbf{a}_1\}$. Computing the entries of $\mathbf{M}$ takes time $O(2n\delta)^{d+1}$. $\mathbf{M}(\mathbf{b}, n)$ indicates the feasibility of $\mathbf{Ax} = \mathbf{b}$. Computing this for all $\mathbf{b}$ takes time $O(2n\delta)^{d+1}$. Let $S \subseteq T$ be the set of points $\mathbf{b}$ in Z such that $\mathbf{Ax} = \mathbf{b}$ for some $\mathbf{x} \in \{0,1\}^n$, and set $|S| = N$.

Apply Lemma 11 to the points of S in ℓ_∞-norm. The output is some radius r and point $\mathbf{x}^*$ such that the ℓ_∞-ball centered at $\mathbf{x}^*$ with radius r is the largest such ball with center inside the convex hull of S not containing any points of S. Note that r is in-fact the linear discrepancy of $\mathbf{A}$. Since r and $\mathbf{x}^*$ can be computed in time $O(N^d)$, $\text{lindisc}(\mathbf{A})$ can be computed in time $O(2n\delta)^{d^2+d}$. ◀

4.3 Poly-time Approximation Algorithm

Next, we prove Theorem 6 present a 2^n-approximation algorithm for linear discrepancy. Recall that $\text{rd}(\mathbf{w})$ is the function which rounds each coordinate of $\mathbf{w}$ to its nearest integer (with ties broken arbitrarily). Let the operator norms of a matrix $\mathbf{A}$ be:

$$\|\mathbf{A}\|_{p\to q} = \max_{\mathbf{x}\in\mathbb{R}^n\setminus\{0\}} \frac{\|\mathbf{Ax}\|_q}{\|\mathbf{x}\|_p}.$$

Note that

$$\text{lindisc}(\mathbf{A}) \leq \max_{\mathbf{w}\in[0,1]^n} \|\mathbf{A}(\mathbf{w} - \text{rd}(\mathbf{w}))\|_\infty \leq \frac{1}{2} \max_{\mathbf{z}\in[-1,1]^n} \|\mathbf{A}\mathbf{z}\|_\infty = \frac{1}{2}\|\mathbf{A}\|_{\infty\to\infty}.$$

To bound $\text{lindisc}(\mathbf{A})$ from below, we show that $\|\mathbf{A}\|_{\infty\to\infty} \leq 2^{n+1} \cdot \text{lindisc}(\mathbf{A})$. This completes the proof of the theorem, since $\|\mathbf{A}\|_{\infty\to\infty}$ equals the largest ℓ_1 norm of any row of $\mathbf{A}$, and can be computed in polynomial time.

Let us try to interpret the statement $\|\mathbf{A}\|_{\infty\to\infty} \leq 2^{n+1} \cdot \text{lindisc}(\mathbf{A})$. Note that $\|\mathbf{A}\mathbf{z}\|_\infty$ is equal to the Minkowski $\mathcal{P}$-norm $\|\mathbf{z}\|_\mathcal{P}$ for $\mathcal{P} = \{\mathbf{x} : \|\mathbf{A}\mathbf{x}\|_\infty \leq 1\}$ i.e. $\|\mathbf{z}\|_\mathcal{P} = \inf\{t \geq 0 : \mathbf{z} \in t\mathcal{P}\}$ so

$$\|\mathbf{A}\|_{\infty\to\infty} = \max_{\mathbf{z}\in[-1,1]^n} \|\mathbf{A}\mathbf{z}\|_\infty = \max_{\mathbf{z}\in[-1,1]^n} \|\mathbf{z}\|_\mathcal{P}.$$

By interpreting $\mathbf{z}$ as the difference of two vectors $\mathbf{x}, \mathbf{x}' \in [0,1]^n$ we have that

$$\|\mathbf{A}\|_{\infty\to\infty} = \max_{\mathbf{z}\in[-1,1]^n} \|\mathbf{z}\|_\mathcal{P} = \max_{\mathbf{x},\mathbf{x}'\in[0,1]^n} \|\mathbf{x} - \mathbf{x}'\|_\mathcal{P}.$$

It is an easy, and well-known fact that $\text{lindisc}(\mathbf{A})$ is the smallest t such that $[0,1]^n \subseteq \bigcup_{\mathbf{x}\in\{0,1\}^n} (\mathbf{x} + \mathcal{P})$; see [15]. We then just need to show that the diameter of the unit hypercube with respect to the Minkowski $\mathcal{P}$-norm is no more than this scale-factor t times $O(2^n)$. We prove the following more general statement.

▶ **Lemma 10.** *Let $\mathcal{K}$ be a convex symmetric polytope and $S \subset \mathbb{R}^n$ be convex. Suppose there exist N elements $x_1, ..., x_N \in S$ such that*

$$S \subseteq \bigcup_{x_i} x_i + t\mathcal{K}.$$

Then $\max_{x,x'\in S} \|x - x'\|_\mathcal{K} \leq 2tN$.

Proof. Fix any two points x and x' in S. Let $\mathcal{P}_i$ be the polytope $x_i + t\mathcal{K}$. Since S is convex, the line segment $\lambda x + (1-\lambda)x'$ for $\lambda \in [0,1]$ is in S. Therefore $\lambda x + (1-\lambda)x'$ intersects a sequence of polytopes $\mathcal{P}_{k_1}, ..., \mathcal{P}_{k_r}$ with centres $x_{k_1}, ..., x_{k_r}$, such that any two consequtive polytopes in the sequence intersect. Since the polytopes are convex, we can assume that they appear in the sequence at most once, so $r \leq N$. By the triangle inequality we have

$$\begin{aligned}\|x - x'\|_K &= \|(x - x_{k_1}) + (x_{k_1} - x_{k_2}) + \cdots + (x_{k_r} - x')\|_K \\ &\leq \|x - x_{k_1}\|_K + \|x_{k_1} - x_{k_2}\|_K + \cdots + \|x_{k_r} - x'\|_K \\ &\leq t + 2t(N-1) + t = 2tN\end{aligned}$$

where the last inequality follows as $x \in \mathcal{P}_{k_1}$, $x' \in \mathcal{P}_{k_r}$, and $\|x_{k_i} - x_{k_{i+1}}\|_K \leq 2t$. ◀

Proof of Theorem 6. In Lemma 10, set $\mathcal{K}$ to be the parallelepiped defined by $\mathbf{A}$, $S = [0,1]^n$, $t = \text{lindisc}(\mathbf{A})$, and $\{x_1, ..., x_N\} = \{0,1\}^n$. ◀

5 Open Problems

Because of the similarity between the closest vector problem and linear discrepancy, we suspect that linear discrepancy is also Π_2-complete, and the hardness result of Theorem 2 is, in this sense, not tight. Further, Haviv and Regev also showed that CRP is Π_2-hard to approximate to with-in a factor of $\frac{3}{2}$, and we conjecture that a similar hardness of approximation result should hold for linear discrepancy.

We suspect that the algorithm used to prove Theorem 3 can be generalized to matrices $\mathbf{A} \in \mathbb{Q}^{d \times n}$ with running time $\tilde{O}(n^d)$. This would be a substantial improvement on the $O\left(d(n\delta)^{d^2}\right)$ running time algorithm used to prove Theorem 5, and would be independent of the magnitude of the largest entry of $\mathbf{A}$.

It is also interesting to extend the largest empty ball algorithm from Lemma 11 to other ℓ_p norms, or even arbitrary norms, given appropriate access to the norm ball. Currently, this seems rather difficult as Voronoi diagrams with respect to the ℓ_p-norm for $p \in (2, \infty)$ are poorly behaved. For the standard ℓ_2-norm Voronoi diagram in $\mathbb{R}^d$, it is the case that $d+1$ affinely independent vertices are equidistant to exactly one point. This is no longer the case even in $\mathbb{R}^3$ for ℓ_4-norm [13]. In particular, there exists a set of four vertices such that the intersection of their pair-wise bisectors has size three. The situation is even worse for general strictly convex norms. There exists such norms where the pair-wise bisectors of a set of four points in $\mathbb{R}^3$ can have arbitrarily many intersections.

We currently also have no evidence that the approximation factor in Theorem 6 is tight. One possibility is that there exists an approximation preserving reduction from the closest vector problem in lattices to linear discrepancy. This would show that one cannot expect a significant improvement to Theorem 6 without also improving the best polynomial time approximation to the covering radius, which is currently also exponential in the dimension n. On the other hand, we also conjecture that the approximation factor in Theorem 6 can be taken to be a function of $\min\{m, n\}$, or even of the rank of the matrix $\mathbf{A}$.

A Appendix

A.1 Bit Complexity of Linear Discrepancy

Proof of Lemma 7. Let $\mathbf{r}_i$ for $i \in [m]$ be the rows of $\mathbf{A}$, $\text{lindisc}(\mathbf{A}) = \lambda_A$, and $\mathbf{w}^*$ be a deep-hole of $\mathbf{A}$. For every $\mathbf{x} \in \{0,1\}^n$ there exists an $i \in [m]$ and $\sigma \in \{-1,1\}$ such that $\sigma\mathbf{r}_i(\mathbf{w}^* - \mathbf{x}) \geq \lambda_A$. Let $\mathbf{b}_x = \sigma\mathbf{r}_i$ and consider the following linear program over the variables $\mathbf{w} \in \mathbb{R}^n$ and $\lambda \in \mathbb{R}$:

$$\begin{aligned} \text{Maximize: } & \lambda \\ \text{Subject to: } & \mathbf{b_x}(\mathbf{w} - \mathbf{x}) \geq \lambda && \text{for all } \mathbf{x} \in \{0,1\}^n \\ & \mathbf{0} \leq \mathbf{w} \leq \mathbf{1} \end{aligned}$$

Let λ^* be the optimum value of this linear program. First note that $\lambda_A \leq \lambda^*$ since $(\mathbf{w}^*, \lambda)$ satisfies the constraints. Next we show that $\lambda_A \geq \lambda^*$. Suppose, towards contradiction, that $\lambda_A < \lambda^*$. Then there exists $\mathbf{w}' \in [0,1]^n$ such that

$$\|\mathbf{A}(\mathbf{w}' - \mathbf{x})\|_\infty \geq \mathbf{b}_x(\mathbf{w}' - \mathbf{x}) \geq \lambda^* > \lambda_A$$

for every $\mathbf{x} \in \{0,1\}^n$. Since $\lambda_A = \text{lindisc}(\mathbf{A})$, we cannot have $\text{lindisc}(\mathbf{A}, \mathbf{w}') > \lambda_A$. Thus $\lambda^* = \text{lindisc}(\mathbf{A})$. Since this LP has n variables, the number of bits required to express the linear discrepancy and some deep-hole $\mathbf{w}^*$ of $\mathbf{A}$ are polynomial in n and the bit complexity of the largest entry of $\mathbf{A}$ [19]. ◀

A.2 Largest Empty Ball Problem

Let V be a set of n points in the plane and let $\text{ch}(V)$ denote the convex hull of V. The largest empty circle problem, denoted LEC, takes V and outputs both a radius r and point $\mathbf{x}^* \in \text{ch}(V)$ such that the circle centered at $\mathbf{x}^*$ with radius r is the largest empty circle not containing any point of V. We generalize this problem to other norms and to higher

dimensions as follows: V is a set of n points in $\mathbb{R}^d$, and the goal is to compute a point $\mathbf{x}^*$ in $\mathrm{ch}(V)$ such that $\mathbf{x}^* + rB$ does not contain any point of V, where B is the unit ball of either the ℓ_2^d or the ℓ_∞^d norm. In the following we present an algorithm which solves this largest empty ball (LEB) problem.

▶ **Lemma 11** (LEC in Higher Dimensions)**.** *Let V be a set of n points in $\mathbb{R}^d$ for some fixed constant d. The LEB of V, in both ℓ_2- and ℓ_∞-norms, can be computed in time $O(n^d)$.*

Proof. We use the following terminology. Define a face F of the Voronoi diagram $\mathrm{vd}(V)$ of V to be a subset of $\mathbb{R}^d$ such that, for some $S \subseteq V$, and every $\mathbf{x} \in F$, S are the points in V closest to $\mathbf{x}$. In particular, this means that any $\mathbf{x} \in F$ is equidistant from all points in S.

The algorithm of Toussaint [20] computes the LEB of n points V in the plane with respect to the ℓ_2-norm as follows,

1. Compute $\mathrm{vd}(V)$. Note that $\mathrm{vd}(V)$ is the union of Voronoi faces of dimension k, the set of which we denote $\mathrm{vd}_k(V)$, over all $k = 0, ..., d-1$.
2. Compute the convex hull of V, denoted $\mathrm{ch}(V)$. Let h be the number of facets of $\mathrm{ch}(V)$.
3. Preprocess the points of $\mathrm{ch}(V)$ so that queries of the form "Is a point x in $\mathrm{ch}(V)$?" can be answered in time $O(\log h)$. For every $v \in \mathrm{vd}_0(V)$, determine if $v \in \mathrm{ch}(V)$. Let $C_1 = \{v \in \mathrm{vd}_0(V) : v \in \mathrm{ch}(V)\}$.
4. Determine the intersection points of faces in $\mathrm{vd}_k(V)$ with faces of $\mathrm{ch}(V)$ of co-dimension k, for pairs of such faces that intersect at a unique point. Let C_2 be the set of all such intersection points.
5. For all points $v \in C_1 \cup C_2$, find the largest empty circle centered at v. Output a v which maximizes this radius.

We find the analogue of each step for points in $\mathbb{R}^d$ with respect to the ℓ_2-norm, and then adapt the algorithm to the ℓ_∞-norm.

In the following let $N = n^{\lceil d/2 \rceil}$. The complexity, i.e. total number of faces of every dimension, of the ℓ_2-Voronoi diagram in $\mathbb{R}^d$ for fixed d is $O(N)$ and can be computed in time $O(N + n \log n)$ by a classic result of Chazelle [7]. The complexity of $\mathrm{ch}(V)$ is $O(N)$ and can also be computed in time $O(N + n \log n)$.

To determine the set C_1 of Voronoi intersection points inside the convex hull, we let $\mathcal{H}$ be the set of bounding hyperplanes of $\mathrm{ch}(V)$. Assume, without loss of generality, that $\mathrm{ch}(V)$ contains the origin, and, for each $H \in \mathcal{H}$, let H^- be the half-space with H as its boundary containing the origin. Then $\mathrm{ch}(V) = \bigcap_{H \in \mathcal{H}} H^-$. We simply test, for each Voronoi intersection point $\mathbf{v}$, whether $\mathbf{v} \in H^-$ for each $H \in \mathcal{H}$, in total time $O(N)$. Since there are at most $O(N)$ Voronoi intersection points, we can find C_1 in time $O(N^2)$.

To determine the set C_2 of all unique intersection points of k-faces of $\mathrm{vd}_k(V)$ and faces of $\mathrm{ch}(V)$ of co-dimension k will require solving several linear systems. Note that the points in each face F in $\mathrm{vd}_k(V)$ satisfy $d-k$ equality constraints $\langle \mathbf{a}_1, \mathbf{x} \rangle = b_1, \langle \mathbf{a}_k, \mathbf{x} \rangle = b_k$ for linearly independent vectors $\mathbf{a}_1, ...\mathbf{a}_k \in \mathbb{R}^d$. Similarly, the points in each face of co-dimension k of $\mathrm{ch}(V)$ satisfy k linearly independent equality constraints. Since there are at most $O(2^d N) = O(N)$ faces of $\mathrm{ch}(V)$, there are at most that many faces of $\mathrm{ch}(V)$ of co-dimension k. We can then go over all Voronoi faces F of dimension k, and all faces G of $\mathrm{ch}(V)$ of co-dimension k, and solve the corresponding system of $(d-k)+k = d$ linear equations. If the system has a unique solution, we check if that solution is in $F \cap G$, and, if so, we add it to C_2. Thus, for constant d, the size of C_2 and the time to compute it are bounded bounded above by $O(N \cdot 2^d N) = O(N^2)$.

In total there are at most $O(N + N^2)$ points in $C_1 \cup C_2$ which can be computed in time $O(N^2)$. Thus solving the largest empty ball problem in dimension d for constant d takes time $O(n^d)$.

Next we consider the largest empty ball problem in ℓ_∞-norm. The convex hull remains the same, so we just have to consider the Voronoi diagram with respect to the ℓ_∞-norm. Again, constructing the Voronoi diagram can be done in expected time $O(n^{\lceil d/2 \rceil} \log^{d-1} n)$ using the randomized algorithm of Boissonnat et al. [5]. Next we consider the number of intersections between the Voronoi diagram and the convex hull. First note that Voronoi diagrams with respect to the ℓ_∞-norm need not consist of only hyperplanes and their intersections. Indeed, in $\mathbb{R}^d$, for two points with the same y-coordinate, there exists regions with affine dimension two which are equidistant to both points. To remedy this, we assume that no two points in V have the same i-th coordinate, for any $i \in [d]$. This is without loss of generality, by perturbing the points in V slightly. It remains to consider the complexity of each bisector in ℓ_∞-norm. By Claim 12, in constant dimension d, each such bisector can have at most $O(d^2)$ facets. Therefore, the complexity of any face of the Voronoi diagram, being the intersection of at most d bisectors, is bounded by a function of d. Thus the bounds of the ℓ_2-norm algorithm still hold, up to constant factors that depend on d. ◀

▷ Claim 12 (Bound on Number of Facets of ℓ_∞ Bisectors). Let $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$ be such that assume that $u_i \neq v_i$ for all $i \in [d]$. Then the bisector $\{\mathbf{x} : \|\mathbf{x} - \mathbf{u}\|_\infty = \|\mathbf{x} - \mathbf{v}\|_\infty\}$ has at most $O(d^2)$ facets.

Proof. Let $\mathbf{x}$ be a point in the bisector at ℓ_∞ distance r from $\mathbf{u}$ and $\mathbf{v}$. Pick coordinates i and j and signs σ and τ in $\{-1, +1\}$ such that

$$\sigma_i(x_i - u_i) = \tau_j(x_j - v_j) = r. \tag{4}$$

Moreover, let us make this choice so that either $i \neq j$ or $\sigma_i \neq \tau_i$. This is always possible, since, otherwise, the assumption on $\mathbf{u}$ and $\mathbf{v}$ is violated. Then, (4) defines a hyperplane in $\mathbb{R}^d$, namely $H_{i,j,\sigma,\tau} = \{\mathbf{x} : \sigma_i x_i - \tau_j x_j = \sigma_i u_i - \tau_j v_j\}$. Note that there are at most $\binom{2d}{2} \in O(d^2)$ such hyperplanes, and each $\mathbf{x}$ in the bisector lies in at at least one of them. Moreover, a point $\mathbf{x}$ in $H_{i,j,\sigma,\tau}$ lies in the bisector if and only if it satisfies the inequalities

$$|x_k - u_k| \leq \sigma_i(x_i - u_i) \quad \forall k \in [d],$$
$$|x_k - v_k| \leq \tau_j(x_j - v_j) \quad \forall k \in [d].$$

Thus, the bisector is the union of $(d-1)$-dimensional convex polyhedra, one per each of the $O(d^2)$ hyperplanes $H_{i,j,\sigma,\tau}$. ◁

Abstract

For any undirected graph $G = (V, E)$ and a set E_W of candidate edges with $E \cap E_W = \emptyset$, the (k, γ)-spectral augmentability problem is to find a set F of k edges from E_W with appropriate weighting, such that the algebraic connectivity of the resulting graph $H = (V, E \cup F)$ is least γ. Because of a tight connection between the algebraic connectivity and many other graph parameters, including the graph's conductance and the mixing time of random walks in a graph, maximising the resulting graph's algebraic connectivity by adding a small number of edges has been studied over the past 15 years, and has many practical applications in network optimisation.

In this work we present an approximate and efficient algorithm for the (k, γ)-spectral augmentability problem, and our algorithm runs in almost-linear time under a wide regime of parameters. Our main algorithm is based on the following two novel techniques developed in the paper, which might have applications beyond the (k, γ)-spectral augmentability problem:

- We present a fast algorithm for solving a feasibility version of an SDP for the algebraic connectivity maximisation problem from [16]. Our algorithm is based on the classic primal-dual framework for solving SDP, which in turn uses the multiplicative weight update algorithm. We present a novel approach of unifying SDP constraints of different matrix and vector variables and give a good separation oracle accordingly.
- We present an efficient algorithm for the subgraph sparsification problem, and for a wide range of parameters our algorithm runs in almost-linear time, in contrast to the previously best known algorithm running in at least $\Omega(n^2mk)$ time [22]. Our analysis shows how the randomised BSS framework can be generalised in the setting of subgraph sparsification, and how the potential functions can be applied to approximately keep track of different subspaces.

1 Introduction

Graph expansion is the metric quantifying how well vertices are connected in a graph, and has applications in many important problems of computer science: in complexity theory, graphs with good expansion are used to construct error-correcting codes [38, 42] and pseudorandom generators [18]; in network design, expander graphs have been applied in constructing super concentrators [40]; in probability theory, graph expansion is closely related to the behaviours of random walks in a graph [29, 37]. On the other side, as most graphs occurring in practice might not be expander graphs and a subset of vertices of low expansion is usually viewed as the

bottleneck of a graph, finding the set of vertices with minimum expansion has many practical applications including image segmentation [27], community detection [31, 36], ranking web pages, among many others. Because of these, both the approximation algorithms for the graph expansion problem and the computational complexity of the problem itself have been extensively studied over the past three decades.

In this paper we study the following graph expansion optimisation problem: given an undirected and weighted graph $G = (V, E, w)$, a set E_W of candidate edges, and a parameter $k \in \mathbb{N}$ as input, we are interested in (i) finding a set $F \subseteq E_W$ of k edges and their weights such that the resulting graph $H = (V, E \cup F, w')$ with weight function[1] $w' : E \cup F \to \mathbb{R}_{\geq 0}$ has good expansion, or (ii) showing that it's impossible to significantly improve the graph's expansion by adding k edges from E_W. Despite sharing many similarities with the sparest cut problem, our proposed problem has many of its own applications: for example, assume that the underlying graph G is a practical traffic or communication network and, due to physical constraints, only certain links can be used to improve the network's connectivity. For any given k and a set of feasible links, finding the best k links to optimise the network's connectivity is exactly the objective of our graph expansion optimisation problem.

To formalise the problem, we follow the work of [15, 16, 22] and define the *algebraic connectivity* of G by the second smallest eigenvalue $\lambda_2(L_G)$ of the Laplacian matrix L_G of G defined by $L_G \triangleq D_G - A_G$, where D_G is the diagonal matrix consisting of the degrees of the vertices and A_G is the adjacency matrix of G. Given an undirected and weighted graph $G = (V, E, w)$ with n vertices, $O(n)$ edges[2], a set E_W of candidate edges defined on V satisfying $E_W \cap E = \emptyset$ and a parameter k, we say that G is (k, γ)-*spectrally-augmentable with respect to* $W = (V, E_W)$, if there is $F \subseteq E_W$ with $|F| = k$ together with edge weights $\{w_e\}_{e \in F}$ such that $H = (V, E \cup F, w)$ satisfies $\lambda_2(L_H) \geq \gamma$. The main result of our work is an almost-linear time[3] algorithm that either (i) finds a set of $O(k)$ edges from E_W if G is (k, γ)-spectrally augmentable for some $\gamma \geq \Delta \cdot n^{-1/q}$, or (ii) returns "no" if G is not $(O(kq), O(\Delta \cdot n^{-2/q}))$-spectrally augmentable, where Δ is an upper bound of both the maximum degree of G and W, and $q \geq 10$ is an arbitrary integer. The formal description of our result is as follows:

▶ **Theorem 1.** *Let $G = (V, E, w)$ be a base graph with n vertices, $O(n)$ edges, and weight function $w : E \to \mathbb{R}_{\geq 0}$, and let $W = (V, E_W)$ be the candidate graph of m edges such that the maximum degrees of G and W is at most Δ. Then, there is an algorithm such that for any integer $k \geq 1$ and $q \geq 10$, the following statements hold:*

- *if G is $\left(k, \Delta \cdot n^{-1/q}\right)$-spectrally-augmentable with respect to W, then the algorithm finds a set $F \subseteq E_W$ of edges and a set of edge weights $\{w(e) : e \in F\}$ such that $|F| = O(qk)$, $\sum_{e \in F} w(e) \leq O(k)$, and the resulting graph $H = (V, E \cup F)$ satisfies that $\lambda_2(L_H) \geq c\lambda_\star^2 \Delta$, for some constant $c > 0$, where $\lambda_\star \cdot \Delta$ is the optimum solution[4].*

---

[1] We remark that the weight function w' needs to satisfy that $w'(e) = w(e)$ for any edge $e \in E$.

[2] Since a spectral sparsifier of G with $O(n)$ edges preserves the eigenvalues of the Laplacian matrix of G, we assume that G has $O(n)$ edges throughout the paper. Otherwise one can always run the algorithm in [25] to get a linear-sized spectral sparsifier of G and use this sparsifier as the input of our problem. Therefore, the number of edges in G will not be mentioned in our paper to simplify the notation.

[3] We say that a graph algorithm runs in almost-linear time if the algorithm's runtime is $O((m+n)^{1+c})$ for an arbitrary small constant c, where n and m are the number of vertices and edges of G, respectively. Similarly, we say that a graph algorithm runs in nearly-linear time if the algorithm's runtine is $O((m+n) \cdot \log^c(n))$ for some constant c.

[4] Note that since G is $(k, n^{-1/q} \cdot \Delta)$-spectrally-augmentable with respect to W, it always holds that $\lambda_\star \geq n^{-1/q}$.

- *if G is not $\left(O(kq), O(\Delta \cdot n^{-2/q})\right)$-spectrally-augmentable with respect to W, then the algorithm rejects the input G, W.*

Moreover, the algorithm runs in $\widetilde{O}\left(\min\left\{qn^{\omega+O(1/q)}, q(m+n)n^{O(1/q)}k^2\right\}\right)$ time. Here, the $\widetilde{O}(.)$ notation hides $\operatorname{poly}\log n$ factors, and ω is the constant for matrix multiplication.

We remark that the most typical application of our problem is the scenario in which only a low number of edges are needed such that the resulting graph enjoys good expansion, and these correspond to the regime of $k = n^{o(1)}$ and $\lambda_\star \in (n^{-1/q}, O(1))$ [34], under which our algorithm runs in almost-linear time and achieves an $\Omega(\lambda_\star)$-approximation. In particular, when it is possible to augment G to be an expander graph, i.e. $\lambda_\star = \Theta(1)$, our algorithm achieves a constant-factor approximation. Our algorithm runs much faster than the previously best-known algorithm for a similar problem that runs in *at least* $\Omega\left(n^2mk\right)$ time [22], though their algorithm solves the more general problem: for any instance G, W, k, if the optimum solution is $\lambda_\star\Delta$, i.e., G is $(k, \lambda_\star\Delta)$-spectrally-augmentable with respect to W, for *any* $\lambda_\star \in [0, 1)$, then their algorithm finds a graph $H = (V, E \cup F)$ with $\lambda_2(L_H) \geq c\lambda_\star^2\Delta$ such that $|F| = O(k)$ and the total sum of weights of edges in F is at most k. Our algorithm can only find a graph H when $\lambda_\star \in (n^{-1/q}, 1)$.

To give an overview of the proof technique for Theorem 1, notice that our problem is closely linked to the *algebraic connectivity maximisation problem* studied in [16], which looks for k edges from the candidate set to maximise $\lambda_2(L_H)$ of the resulting graph H. It is known that the algebraic connectivity maximisation problem is **NP**-hard [30], and Ghosh and Boyd [16] show that this problem can be formulated as an SDP, which we call the GB-SDP. Inspired by this, we study the following P-SDP, which is the feasibility version of the GB-SDP parameterised by some γ. Here, $P_\perp$ is the projection on the space orthogonal to $\mathbf{1} \triangleq (1, \ldots, 1)^\intercal$, i.e., $P_\perp = I - \frac{1}{n}\mathbf{1}\mathbf{1}^\intercal$.

$$\text{P-SDP}(G, W, k, \gamma) \qquad \begin{aligned} \lambda &\geq \gamma \\ L_G + \sum_{e \in E_W} w_e L_e &\succeq \lambda\Delta P_\perp \\ k - \sum_{e \in E_W} w_e &\geq 0 \\ 1 - w_e &\geq 0, \qquad \forall e \in E_W \\ w_e &\geq 0, \qquad \forall e \in E_W \\ \gamma &\geq 0. \end{aligned}$$

Notice that, if G is $(k, \gamma\Delta)$-spectrally-augmentable with respect to W, then there is a set F of k edges such that, by setting $w_e = 1$ if $e \in F$ and $w_e = 0$ otherwise, it holds that $L_G + \sum_{e \in E_W} L_e \succeq \gamma\Delta P_\perp$. Therefore, there is a feasible solution of P-SDP(G, W, k, γ). Our algorithmic result for solving the P-SDP is summarised as follows:

▶ **Theorem 2.** *Let $\delta' > 0$ be any constant. There exists an algorithm running in $\widetilde{O}((m+n)/\gamma^2)$ time that either finds a solution to P-SDP$(G, W, k, (1-\delta')\gamma)$ or certifies that there is no feasible solutions for P-SDP(G, W, k, γ).*

Since the solution to the P-SDP only guarantees that the total weights of the selected edges are at most k if G is $(k, \gamma\Delta)$-spectrally augmentable, following [22] we use a subgraph sparsification algorithm to round our SDP solution, such that there are only $O(k)$ edges selected in the end. To give a high-level overview of this rounding step, we redefine the set E_W of candidate edges, and assume that E_W consists of the edges whose weight from the P-SDP solution is non-zero. Therefore, our objective is to find $O(k)$ edges from E_W and new weights, which form an edge set F, such that the Laplacian matrix L_H of the

resulting graph $H = (V, E \cup F)$ is close to L_{G+W}. That is, the subgraph sparsification problem asks for a sparse representation of $G + W$ while keeping the entire base graph G in the resulting representation. Our improved algorithm shows that, as long as $k = n^{o(1)}$, a subgraph sparsifier can be computed in almost-linear time[5]. Our result on subgraph sparsification will be formally described in Theorem 9.

1.1 Our techniques

In this section we will explain the techniques used to design the fast algorithm for the P-SDP, and an almost-linear time algorithm for subgraph sparsification.

Faster algorithm for solving the P-SDP. Our efficient SDP solver is based on the primal-dual framework developed in [5], which has been used in many other works [19, 33]. In this primal-dual framework, we will work on both the original SDP P-SDP(G, W, k, γ) and its dual D-SDP(G, W, k, γ) that is defined as follows:

$$\begin{aligned} Z \bullet L_G + kv + \sum_{e \in E_W} \beta_e &< \gamma \\ Z \bullet \Delta P_\perp &= 1 \\ \text{D-SDP}(G, W, k, \gamma) \qquad Z \bullet L_e &\le v + \beta_e, \qquad \forall e \in E_W \\ Z &\succeq 0 \\ \beta_e &\ge 0, \qquad \forall e \in E_W \\ v &\ge 0. \end{aligned}$$

We then apply the matrix multiplicative weight update (MWU) algorithm. Formally speaking, starting with some initial embedding $X^{(1)}$, for each $t \ge 1$ our algorithm iteratively uses a carefully constructed oracle Oracle for D-SDP(G, W, k, γ) to check whether the current embedding $X^{(t)}$ is good or not:

- If $X^{(t)}$ satisfies some condition, denoted by $\mathcal{C}\left(X^{(t)}\right)$, then the oracle fails and this implies that we can find a feasible solution from $X^{(t)}$ to D-SDP(G, W, k, γ). This implies that the primal SDP P-SDP(G, W, k, γ) has no feasible solution, which certifies that G is not (k, γ)-spectrally-augmentable with respect to W.
- If $X^{(t)}$ does not satisfy the condition $\mathcal{C}\left(X^{(t)}\right)$, then the oracle does not fail, which certifies that the current solution from $X^{(t)}$ is not feasible for D-SDP(G, W, k, γ), and will output a set of numbers $\left(\lambda^{(t)}, w^{(t)}\right)$ for updating the embedding.

The procedure above will be iterated for T times, for some T depending on the oracle and the approximate parameter $\delta' > 0$: if the oracle fails in any iteration, then P-SDP is infeasible; otherwise, the oracle does not fail for all T iterations and we find a feasible solution to P-SDP$(G, W, k, (1 - \delta')\gamma)$.

The main challenge for applying the above framework in our setting is to construct the Oracle and deal with the complicated constraints in our SDPs, which include both matrix inequality constraint and vector inequality constraints of different variables. To work with these constraints, our strategy is to unify them through a diagonal block matrix X, and through this we turn all individual constraints into a single matrix constraint. The embedding in each iteration is constructed in nearly-linear time in $n + m$ by the definition

[5] We remark that, when $k = \Theta(n)$, our problem can be solved directly by using a spectral sparsifier $\widetilde{W}$ of the graph W with $O(n)$ edges, which can be computed in nearly-linear time. This will imply that the two Laplacians $L_{G+\widetilde{W}} = L_G + L_{\widetilde{W}}$ and $L_{G+W} = L_G + L_W$ are close.

of the embedding. To construct the ORACLE, we carefully design the condition $\mathcal{C}(X)$ with the intuition that if the candidate solution corresponding to X has a relatively small dual objective value, then a re-scaling of X gives a feasible solution to D-SDP. Then we use a case analysis to show that if $\mathcal{C}(X)$ is not satisfied, we can very efficiently find updating numbers $(\lambda^{(t)}, w^{(t)})$ by distinguishing edges satisfying one constraint (in D-SDP) from those that do not satisfy it and assigning different weights $w^{(t)}$ to them accordingly.

Faster algorithm for subgraph sparsification. The second component behind proving our main result is an efficient algorithm for the subgraph sparsification problem. Our algorithm is inspired by the the original deterministic algorithm for subgraph sparsification [22] and the almost-linear time algorithm for constructing linear-sized spectral sparsifiers [26]. In particular, both algorithms follow the BSS framework, and proceed in iterations: it is shown that, with the careful choice of barrier values u_j and ℓ_j in each iteration j and the associated potential functions, one or more vectors can be selected in each iteration and the final barrier values can be used to bound the approximation ratio of the constructed sparsifier.

However, in contrast to most algorithms for linear-sized spectral sparsifiers [4, 25, 26], both the barrier values and the potential functions in [22] are employed for a slightly different purpose. In particular, instead of expecting the final constructed ellipsoid to be close to a sphere, the final constructed ellipsoid for subgraph sparsification could be still very far from being a sphere, since the total number of added edges is $O(k)$. Because of this, the two potential functions in [22] are used to quantify the contribution of the added vectors towards *two different subspaces*: one fixed k-dimensional subspace denoted by S, and one variable space defined with respect to the currently constructed matrix. Based on analysing two different subspaces for every added vector, which is computationally expensive, the algorithm in [22] ensures that the added vectors will significantly benefit the "worst subspace", the subspace in $\mathbb{R}^n$ that limits the approximation ratio of the final constructed sparsifier.

Because of these different roles of the potential functions in [22] and [6, 26], when applying the randomised BSS framework [26] for the subgraph sparsification problem, more technical issues need to take into account: (1) Since [22] crucially depends on some projection matrix denoted by P_S, of which the exact computation is expensive, to obtain an efficient algorithm for subgraph sparsification one needs to obtain some projection matrix close to P_S and such a projection matrix can be computed efficiently. (2) Since the upper and lower potential functions keep track of different subspaces whose dimensions are of different orders in most regimes, analysing the impact of multiple added vectors to the potential functions are significantly more challenging than [26].

To address the first issue, we show that the problem of computing an approximate projection close to P_S while preserving relevant proprieties can be reduced to the generalised eigenvalue problem, which in turn can be efficiently approximated by a recent algorithm [2]. For the second issue, we meticulously bound the *intrinsic dimension* of the matrix corresponding to the multiple added vectors, and by a more refined matrix analysis than [26] we show that the potential functions and the relative effective resistances decease in each iteration. We highlight that developing a fast procedure to computing all the quantities that involve a fixed projection matrix and analysing the impact of multiple added vectors with respect to two different subspaces constitute the most challenging part of the design of our algorithm.

Finally, we remark that, although the almost-linear time algorithm [26] has been improved by the subsequent paper [25], it looks more challenging to adapt the technique developed in [25] for the setting of subgraph sparsification. In particular, since the two potential functions

in [25] are used to analyse the same space $\mathbb{R}^n$, it is shown in [25] that it suffices to analyse the one-sided case through a one-sided oracle. However, the two potential functions defined in our paper are used to analyse two different subspaces, and it remains unclear whether we can reduce our problem to the one-sided case. We will leave this for future work.

1.2 Other related work

Spielman and Teng [39] present the first algorithm for constructing spectral sparsifiers: for any parameter $\varepsilon \in (0,1)$, and any undirected graph G of n vertices and m edges, they prove that a spectral sparsifier of G with $\widetilde{O}\left(n/\varepsilon^2\right)$ edges exists, and can be constructed in $\widetilde{O}\left(m/\varepsilon^2\right)$ time. Since then, there has been extensive studies on different variants of spectral sparsifiers and their efficient constructions in various settings. In addition to several results on several constructions of linear-sized spectral sparsifiers mentioned above, there are many studies on constructing spectral sparsifiers in streaming and dynamic settings [1, 20, 21]. The subgraph sparsification problem has many applications, including constructing precondtioners and nearly-optimal ultrasparsifiers [22, 35], optimal approximate matrix product [11], and some network optimisation problems [28]. Our work is also related to a sequence of research on network design, in which the goal is to find minimum cost subgraphs under some "connectivity constraints". Typical examples include constraints on vertex connectivity [8, 9, 10, 14, 23, 24], shortest path distances [12, 13], and spectral information [3, 7, 17, 32].

2 A fast SDP solver

We use the primal-dual framework introduced in [5] to solve the SDP $\mathsf{P\text{-}SDP}(G, W, k, \gamma)$ and prove Theorem 2. The framework is based on the matrix multiplicative weight update (MWU) algorithm on both the primal SDP $\mathsf{P\text{-}SDP}(G, W, k, \gamma)$ and its dual $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$.

Notation. For any given vector β, we use $\mathbf{Diag}(\beta)$ to denote the diagonal matrix such that each diagonal entry $[\mathbf{Diag}(\beta)]_{ii} = \beta_i$. Given matrix Z, scalar v and vector β, we use $\mathbf{Diag}(Z, v, \beta)$ to denote the diagonal 3-block matrix with blocks Z, v and $\mathbf{Diag}(\beta)$. We use I_V and I_{E_W} to denote the identity matrices on vertex set V and edge set E_W with $|E_W| = m$, respectively. We further define

$$\begin{aligned} &E \triangleq \mathbf{Diag}(\Delta \cdot I_V, m, I_{E_W}), \quad \Pi \triangleq \mathbf{Diag}(P_\perp, 1, I_{E_W}), \\ &N \triangleq \mathbf{Diag}(\Delta \cdot P_\perp, m, I_{E_W}) = E^{1/2}\Pi E^{1/2}. \end{aligned} \tag{1}$$

For any given parameter λ and vector w, we define $V(\lambda, w) \triangleq \lambda$, $A(\lambda, w) \triangleq L_G + \sum_{e\in E_W} w_e L_e - \lambda\Delta P_\perp$, and $B(\lambda, w) \triangleq k - \sum_{e\in E_W} w_e$. Let $c = c(\lambda, w) \in \mathbb{R}^m$ denote the vector with $c_e = 1 - w_e$ for each $e \in E_W$, and $C = C(\lambda, w) = \mathbf{Diag}(c(\lambda, w))$ be the diagonal $m \times m$ matrix with the diagonal entry $1 - w_e$ corresponding to edge e. Then we define

$$M(\lambda, w) \triangleq \mathbf{Diag}\left(A(\lambda, w), B(\lambda, w), C(\lambda, w)\right) = \begin{bmatrix} A(\lambda, w) & 0 & 0 \\ 0 & B(\lambda, w) & 0 \\ 0 & 0 & C(\lambda, w) \end{bmatrix}. \tag{2}$$

▶ **Definition 3.** *An (ℓ, ρ)-oracle for $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$ is an algorithm that on input $\langle Z, v, \beta\rangle$ with $\mathbf{Diag}(Z, v, \beta) \bullet N = 1$, either fails or outputs (λ, w) with $\lambda \geq 0$, $w \in \mathbb{R}^m_{\geq 0}$ that satisfies*

$$V(\lambda, w) \geq \gamma, \qquad A(\lambda, w) \bullet Z + B(\lambda, w) \cdot v + c(\lambda, w) \cdot \beta \geq 0, \qquad -\ell N \preceq M(\lambda, w) \preceq \rho N.$$

▶ **Fact 4.** *If an (ℓ, ρ)-oracle for D-SDP(G, W, k, γ) does not fail on input $\langle Z, v, \beta\rangle$ with $\boldsymbol{Diag}(Z, v, \beta) \bullet N = 1$, then $\langle Z, v, \beta\rangle$ is infeasible for D-SDP(G, W, k, γ).*

In order to apply the MWU algorithm, in the following we use $U_\varepsilon(A)$ to denote the matrix

$$U_\varepsilon(A) \triangleq \frac{E^{-1/2}(1-\varepsilon)^{E^{-1/2}AE^{-1/2}}E^{-1/2}}{\Pi \bullet (1-\varepsilon)^{E^{-1/2}AE^{-1/2}}},$$

where E and Π are matrices defined in (1).

2.1 The MWU algorithm

In the framework of MWU for solving our SDP, we sequentially produce candidate dual solutions $\langle Z^{(t)}, v^{(t)}, \beta^{(t)}\rangle$ such that $\mathbf{Diag}(Z^{(t)}, v^{(t)}, \beta^{(t)}) \bullet N = 1$ for any t. Specifically, for any given k, γ, we start with a solution $Z^{(1)} = \frac{1}{\Delta(n-1)}I$, $v^{(1)} = \frac{2}{n-1}$ and $\beta_e^{(1)} = 0$ for any $e \in E_W$. At each iteration t, we invoke a good separation oracle that takes $\mathbf{Diag}(Z^{(t)}, v^{(t)}, \beta^{(t)})$ as input, and either guarantees that $\mathbf{Diag}(Z^{(t)}, v^{(t)}, \beta^{(t)})$ is already good for dual SDP (and thus certifies infeasibility of primal SDP), or outputs $(\lambda^{(t)}, w^{(t)})$ certifying the infeasibility of $\mathbf{Diag}(Z^{(t)}, v^{(t)}, \beta^{(t)})$.

If $\left(\lambda^{(t)}, w^{(t)}\right)$ is returned by the oracle, then the algorithm updates the next candidate solution based on $X^{(t)} = U_\varepsilon\left(\frac{1}{2\rho}\sum_{s=1}^{t-1} M^{(s)}\right)$, where $M^{(s)} \triangleq M\left(\lambda^{(s)}, w^{(s)}\right)$ is as defined before and ε is a parameter of the algorithm. By definition, we have that $X^{(t)} \bullet N = 1$. Moreover, since $M^{(t)}$ can be viewed as a 3-block diagonal matrix with diagonal entries $A^{(t)}, B^{(t)}, C^{(t)}$, we have that $\exp(M^{(t)}) = \mathbf{Diag}\left(\exp\left(A^{(t)}\right), \exp\left(B^{(t)}\right), \exp\left(C^{(t)}\right)\right)$. Therefore, we can decompose $X^{(t)}$ as

$$X^{(t)} = \mathbf{Diag}\left(Z^{(t)}, v^{(t)}, \beta^{(t)}\right).$$

Note that $X^{(t)} \bullet N = 1$ is equivalent to

$$\Delta \cdot Z^{(t)} \bullet P_\perp + m \cdot v^{(t)} + \sum_{e \in E_W} \beta_e^{(t)} = 1.$$

The following theorem guarantees that, after a small number of iterations, the algorithm either finds a good enough dual solution, or a feasible solution to the primal SDP.

▶ **Theorem 5.** *Let Oracle be an (ℓ, ρ)-oracle for D-SDP(G, W, k, γ), and let $\delta > 0$. Let N, $X^{(t)}$, and $M^{(t)}$ be defined as above, for any $t \geq 1$. Let $\varepsilon = \min\{1/2, \delta/2\ell\}$. Suppose that Oracle does not fail for T rounds, where*

$$T = O\left(\frac{\rho \log n}{\delta\varepsilon}\right) \leq \max\left\{O\left(\frac{\rho \log n}{\delta}\right), O\left(\frac{\rho\ell \log n}{\delta^2}\right)\right\},$$

then $(\bar{\lambda} - 3\delta, \bar{w} - \delta)$ is a feasible solution to P-SDP$(G, W, k, \gamma - 3\delta)$, where $\bar{\lambda} \triangleq \frac{1}{T}\sum_{t=1}^{T}\lambda^{(t)}$ and $\bar{w} \triangleq \frac{1}{T}\sum_{t=1}^{T} w^{(t)}$.

Approximate computation. By applying the Johnson-Linderstrauss (JL) dimensionality reduction to the embedding corresponding to U_ε, we can approximate $X^{(t+1)}$ by $\widetilde{X}^{(t+1)}$ while preserving the relevant properties. Specifically, let $\widetilde{U}_\varepsilon$ be a randomised approximation to U_ε from applying the JL Lemma, and we compute in nearly-linear time the matrix $\widetilde{X}^{(t+1)} = \widetilde{U}_\varepsilon\left(\frac{1}{2\rho}\sum_{s=1}^{t-1} M^{(s)}\right)$ and decompose it into 3 blocks:

$$\widetilde{X}^{(t+1)} = \mathbf{Diag}\left(\widetilde{Z}^{(t+1)}, \widetilde{v}^{(t+1)}, \mathbf{Diag}\left(\widetilde{\beta}^{(t+1)}\right)\right).$$

Moreover, $\widetilde{X}^{(t+1)} \bullet L_H$ well approximates $X^{(t+1)} \bullet L_H$ for any graph H, which suffices for our oracle. Hence, we assume that the oracle receives $\widetilde{X}^{(t+1)}$ as input instead of $X^{(t+1)}$. We defer the formal lemma we are using to the full version.

2.2 The oracle

In this subsection, we will present and analyse the oracle for our SDP $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$, which is presented in Algorithm 1. For the simplicity of presentation, we abuse notation and use $X = \mathbf{Diag}(Z, v, \beta)$ to denote the input to the oracle, although it should be clear that the input is the approximate embedding $\widetilde{X} = \mathbf{Diag}(\widetilde{Z}, \widetilde{v}, \mathbf{Diag}(\widetilde{\beta}))$ of X.

Algorithm 1 ORACLE for SDP $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$.

Require: Candidate solution $\langle Z, v, \beta \rangle$ with $\Delta \cdot Z \bullet P_\perp + m \cdot v + \sum_{e \in E_W} \beta_e = 1$, target value γ

Let $B := \{e : v + \beta_e < L_e \bullet Z\}$, $\Gamma := \sum_{e \in B}(L_e \bullet Z - v - \beta_e)$, and $T := Z \bullet \Delta P_\perp$.
Let $T_{\mathrm{tol}} := L_G \bullet Z + kv + \sum_{e \in E_W} \beta_e$.
if $\Gamma \leq T\gamma - T_{\mathrm{tol}}$ **then**
    Output "fail". ▷ In this case, $\langle Z, v, \beta \rangle$ is "good" enough
else if $T_{\mathrm{tol}} > \gamma m - \gamma \sum_{e \in E_W} Z \bullet L_e$ **then**
    return $w_e = \gamma$, and $\lambda = \gamma$.
else
    return $w_e = 1$ for $e \in B$, $w_e = 0$ for $e \in E_W \setminus B$ and $\lambda = \gamma$

To analyse the oracle, we prove the following technical lemma. First of all, we show that if the ORACLE fails, then we can find a dual feasible solution for $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$.

▶ **Lemma 6.** *Let $\langle Z, v, \beta \rangle$ be a candidate solution. Suppose that for $B \triangleq \{e : v + \beta_e - L_e \bullet Z < 0\}$, $T \triangleq Z \bullet \Delta P_\perp$ and $T_{tol} \triangleq L_G \bullet Z + kv + \sum_{e \in E_W} \beta_e$, then it holds that $\Gamma \triangleq \sum_{e \in B}(L_e \bullet Z - v - \beta_e) \leq T\gamma - T_{tol}$. Moreover, by setting $Z' = \frac{Z}{T}$, $v' = \frac{v}{T}$, and $\beta'_e = \frac{\beta_e}{T}$ if $e \in E_W \setminus B$ and $\beta'_e = \frac{L_e \bullet Z - v}{T}$ if $e \in B$, we have that $\langle Z', v', \beta' \rangle$ is a dual feasible for $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$.*

Secondly, we show that, if ORACLE does not fail, then it returns (λ, w) that satisfies the properties of (ℓ, ρ)-oracle for $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$ for appropriate ℓ, ρ.

▶ **Lemma 7.** *When ORACLE described in the algorithm does not fail, it returns a vector w and value λ such that $V(\lambda, w) \geq \gamma$, and for the matrix $M(\lambda, w) = \mathbf{Diag}(A(\lambda, w), B(\lambda, w), C(\lambda, w))$, $A(\lambda, w) \bullet Z + B(\lambda, w) \cdot v + C(\lambda, w) \cdot \beta \geq 0$. Moreover, it holds that $-N \preceq M(\lambda, w) \preceq 3N$.*

Combining these two lemmas together, we obtain the following theorem which summarise the performance of Algorithm 1.

▶ **Theorem 8.** *On input $\widetilde{X}^{(t)}$, there exists an algorithm ORACLE that runs in $\widetilde{O}(n + m)$ time and is an (ℓ, ρ)-oracle for SDP $\mathsf{D\text{-}SDP}(G, W, k, \gamma)$, where $\ell = 1$ and $\rho = 3$.*

2.3 Proof of Theorem 2

Now we are ready to prove Theorem 2.

Proof of Theorem 2. Let $\delta' > 0$ be any constant. We specify $\delta = \frac{\delta'\gamma}{3}$ in our MWU algorithm, which is described in the previous subsections. We set $\rho = 3$ and $\ell = 1$, and let

$$T \triangleq O\left(\frac{\rho \ell \log n}{\delta^2}\right) = O\left(\frac{\log n}{(\delta')^2 \gamma^2}\right) = O\left(\frac{\log n}{\gamma^2}\right).$$

In the MWU algorithm, if the ORACLE fails in the t-th iteration for some $1 \le t \le T$, then the corresponding embedding $\widetilde{X}^{(t)} = \mathbf{Diag}(\widetilde{Z}^{(t)}, \widetilde{v}^{(t)}, \mathbf{Diag}(\beta^{(t)}))$ provides a good enough solution: the precondition of Lemma 6 is satisfied, which further implies that $\widetilde{X}^{(t)}$ can be turned into a dual feasible solution with objective at most γ, i.e., we find a solution to D-SDP(G, W, k, γ). Therefore, the primal SDP P-SDP(G, W, k, γ) is infeasible. Otherwise, we know that the ORACLE does not fail for T iterations; by Theorem 5 and Lemma 7, it holds that for $\bar{\lambda} \triangleq \frac{1}{T}\sum_{t=1}^{T} \lambda^{(t)}, \bar{w} \triangleq \frac{1}{T}\sum_{t=1}^{T} w^{(t)}$, $(\bar{\lambda} - 3\delta, \bar{w} - \delta)$ is a feasible solution for P-SDP$(G, W, k, \gamma - 3\delta)$ = P-SDP$(G, W, k, \gamma - \delta'\gamma)$.

Now we analyse the algorithm's runtime. By Theorem 8 and the approximate computation of $X^{(t+1)}$, each iteration can be implemented in $\widetilde{O}(n+m)$ time. Thus, in $\widetilde{O}((n+m)/\gamma^2)$ time, we either find a solution to our SDP with objective value at least $(1-\delta')\gamma$ for any constant $\gamma' > 0$, or we certify that the P-SDP(G, W, k, γ) is infeasible (in case the ORACLE fails). ◀

3 Algorithm for subgraph sparsification

Now we give an overview of our efficient algorithm for constructing subgraph sparsifiers. Recall that, for any $k \in \mathbb{N}$, parameter $\kappa \ge 1$, and two weighted graphs $G = (V, E)$ and $W = (V, E_W)$, the subgraph sparsification problem is to find a set $F \subseteq E_W$ of $|F| = O(k)$ edges with weights $\{w_e\}_{e\in F}$, such that the resulting graph $H = (V, E + F)$ is a κ-approximation of $G + W$, i.e.,

$$L_{G+W} \preceq L_G + \sum_{e\in F} w_e b_e b_e^{\intercal} \preceq \kappa \cdot L_{G+W}. \tag{3}$$

To construct the required edge set F, we apply the standard reduction for constructing graph sparsifiers by setting $v_e \triangleq L_{G+W}^{\dagger/2} b_e$ for every $e \in E_W$, and (3) is equivalent to

$$I_{\mathsf{im}(L_{G+W})} \preceq L_{G+W}^{\dagger/2} L_G L_{G+W}^{\dagger/2} + \sum_{e\in F} w_e v_e v_e^{\intercal} \preceq \kappa \cdot I_{\mathsf{im}(L_{G+W})},$$

where $I_{\mathsf{im}(L_{G+W})}$ is the identity on $\mathsf{im}(L_{G+W})$. Our main result is summarised as follows:

▶ **Theorem 9.** *Let ε and q be arbitrary constants such that $\varepsilon \le 1/20$ and $q \ge 10$. Then, there is a randomised algorithm such that, for any two graphs $G = (V, E)$ and $W = (V, E_W)$ defined on the same vertex set as input, by defining $X = \left(L_{G+W}^{\dagger/2} L_G L_{G+W}^{\dagger/2}\right)\Big|_{\mathrm{Im}(L_{G+W})}$ and $\overline{M} \triangleq \left(\sum_{i=1}^{m} v_i v_i^{\intercal}\right)|_{\mathrm{Im}(L_{G+W})}$ where every v_i is of the form $L_{G+W}^{\dagger/2} b_e$ for some edge $e \in E_W$, the algorithm outputs a set of non-negative coefficients $\{c_i\}_{i=1}^{m}$ with $|\{c_i \mid c_i \ne 0\}| = K$ for some $K = O\left(qk/\varepsilon^2\right)$ such that it holds for some constant C that*

$$C \cdot (1 - O(\varepsilon)) \cdot \min\{1, K/T\} \cdot \lambda_{k+1}(X) \cdot I \preceq X + \sum_{i=1}^{m} c_i v_i v_i^{\intercal} \preceq (1 + O(\varepsilon)) \cdot I, \tag{4}$$

where $T \triangleq \lceil \mathrm{tr}\left(\overline{M}\right) \rceil$. Moreover, if we assume that every v_i is associated with some cost denoted by $cost_i$ such that $\sum_{i=1}^{m} cost_i = 1$, then with constant probability the coefficients $\{c_i\}_{i=1}^{m}$ returned by the algorithm satisfy $\sum_{i=1}^{m} c_i \cdot cost_i \le O(1/\varepsilon^2) \cdot \min\{1, k/T\}$. The algorithm runs in time

$$\widetilde{O}\left(\min\left\{n^{\omega}, \frac{mk + nk^2}{\sqrt{\lambda_{k+1}(X)}}\right\} + q \cdot n^{O(1/q)} \left(\frac{mn^{2/q}}{\varepsilon^{2+2/q}} + \min\left\{n^{\omega}, mk + nk^2 + k^{\omega}\right\}\right) \Big/ \varepsilon^5\right).$$

Without loss of generality, we assume that $\overline{M}$ is a full-rank matrix, which can be achieved by adding n self-loops each of small weight $\gamma = \Theta(1/\mathrm{poly}(n))$, so that with constant probability these self-loops will not be sampled by the algorithm.

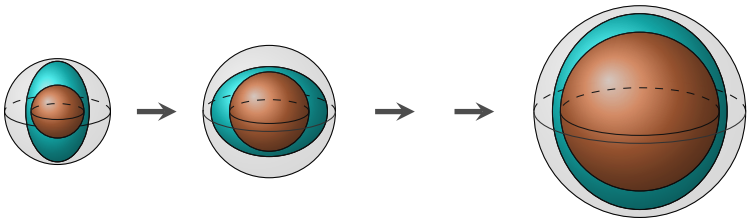

Figure 1 Illustration of the BSS framework: the light grey and orange balls in iteration j represent the spheres $u_j \cdot I$ and $\ell_j \cdot I$, and the cyan ellipsoid sandwiched between the two balls corresponds to the constructed ellipsoid in iteration j. After each iteration j, the algorithm increases the value of ℓ_j and u_j by some $\delta_{\ell,j}$ and $\delta_{u,j}$ so that the invariant (5) holds in iteration $j+1$. This process is repeated for τ iterations, so that the final constructed ellipsoid is close to be a sphere.

3.1 Overview of our algorithm

The BSS framework. At a high level, our algorithm follows the BSS framework for constructing spectral sparsifiers [6]. The BSS algorithm proceeds by iterations: in each iteration j the algorithm chooses one or more vectors, denoted by $v_{j_1}, \ldots, v_{j_k}$, and adds $\Delta_j = \sum_{i=1}^{k} c_{j_i} v_{j_i} v_{j_i}^\intercal$ to the currently constructed matrix by setting $A_j = A_{j-1} + \Delta_j$, where $c_{j_1}, \ldots, c_{j_k}$ are scaling factors, and $A_0 = \mathbf{0}$ initially. Moreover, two barrier values, the *upper barrier* u_j and the *lower barrier* ℓ_j, are maintained such that the constructed ellipsoid $\mathsf{Ellip}(A_j)$ is sandwiched between the outer sphere $u_j \cdot I$ and the inner sphere $\ell_j \cdot I$ for any iteration j. To ensure this, all the previous analysis uses a potential function $\Phi(A_j, u_j, \ell_j)$ defined by

$$\Phi\left(A_j, u_j, \ell_j\right) = \operatorname{tr}[f(u_j I - A_j)] + \operatorname{tr}[f(A_j - \ell_j I)]$$

for some function f, and a bounded value of $\Phi\left(A_j, u_j, \ell_j\right)$ implies that

$$\ell_j \cdot I \prec A_j \prec u_j \cdot I. \tag{5}$$

After each iteration, the two barrier values ℓ_j and u_j are increased properly by setting $u_{j+1} = u_j + \delta_{u,j}$ and $\ell_{j+1} = \ell_j + \delta_{\ell,j}$ for some positive values $\delta_{u,j}$ and $\delta_{\ell,j}$. The careful choice of $\delta_{u,j}$ and $\delta_{\ell,j}$ ensures that after τ iterations $\mathsf{Ellip}(A_\tau)$ is close to being a sphere, which implies that A_τ is a spectral sparsifier of $\ell_\tau \cdot I$, see Figure 1 for illustration.

The BSS framework for subgraph sparsification. The BSS framework ensures that, when starting with the zero matrix, after choosing $O(n)$ vectors, the final constructed matrix is close to I. However, applying the BSS framework to construct a subgraph sparsifier is significantly more challenging due to the following two reasons:

- Instead of starting with the zero matrix, we need to start with some *non-zero* matrix $A_0 = X$, and the number of added vectors is $K = O(k)$, which could be much smaller than n. This implies that the ellipsoid corresponding to the final constructed matrix could be still very far from being a sphere.
- Because of this and every rank-one update has different contribution towards each direction in $\mathbb{R}^n$, to "optimise" the contribution of $O(k)$ rank-one updates we have to ensure that the added vectors will significantly benefit the "worst subspace", the subspace in $\mathbb{R}^n$ that limits the approximation ratio of the final constructed sparsifier.

To address these two challenges, in the celebrated paper Kolla et al. [22] propose to keep track of the algorithm's progress with respect to two subspaces, each of which is measured by some potential function. Specifically, in each iteration j they define $A_j \triangleq X + \sum_i c_i v_i v_i^\intercal$,

where $\sum_i c_i v_i v_i^\intercal$ is the sum of currently picked rank-one matrices after reweighting during the first j iterations. For the upper barrier value u_j in iteration j, they define the upper potential function

$$\Phi^{u_j}(A_j) \triangleq \operatorname{tr}\left(P_{L(A_j)}\left(u_j I - A_j\right) P_{L(A_j)}\right)^\dagger,$$

where $L(A_j)$ is the T-dimensional subspace of A_j spanned by the T largest eigenvectors of A_j and $P_{L(A_j)}$ is the projection onto that subspace. Notice that $\Phi^{u_j}(A_j)$ is defined with respect to a variable space $L(A_j)$ that *changes after every rank-one update*, in order to upper bound the maximum eigenvalue of the final constructed matrix in the entire space. Similarly, for the same matrix A_j and lower barrier ℓ_j in iteration j, they define the lower potential function by

$$\Phi_{\ell_j}(B_j) \triangleq \operatorname{tr}\left(P_S(B_j - \ell_j I)P_S\right)^\dagger,$$

where P_S is the orthogonal projection onto S, the subspace generated by the bottom k eigenvectors of X, and the matrix B_j is defined by $B_j = Z(A_j - X)Z$, for $Z = \left(P_S(I - X)P_S\right)^{\dagger/2}$. Since the total number of chosen vectors is $K = O(k)$, instead of expecting the final constructed matrix A_τ approximating the identity matrix, the objective of the subgraph sparsification is to find coefficients $\{c_i\}$ with $K = O(k)$ non-zeros such that the following two conditions hold for some positive constants $\theta_{\min}, \theta_{\max}$:

- it holds that $X + \sum_{i=1}^m c_i v_i v_i^\intercal \preceq \theta_{\max} I$, and
- it holds that $\sum_{i=1}^m c_i Z v_i v_i^\intercal Z \succeq \theta_{\min} P_S$.

Informally, the first condition above states that the length of any axis of $\mathsf{Ellip}(A_j)$ is upper bounded, and the second condition ensures that the final matrix A_τ has significant contribution towards the bottom k eigenspace X. In other words, instead of ensuring $\ell_j \cdot I \prec A_j \prec u_j \cdot I$, $\Phi^{u_j}(A_j)$ and $\Phi_{\ell_j}(B_j)$ are used to "quantify" the shapes of the two ellipsoids with different dimensions:

- The function $\Phi^{u_j}(A_j)$ studies the ellipsoid A_j projected onto its own top eigenspaces, the subspace that *changes* after each iteration;
- The function $\Phi_{\ell_j}(B_j)$ studies $A_j - X$ projected onto the bottom k eigenspace of X, the subspace that remains *fixed* during the entire BSS process.

Proving the existence of some vector in each iteration so that the algorithm will make progress is much more involved, and constitutes one of the key lemmas used in [22] for constructing a subgraph sparsifier. However, the subgraph sparsification algorithm in [22] requires the computation of the projection matrices $P_{L(A_j)}$ in each iteration. Because of this, the algorithm presented in [22] runs in $\Omega\left(n^2 mk\right)$ time.

Our approach. At a very high level, our algorithm and its analysis can be viewed as a neat combination of the algorithm presented in [26] and the algorithm presented in [22]. Specifically, for any iteration j with the constructed matrix A_j, we set $B_j \triangleq Z(A_j - X)Z$, where $Z \triangleq \left(P_{\mathcal{V}}(I - X)P_{\mathcal{V}}\right)^{\dagger/2}$, and define the two potential functions by

$$\Phi^{u_j}(A_j) \triangleq \operatorname{tr}\left(P_{L(A_j)}\left(u_j I - A_j\right) P_{L(A_j)}\right)^{\dagger q},$$

and

$$\Phi_{\ell_j}(B_j) \triangleq \operatorname{tr}\left(P_{\mathcal{V}}(B_j - \ell_j I)P_{\mathcal{V}}\right)^{\dagger q}$$

for some fixed projection matrix $P_{\mathcal{V}}$, projecting on a k-dimensional subspace S'. Similar with [26], with the help of the q-th power in the definition of $\Phi^{u_j}(A_j)$ and $\Phi_{\ell_j}(B_j)$ we show that the eigenvalues of our constructed matrices A_j and B_j are never very close to the

two barrier values u_j and ℓ_j. Moreover, although the top T-eigenspace of the currently constructed matrix A_j changes after every rank-one update, multiple vectors can still be selected according to some probability distribution in each iteration.

However, when combining the randomised BSS framework [26] with the algorithm presented in [22], we have to take many challenging technical issues into account. In particular, we need to address the following issues: (1) Both the algorithm and its analysis in [22] crucially depend on the projection matrix P_S, of which the exact computation is expensive. Therefore, in order to obtain an efficient algorithm for subgraph sparsification, one needs to obtain some projection matrix close to P_S and such projection matrix can be computed efficiently. (2) As indicated by our definition of $\Phi_{\ell_j}(B_j)$ above, developing a fast subgraph sparsification algorithm would require efficient approximation of polynomials of the matrix $(P_{\mathcal{V}}(B_j - \ell_j I)P_{\mathcal{V}})^q$. In comparison with [26], the fixed projection matrix $P_{\mathcal{V}}$ sandwiched between two consecutive $(B_j - \ell_j I)$ makes computing the required quantities much more challenging.

To address these issues, we prove that there is a k-dimensional subspace S' close to S, and all of our required quantities that involve the projection onto S', denoted by $P_{\mathcal{V}}$, can be computed efficiently. Moreover, we prove that the quality of our constructed subgraph sparsifer based on the "approximate projection" $P_{\mathcal{V}}$ is the same as the one constructed by [22], in which the "optimal projection" P_S is needed. Our result regarding the approximate subspace S' is summarised as follows:

▶ **Lemma 10.** *There is an algorithm that computes a matrix $\mathbb{V} = L^{-1/2}V$ for matrix V in $t_{10} \triangleq \min\left\{O(n^\omega), \widetilde{O}\left(\frac{mk+nk^2}{\sqrt{\lambda_{k+1}(X)}}\right)\right\}$ time, such that with constant probability the following two properties hold: (1) $P_{\mathcal{V}} = VV^\intercal$ is a projection matrix on a k-dimensional subspace S' of $\mathbb{R}^n$; (2) For any $u \in \mathbb{R}^n$ satisfying $u^\intercal V = 0$, we have that*

$$\frac{u^\intercal X u}{u^\intercal u} \geq \frac{\lambda_{k+1}(X)}{2}.$$

We highlight that, in comparison to [26], in our setting the upper and lower potential functions *keep track of two different subspaces whose dimensions are of different orders in most regimes*, i.e., k versus T, and this makes our analysis much more involved than [26]. On the other side, we also show that the algorithm in [26] can be viewed as a special case of our algorithm, and from this aspect our algorithm presents a general framework for constructing spectral sparsifiers and subgraph sparsifiers.

3.2 Description of our algorithm

Our algorithm proceeds in iterations in which multiple vectors are sampled with different probabilities. In each iteration j, A_j is updated by setting $A_{j+1} = A_j + \Delta_j$, where Δ_j is the sum of the sampled rank-one matrices with reweighting. To compensate for this change, the two barriers u_j and ℓ_j are increased by $\delta_{u,j}$ and $\delta_{\ell,j}$. The algorithm terminates when the difference of the barriers is greater than α, defined by $\alpha \triangleq 4k/\Lambda$. Specifically, in the initialisation step, the algorithm sets $A_0 \triangleq X$,$u_0 \triangleq 2 + \lambda_{\max}(X)$, $\ell_0 \triangleq -2k/\Lambda$, where $\Lambda \triangleq \max\{k, T\}$. In each iteration j, the algorithm keeps track of the currently constructed matrix A_j and hence, also of the matrix $B_j \triangleq Z(A_j - X)Z$, where $Z \triangleq (P_{\mathcal{V}}(I - X)P_{\mathcal{V}})^{\dagger/2}$ for some fixed projection matrix $P_{\mathcal{V}}$. Intuitively, the projection matrix $P_{\mathcal{V}}$ used here is close to P_S, but can be approximated more efficiently than computing P_S precisely. In each iteration j, the algorithm starts by computing the *relative effective resistances*, which are defined as

$$R_i(A_j, B_j, u_j, \ell_j) \triangleq v_i^\intercal \left(u_j I - A_j\right)^{-1} v_i + v_i^\intercal Z \left(P_{\mathcal{V}}(B_j - \ell_j I)P_{\mathcal{V}}\right)^\dagger Z v_i,$$

for all vectors v_i. Then, the algorithm computes the number of vectors N_j that will be sampled, which can be written as

$$N_j \triangleq \left(\frac{\varepsilon}{4\rho_j} \cdot \lambda_{\min}\left[(u_j I - A_j)^{-1}\overline{M}\right] \cdot \frac{\lambda_{\max}\left((u_j I - A_j)^{-1}\overline{M}\right)}{\operatorname{tr}\left[(u_j I - A_j)^{-1}\overline{M}\right]}\right)^{2\varepsilon/q} \cdot \rho_j \cdot \min\left\{\frac{1}{\lambda_{\max}\left((u_j I - A_j)^{-1}\overline{M}\right)}, \frac{1}{\lambda_{\max}\left(P_{\mathcal{V}}(B_j - \ell_j I)P_{\mathcal{V}}\right)^\dagger}\right\},$$

where

$$\rho_j \triangleq \sum_{t=1}^{m} R_t(A_j, B_j, u_j, \ell_j) = \operatorname{tr}\left[(u_j I - A_j)^{-1}\overline{M}\right] + \operatorname{tr}\left[P_{\mathcal{V}}(B_j - \ell_j I)P_{\mathcal{V}}\right]^\dagger.$$

Next, the algorithm samples N_j vectors such that every v_i is sampled with probability proportional to $R_i(A_j, B_j, u_j, \ell_j)$, i.e., the sampling probability of every v_i is defined by

$$p(v_i) \triangleq \frac{R_i(A_j, B_j, u_j, \ell_j)}{\sum_{t=1}^{m} R_t(A_j, B_j, u_j, \ell_j)}.$$

For every sampled v_i, the algorithm scales it to

$$w_i \triangleq \sqrt{\frac{\varepsilon}{q \cdot R_i(A, B, u, \ell)}} \cdot v_i,$$

and gradually adds $w_i w_i^\intercal$ to A_j. After each rank-one update, the algorithm increases the barrier values by the average increases

$$\overline{\delta}_{u,j} \triangleq \frac{(1+3\varepsilon)\cdot\varepsilon}{q\cdot\rho_j} \qquad \text{and} \qquad \overline{\delta}_{\ell,j} \triangleq \frac{(1-3\varepsilon)\cdot\varepsilon}{q\cdot\rho_j},$$

and checks whether the terminating condition of the algorithm is satisfied. Note that between two consecutive iterations j and $j+1$ of the algorithm, the two barriers u_j and ℓ_j are increased by $\delta_{u,j} \triangleq N_j \cdot \overline{\delta}_{u,j}$ and $\delta_{\ell,j} \triangleq N_j \cdot \overline{\delta}_{\ell,j}$, respectively.

The formal description of our algorithm is presented in Algorithm 2. We remark that, in contrast to the algorithm for constructing a spectral sparsifier [26], the total number of vectors needed in the final iteration j could be much smaller than $O(N_j)$. This is why our algorithm performs a sanity check in Line 15 after every rank-1 update $w_i w_i^\intercal$.

3.3 Proof sketch of Theorem 9

In this subsection we give an overview of the main techniques used for proving Theorem 9. We refer the reader to the full version of our paper for a more detailed discussion.

Approximation Guarantee

Firstly, we will focus on showing that, at the end of Algorithm 2, (4) holds. The result is summarised in the following lemma, whose proof will be left for the end of this subsection.

Algorithm 2 Algorithm for constructing subgraph spectral sparsifiers.

Require: $\varepsilon \leq 1/20, q \geq 10$

$u_0 = 2 + \lambda_{\max}(X)$, $\ell_0 = -2k/\Lambda$ ▷ Here u_0 and ℓ_0 are the initial barrier values

$\widehat{u} = u_0$ and $\widehat{\ell} = \ell_0$ ▷ Here $\widehat{u}$ and $\widehat{\ell}$ are the current barrier values

$j = 0$ ▷ j will be the index of the current iteration

$A_0 = X$, $B_0 = \mathbf{0}$

while $\widehat{u} - \widehat{\ell} > \alpha + u_0 - \ell_0$ **do** ▷ Start of iteration j

  Compute $R_t(A_j, B_j, \ell_j, u_j)$ and hence $p(v_t)$ for all vectors v_t

  Compute N_j

  Sample N_j vectors $v_1, \dots v_{N_j}$ according to p

  Set $W_j \leftarrow 0$

  for every subphase $i = 1 \dots N_j$ **do** ▷ Start of subphase i

    $w_i \leftarrow \sqrt{\frac{\varepsilon}{q \cdot R_i(A_j, B_j, u_j, \ell_j)}} \cdot v_i$

    $W_j \leftarrow W_j + w_i w_i^\intercal$

    $\widehat{u} \leftarrow \widehat{u} + \overline{\delta}_{u,j}$

    $\widehat{\ell} \leftarrow \widehat{\ell} + \overline{\delta}_{\ell,j}$

    if $\widehat{u} - \widehat{\ell} > \alpha + u_0 - \ell_0$ **then**

      Stop at the current subphase ▷ End of subphase i

  $A_{j+1} \leftarrow A_j + W_j$

  $B_{j+1} \leftarrow Z(A_{j+1} - X)Z$

  $j = j + 1$ ▷ End of iteration j

Return $M = A_j$

▶ **Lemma 11.** *The condition number of the returned matrix A_τ after τ iterations is at most $1 + O(\varepsilon) \cdot \max\{1, T/k\}$. Moreover, it holds that*

$$\lambda_{\min}(A_\tau) \geq c \cdot (1 - O(\varepsilon)) \cdot \lambda_{k+1}(X) \min\{1, k/T\},$$

for some constant c.

The above result is based on the following technical lemma:

▶ **Lemma 12.** *For all iterations j, the following invariant is preserved by Algorithm 2*

$$A_j \prec (1 - \eta) u_j \cdot I \qquad \text{and} \qquad P_{\mathcal{V}} B_j P_{\mathcal{V}} \succeq (\ell_j + |\ell_j|\eta) P_{\mathcal{V}},$$

for some parameter $\eta = O\left(\frac{\varepsilon^{2+2/q}}{n^{2/q}}\right)$.

In order to prove Lemma 12, we need to develop a sequence of results. For the moment, we fix an iteration j. Recall that in this iteration the algorithm samples N_j vectors independently from $\{v_i\}_{i=1}^m$ such that each sampled vector v_i is further scaled to w_i. Moreover, the algorithm keeps track of the matrix

$$W_j \triangleq \sum_{i=1}^{N_j} w_i w_i^\intercal.$$

Our choice of N_j ensures that, with high probability, the matrix W_j has bounded eigenvalues with respect to the matrix A_j.

▶ **Lemma 13.** *Assume that the number of samples satisfies*

$$N_j \leq \left(\frac{\varepsilon}{4\rho_j} \cdot \lambda_{\min}\left[(u_j I - A_j)^{-1}\overline{M}\right] \cdot \frac{\lambda_{\max}\left((u_j I - A_j)^{-1}\overline{M}\right)}{\operatorname{tr}\left[(u_j I - A_j)^{-1}\overline{M}\right]} \right)^{2\varepsilon/q} \cdot \rho_j \cdot \frac{1}{\lambda_{\max}\left((u_j I - A_j)^{-1}\overline{M}\right)}.$$

Then it holds that

$$\mathbf{P}\left[\mathbf{0} \preceq W_j \preceq \frac{1}{2}(u_j I - A_j)\right] \geq 1 - \frac{\varepsilon}{2n}.$$

Notice that if $W_j \preceq \frac{1}{2}(u_j I - A_j)$, W_j's contribution towards the direction of A_j's eigenvector associating with its largest eigenvalue is upper bounded. Thus, conditioned on this event, we can control better the eigenvalues of the resulting matrix $A_{j+1} = A_j + W_j$. Formally, we show the following result:

▶ **Lemma 14.** *It holds that*

$$\mathbf{E}\left[\Phi^{u_{j+1}}(A_{j+1}) \middle| 0 \preceq W_j \preceq \frac{1}{2}(u_j I - A_j)\right] \leq \Phi^{u_j}(A_j) \quad \textit{and}$$
$$\mathbf{E}\left[\Phi_{\ell_{j+1}}(B_{j+1}) \middle| 0 \preceq W_j \preceq \frac{1}{2}(u_j I - A_j)\right] \leq \Phi_{\ell_j}(B_j).$$

Finally, we show that the careful choice of N_j ensures that a sufficiently large number of vectors are sampled in each iteration. This implies that the total number of iterations executed by the algorithm cannot be too large. The result is summarised below:

▶ **Lemma 15.** *With probability at least* $4/5$*, Algorithm 2 finishes in at most*

$$\tau \leq \frac{80q}{3\varepsilon^2} \cdot \frac{1}{c_N} \cdot \Lambda^{(1+2\varepsilon)/q}$$

iterations, where $c_N = \Omega\left((1/(\operatorname{poly}(n))^{2\varepsilon/q}\right)$.

We are now ready to prove the main technical lemma.

Proof of Lemma 12. By Lemma 13, Lemma 15 and the union bound, with probability at least $3/4$, all matrices picked in

$$\tau \leq \frac{80q}{3\varepsilon^2} \cdot \frac{1}{c_N} \cdot \Lambda^{(1+2\varepsilon)/q} \leq \frac{80q}{3\varepsilon^2} \cdot n^{c/q}$$

iterations, for some small constant $c < q$, satisfy $W_j \preceq \frac{1}{2}(u_j I - A_j)$ for all iterations j. Therefore, by Lemma 14 and conditioning on the event that $\forall i : W_i \preceq 1/2 \cdot (u_i I - A_i)$ we have that

$$\mathbf{E}\left[\Phi^{u_j}(A_j) \middle| \forall i : W_i \preceq (1/2) \cdot (u_i I - A_i)\right] \leq \Phi^{u_0}(A_0) \leq \frac{T}{2^q}$$

and

$$\mathbf{E}\left[\Phi_{\ell_j}(B_j) \middle| \forall i : W_i \preceq (1/2) \cdot (u_i I - A_i)\right] \leq \Phi_{\ell_0}(B_0) \leq k \cdot \left(\frac{\Lambda}{2k}\right)^q.$$

By Markov's inequality, it holds with high probability that

$$(\Phi^{u_j}(A_j))^{1/q} = O\left(T^{1/q} \cdot \tau^{1/q}\right) \quad \text{and} \quad \left(\Phi_{\ell_j}(B_j)\right)^{1/q} = O\left(k^{1/q} \cdot \frac{\Lambda}{k} \cdot \tau^{1/q}\right).$$

For any eigenvalue of A_j, say λ_i, we have

$$(u_j - \lambda_i)^{-q} \leq (u_j - \lambda_{\max}(A_j))^{-q} < \sum_{t=n-T+1}^{n} (u_j - \lambda_t(A_j))^{-q} = \Phi^{u_j}(A_j).$$

Therefore, it holds that

$$\lambda_i < u_j - (\Phi^{u_j}(A_j))^{-1/q} \leq u_j - O\left(\frac{1}{T^{1/q}} \cdot \frac{1}{\tau^{1/q}}\right) \leq u_j - O\left(\frac{2}{T^{1/q}} \cdot \left(\frac{\varepsilon^2}{qn^{c/q}}\right)^{1/q}\right).$$

Since u_j is $O(1/\varepsilon^2)$ and $T \leq n$, we can choose $\eta = O\left(\frac{\varepsilon^{2+2/q}}{n^{2/q}}\right)$ such that $A_j \prec (1-\eta)u_j I$.

The second statement can be shown in a similar way, i.e., we show that for any nonzero eigenvalue λ_i of B_j, it holds that $\lambda_i \geq \ell_j + \left(\Phi_{\ell_j}(B_j)\right)^{-1/q}$. Hence

$$\lambda_i \geq \ell_j + \Omega\left(\frac{1}{k^{1/q}} \cdot \frac{k}{\Lambda} \cdot \left(\frac{\varepsilon^2}{qn^{c/q}}\right)^{1/q}\right).$$

Since $|\ell_j| = O\left(\frac{k}{\Lambda} \cdot 1/\varepsilon\right)$ and $k \leq n$, we can choose $\eta = O\left(\frac{\varepsilon^{2+2/q}}{n^{2/q}}\right)$ such that $P_{\mathcal{V}} B_j P_{\mathcal{V}} \succeq (\ell_j + |\ell_j|\eta) P_{\mathcal{V}}$. ◀

Proof sketch of Lemma 11. Notice that it holds for any iteration j that

$$\frac{\overline{\delta}_{u,j} - \overline{\delta}_{\ell,j}}{\overline{\delta}_{u,j}} = \frac{6\varepsilon}{1+3\varepsilon},$$

which implies that

$$\overline{\delta}_{u,j} = \frac{1+3\varepsilon}{6\varepsilon}\left(\overline{\delta}_{u,j} - \overline{\delta}_{\ell,j}\right) \geq \frac{1}{6\varepsilon}\left(\overline{\delta}_{u,j} - \overline{\delta}_{\ell,j}\right).$$

Let u_τ and ℓ_τ be the barrier values when the algorithm terminates, and our goal is to show that

$$\frac{u_\tau}{\ell_\tau} = \left(1 - \frac{u_\tau - \ell_\tau}{u_\tau}\right)^{-1} = 1 + O(\varepsilon) \cdot \max\{1, T/k\},$$

which suffices to prove that

$$\frac{u_\tau - \ell_\tau}{u_\tau} = O(\varepsilon) \cdot \max\{1, T/k\}.$$

By definition, we know that

$$\frac{u_\tau - \ell_\tau}{u_\tau} \leq \frac{u_0 - \ell_0 + \alpha}{u_0 + (6\varepsilon)^{-1}\alpha} \leq \frac{3 + 6k/\Lambda}{2 + (6\varepsilon)^{-1}4k/\Lambda} \leq O(\varepsilon) \cdot \max\{1, T/k\},$$

where the last inequality holds by the definition of Λ. Similar with [22], in the full version of the paper we prove that

$$\lambda_{\min}(A_K) \geq \frac{\theta_{\min}\lambda_{k+1}(X)/2}{\left((\lambda_{k+1}(X)/2)^{1/2} + \theta_{\min}^{1/2} + \theta_{\max}^{1/2}\right)^2}.$$

assuming that $\lambda_{\max}(A_\tau) \leq \theta_{\max}$ and $\lambda_{\min}\left(B_K\big|_{S'}\right) \geq \theta_{\min}$. By setting $\theta_{\min} = \ell_\tau$ and $\theta_{\max} = u_\tau$, the inequality above implies the second statement of the lemma. ◀

The results for the total number of edges (vectors) sampled as well as the assigned costs are summarised below. Due to space constraints, we defer the proofs to the full version of the paper.

▶ **Lemma 16.** *With probability at least* $3/4$*, Algorithm 2 terminates after choosing at most*

$$K = \frac{20 \cdot q\ k}{3 \cdot \varepsilon^2}$$

vectors.

▶ **Lemma 17.** *It holds with constant probability that* $\sum_{i=1}^{m} c_i \cdot cost_i = O(1/\varepsilon^2) \cdot \min\{1, k/T\}$.

Runtime analysis

Now we discuss a fast approximation of the quantities needed for our subgraph sparsification algorithm. We fix an arbitrary iteration j, and drop this subscript for simplicity. A careful inspection tells us that the efficiency of our algorithm is based on the fast approximation of the following quantities:

1. $v_i^\intercal Z \left(P_{\mathcal{V}} \left(B - \ell I\right) P_{\mathcal{V}}\right)^\dagger Z v_i$
2. $\lambda_{\max} \left(P_{\mathcal{V}}(B - \ell I)P_{\mathcal{V}}\right)^\dagger$
3. $\lambda_{\min} \left[(uI - A)^{-1}\overline{M}\right]$
4. $\lambda_{\max} \left[(uI - A)^{-1}\overline{M}\right]$
5. $\operatorname{tr} \left[(uI - A)^{-1}\overline{M}\right]$
6. $v_i^\intercal \left(uI - A\right)^{-1} v_i$

These are precisely the nontrivial quantities required to compute the values N and $R_i(A, B, u, \ell)$ for all vectors v_i. As previously mentioned, for the first two items we use the approximate projection $P_{\mathcal{V}}$ instead of the actual projection P_S on the bottom k eigenspace of X. This is done in order to overcome the expensive exact computation of P_S. We also remark that, while $P_{\mathcal{V}} = VV^\intercal$ for some unitary matrix V is used in our previous analysis, we do not need to compute the matrices V or $P_{\mathcal{V}}$ explicitly. Instead, it suffices to compute the matrix $\mathbb{V} \triangleq L_{G+W}^{-1/2} V$ in order to approximate our required quantities (1), (2). The fast computation of $\mathbb{V}$ builds upon the work of [2] and our result is summarised in Lemma 10.

Once we have access to the matrix $\mathbb{V}$, we can efficiently approximate the above quantities (1)–(6). The techniques we used are inspired from the previous work [4, 26]. However, the presence of the matrix $\overline{M}$ as well as the projection $P_{\mathcal{V}}$ make the computations nontrivial and require extra work. We summarise our results bellow and refer the reader to the full version of the paper for the details of each individual approximation.

▶ **Lemma 18.** *Let j be an arbitrary iteration of Algorithm 2. We can approximately compute the quantities (1)–(6), for all vectors v_i in time*

$$t_{\text{iteration}} = \widetilde{O}\left(\left(\frac{mn^{2/q}}{\varepsilon^{2+2/q}} + \min\left\{n^\omega, mk + nk^2 + k^\omega\right\}\right)/\varepsilon^3\right).$$

The running time of Algorithm 2 is analysed in the next lemma.

▶ **Lemma 19.** *Assuming Algorithm 2 finishes in $\tau = O\left(q \cdot n^{O(1/q)}/\varepsilon^2\right)$ iterations, then the total running time is*

$$t_{\text{alg}} = \widetilde{O}\left(\min\left\{n^\omega, \frac{mk + nk^2}{\sqrt{\lambda_{k+1}(X)}}\right\} + q \cdot n^{O(1/q)}\left(\frac{mn^{2/q}}{\varepsilon^{2+2/q}} + \min\left\{n^\omega, mk + nk^2 + k^\omega\right\}\right)/\varepsilon^5\right).$$

Proof. By Lemma 10, we can compute the matrix $\mathbb{V}$ in time $t_{10} = \min\left\{O(n^\omega), \widetilde{O}\left(\frac{mk+nk^2}{\sqrt{\lambda_{k+1}(X)}}\right)\right\}$. This is computed only once and will be used throughout every iteration.

By Lemma 18, the running time in each iteration is

$$t_{\text{iteration}} = \widetilde{O}\left(\left(\frac{mn^{2/q}}{\varepsilon^{2+2/q}} + \min\left\{n^\omega, mk + nk^2 + k^\omega\right\}\right)/\varepsilon^3\right).$$

Thus, the algorithm's overall running time is

$$\begin{aligned} t_{\text{alg}} &\triangleq t_{10} + \tau \cdot t_{\text{iteration}} \\ &= \widetilde{O}\left(\min\left\{n^\omega, \frac{mk+nk^2}{\sqrt{\lambda_{k+1}(X)}}\right\} + q \cdot n^{O(1/q)}\left(\frac{mn^{2/q}}{\varepsilon^{2+2/q}} + \min\left\{n^\omega, mk + nk^2 + k^\omega\right\}\right)/\varepsilon^5\right). \end{aligned}$$

◀

4 Proof of the main theorem

Finally we apply our fast SDP solver and the subgraph sparsification algorithm to design an algorithm for the spectral-augmentability problem, and prove Theorem 1. We first give an overview of the main algorithm: for any input $G = (V, E)$, the set E_W of candidate edges, and parameter k, our algorithm applies the doubling technique to enumerate all the possible γ under which the input instance is (k, γ)-spectrally augmentable: starting with the initial γ, which is set to be $1/n^{1/q}$ and increases by a factor of 2 each time, the algorithm runs the SDP solver, a subgraph sparsification algorithm, and a Laplacian solver to verify the algebraic connectivity of the output of our subgraph sparsification algorithm. The algorithm terminates if the algebraic connectivity is greater than some threshold at some iteration, or it is below the initial threshold. See Algorithm 3 for formal description.

The following lemma will be used in our analysis.

▶ **Lemma 20.** *Let $\gamma > 0$. If $G = (V, E)$ is $(k, \gamma\Delta)$-spectrally-augmentable with respect to $W = (V, E_W)$, then the SDP solver finds a feasible solution $(\widehat{\lambda}, w)$ to P-SDP$(G, W, k, (1-\delta')\gamma)$, and the subgraph sparsification algorithm with input $G, E_W, k, \varepsilon, q$ and weights $\{w_e : e \in E \cup E_W\}$ will find a graph $H = (V, E \cup F)$ with $F \subseteq E_W$, $\lambda_2(L_H) \geq c_1\gamma^2 \cdot \Delta$, $|F| \leq O(qk/\varepsilon^2)$ and total new weights of edges in F at most $O(k/\varepsilon^2)$.*

Proof. If G is $(k, \gamma\Delta)$-spectrally-augmentable with respect to W, then there exists a feasible solution to P-SDP(G, W, k, γ) and our SDP solver will find a solution $(\widehat{\lambda}, w)$ to P-SDP$(G, W, k, (1-\delta')\gamma)$, for any constant $\delta' > 0$. Note that $\widehat{\lambda} \geq (1-\delta')\gamma$. Now we use the subgraph sparsification algorithm to sparsify the SDP solution.

We apply Theorem 9 to graphs G, W, by setting $V = \text{im}(L_{G+W}) = \ker(L_{G+W})^\perp$, $X = \left(L_{G+W}^{\dagger/2} L_G L_{G+W}^{\dagger/2}\right)_{|V}$ and $Y_e = w_e\left(L_{G+W}^{\dagger/2} L_e L_{G+W}^{\dagger/2}\right)_{|V}$, and $\overline{M} = \sum_{e\in E_W} Y_e$, $K = O(qk/\varepsilon^2)$, $\lambda^* = \lambda_{k+1}(X)$ and $cost_e = \frac{w_e}{\sum_{f\in E_W} w_f}$. Note that $T = \lceil \text{tr}(\overline{M}) \rceil \leq k$. This is true since $\sum_{e\in E_W} w_e \leq k$, $L_{G+W}^{\dagger/2} L_e L_{G+W}^{\dagger/2} \preceq I$, $L_{G+W}^{\dagger/2} L_e L_{G+W}^{\dagger/2}$ is a rank one matrix and has trace at most 1. We get a set of coefficients $\{c_e\}$ supported on at most K edges, such that

$$\begin{aligned} C(1 - O(\varepsilon)) \cdot \min\{1, K/T\} \cdot \lambda_{k+1}(X) &\leq \lambda_{\min}\left(X + \sum_{e\in E_W} c_e Y_e\right) \\ &\leq \lambda_{\max}\left(X + \sum_{e\in E_W} c_e Y_e\right) \leq 1 + O(\varepsilon). \end{aligned}$$

Algorithm 3 Algorithm for augmenting the algebraic connectivity.

Require: the base graph $G = (V, E)$, and the set E_W of m edges defined on V, and $k \in \mathbb{Z}^+$.

$\gamma_0 \leftarrow 1/n^{\frac{1}{q}}$;
$\gamma \leftarrow \gamma_0$;
$\alpha \leftarrow 0$;
$F \leftarrow \emptyset$; ▷ the set of edges added to G
while $\gamma < 1$ **do**
  $\gamma \leftarrow 2 \cdot \gamma$, and run the SDP solver from Theorem 2 for P-SDP(G, W, k, γ)
  if the solver certifies that P-SDP(G, W, k, γ) is infeasible **then**
    if $\alpha = 0$ **then**
      Abort and output **Reject**.
    else
      return graph $H = (V, E(G) \cup F)$. ▷ $\lambda_2(L_H) \geq c_1\alpha^2\Delta$
  else the solver finds a feasible solution for P-SDP$(G, W, k, 0.9\gamma)$ with weights $\{w_e\}_{e\in E_W}$
    $\alpha \leftarrow \gamma$
    Let $H = (V, E(G) \cup F)$ be the output of our subgraph sparsification algorithm with edge weights $\{w_e\}_{e\in E_W}$, q, k and a sufficiently small constant ε.
    $\eta_2 \leftarrow$ a 1.1-approximation of $\lambda_2(L_H)$ ▷ apply the Laplacian solver to compute η_2
    if $\eta_2 \leq O\left(\Delta \cdot n^{-2/q}\right)$ **then**
      Abort and output **Reject**.

From the above and the fact that $T \leq k$, $K = O(qk/\varepsilon^2)$, we have that

$$\begin{aligned}\lambda_2\left(L_G + \sum_e c_e w_e L_e\right) &\geq C(1 - O(\varepsilon)) \cdot \min\{1, K/T\} \cdot \lambda_{k+1}(X) \cdot \lambda_2\left(L_G + \sum_e w_e L_e\right)\\ &\geq C' \cdot \frac{\lambda_{k+2}(L_G)}{4\Delta} \cdot \widehat{\lambda} \cdot \Delta\\ &= \frac{C'}{4} \cdot \widehat{\lambda} \cdot \lambda_{k+2}(L_G)\end{aligned}$$

for some constant $C' > 0$, where the last inequality follows from the fact that

$$\lambda_i(X) = \lambda_i\left(\left(L_{G+W}^{\dagger/2} L_G L_{G+W}^{\dagger/2}\right)\Big|_V\right) \geq \frac{\lambda_{i+1}(L_G)}{4D},$$

for any $i \geq 1$.

▷ Claim 21. It holds that $\lambda_{k+2}(L_G) \geq \lambda_{\mathrm{OPT}}$, the maximum algebraic connectivity of adding a subset set of k edges from E_W to G.

Proof. Let L_R be the Laplacian matrix of the graph which is formed by the optimum solution R. Then $\dim\ker(L_R) \geq n-k$ as $\mathrm{rank}(L_R) \leq |E| \leq k$. Consider the space S spanned by all the eigenvectors of L_G corresponding to $\lambda_2(L_G), \ldots, \lambda_{k+2}(L_G)$. Since $\dim(S) + \dim\ker(L_R) > n$, there exists a unit vector $v \in \ker(L_R) \cap \dim(S)$ such that $v \perp \mathbf{1}$, and

$$v(L_G + L_R)v^{\intercal} \leq \lambda_{k+2}(L_G) + 0 = \lambda_{k+2}(L_G).$$

This further implies that $\lambda_{\mathrm{OPT}} = \lambda_2(L_G + L_R) \leq \lambda_{k+2}(L_G)$. ◁

Therefore, if we let $F = \{e : e \in E_W, c_e > 0\}$ and set the edge weights to be $\{c_e \cdot w_e : e \in F\}$, then the resulting graph $H = (V, E + F)$ with the corresponding weights satisfies that

$$\lambda_2(L_H) = \lambda_2\left(L_G + \sum_e c_e w_e L_e\right) \geq c \cdot \gamma \cdot \lambda_{\mathrm{OPT}} \geq c \cdot \gamma^2 \Delta$$

for some constant $c > 0$, where the last inequality follows from the assumption G is $(k, \gamma\Delta)$-spectrally-augmentable with respect to W and thus $\lambda_{\mathrm{OPT}} \geq \gamma\Delta$. Since

$$\sum_{e \in E_W} cost_e \cdot c_e \leq O(1/\varepsilon^2) \min\{1, K/T\} = O(1/\varepsilon^2),$$

the total weights of added edges become

$$\sum_{e \in E_W} c_e w_e = \left(\sum_{e \in E_W} w_e\right) \cdot \left(\sum_{e \in E_W} cost_e \cdot c_e\right) O(1/\varepsilon^2) \cdot k = O(k/\varepsilon^2). \qquad \blacktriangleleft$$

Finally, we are ready to prove the main theorem of the paper.

Proof of Theorem 1. Let G and W be the input to Algorithm 3. Note that the algorithm only returns a subgraph H with $\lambda_2(L_H) \geq c_1\gamma_0^2\Delta$, and H contains at most $K = O(kq)$ edges from E_W. Hence, if G is not $(O(kq), c_1\gamma_0^2\Delta)$-spectrally-augmentable with respect to W, then the algorithm will reject the input instance.

Without loss of generality, in the following analysis we assume that G is $(k, \lambda_\star\Delta)$-augmentable for some $\lambda_\star > \gamma_0$, where $\lambda_\star\Delta$ is the optimum solution. In this case, by the geometric search over γ in the algorithm, when $\gamma \in (\frac{\lambda_\star}{2}, \lambda_\star)$, the SDP solver will find a feasible solution for P-SDP$(G, W, k, 0.9\gamma)$ and the graph H returned by the subgraph sparsification algorithm with input G, W, q, k and constant ε satisfies that $\lambda_2(L_H) \geq c_1\gamma^2\Delta \geq c_1'\lambda_\star^2\Delta$. If $\gamma \geq \lambda_\star$, then the algorithm will either return the graph H that we constructed corresponding to the value $\gamma \in (\frac{\lambda_\star}{2}, \lambda_\star)$, or finds a graph H with $\lambda_2(L_H) \geq c_1\gamma^2\Delta \geq c_1'\lambda_\star^2\Delta$. By Lemma 20, the number of added edges and the total sum of their weights are $O(qk)$ and $O(k)$, respectively.

Furthermore, since $\lambda_\star \geq \gamma_0$, it only takes $O(\log n)$ iterations to reach γ with $\gamma \in (\frac{\lambda_\star}{2}, \lambda_\star)$. In each iteration, by Theorem 2, the running time for solving P-SDP$(G, W, k, 0.9\gamma)$ for $\gamma \geq \gamma_0$ is $\widetilde{O}(m+n)/\gamma^2) = \widetilde{O}((m+n)n^{O(1/q)})$; by Theorem 9, the time for applying subgraph sparsification with input G, W and constant ε is $\widetilde{O}(\min\left\{qn^{\omega+O(1/q)}, q(m+n)n^{O(1/q)}k^2\right\})$. For the latter, we note that whenever we apply the subgraph sparsification from Theorem 9, the corresponding matrix X satisfies that

$$\lambda_{k+1}(X) \geq \frac{\lambda_{k+2}(L_G)}{4\Delta} \geq \frac{\lambda_{\mathrm{OPT}}}{4\Delta} = \frac{\lambda_\star\Delta}{4\Delta} \geq \frac{\gamma_0\Delta}{4\Delta} = \Omega\left(n^{-1/q}\right)$$

and thus we obtain the claimed runtime. Furthermore, we can compute an estimate η_2 of $\lambda_2(L_H)$ by the algorithm given in [41], which takes $\widetilde{O}(|E(H)|+n) = \widetilde{O}(n+k)$ time. Thus, the total running time is $\widetilde{O}\left(\min\left\{qn^{\omega+O(1/q)}, q(m+n)n^{O(1/q)}k^2\right\}\right)$. This completes the proof of the theorem. $\blacktriangleleft$

Chordless Cycle Packing Is Fixed-Parameter Tractable

Dániel Marx
CISPA Helmholtz Center for Information Security, Saarbrücken, Germany
marx@cispa.saarland

Abstract

A *chordless cycle* or *hole* in a graph G is an induced cycle of length at least 4. In the Hole Packing problem, a graph G and an integer k is given, and the task is to find (if exists) a set of k pairwise vertex-disjoint chordless cycles. Our main result is showing that Hole Packing is fixed-parameter tractable (FPT), that is, can be solved in time $f(k)n^{O(1)}$ for some function f depending only on k.

1 Introduction

The area of graph modification problems contains algorithmic tasks of the following form: given a graph G, find the minimum number of allowed editing operations to make the graph belong to a certain target graph class $\mathcal{G}$. For example, if we allow only vertex deletions and the target graph class is the set of edgeless graphs, forests, directed acyclic graphs, bipartite graphs, then we get well-known Vertex Cover, Feedback Vertex Set, Directed Feedback Vertex Set, Bipartite Deletion problems, respectively. Most of the natural graph modification problems are NP-hard [21, 30, 31]. However, there is a large literature on the fixed-parameter tractability of graph modification problems (see, e.g., [4, 8, 12, 13, 15]). Several problems of this form are known to be solvable in time $f(k)n^{O(1)}$, where k is the number of editing operations allowed (e.g., maximum number of vertices to be deleted) and f is a computable function depending only on k [9].

Let us consider the $\mathcal{G}$ Vertex Deletion problem where, given a graph G and an integer k, the task is to delete k vertices to make the graph belong to class $\mathcal{G}$. If $\mathcal{G}$ is closed under taking induced subgraphs, then there is a (finite or infinite) set $\mathcal{F}$ of obstructions such that a graph is in $\mathcal{G}$ if and only if it does not have an induced subgraph isomorphic to a member of $\mathcal{F}$. Then $\mathcal{G}$ Vertex Deletion can be equivalently expressed as finding k vertices that cover every induced copy of a member of $\mathcal{F}$. For many natural graph properties, the obstruction set $\mathcal{F}$ contains graphs that are simple to describe. For example, the problems Vertex Cover, Feedback Vertex Set, Directed Feedback Vertex Set, and Bipartite Deletion correspond to covering every edge, undirected cycle, directed cycle, and odd cycle, respectively.

Given the interpretation of $\mathcal{G}$ Vertex Deletion as covering objects from the obstruction set $\mathcal{F}$, there is natural dual problem: in the $\mathcal{F}$ Packing problem a graph G and an integer k are given, the task is to find k vertex-disjoint induced subgraphs isomorphic to members of $\mathcal{F}$.

In many cases, packing problems seem to be harder than the corresponding covering problems. First of all, if the graph class $\mathcal{G}$ is recognizable in polynomial-time, then the covering problem can be solved in $n^{O(k)}$ time by brute force, while there is no such immediate argument for the packing problem, even when the class $\mathcal{F}$ consists of very simple objects, such as cycles. For example, Directed Feedback Vertex Set is FPT [6], while the dual problem Directed Cycle Packing is W[1]-hard [28] and it requires a highly nontrivial result to show that it is polynomial-time solvable for fixed k [25]. Even when both problems are FPT, the techniques behind the algorithms could be significantly different. Bipartite Deletion has a very elegant elementary FPT algorithm using iterative compression [26], while the fixed-parameter tractability of the dual problem Odd Cycle Packing required the use of sophisticated techniques, including the introduction of odd minors [18, 19]. Another aspect from which the packing problem proved to be more difficult is the existence of polynomial kernels. For example, Feedback Vertex set (that is, covering cycles) admits a polynomial kernel [29], while the dual problem of finding k vertex-disjoint cycles does not have a polynomial kernel, under the standard complexity assumption $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$ [3].

There is a natural combinatorial question connecting the covering and packing problems. A classic result of Erdős and Pósa [11] shows that if the maximum number of vertex-disjoint cycles in graph G is k, then every cycle of G can be covered by $O(k \log k)$ vertices. A similar question can be asked about other obstructions, connecting the packing and covering problems: if the maximum number of disjoint obstructions from the set $\mathcal{F}$ is at most k, then is it true that every obstruction can be covered by $f(k)$ vertices for some function f? A positive answer is known for example when $\mathcal{F}$ is the set of edges (easy), undirected cycles going through a set S [17, 23], or directed cycles [25], but it is known that no such Erdős-Pósa property holds for odd cycles [24]. Let us observe that, as the cases of odd cycles and directed cycles show, even when the covering problem is FPT, the existence of the Erdős-Pósa property does not give a good prediction on the fixed-parameter tractability of the packing problem.

Chordal graphs. After this general introduction, let us turn our attention to chordal graphs, the main topic of the current paper. A *chordless cycle* or *hole* in a graph G is an induced cycle of length at least 4 (for brevity, we will use the term "hole" throughout the paper). A graph is *chordal* if it does not contain any hole. Chordal graphs form a well-known class of perfect graphs and it is known that a graph is chordal if and only if it can be represented as the intersection graph of a set of subtrees of a tree [14]. Chordal graphs can be recognized in linear time [27]. In the Chordal Vertex Deletion problem, a graph G and an integer k are given, and the task is to find a set S of at most k vertices such that $G - S$ is chordal. While the problem can be solved in time $n^{O(k)}$ by trying every subset of size at most k and then testing for chordality, it is also known to be FPT.

▶ **Theorem 1** ([1, 5, 16, 22]). Chordal Vertex Deletion *is FPT.*

Kim and Kwon gave a constructive proof showing that holes have the Erdős-Pósa property.

▶ **Theorem 2** (Kim and Kwon [20]). *There is a polynomial-time algorithm that, given a graph G and integer k, produces either*

1. *a set of $k+1$ disjoint holes, or*
2. *a set of $O(k^2 \log k)$ vertices covering every hole.*

Our main result concerns the Hole Packing problem, where given a graph G and an integer k, the task is to find a set of k pairwise vertex-disjoint holes.

▶ **Theorem 3** (Main Result). Hole Packing *is FPT.*

Let us remark that it is known that Chordal Vertex Deletion admits a polynomial kernel [1,16], while an easy reduction gives negative evidence for Hole Packing. Bodlaender et al. [3] showed that the problem of finding k pairwise vertex-disjoint cycles does not admit a polynomial kernel under the complexity assumption $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$. If we subdivide every edge of a simple graph, then every cycle has length at least 6, which means that the holes of the new graph are in one-to-one correspondence with the cycles of the original graph. Therefore, the result of Bodlaender et al. [3] immediately implies that Hole Packing has no polynomial kernel, assuming $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$. This can be seen as an indication that the dual problem Hole Packing is more challenging than Chordal Vertex Deletion, and it can be expected that more involved algorithmic ideas are needed for this problem.

Our techniques. To explain the main ideas and challenges behind the algorithm of Theorem 3, let us briefly overview the Chordal Vertex Deletion algorithm of Marx [22]; our algorithm mirrors the technical ideas from that result up to a certain point, but then it needs to deviate from it significantly. When solving Chordal Vertex Deletion, the standard technique of iterative compression [26] allows us to assume that we know a set W of $k+1$ vertices such that $G-W$ is chordal and furthermore we can assume that the solution S of size k we are looking for is disjoint from W. If the size of the largest clique in $G-W$ can be bounded by a function of k, then the treewidth of the chordal graph $G-W$ and hence also the treewidth of the slightly larger (not necessarily chordal) G can be bounded by a function of k. In this case, the problem can be solved on the graph G using standard algorithmic techniques on graphs of bounded treewidth, for example, using Courcelle's Theorem [7].

If $G-W$ has a large clique K, then, intuitively, we want to argue that a large part of the clique is not really important for the problem. More formally, we want to identify a vertex $v \in K$ such that removing k from G does not make the problem any easier. We say that v is *irrelevant* if for every set of S of size at most k disjoint from W, if there is a hole in $G-S$, then there is a hole in $G-(S \cup \{v\})$ as well. The algorithm of Marx [22] marks a certain number of vertices in K as important and then it is argued that every other vertex $v \in K$ is irrelevant in this sense. The proof is mostly a rerouting argument: if there is a hole going through v in $G-S$, then it has to be shown that the hole can be modified to avoid v.

To solve the Hole Packing problem, let us observe that Theorem 2 allows us to assume that we have a set W of $O(k^2 \log k)$ vertices such that $G-W$ is chordal: if the algorithm of Theorem 2 terminates with Outcome 1, then we are done. If $G-W$ has maximum clique size bounded by function of k, then G has bounded treewidth and we can use standard techniques to find a set of k vertex-disjoint holes. Thus our goal again is to argue that we can find an irrelevant vertex v in a large clique K. But now our notion of irrelevant vertex is different: for Chordal Vertex Deletion, a vertex needed to be irrelevant with respect to a deletion set S of at most k vertices, while for Hole Packing, vertex v needs to be irrelevant with respect to a set of $k-1$ holes. Formally, now we can say that v is *irrelevant* if whenever G has a set $\mathcal{H}$ of k disjoint holes, then there is such a set avoiding v. The set W splits $\mathcal{H}$ into at most k induced paths. Therefore, we again need a rerouting argument: the induced path going through v needs to be rerouted to avoid the other at most $|W|-1$ induced paths.

Rerouting a path to avoid a bounded number of induced paths seems to be a significantly more challenging task compared to avoiding a bounded number of vertices: the paths can be arbitrarily long and we cannot bound the number of vertices they contain. However, it is useful to observe that an induced path can contain at most two vertices from a clique. Therefore, looking locally at a clique, avoiding a bounded number of induced paths is not all that different from avoiding a bounded number of vertices. Indeed, it seems that we can

reuse many of the technical ideas from [22] to Hole Packing (we found it convenient to use somewhat different notation and streamlined some of the proofs, but we face essentially the same difficulties and similar arguments are needed). However, we did not manage to fully translate the approach to Hole Packing and to reduce the maximum clique size of $G - W$ (and hence the treewidth of G) to be bounded by a function of k. There is a particular situation where no vertex of a large clique can be declared irrelevant under our definition; Section 5 describes an example.

The first part of our algorithm uses these irrelevant vertex arguments to find a bounded-treewidth subgraph of G that contains the solution, except a few vertices of the solution that appear in a very specific situation (Section 3). This part of the proof uses ideas similar to the Chordal Vertex Deletion algorithm of [22], with appropriate modifications to account for induced paths. The main technical novelty of the paper appears in the way the problem is treated after this step. We find a way of encoding the problem in a bounded-treewidth labeled graph; however, for this to work, we need to leave the setting of the Hole Packing problem and introduce a technical variant of the problem which we call Special Hole Packing (Section 4). This problem involves finding k pairwise disjoint holes subject to certain technical conditions on the labels of vertices used by the holes. We show that when we move to this problem, then the large cliques can be reduced. Essentially, if there is a vertex v in a large clique K, then we look at the subtree intersection representation of the chordal graph $G - W$, and replace the subtree T_v representing v with a set of vertices representing the leaves of T_v. Applying this operation to every vertex of every large clique results in a graph with bounded treewidth. An appropriate choice of labeling, provided by the Color Coding [2] method, ensures that the reduction results in an instance of Special Hole Packing whose solution gives a solution to the original problem.

2 Preliminaries

We use standard graph-theoretic notation, see e.g. [10]. For background on parameterized algorithms, see [9]. In this section, we only discuss notation and basic results related to treewidth and chordal graphs.

Treewidth. A *tree decomposition* of a graph G is a pair $(T, \mathcal{B})$ in which T is a tree and $\mathcal{B} = \{B_t \mid t \in V(T)\}$ is a family of subsets of $V(G)$ such that

1. $\bigcup_{t \in V(T)} B_i = V(G)$;
2. for each edge $e = uv \in E(G)$, there exists an $t \in V(T)$ such that both u and v belong to B_t; and
3. the set of nodes $\{t \in V(T) \mid v \in B_t\}$ forms a connected subtree of T for every $v \in V(G)$.

To distinguish between vertices of the original graph G and vertices of T in the tree decomposition, we call vertices of T *nodes* and their corresponding B_i's *bags*. The *width* of the tree decomposition is the maximum size of a bag in $\mathcal{B}$ minus 1. The *treewidth* of a graph G, denoted by $\mathrm{tw}(G)$, is the minimum width over all possible tree decompositions of G.

Sentences in *Monadic Second Order Logic of Graphs* (MSO) contain quantifiers, logical connectives ($\neg$, $\vee$, and $\wedge$), vertex variables, vertex set variables, binary relations $\in$ and $=$, and the atomic formula $E(u, v)$ expressing that u and v are adjacent. Courcelle's Theorem states that if a graph property can be described in this language, then this description can be turned into an algorithm:

▶ **Theorem 4** (Courcelle [7]). *If a graph property can be described as a formula ϕ in the Monadic Second Order Logic of Graphs, then it can be recognized in time $f(|\phi|, \mathrm{tw}(G)) \cdot (|E(G)| + |V(G)|)$ if a given graph G has this property.*

Courcelle's Theorem works also in the more general setting of relational structures. For our purposes, it will be sufficient to know that the result can be extended in such a way that the input graph G comes with a labeling $\lambda : V(G) \to [c]$ of the vertices and the formula ϕ may contain unary predicates $C_1(v), \ldots, C_c(v)$, stating that vertex v has a label.

Chordal graphs. A *chordless cycle* or *hole* in a graph G is an induced cycle of length at least 4. A graph is *chordal* if it does not contain any hole. It is well known that a graph is chordal if and only if it can be represented as the intersection graph of subtrees of a tree. That is, every chordal graph G can be represented by a tree T and a subtree T_v of T corresponding to every $v \in V(G)$ such that $u, v \in V(G)$ are adjacent if and only if T_u and T_v share at least one node in T. Equivalently, a graph G is chordal if and only if it has a tree decomposition $(T, \mathcal{B})$ where every bag B_t induces a clique $G[B_t]$ for every $t \in V(T)$. Such a tree decomposition is also called a *clique tree decomposition*. We will use the well-known fact that if K is a clique in the chordal graph, then the clique tree decomposition contains a node t with $K \subseteq B_t$.

The following lemma is straightforward:

▶ **Lemma 5.** *Let x and y be two nonadjacent neighbors of v and let P be an $x - y$ path whose internal vertices are not in the closed neighborhood of v. Then the graph induced by $V(P) \cup \{v\}$ contains a hole.*

Induced paths. Suppose that $\mathcal{H}$ is a collection of holes in a graph G and W is a set of vertices that intersects each hole in $\mathcal{H}$. Then W splits each hole in $\mathcal{H}$ into some number of induced paths, that is, what remains from $\mathcal{H}$ is a collection of at most $|W|$ induced paths. This motivates the following definition.

▶ **Definition 6.** *A set X of vertices of a graph G is a* k-IP set *if it has partition $(X_1, \ldots, X_{k'})$ into $k' \leq k$ classes such that each $G[X_i]$ is an induced path (possibly of length 0, i.e., consisting only of a single vertex).*

Note that this definition allows the existence of arbitrary edges between X_i and X_j for $i \neq j$. The first basic observation is that such a set has small intersection with a clique.

▶ **Lemma 7.** *Let X be a k-IP set in a graph G and let K be a clique in G. Then X contains at most $2k$ vertices of K.*

Proof. Let $(X_1, \ldots, X_{k'})$ be a partition of X into induced paths. It is clear that an induced path can contain at most two vertices of the clique K, hence $|X \cap K| \leq 2k' \leq 2k$. ◀

The second observation is that a k-IP set can enter only a bounded number of components after the removal of a clique (or, more generally, if the neighborhood of each resulting component is a clique).

▶ **Lemma 8.** *Let X be a k-IP set in graph G and let Y be a set of vertices such that it is true for every component C of $G - Y$ that the neighborhood of C in Y is a clique. Then X intersects at most $2k$ components of $G - Y$.*

Proof. Let $(X_1, \ldots, X_{k'})$ be a partition of X into induced paths. We claim that each X_i can intersect at most two components of $G - Y$. If X_i intersects three components, then it is true for some component C that the induced path $G[P_i]$ enters C from Y and then later leaves C to Y. But the neighborhood of C in Y is a clique, contradicting the assumption that $G[X_i]$ is an induced path. Thus in total X can intersect at most $2k' \leq 2k$ components of $G - Y$. ◀

3 Part 1: Treewidth reduction (almost)

Given an instance (G, k) of Hole Packing, an application of Theorem 2 gives us a set W of $O(k^2 \log k)$ vertices such that $G - W$ is chordal. The main result of this section is a marking procedure (Lemma 9) that identifies a bounded-treewidth part of the graph that *almost* contains the solution. As $G - W$ is chordal, every hole in G contains at least one vertex of W. A *special hole* is a hole that contains exactly one vertex of W. The *special vertices* of a special hole H going through $w \in W$ are the two neighbors of w in H. Note that, as every hole has length at least 4, the two special vertices of a special hole are not adjacent.

▶ **Lemma 9.** *Let G be graph and W be a set of vertices such that $G - W$ is chordal, and let k be an integer. In polynomial time, we can find a set $S \subseteq V(G) \setminus W$ of vertices such that the following holds:*

1. *If G has a set of k pairwise disjoint holes, then there is such a set $\mathcal{H}$ where every vertex of every hole is in $S \cup W$, except possibly some of the special vertices of the special holes.*
2. *The maximum clique size in $G[S]$ is $12(|W| + 2)^4$.*

The proof of Lemma 9 starts with $S = V(G) \setminus W$ and if $G[S]$ contains a large clique K, then it tries to identify a vertex $v \in K$ that can be excluded from S without violating Requirement 1. Towards this goal, the following lemma either finds a collection of paths that are useful for creating holes going through K (Outcome 1), or marks a bounded-sized set M of vertices that are somehow important in the clique and a path reaching the clique at a vertex of $K \setminus M$ can be rerouted to reach the clique at some other vertex (Outcome 2).

▶ **Lemma 10.** *Let K be a clique in a chordal graph G, A be a set of vertices, and k be an integer. There is a polynomial-time algorithm that produces one of the following two outcomes:*

1. *A collections $\mathcal{P}$ of paths such that*
   - *every path in $\mathcal{P}$ is a path of length at least one from A to K with exactly one vertex in A,*
   - *the first endpoints of the paths in $\mathcal{P}$ form an independent set of A, and*
   - *if X is a k-IP set, then at least* two *of the paths in $\mathcal{P}$ are disjoint from X.*
2. *A subset M of K having size at most $(2k + 1)(4k + 2)$ such that following holds: if P is a path of length at least one from $a \in A$ to $v \in K \setminus M$ having exactly one vertex in A, and X is a k-IP set disjoint from $V(P)$, then there is a path P' from vertex $a \in A$ to a vertex of K such that P' is disjoint from $X \cup \{v\}$ and moreover $V(P') \setminus V(P) \subseteq K$. (Note that path P' can have length 0 and may contain more than one vertex from A.)*

Proof. Let us consider a subtree representation of the chordal graph G over the tree T. For every node $x \in V(T)$, let us denote by bag B_x the set of those vertices whose subtrees contain x. Let U be the set of nodes y for which $|B_y \cap K| > 2k + 1$. It is easy to see that U induces a connected subtree of T. Let subtrees $T_1, \ldots, T_c$ be the components of $T - U$ and let C_i contain those vertices of G whose subtrees are completely contained in the subtree T_i. Every T_i has a unique node w_i that is adjacent to U. Let us observe that the neighborhood

of every C_i is a clique: if a vertex v has a neighbor in C_i, but it is not itself in C_i, then the subtree T_v has to contain a node of T_i and a node not in T_i. This is only possible if the subtree T_v contains node w_i and such vertices v form a clique.

For every $1 \leq i \leq c$, let $M_i \subseteq K$ be defined the following way. If for a vertex $v \in K$, there is a path P_v^i of length at least one from a vertex of A to v such that P_v^i has exactly one vertex in A and every vertex of P_v^i except v is in C_i, then we put v into M_i. For the rest of the proof, let us fix such a path P_v^i for every vertex $v \in M_i$. Let us observe that if $v \in M_i$, then the subtree of v contains a node of T_i and a node of U, hence it contains the node w_i. As $w_i \notin U$ by definition, there are at most $2k+1$ vertices of K whose subtree contains w_i and $|M_i| \leq 2k+1$ follows.

Let $M = \bigcup_{i=1}^{c} M_i$. We consider two cases. If $|M| > (2k+1)(4k+1)$, then we claim the set of paths required by Outcome 1 exist. In this case, a simple greedy selection argument shows the existence of a subset of $t = 4k+2$ paths $P_{v_1}^{i_1}, \ldots, P_{v_t}^{i_t}$ of the paths defined above such that the integers $i_1, \ldots, i_t$ and the vertices $v_1, \ldots, v_t$ are all distinct. That is, if we have already selected $j \leq 4k+1$ of these paths, then they together can block at most $(2k+1)j \leq (2k+1)(4k+1)$ vertices of M, hence we can add one more path $P_{v_{j+1}}^{i_{j+1}}$ to our collection. We claim that these paths satisfy the requirements. Path $P_{v_j}^{i_j}$ starts in a vertex of $A \cap C_{i_j}$, whose subtree is fully contained in T_{i_j}. As $i_1, \ldots, i_t$ are distinct integers, the start vertices of these paths are independent vertices of A, as required. Let now X be a k-IP. By Lemma 7, X contains at most $2k$ vertices of K, thus it can intersect at most $2k$ of the vertices $v_1, \ldots, v_h$. By Lemma 8, X can intersect at most $2k$ of the sets $C_{i_1}, \ldots, C_{i_h}$: recall that the neighborhood of each C_j is a clique. In summary, X contain at most $2k$ of $v_{i_1}, \ldots, v_{i_t}$ and intersects at most $2k$ of $C_{i_t}, \ldots, C_{i_t}$, hence there are at least *two* values of j for which X is disjoint from $P_{v_j}^{i_j}$, as required.

The second case is when $|M| \leq (2k+1)(4k+2)$. In this case, we show that M satisfies the requirements of Outcome 2. Let $P = p_1, \ldots, p_\ell$ be a path as in the statement of the lemma with $\ell \geq 2$, $p_1 = a \in A$, and $p_\ell = v \in K \setminus M$ and suppose that $V(P)$ is disjoint from a k-IP set X. If $p_{\ell'} \in K$ for some $1 \leq \ell' < \ell$, then the subpath P' of P from a to $p_{\ell'}$ satisfies the requirements (this includes the case when $a \in K$; Outcome 2 allows that P' has length 0). If $p_{\ell'}$ has more than $2k+1$ neighbors in K for some $1 \leq \ell' < \ell$, then $p_{\ell'}$ has a neighbor $v' \in K \setminus (X \cup \{v\})$ (as $|X \cap K| \leq 2k$ by Lemma 5). Then the path $P' = p_1, \ldots, p_{\ell'}, v'$ satisfies the requirements. Suppose therefore that each vertex $p_{\ell'}$ with $\ell' \in [\ell - 1]$ has at most $2k+1$ neighbors in K. This implies that the subtrees corresponding to these vertices do not intersect U and it follows that all these vertices are in the same set C_i. Now the path P shows that $v \in M_i \subseteq M$, a contradiction. ◀

There is a particularly problematic special case that we handle in a separate lemma. It concerns the case when a hole contains a single vertex v from a clique K and the two neighbors of v are in W. It may seem like an easy, degenerate case (after all, rerouting to avoid v means finding another common neighbor of the two neighbors of w in W), but actually it is relatively complicated to find a replacement of v without introducing unwanted adjacencies.

▶ **Lemma 11.** *Let G be a graph with two vertices w_x and w_y such that $G - \{w_x, w_y\}$ is chordal, let K be a clique in $G - \{w_x, w_y\}$, and let k be an integer. In polynomial time, we can find a set $M \subseteq K$ of at most $(2k+4)(2k+1)$ vertices such that the following holds: If X is a k-IP set, and H is a hole disjoint from X and with $V(H) \cap W = \{w_x, w_y\}$ such that H has a vertex $v \in K \setminus M$ adjacent to both w_x and w_y, then there is a hole H' disjoint from $X \cup \{v\}$.*

Proof. Let us consider a subtree representation of the chordal graph G over the tree T. For every node $x \in V(T)$, let us denote by bag B_x the set of those vertices whose subtrees contain x. Let us assume that T is a rooted at a node r and that subtree T_u for every $u \in K$ contains r. For a node x of T, let us define $C_x \subseteq V(G) \setminus \{w_1, w_2\}$ the following way: a vertex u is in C_x if the subtree T_u of u is fully contained in the subtree of T rooted at x. Observe that the neighborhood of C_x (in $G - \{w_1, w_2\}$) is a clique: if u has a neighbor in C_x, but is not itself in C_x, then T_u has to contain the parent node of x.

We say that path P is a *good path* if it is either a path of length 0 consisting a single vertex adjacent to both w_x and w_y, or a path of length at least 1 where the unique vertex adjacent to w_x is one of the endpoints, and the unique vertex adjacent to w_y is the other endpoint. Observe that if P_1 and P_2 are two good paths that have no adjacent vertices, then P_1, P_2, w_x, w_y together form a hole of length at least 4.

Let Z be the set of nodes of T with the following property: a node x is in Z if $G[C_x]$ contains a good path. By definition, Z induces a subtree of T rooted at r: if a node is in Z, then all its ancestors are also in Z. Let $\ell_1, \ldots, \ell_t$ be the leaves of Z.

Let us consider first the case when $T[Z]$ has at least $2k + 5$ leaves. We claim that in this case returning $M = \emptyset$ is a valid answer. As the sets $C_{\ell_1}, \ldots, C_{\ell_t}$ are disjoint, nonadjacent, and the neighborhood of each of them is a clique, Lemma 8 implies that the $(k + 1)$-IP set $X \cup \{v\}$ can intersect at most $2k + 3$ of the sets $C_{\ell_1}, \ldots, C_{\ell_t}$. This means that there are at least two such sets that are disjoint from X; assume, without loss of generality that $X \cup \{v\}$ is disjoint from C_{ℓ_1} and C_{ℓ_2}. By assumption, there are two good paths P_i for $i = 1, 2$ such that P_i is in $G[C_{\ell_i}]$. As there are no edges between P_1 and P_2, we have that P_1, P_2, w_x, w_y together form a hole H' that is disjoint from $X \cup \{v\}$.

Assume therefore that $t \leq 2k + 4$. We construct M using the following procedure. For every $x \in Z$, let M_x contain the vertices $u \in K$ with the property that u is adjacent to both w_1 and w_2, and moreover T_u does not contain x. Observe that $M_x \subseteq M_y$ if x is an ancestor of y. Set $M = \emptyset$ initially. Let us consider the nodes of Z in a top down order, i.e., in a nondecreasing ordering by the distance from the root r. When considering $x \in Z$, extend M using vertices of M_x until either $|M \cap M_x| \geq 2k + 1$ or $M_x \subseteq M$. This completes the definition of M.

We claim that $|M| \leq (2k + 4)(2k + 1)$. Let the weight h_x be the number of vertices added to M when considering node x. We claim that the total weight of a node x and all its ancestors is at most $(2k + 1)$. To prove this, consider a node x such that the total weight of its proper ancestors is $h < 2k + 1$, but $h + h_x > 2k + 1$. Observe that the h vertices added to M by the proper ancestors all appear in M_x and hence we should have added only $2k + 1 - h < h_x$ new vertices of M_x when considering node x, a contradiction. In particular, the statement holds for the leaves of $G[Z]$, hence it follows that the total weight (i.e., the size of M) is at most $t(2k + 1) \leq (2k + 4)(2k + 1)$.

It remains to show that M satisfies the statement of the lemma. Observe that if we remove v, w_x, w_y from the hole H, then what remains is a good path P. Let us choose x to be node of T such that C_x contains P and x has maximum distance to the root r. This means that the bag B_x contains a vertex of P, which also implies that T_v cannot contain x, that is, $v \in M_x$. If $|M_x| \leq 2k + 1$, then the construction of M ensures $M_x \subseteq M$, contradicting $v \in K \setminus M$. If $|M_x| \geq 2k + 2$, then by Lemma 7, M_x contains a vertex v' disjoint from the k-IP set X and different from v. As P is in C_x and $v' \in M_x$, vertex v' is not adjacent to any vertex of P. Thus replacing v with v' in the hole H results in a hole H' that is disjoint from $X \cup \{v\}$. ◀

We are now ready to prove the main result of the section, Lemma 9.

Proof (of Lemma 9). The set $S = V(G) \setminus W$ trivially satisfies Requirement 1. We show that if S satisfies Requirement 1 and has a large clique violating Requirement 2, then we can remove a vertex from S in a way that Requirement 1 remains satisfied. After repeated applications of this argument, we eventually arrive to a set S that satisfies both Requirements 1 and 2.

Suppose that S satisfies Requirement 1, but $G[S]$ has a clique K of size greater than $12(|W|+2)^4$ (as $G[S]$ is chordal, such a clique can be found in polynomial time). We define a set $M \subseteq K$ by invoking the procedure of Lemma 10 with different values for the parameters (G, K, A, k) and then argue that removing from S any vertex $v \in K \setminus M$ does not violate Requirement 1. We need some definitions first. For $w \in W$, let A_w be the neighborhood of w in S. For $w_1, w_2 \in W$, let $A_{w_1,w_2} = A_{w_1} \cap A_{w_2}$ and $A_{w_1,\overline{w_2}} = A_{w_1} \setminus A_{w_2}$. Let $K_{w_1} = K \cap A_{w_1}$, $K_{\overline{w_1}} = K \setminus A_{w_1}$, $K_{w_1,w_2} = K \cap A_{w_1,w_2}$, and $K_{w_1,\overline{w_2}} = K \cap A_{w_1,\overline{w_2}}$.

The set M is the defined the following way. We invoke the algorithm of Lemma 10 with various graphs and sets as listed below.

1. For every $w \in W$, we invoke the procedure with $(G[S], K_{\overline{w}}, A_w, |W|+1)$ and we let $\mathcal{P}_w$ be the set of paths in case of Outcome 1 and M_w be the resulting set in case of Outcome 2.
2. For every $w_1, w_2 \in W$ with $w_1 \neq w_2$, we invoke the procedure with $(G[S \setminus A_{w_2}], K_{\overline{w_2}}, A_{w_1,\overline{w_2}}, |W|+1)$ and we let $\mathcal{P}_{w_1,\overline{w_2}}$ be the set of paths in case of Outcome 1 and $M_{w_1,\overline{w_2}}$ be the resulting set in case of Outcome 2.

The set M is defined to be the union of all these sets M_w and $M_{w_1,\overline{w_2}}$ (for all the values w and $(w_1, \overline{w_2})$ for which the algorithm of Lemma 10 terminated with Outcome 2). Additionally, for every distinct $w_1, w_2 \in W$, we extend M the following way:

1. We put arbitrarily $2|W|+1$ vertices of $K_{w_1,\overline{w_2}}$ into M or all such vertices, if fewer than $2|W|+1$ such vertices exist.
2. We put arbitrarily $2|W|+1$ vertices of K_{w_1,w_2} into M or all such v
3. We extend M with the set returned by the algorithm of Lemma 11 for $G[S \cup \{w_1, w_2\}]$, the clique K, and $k = |W|$.

To bound the size of M, let us observe that we invoke the algorithm of Lemma 10 exactly $|W|+|W|(|W|-1)$ times, each time with parameter $k = |W|+1$. As each call returns a set of size at most $(2k+1)(4k+2)$, the total number of vertices in M obtained this way is at most $8(|W|+2)^4$. Additionally, we include at most $|W|^2(2(2|W|+1)+(2|W|+4)(2|W|+1)) \leq 4(|W|+2)^4$ vertices into M, resulting in at most $12(|W|+2)^4$ vertices in total. We assumed that K has size greater than $12(|W|+2)^4$, hence there exists at least one vertex in $K \setminus M$.

The rest of the proof is devoted to showing that Requirement 1 remains satisfied after removing a vertex $v \in K \setminus M$ from S. If G has no k pairwise disjoint holes, then there is nothing to show; otherwise, as let us fix a collection $\mathcal{H}$ of k pairwise disjoint holes such that every vertex of these holes is in $S \cup W$, except possibly some of the special vertices. Let us choose $\mathcal{H}$ such that the total number of vertices used from W is minimized.

If no hole goes through vertex v, then we are done. Otherwise, let $H \in \mathcal{H}$ be the hole containing v. We may assume that v is not a special endpoint of H, otherwise $S \setminus \{v\}$ still satisfies Requirement 1. Let X be the union of the vertices in $V(G) \setminus W$ used by the holes in $\mathcal{H} \setminus \{H\}$. It is clear that X is a $|W|$-IP set: each hole uses at least one vertex of W and the vertices of W split these holes into a collection of at most $|W|$ induced paths. It also follows that $X \cup \{v\}$ is a $(|W|+1)$-IP set.

As $G - W$ is chordal, H contains at least one vertex of W. The following claim shows that in the definition of M above, the set M_w was defined for every vertex $w \in V(H) \cap W$ (and the same is true for $M_{w,\overline{w'}}$ for any $w' \in W$).

▷ Claim 12. For every $w \in V(H) \cap W$,

1. the set M_w is defined,
2. the set $M_{w,\overline{w'}}$ is defined for every $w' \in W$ with $w' \neq w$.

Proof. If M_w was not defined, then the algorithm of Lemma 10 terminated with Outcome 1 on input $(G[S], K_{\overline{w}}, A_w, |W|+1)$, resulting in a set $\mathcal{P}_w$ of paths satisfying the requirements of Outcome 1. This means that there are two paths $P_1, P_2 \in \mathcal{P}_w$ of length at least one that are disjoint from the $(|W|+1)$-IP set $X \cup \{v\}$. For $i = 1, 2$, let $a_i \in A_w$ and $z_i \in K$ be the endpoints of P_i. Now z_1 and z_2 either coincide or are adjacent in the clique K, thus concatenating them gives a walk that contains an $a_1 - a_2$ simple path P. From the conditions on P_1 and P_2, we also know that a_1 and a_2 are independent and the internal vertices of P are not in A_w, that is, not adjacent to w. Thus Lemma 5 shows that w and P form a hole H' of length at least 4 disjoint from $X \cup \{v\}$ and fully contained in $S \cup W$. Replacing H with H' in $\mathcal{H}$ would give a collection of k holes satisfying Requirement 1, even if v is removed from S, what we wanted to show.

In an analogous way, we can show that if the algorithm of Lemma 10 terminated with Outcome 1 on input $(G[S \setminus A_{w'}], K_{\overline{w'}}, A_{w,\overline{w'}}, |W|+1)$, then there is a path of length at least 2 connecting two independent vertices of $A_{w,\overline{w'}}$ in $G[S \setminus A_w]$ that is disjoint from $X \cup \{v\}$, forming a hole with w. This proves the second statement. ◁

The set $V(H) \setminus W$ induces a set of at least one and at most $|W|$ induced paths in $G - W$ (a path can consists of only a single vertex). Let P be the subpath of H that contains v. Fixing an orientation of H, let $w_x, w_y \in W$ be the previous and next vertices of H (note that $|V(H) \cap W| = 1$ if and only if $w_x = w_y$). We try to reroute P to obtain a path P' that avoids v. Then we replace P with P' in the hole H and try to obtain a hole H' that avoids v, showing that there is a collection of k disjoint holes that satisfies Requirement 1 even if v is removed from S. For this, we need to ensure that the new path P' is independent from the rest of H in a certain way. Thus there are two challenges here: finding the rerouted path P' that avoids v and ensuring that replacing P with P' results in hole.

The rest of the proof depends on the size $V(H) \cap W$. The most generic case is when $V(H) \cap W$ has at least 3 vertices. In this case, we can use that H visits a third vertex $w_z \in H$ different w_x, w_y and P is not adjacent to P; then it is sufficient to ensure that P' is also not adjacent to w_y. The case $|V(H) \cap W| = 2$ is similar, but then we need different arguments to ensure that H' is a hole. In the case $|V(H) \cap W| = 1$, an additional complication is that $w_x = w_y$, hence the endpoints of P' need to be nonadjacent.

Case A: $|V(H) \cap W| \geq 3$. Then $w_x \neq w_y$ and there is at least one other $w_z \in V(H) \cap W$ different from w_x and w_y. Our goal is to show that there is an $A_{w_x,\overline{w_z}} - A_{w_y,\overline{w_z}}$ path P' in $G[S \setminus A_{w_z}]$ that is disjoint from $X \cup \{v\}$. Assuming there is such a path P', let u_1 and u_2 be the two neighbors of w_z on the hole H (note that $u_1, u_2 \notin P$). Replacing P with P' in the hole H shows that that there is a $u_1 - u_2$ walk whose internal vertices are not adjacent to w_z (here we use that the endpoints of P' are adjacent to w_x and w_y, respectively, and the vertices of P' are not adjacent to w_z). Thus by Lemma 5, there is a hole disjoint from $X \cup \{v\}$.

The path P' is constructed as follows. We will construct two paths P'_x and P'_y in $G[S \setminus A_{w_z}]$ such that P'_x and P'_y are $A_{w_x,\overline{w_z}} - K_{\overline{w_z}}$ and $A_{w_y,\overline{w_z}} - K_{\overline{w_z}}$ paths, respectively, and they are both disjoint from $X \cup \{v\}$. As any two vertices of $K_{\overline{w_z}}$ are adjacent, the concatenation of the two paths gives a walk that can be simplified to the required path P'.

The path P can be split into a path P_x going from a vertex $v_x \in A_{w_x,\overline{w_z}}$ to v, and into a path P_y going from a vertex $v_y \in A_{w_y,\overline{w_z}}$ to v (now one or both of these paths can be of length 0). We show how to construct P'_x; the construction of P'_y is analogous. If P_x has length at least one, then we use that, by Claim 12, Outcome 2 was the result of applying Lemma 10 when defining $M_{w_x,\overline{w_z}}$. As P_x is a path from v_x to $v \in K_{\overline{w_z}} \setminus M \subseteq K_{\overline{w_z}} \setminus M_{w_x,\overline{w_z}}$ and it is disjoint from X, Outcome 2 guarantees the existence of a path P'_x from v_x to $K_{\overline{w_z}}$ that is disjoint from $X \cup \{v\}$. If P_x has length 0, then $v_x = v$ is in $K_{w_x,\overline{w_z}}$. When defining the set M, we tried to put $2|W|+1$ vertices of $K_{w_x,\overline{w_z}}$ into M. As v was not put into this set, we have that M contains $2|W|+1$ other vertices of $K_{w_x,\overline{w_z}}$. As the $|W|$-IP set X can contain at most $2|W|$ vertices of $K_{\overline{w_z}}$ (Lemma 7), there is a vertex $v' \in K_{w_x,\overline{w_z}} \setminus X$ different from v. Now the path P'_x of length 0 consisting of only v' satisfies the requirements. Path P'_y can be obtained in a similar way, completing our proof for the existence of the path P'.

Case B: $|V(H) \cap W| = 2$. In this case, $H - W$ consists of either only the path P, or two paths P and P^*. Note that if $H - W$ consists of only P, then the two vertices in $w_x, w_y \in V(H) \cap W$ are adjacent and P has length at least two. Let us first handle the case when P has length 0, i.e., it consist of a single vertex v adjacent to both w_x and w_y. Then the fact that M includes the set returned by Lemma 11 for graph $G[S \cup \{w_x, w_y\}]$, clique K, $k = |W|$ implies that there is a hole H' disjoint from the $|W|$-IP set X and from v.

In the following, we assume that P has length at least 1 (which in particular implies that P has no vertex adjacent to both w_x and w_y). If P^* exists, then we claim that no vertex of P^* is adjacent to a vertex $u \in K \setminus (X \cup K_{w_x,w_y})$. Otherwise, without loss of generality, assume that u is not adjacent to w_x (the other case being symmetric). Let v_x be an endpoint of P adjacent to w_x, and consider the subpath Q of P from v to v_x. Let v^*_x be an endpoint of P^* adjacent to w_x and consider the subpath Q^* of P^* from v^*_x to a vertex u^* that is adjacent to u. Now v_x and v^*_x are nonadjacent neighbors of w_x (because the paths P and P^* are not adjacent) and the walk Q^*u^*uvQ goes from v^*_x to v_x. Note that no internal vertex of this walk is adjacent to w_x (as we assumed that this is true for u). Therefore, there is a hole H' that is disjoint from the holes in $\mathcal{H} \setminus \{H\}$ (the only vertex possibly used by H' that is not used by H is $u \in K \setminus X$) and uses only one vertex of W, contradicting the minimal choice of $\mathcal{H}$.

If P has length at least 1, then it has an endpoint $v_x \in A_{w_x,\overline{w_y}}$ and an endpoint $v_y \in A_{w_y,\overline{w_x}}$. Then we proceed very similarly to Case A above. The path P can be split into a path P_x going from vertex $v_x \in A_{w_x,\overline{w_y}}$ to v, and into a path P_y going from vertex $v_y \in A_{w_y,\overline{w_y}}$ to v (one, but not both, of these paths can be of length 0). We construct two paths P'_x and P'_y in G such that P'_x and P'_y are $A_{w_x,\overline{w_y}} - K$ and $A_{w_y,\overline{w_x}} - K$ paths, respectively, and they are both disjoint from $X \cup \{v\}$. If P_x has length at least 1, then the definition of M_{w_x} obtained by Outcome 2 of Lemma 10 (which exists by Claim 12) shows that a path P'_x disjoint from $X \cup \{v\}$ exists, and moreover any vertex of P'_x not in $V(P_x)$ is in $K_{\overline{w_x}}$. If P_x is only a single vertex, $v_x = v$ and the definition of M includes at least $2|W|+1$ vertices from $K_{w_x,\overline{w_y}}$ and there exists a vertex $v' \in K_{w_x,\overline{w_y}} \setminus (X \cup \{v\})$. Path P'_y can be constructed similarly. Putting together these two paths gives an $A_{w_x,\overline{w_y}} - A_{w_y,\overline{w_x}}$ walk Q. Observe that no vertex of Q is in A_{w_x,w_y}: there is no such vertex in $V(P_x) \cup V(P_y)$ and the new vertices we may introduce when defining P'_x or P'_y came from $K_{\overline{w_y}}$ or from $K_{\overline{w_x}}$, hence they cannot be in A_{w_x,w_y} either. Therefore, walk Q has a simple $A_{w_x,\overline{w_y}} - A_{w_y,\overline{w_x}}$ subpath P' of length at least 1 whose internal vertices are disjoint from A_{w_x} and A_{w_y}. As P' was constructed in such a way that any vertex of it not in $V(P)$ is in the clique $K \setminus (X \cup K_{w_x,w_y})$, our claim in the previous paragraph shows that P^* (if exists) is not adjacent to P'. Thus replacing w_xPw_y with $w_xP'w_y$ in the hole H shows the existence of a hole H' disjoint from $X \cup \{v\}$.

Case C: $|V(H) \cap W| = 1$. Let $V(H) \cap W = \{w\}$. We again proceed similarly as in Case A, but we use the fact v is not a special endpoint of H, that is, v is not an endpoint of P. The path P can be split into a path P_x going from a vertex $v_x \in A_w$ to v, and into a path P_y going from a vertex $v_y \in A_w$ to v; both paths have length at least 1 (as v is not a special endpoint) and v_x and v_y are not adjacent. We will construct a $v_x - K$ path P'_x and a $v_y - K$ path P'_y in G that are disjoint from $X \cup \{v\}$ and moreover v_x and v_y are the only vertices of A_w on these paths. To construct P'_x, consider the set M_w, which was defined by Outcome 2 of Lemma 10 applied on $(G[S], K_{\overline{w}}, A_w, |W| + 1)$ (by Claim 12, the set M_w is defined). As P_x has length at least 1 and $v \notin A_w$, the assumption $v \notin K \setminus M_w$ implies that there is a path P'_x from v_x to a vertex of K that is disjoint from $X \cup \{v\}$ and has exactly one vertex in A_w (namely, v_x). Moreover, any vertex of P'_x not in $V(P_x)$ is in $K_{\overline{w}}$, it follows that v_x is the only vertex of P'_x in A_w, as required. Path P'_y can be constructed in a similar way. Then P'_x and P'_y show that existence of a path P' from v_x to v_y with no internal vertices in A_w. Finally, Lemma 5 applied on w and P' shows the existence of a hole H' disjoint from $X \cup \{v\}$. ◀

4 Part 2: Special Hole Packing

Lemma 9 did not manage to fully reduce the treewidth of the Hole Packing instance. To proceed, we introduce a generalization Hole Packing and show that in this generalization it is possible to encode the original instance of Hole Packing in a way that the treewidth is reduced to a function of size of the chordal deletion set W given in the input.

We define the Special Hole Packing problem the following way. The input is a vertex-labeled graph G and two integers $\ell \leq k$. The possible labels of the vertices are 0, i, or i^* for $i \in [\ell]$ (i.e., there are $2\ell + 1$ different labels). The task is to find k pairwise vertex-disjoint holes $H_1, \ldots, H_k$ with the following additional conditions. For $\ell < i \leq k$, every vertex of H_i should have label 0. For $i \in [\ell]$, hole H_i should have exactly one vertex v_i with label i and every other vertex of H_i has label 0. Moreover, if v'_i, v''_i are the neighbors of v_i in H_i, then there should exist a $v'_i - v''_i$ path P_i whose internal vertices have label i^*.

Using Courcelle's Theorem (Theorem 4), it is not difficult to show that Special Hole Packing is FPT with combined parameters k and the treewidth of G: it is routine to describe the problem in Monadic Second Order Logic. A tedious but standard dynamic programming algorithm can also show that running time $2^{\mathrm{poly}(k+\mathrm{tw}(G))} \cdot n$ is also possible.

▶ **Lemma 13.** Special Hole Packing *is FPT parameterized by* $k + \mathrm{tw}(G)$.

The final part of the proof is to reduce Hole Packing to Special Hole Packing on a bounded treewidth graph. The main idea is the following. We first use Lemma 9 to mark a set S of vertices in the chordal graph $G - W$. We can assume that if a vertex v is not in $S \cup W$, then it may only be used as a special vertex of a special hole. We treat such vertices v as follows. Suppose that v is adjacent to w_i and represented by a subtree T_v in the clique tree decomposition of $G - W$. Let $a_1, \ldots, a_t$ be the leaves of T_v. Then we "blow up" v: we remove it and for each a_j, we introduce a new vertex v_j that is adjacent to w_i and whose representation in the clique tree decomposition is just the single node a_j. We perform this step for every $v \notin S \cup W$. Using easy transformations of the clique tree, we can ensure that every node of the clique tree is the leaf of at most one subtree, hence we add at most one new vertex at each node. This ensures that the resulting modified graph has bounded treewidth.

There are at least two obvious problems with this transformation. First, vertex v is replaced by multiple vertices $v_1, \ldots, v_t$ and the solution may use more than one of them, effectively using v in more than one hole. However, we can use the Color Coding [2] technique

in a straightforward way to enforce that each vertex is used only in one hole as special vertex. The second problem is that the transformation loses information about adjacency. Suppose that we find a solution that contains a special hole H_i that consists of vertex w_i and a path P, where path P connects a newly introduced vertex v_j with a vertex u (that is not adjacent to v_j). Now the orginial vertex v could be adjacent to u in the original graph, hence replacing v_j with v may not give a hole in the original graph. This is the point where the required path P_i on vertices with label i^* comes into play: we introduce these vertices in a way that forces the $v_j - u$ path to "go away" from the tree T_v, making sure that it ends at a vertex u that is not a neighbor of v. More precisely, we introduce a tree-like "scaffolding" with label i^* and then we break this scaffolding in a way that potential paths of label i^* can touch only the leaves of every such tree T_v.

We state the main result of the section as the fixed-parameter tractability of Hole Packing parameterized by the size of a chordal deletion set given in the input.

▶ **Lemma 14.** *Given a graph G, integer k, and vertex set $W \subseteq V(G)$ such that $G - W$ is chordal, the* Hole Packing *instance (G, k) can be solved in time $f(|W|)n^{O(1)}$.*

Proof. Let S be the set given by Lemma 9 and let us fix a hypothetical solution $\mathcal{H}$ of k holes such that every vertex of every hole is in $S \cup W$, except perhaps some of the special vertices. If $w_1, \ldots, w_\ell$ are distinct vertices from W, then we say that $\mathcal{H}$ is *consistent* with the tuple $(w_1, \ldots, w_\ell)$ if each w_i for $i \in [\ell]$ is in a special hole and no other vertex of W is in a special hole; in particular, this implies that there are exactly ℓ special holes. The algorithm first guesses a tuple $(w_1, \ldots, w_\ell)$ with which $\mathcal{H}$ is consistent (as the order of the w_i's do not matter, we have $2^{|W|}$ different possibilities). In the following, let $H_i \in \mathcal{H}$ be the special hole going through w_i (note that each special hole uses exactly one vertex of W hence the H_i's are distinct).

Let $\lambda : V(G) \setminus (W \cup S) \to [\ell]$ be an arbitrary labeling and let X_i be the set of vertices with label i. We say that $\mathcal{H}$ is *consistent* with $(\lambda; w_1, \ldots, w_\ell)$ if it is consistent with $(w_1, \ldots, w_\ell)$ and moreover the special endpoints of H_i are in $X_i \cup S$. Observe that this definition puts a requirement on the labeling of at most 2ℓ vertices. Thus we can use Color Coding [2]: by going through a 2ℓ-perfect family of hash functions of size $2^{O(\ell)} \cdot n$, we can assume that we have a fixed $(\lambda; w_1, \ldots, w_\ell)$ with which the hypothetical solution $\mathcal{H}$ is consistent.

Given G and $(\lambda; w_1, \ldots, w_\ell)$, our goal is to obtain a labeled bounded-treewidth graph G' and invoke the algorithm of Lemma 13 for Special Hole Packing on (G', k). To define G', let us fix a clique tree decomposition of the chordal graph $G - W$. It will be convenient to assume the following extra properties of the clique tree decomposition:

(P1) Every tree T_x has at least two vertices.
(P2) The maximum degree of T is at most 3.
(P3) If u and v are adjacent in T and one of them has degree 3, then $B_u = B_v$.
(P4) Every leaf of every subtree T_x is in a degree-2 node of T.
(P5) Every node of u is the leaf of at most one subtree T_x.

Property (P1) can be achieved by attaching a new leaf to each node u, having the same bag B_u. Properties (P2) and (P3) can be achieved by replacing each node u of degree $d \geq 3$ with a binary tree having d leaves and each node having the same bag B_u. Then the neighbors of u can be connected to the leaves of this tree. This replacement also ensures that every leaf of every subtree T_x is in a node with degree at most 2. Therefore, Property (P4) can be achieved simply by attaching a new node with empty bag to each leaf node of T (to avoid that some T_x has a leaf in a degree-1 node). Property (P5) can be achieved by an appropriate sequence of subdivisions at each edge of T.

To construct G', let us start with $G[S \cup W]$, let us assign label i to w_i and label 0 to every other vertex. For every $i \in [\ell]$, we proceed the following way. We will add new vertices to G' and the way we are describing these new vertices is by adding new subtrees to the clique tree decomposition of $G - W$ (which defines how these new vertices are adjacent to the vertices not in W) and explicitly specifying how the new vertices are adjacent to W. Note that $G' - W$ will be a chordal graph defined by this clique tree decomposition. First, for every edge uv of T, we introduce a new vertex with label i^* whose subtree consists of nodes u and v. Next, for every vertex $x \in X_i$ that is adjacent to w_i, and for every leaf u of T_x, we do the following. By (P1), subtree T_u has at least two vertices, thus u has a unique neighbor v that is in T_x. We remove the vertex with label i^* whose subtree consists of $\{u, v\}$ and introduce a new vertex with label 0 that is adjacent to w_i and whose subtree consists of only $\{u\}$. This completes the description of G'.

We claim that G' has treewidth at most $12(|W|+2)^2+4|W|$. The graph $G[S]$ is a chordal graph with maximum clique size $12(|W|+2)^4$, hence each bag contains at most that many vertices. For every i, we introduce at most 3 new vertices with label i^* in each bag (as (P2) requires that every node of T have degree at most 3). Furthermore, as each node of T contains the leaf of at most one subtree T_x by (P5), we may introduce at most one new vertex with label 0 in each bag. Therefore, $G' - W$ has a clique tree decomposition where every bag has size at most $12(|W|+2)^2+3|W|+1$. This means that $G' - W$ has treewidth at most $12(|W|+2)^2+3|W|$ and hence G' has treewidth at most $12(|W|+2)^2+4|W|$. Therefore, by Lemma 13, we can solve Special Hole Packing for (G', k) in time $f(|W|) \cdot n^{O(1)}$. The following claim shows that in case we find a solution to this Special Hole Packing instance, then it allows us to find k disjoint holes in G.

▷ Claim 15. Given a solution for the Special Hole Packing instance (G', k), we can construct in polynomial time a set of k pairwise vertex-disjoint holes in G.

Proof. Let $H'_1, \ldots, H'_k$ be the solution of the Special Hole Packing instance (G', k). We show first that for $i > \ell$, hole H'_i in G' is a hole in G as well. Recall that for $i > \ell$, hole H'_i contains only vertices of label 0. The only potential problem is that H'_i contains a vertex x^* that do not appear in G, but was added during the construction of G'. But recall that every such vertex x^* was defined by introducing a subtree T_{x^*} containing only a single node u of T and x^* was also made adjacent to a single w_j for some $j \in [\ell]$. Thus the neighbors of x^* is w_j plus a clique, which means that any hole going through x^* has to go through w_j as well. As w_j is the only vertex with label j, we have that H'_j has to contain it and hence hole H'_i for $i > \ell$ does not contain w_j. This shows that H'_i is a hole in G as well.

Consider now the hole H'_i for some $i \in [\ell]$ and the path P_i that connect neighbors x, y of w_i in H'_i and whose internal vertices are labeled i^*. This hole may contain vertices not present in G, but the argument in the previous paragraph shows that there are at most two such vertices: x and y. We show that if these vertices are not present in G, then they can be replaced by vertices in X_i, resulting in a hole H_i of G.

As x and y are not adjacent, there is a path $p_1 p_2 \ldots p_t$ in T with $t \geq 1$ such that p_1 is the only vertex of the path in T_x and p_t is the only vertex of the path in T_y. For every $j \in [t-1]$, the construction of G' involved introducing an i^*-labeled vertex z_j whose subtree is exactly $\{p_j, p_{j+1}\}$. It is clear that the path P_i consists of the vertices x, z_1, $\ldots$, z_t, y: there is no other way of connecting x and y with a simple path whose internal vertices have label i^*. If x is not a vertex of G, then x was introduced in the construction of G' because there is a vertex $x_0 \in X_i$ that is adjacent to w_i and p_1 is the leaf of the subtree T_{x_0}; let us replace x with x_0 in the hole H'_i. Similarly, if y is not part of G, then y can be replaced by a vertex $y_0 \in X_i$ that is adjacent to w_i and whose subtree T_{y_0} contains p_t. We have to verify

that the hole H_i obtained by replacing x with x_0 and/or y with y_0 is indeed a hole. First, $V(T_x) \subseteq V(T_{x_0})$ (as T_x contains only node p_1), hence x_0 is adjacent to every neighbor of x. Therefore, we only need to verify that no unwanted new edge appears in H_i after the replacement. The crucial point here is that p_2 is not in T_{x_0}: in that case, we would have removed vertex z_1 during the construction of G'. Thus p_1 is the only node of T_{x_0} on the path $p_1, \ldots, p_t$. Similarly, if y is replaced by y_0, then p_t is the only node of T_{y_0} on this path. It is easy to see that the subtree of every vertex of $V(H'_i) \setminus \{w_i\}$ contains a node from this path and therefore if, e.g., x_0 is adjacent to such a vertex, then already x was adjacent to that. Thus after the replacements, we indeed obtain a hole H_i in G. Performing this step for every $i \in [\ell]$ gives a set $H_1, \ldots, H_\ell, H'_{\ell+1}, \ldots, H'_k$ of holes. The disjointness of these holes follow from the disjointness of $H'_1, \ldots, H'_k$ and from the fact that $V(H_i) \setminus V(H'_i)$ is in X_i, and these vertices cannot be used by any hole other than H_i. ◁

Conversely, the (contraposition of the) following claim shows that if the answer to the Special Hole Packing instance is no, then we know that there is no set of disjoint holes consistent with our current choice of $(\lambda; w_1, \ldots, w_\ell)$.

▷ Claim 16. If G has a set $\mathcal{H}$ of pairwise disjoint holes consistent with $(\lambda; w_1, \ldots, w_\ell)$, then Special Hole Packing for (G', k) has a solution.

Proof. Let $H_1, \ldots, H_k$ be disjoint holes in G such that H_i for $i \in [\ell]$ is a special hole going through vertex w_i. For special hole H_i where vertices x and y are the neighbors of w_i, we define the *gap size* of H_i to be the distance of T_x and T_y in T. As x and y are not adjacent, the gap size is positive. Let us choose $H_1, \ldots, H_k$ such that the sum of gap sizes is minimum possible.

For $i > \ell$, the vertices of H_i are contained in $S \cup W$, hence they are also holes in G' as well with every vertex having label 0. Consider now the special hole H_i for $i \in [\ell]$ and suppose it has the form $w_i x x' P y' y$ where P is an $x' - y'$ path (with $x' = y'$ if H_i has length 4).

As x and y are not adjacent, there is a path $p_1 p_2 \ldots p_t$ in T with $t \geq 1$ such that p_1 is the only vertex of the path in T_x and p_t is the only vertex of the path in T_y. Observe that this means that the gap size of H_i is exactly $t - 1$. It easy to see that every bag B_{p_i} for $i \in [t]$ contains at least one vertex of the path P. By (P4), the leaves are in degree-2 nodes, hence there is a unique vertex p_0 before p_1 and a unique vertex p_{t+1} after p_t. For every $j \in [t-1]$, the construction of G' involved introducing an i^*-labeled vertex z_j whose subtree is exactly $\{p_j, p_{j+1}\}$. We argue that none of these vertices z_j were removed during the construction of G'. Recall that z_j was removed if there was a vertex $q \in X_i$ that is adjacent to w_i and either T_q has a leaf in p_{j+1} and T_q contains p_j, or T_q has a leaf in p_j and T_q contains p_{j+1}. We show that if a z_j was removed during the construction of G', then H_i can be replaced with another hole that has strictly smaller gap size and is still disjoint from the rest of the holes. This would contradict the minimality of the choice of $\mathcal{H}$.

Let α be the largest integer $\leq t$ such that there is a vertex in $x^* \in X_i \cup \{x\}$ whose subtree has a leaf in p_α and contains $p_{\alpha-1}$. Vertex x shows that α is well-defined and at least 1. Furthermore, vertex y shows that α cannot be t: by (P5), node p_t is the leaf of only T_y and this subtree does not contain p_{t-1}. Let $\beta \geq \alpha$ be the smallest integer such that there is a vertex in $y^* \in X_i \cup \{y\}$ whose subtree has a leaf in p_β and contains $p_{\beta+1}$. Vertex y shows that β is well-defined and $\beta \leq t$. Furthermore, we have that $\beta \neq \alpha$, as otherwise both x^* and y^* would have a leaf at the same node (and they are distinct vertices). Now $\beta > \alpha$ implies that x^* and y^* are not adjacent. It can be also observed that vertex z_j with $\alpha \leq j \leq \beta - 1$ was not removed: removing it because of a subtree with leaf in p_{j+1} and containing p_j would contradict the maximality of α; removing it because of a subtree with

leaf in p_j and containing p_{j+1} would violate the minimality of β. Therefore, if $\alpha = 1$ and $\beta = t$, then none of $z_1, \ldots, z_{t-1}$ was removed, what we wanted to show. Otherwise, there is an $x^* - y^*$ path whose internal vertices are in $V(P)$ (as every bag $B_{p_\alpha}, \ldots, B_{p_\beta}$ contains a vertex of P). Then Lemma 5 implies that there is a hole H_i^* going through x^*, w_i, and y^*. This hole is disjoint from the other holes in $\mathcal{H} \setminus \{H_i\}$: vertices in $V(H_i^*) \setminus V(H_i)$ are from X_i, and consistency of $\mathcal{H}$ with $(\lambda; w_1, \ldots, w_\ell)$ means that only H_i could use vertices from X_i. Now the gap size of H_i^* is $\beta - \alpha < t - 1$, strictly smaller than the gap size of H_i, contradicting the minimal choice of $\mathcal{H}$. This completes the proof that all of the vertices z_1, $\ldots$, z_{t-1} are in G'.

Let us show now the existence of a hole H_i' required by the Special Hole Packing problem. If $x, y \in S$, then they are present in G' with label 0, hence H_i is a hole in G' with every vertex except w_i having label 0. Then $P_i = xz_1 \ldots z_{t-1}y$ is a path with internal vertices labeled i^*, as required. Otherwise, suppose that $x \notin S$. As $\mathcal{H}$ is consistent with $(\lambda; w_1, \ldots, w_\ell)$, this is only possible if $x \in X_i$. As x is adjacent to w_i and p_1 is a leaf of T_x, we have introduced a vertex x^* that is adjacent to w_i and whose subtree consists of only p_1. Let us observe that x^* is adjacent to x': this follows from the fact that the induced path $xx'Py'y$ connects x and y, hence the subtree $T_{x'}$ should contain a node of the component of $T - V(T_x)$ that contains T_y. As $V(T_{x^*}) \subseteq V(T_x)$, vertex x^* cannot be adjacent to any vertex that is not a neighbor of x. Let us replace x with x^*; in a similar way, if $y \notin S$, then we can replace it with an appropriate vertex y^* that is adjacent to w_i and y'. Then the resulting hole H_i' is a hole in G' where every vertex except w_i has label 0. Furthermore, the two neighbors of w_i in H_i' can be connected by a path P_i whose internal vertices are $z_1, \ldots, z_{t-1}$, as required in the definition of Special Hole Packing. ◁

In summary, we can solve Hole Packing the following way. We enumerate every possibility for $(w_1, \ldots, w_\ell)$ and every mapping λ in a 2ℓ-perfect family of hash functions. For each choice of $(\lambda; w_1, \ldots, w_\ell)$, we construct the graph G' and solve the Special Hole Packing instance (G', k) using the algorithm of Lemma 13. If it returns a solution, then Claim 15 allows us to turn this into a solution of Hole Packing. The correctness of the algorithm follows from the fact if there is a set $\mathcal{H}$ of k pairwise disjoint holes, then at some point we reach a tuple $(\lambda; w_1, \ldots, w_\ell)$ with which $\mathcal{H}$ is consistent. At this point, Claim 16 shows that the Special Hole Packing instance (G', k) has a solution, and hence our algorithm indeed returns a solution for Hole Packing. ◀

To prove our main result Theorem 3, let us invoke the algorithm of Theorem 2 on the Hole Packing instance (G, k). If it returns a set of $k + 1$ disjoint holes, then we are done. Otherwise, we can assume that we have a set W of $O(k^2 \log k)$ vertices such that $G - W$ is chordal. Then we can use Lemma 14 to solve the problem in time $f(|W|)n^{O(1)} = f'(k)n^{O(1)}$.

5 A difficult situation

The set S computed by Lemma 9 does not necessarily cover the special vertices of the special holes. If we could ensure that set S covers every vertex of the solution, then we could immediately apply Courcelle's Theorem and we would not need the arguments in Section 4. This raises the question whether we could improve the proof of Lemma 9 in such a way.

Of course, a solution can use at most $2k$ vertices from a clique, so a large clique certainly has a vertex v not needed for a solution. Therefore, technically speaking, we can prove a variant of Lemma 9 without the extra condition for the special vertices: using our algorithm for Hole Packing, we can find a set k disjoint holes and we can set S to be the vertices of these holes. A better question is whether we can prove the inductive rerouting argument in the proof of Lemma 9 without the extra provision for the special vertices. Notice that the

proof of Lemma 9 shows the following: if a hole of the solution goes through a vertex $v \notin S$ of a large clique, then we can reroute that hole *without modifying any of the other holes.* Therefore, the question is whether we can find a vertex in a large clique that is irrelevant for the existence of a hole, even after the deletion of a set of other holes.

▶ **Question 17.** *Let G be a graph and W a set of vertices such that $G - W$ is chordal and let K be a clique in $G - W$. We say that $v \in K$ is* irrelevant *if whenever $\mathcal{H}$ is a collection of disjoint holes*[1] *in G such that $G-(\bigcup_{H\in\mathcal{H}} V(H))$ contains a hole, then $G-(\bigcup_{H\in\mathcal{H}} V(H)\cup\{v\})$ contains a hole as well. Is there a function f such that every clique K of $G - W$ having size at least $f(|W|)$ contains an irrelevant vertex?*

We construct a simple example that gives a negative answer to this question. Therefore, when trying to declare a vertex v as irrelevant, we cannot argue just by rerouting the hole going through v in the solution: we may need to reroute some other holes of the solution as well. This shows that a version of Lemma 9 without the provision for the special vertices would require a proof of very different flavor.

We define first a chordal graph G_0 the following way. Let the tree T contain nodes x_0, $\ldots$, x_{n+1} forming a path and let y_i be a degree-1 neighbor of x_i for $i \in [n]$. We define chordal graph G_0 as the intersection graph of subtrees of T:

- For $i \in [n]$, vertex $a_i \in V(G_0)$ corresponds to a subtree with nodes $\{x_{i-1}, x_i, x_{i+1}, y_i\}$.
- For $3 \leq i \leq n-2$, vertex $b_i \in V(G_0)$ corresponds to a subtree with nodes $\bigcup_{j\in[n]}\{x_j, y_j\} \setminus \{y_i\}$.
- For $i \in [n]$, vertex $c_i \in V(G_0)$ corresponds to a subtree with node $\{y_i\}$.

Observe that the a_i's form a path P, the b_i's form a clique K and the c_i's form an independent set I. Graph G is defined by adding three new vertices w_1, w_2, w_3 to G_0, making w_1 and w_2 adjacent to I, and making w_3 adjacent to $K \cup I$.

Let us choose an arbitrary $3 \leq i \leq n-2$. Consider the holes $H_1 = w_1c_1a_1a_2 \ldots a_{i-1}c_{i-1}w_1$ and $H_2 = w_2c_{i+1}a_{i+1}a_{i+2} \ldots a_nc_nw_2$. We claim that $H_3 = w_3c_ia_ib_iw_3$ is the only hole in $G - (V(H_1) \cup V(H_2))$, showing that b_i is not an irrelevant vertex. As $G - \{w_1, w_2, w_3\}$ is chordal, such a hole has to go through a w_3 and then contain two nonadjacent neighbors of w_3. As K is a clique, this means that hole H contains c_j for some $j \in [n]$. Consider the neighbor of c_j in H different from w_3. This vertex cannot be from K (as it cannot be a neighbor of w_3), hence a_j is the only possible neighbor of c_j. Hole H_1 uses the vertices a_1, $\ldots$, a_{i-1}, while hole H_2 uses the vertices a_{i+1}, $\ldots$, a_n, which leaves only a_i, and $i = j$ follows. Therefore, hole H contains vertices $w_3c_ia_i$, which can be completed to a hole only by vertex b_i (the only vertex of K not adjacent to c_i), as claimed. As this argument holds for every $3 \leq i \leq n-2$, none of the $n-4$ vertices of the clique K are irrelevant. The construction is valid for arbitrary large n and we have $|W| = 3$, which rules out the possibility that the function f of Question 17 depending only on $|W|$ exists.

Abstract

Given a graph G and an integer k, the H-free Edge Editing problem is to find whether there exist at most k pairs of vertices in G such that changing the adjacency of the pairs in G results in a graph without any induced copy of H. The existence of polynomial kernels for H-free Edge Editing (that is, whether it is possible to reduce the size of the instance to $k^{O(1)}$ in polynomial time) received significant attention in the parameterized complexity literature. Nontrivial polynomial kernels are known to exist for some graphs H with at most 4 vertices (e.g., path on 3 or 4 vertices, diamond, paw), but starting from 5 vertices, polynomial kernels are known only if H is either complete or empty. This suggests the conjecture that there is no other H with at least 5 vertices were H-free Edge Editing admits a polynomial kernel. Towards this goal, we obtain a set $\mathcal{H}$ of nine 5-vertex graphs such that if for every $H \in \mathcal{H}$, H-free Edge Editing is incompressible and the complexity assumption $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$ holds, then H-free Edge Editing is incompressible for every graph H with at least five vertices that is neither complete nor empty. That is, proving incompressibility for these nine graphs would give a complete classification of the kernelization complexity of H-free Edge Editing for every H with at least 5 vertices.

We obtain similar result also for H-free Edge Deletion. Here the picture is more complicated due to the existence of another infinite family of graphs H where the problem is trivial (graphs with exactly one edge). We obtain a larger set $\mathcal{H}$ of nineteen graphs whose incompressibility would give a complete classification of the kernelization complexity of H-free Edge Deletion for every graph H with at least 5 vertices. Analogous results follow also for the H-free Edge Completion problem by simple complementation.

1 Introduction

In a typical graph modification problem, the input is a graph G and an integer k, and the task is to make at most k allowed editing operations on G to make it belong to a certain graph class or satisfy a certain property. For example, Vertex Cover (remove k vertices to make the graph edgeless), Feedback Vertex Set (remove k vertices to make the graph acyclic), Odd Cycle Transversal (remove k edges/vertices to make the graph bipartite),

and Minimum Fill-in (add k edges to make the graph chordal) are particularly well-studied members of this problem family. Most natural graph modification problems are known to be NP-hard, in fact, there are general hardness results proving hardness for many problems [19, 21, 22]. On the other hand, most of these problems are fixed-parameter tractable (FPT) parameterized by k: it can be solved in time $f(k)n^{O(1)}$, where f is a computable function depending only on k [3, 8, 17, 18]. Looking at the parameterized complexity literature, one can observe that, even though there are certain recurring approaches and techniques, these FPT results are highly problem specific, and often rely on a very detailed understanding of the graph classes at hand.

A class of problems that can be treated somewhat more uniformly is H-free Edge Editing. This is a separate problem for every fixed graph H: given a graph G and an integer k, the task is to find whether there exist at most k pairs of vertices in G such that changing the adjacency of the pairs in G results in a graph without any induced copy of H. Aravind et al. [2] proved that H-free Edge Editing is NP-hard for every graph H with at least 3 vertices. However, a simple application of the technique of bounded-depth search trees shows that H-free Edge Editing is FPT parameterized by k for every fixed H [3].

Graph modification problems were explored also from the viewpoint of polynomial kernelization: is there a polynomial-time preprocessing algorithm that does not necessarily solve the problem, but at least reduces the size of the an instance to be bounded by a polynomial of k? The existence of a polynomial kernelization immediately implies that the problem is FPT (after the preprocessing, one can solve the reduced instance by brute force or any exact method). Therefore, one can view polynomial kernelization as a special type of FPT result that tries to formalize the question whether the problem can be efficiently preprocessed in a way that helps exhaustive search methods. There is a wide literature on algorithms for kernelization (see, e.g., [14]). Conversely, incompressibility results can show, typically under the complexity assumption $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$, that a parameterized problem has no polynomial kernelization.

Most of the highly nontrivial FPT algorithms for graph modification problems do not give kernelization results and, in many cases, it required significant amount of additional work to obtain kernelization algorithms. In particular, the FPT algorithm for H-free Edge Editing based on the technique of bounded-depth search trees does not give polynomial kernels. For the specific case when $H = K_r$ is a complete graph, it is easy to see that there is a solution using only deletions. Now the problem essentially becomes a Hitting Set problem with sets of bounded size: we have to select at least one edge from the edge set of each copy of K_r. Therefore, known kernelization results for Hitting Set can be used to show that K_r-free Edge Editing has a polynomial kernel for every fixed r. A similar argument works if H is an empty graph on r vertices.

Besides cliques and empty graphs, it is known for certain graphs H of at most 4 vertices (diamond [5, 9], path [6, 15, 16], paw [7, 13], and their complements) that H-free Edge Editing has a polynomial kernel, but these algorithms use very specific arguments exploiting the structure of H-free graphs. As there is a very deep known structure theory of claw-free (i.e, $K_{1,3}$-free) graphs, it might be possible to obtain a polynomial kernel for Claw-free Edge Editing, but this is currently a major open question [4, 10, 12]. However, besides cliques and empty graphs, no H with at least 5 vertices is known where H-free Edge Editing has a polynomial kernel and there is no obvious candidate H for which one would expect a kernel. This suggests the following conjecture:

▶ **Conjecture 1.** *If H is a graph with at least 5 vertices, then H-free Edge Editing has a polynomial kernel if and only if H is a complete or empty graph.*

We are not able to resolve this conjecture, but make substantial progress towards it by showing that only a finite number of key cases needs to be understood. Our main result for H-free Edge Editing is the following.

▶ **Theorem 1.** *There exists a set $\mathcal{H}^E$ of nine graphs, each with five vertices such that if H-free Edge Editing is incompressible for every $H \in \mathcal{H}^E$, then for a graph H with at least five vertices H-free Edge Editing is incompressible if and only if H is neither complete nor empty, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

The set $\mathcal{H}^E$ of nine graphs are shown in Figure 1a. Note that a simple reduction by complementation shows that H-free Edge Editing and $\overline{H}$-free Edge Editing have the same complexity. Therefore, for each of these nine graphs, we could put either it or its complement into the set $\mathcal{H}^E$. As it will be apparent later, we made significant efforts to reduce the size of $\mathcal{H}^E$ as much as possible. However, the known techniques for proving incompressibility do not seem to work for these graphs. Let us observe that most of these graphs are very close to the known cases that admit a polynomial kernel: for example, they can be seen as a path, paw, or diamond with an extra isolated vertex or with an extra degree-1 vertex attached. Thus resolving the kernelization complexity of H-free Edge Editing for any of these remaining graphs seems to be a particularly good research question: either one needs to extend in a nontrivial way the known kernelization results, or a significant new ideas are needed for proving hardness.

The reader might not be convinced of the validity of Conjecture 1 and may wonder about the value of Theorem 1 when the conjecture is false. However, we can argue that Theorem 1 is meaningful even in this case. It shows that if there is any H violating Conjecture 1, then one of the 9 graphs in $\mathcal{H}^E$ also violates it. That is, if we believe that there are kernelization results violating the conjecture, then we should focus on the 9 graphs in $\mathcal{H}^E$, as these are the easiest cases where we may have a kernelization result. In other words, Theorem 1 precisely shows the frontier where new algorithmic results are most likely to exist.

H-free Edge Deletion is the variant of H-free Edge Editing where only edge removal is allowed. For the same fixed graph H, it seems that H-free Edge Deletion should be a simpler problem than H-free Edge Editing, but we want to emphasize that H-free Edge Deletion is *not* a special case of H-free Edge Editing. There is no known general reduction from the former to the latter, although the technique of completion enforcers (see Section 5 and [4]) can be used for many specific graphs H. There is a known case where H-free Edge Deletion seems to be strictly easier: if H has at most one edge, then there is only one way of destroying a copy of an induced H by edge removal, making the problem polynomial-time solvable. Aravind et al. [1] showed that having at most one edge is the only condition that makes H-free Edge Deletion polynomial-time solvable: if H has at least two edges, then the problem is NP-hard. Therefore, the counterpart of Conjecture 1 for H-free Edge Deletion should take this case also into account.

▶ **Conjecture 2.** *If H is a graph with at least 5 vertices, then H-free Edge Deletion has a polynomial kernel if and only if H is a complete graph or has at most one edge.*

Working toward this conjecture, we show that only a finite number of cases needs to be shown incompressible.

▶ **Theorem 2.** *There exists a set $\mathcal{H}^D$ of nineteen graphs, each with either five or six vertices such that if H-free Edge Deletion is incompressible for every $H \in \mathcal{H}^D$ then for a graph H with at least five vertices, H-free Edge Deletion is incompressible if and only if H is a graph with at least two edges but not complete, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

Figure 2 All non-empty and non-complete graphs with at most four vertices.

The set $\mathcal{H}^D$ contains the graphs in set $\mathcal{H}^E$, as well their complements. This seems reasonable and hard to avoid: if we do not have an incompressibility result for H-free Edge Editing for some $H \in \mathcal{H}^E$, then it is unlikely that we can find such a result for H-free Edge Deletion (even though, as discussed above, there is no formal justification for this). Together with these 17 graphs (note that H_9 is the same as its complement), we need to include into

$\mathcal{H}^D$ the two graphs D_1 and D_2 shown in Figure 1c. In the case of editing, we can prove incompressibility for these two graphs by a reduction from H-free Edge Editing where H is the graph with 5 vertices and one edge. However, H-free Edge Deletion for this H is polynomial-time solvable.

Finally, let us consider the H-free Edge Completion problem, where we have to make G induced H-free by adding at most k edges. As H-free Edge Completion is essentially the same problem as $\overline{H}$-free Edge Deletion, we can obtain a counterpart of Theorem 2 by simple complementation:

▶ **Theorem 3.** *There exists a set $\mathcal{H}^C$ of nineteen graphs, each with either five or six vertices such that if H-free Edge Completion is incompressible for every $H \in \mathcal{H}^C$ then for a graph H with at least five vertices, H-free Edge Completion is incompressible if and only if H is a graph with at least two nonedges but not empty, where the incompressibility assumes* $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$.

Our techniques. We crucially use two earlier results. First, Cai and Cai [4] proved that H-free Edge Editing is incompressible (assuming $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$) when H or $\overline{H}$ is a cycle or a path of length at least 4, or 3-connected but not complete. While these result handle many graphs and prove to be very useful for our proofs, they do not come close to a complete classification. Second, we use a key tool in the polynomial-time dichotomy result of Aravind et al. [1]: if V_ℓ is the set of lowest degree vertices of H, then $(H - V_\ell)$-free Edge Editing can be reduced to H-free Edge Editing. The same statement holds for the set V_h of highest degree vertices.

Our proofs of Theorems 1–3 introduce new incompressibility results and new reductions, which we put together to obtain an almost complete classification by a graph-theoretic analysis. Additionally, to make the arguments simpler, we handle small graphs by an exhaustive computer search. In the following, we highlight some of the main ideas that appear in the paper.

- **Analysis of graphs.** Our goal is to prove Theorem 1 by induction on the size of H. First we handle the case when H is regular: we show that this typically implies that either H or $\overline{H}$ is 3-connected, and the result of Cai and Cai [4] can be used. If H is not regular, then the graphs $H - V_\ell$ and $H - V_h$ are nonempty and have stricly fewer vertices than H. If one of them, say $H - V_\ell$, has at least 5 vertices and is neither complete nor empty, then the induction hypothesis gives an incompressibility result for $(H - V_\ell)$-free Edge Editing, which gives an incompressibility result for H-free Edge Editing by the reduction of Aravind et al. [1]. Therefore, we only need to handle those graphs H where it is true for both $H - V_\ell$ and $H - V_h$ that they are either small, complete, or empty. But we can obtain a good structural understanding of H in each of these cases, which allows us to show that either H or $\overline{H}$ is 3-connected, or H has some very well defined structure. With these arguments, we can reduce the problem to the incompressibility of H-free Edge Editing for a few dozen specific graphs H and for a few well-structured infinite families (such as $K_{2,t}$).
  For H-free Edge Deletion, we have the additional complication that one or both of $H - V_\ell$ and $H - V_h$ can be near-empty (i.e., has exactly one edge), which is not an incompressible case for this problem. We need additional case analysis to cover such graphs, but the spirit of the proof remains the same.
- **Computer search.** Our analysis of graphs becomes considerably simpler if we assume that H is not too small. In this case, we can assume that at least one of $H - V_\ell$ and $H - V_h$ is a complete or empty graph of certain minimum size, which is a very helpful

starting point for proving the 3-connectivity of H or $\bar{H}$, respectively. Therefore, we handle every graph with at most 9 vertices using an exhaustive computer search and assume in the proof that H has at least 10 vertices. The list provided by McKay [20] shows that there are 288266 different graphs with at most 9 vertices, which is feasible for a computer search. In principle, it would be possible to extend our case analysis to avoid this computer search, but it would significantly complicate the proof and is not clear what additional insight it would give.

- **Reductions.** We investigate different reductions that allow us to reduce H'-free Edge Editing to H-free Edge Editing when H' is an induced subgraph of H satisfying certain conditions. With extensive use of such reductions, we can reduce the remaining cases of H-free Edge Editing that needs to be handled to a smaller finite set.
- **Incompressibility results.** We carefully revisit the proof of Cai and Cai [4] showing the incompressibility of H-free Edge Editing when H is 3-connected, and observe that, with additional ideas, it can be made to work also for certain 2-connected graphs that are not 3-connected (the set $\mathcal{A}$ of graphs shown in Figure 1b and the set $\mathcal{B}$ of graphs shown in Figure 1c). This allows us to handle every graph, except those finite sets that are mentioned in Theorems 1–3. A key step in many of these incompressibility results is to establish first incompressibility for the Restricted H-free Edge Deletion problem, which is the generalization of H-free Edge Deletion where some of the edges of G are marked as forbidden in the input, and the solution is not allowed to delete forbidden edges. Then we use deletion and completion enforcer gadgets specific to H to reduce Restricted H-free Edge Deletion to H-free Edge Editing.

The paper is organized as follows. Preliminaries are in Section 2. Section 3 presents the churning procedure, our main technical tool in the analysis of graphs, and shows that it reduces the problem to a finite number of graphs, plus a few well-defined infinite families. Section 4 presents reductions (old and new) that allow us to further reduce the number of graphs we need to handle. Finally, in Setion 5, we give new incompressibility results, showing that only the cases stated in Theorems 1–3 need to be proved incompressible to complete the exploration of the complexity landscape of the problems. All proofs have been moved to a full version of the paper due to space constraints.

2 Preliminaries

Graph-theoretic notation and terminology. For a graph G, $V(G)$ and $E(G)$ denote the set of vertices and the set of edges of G respectively. For a set $V' \subseteq V(G)$, $G - V'$ denotes the graph obtained by removing all vertices in V' and their incident edges from G. For a set F of pairs of vertices and a graph G, $G \triangle F$ denotes the graph G' such that $V(G') = V(G)$ and $E(G') = \{(u,v) \mid ((u,v) \in E(G) \text{ and } (u,v) \notin F) \text{ or } (u,v \in V(G),\ (u,v) \notin E(G), \text{ and } (u,v) \in F)\}$. Whenever we say that a set of (non)edges F is a solution of an instance (G,k) of a problem, we refers to a subset of F containing all (non)edges where both the end vertices are in $V(G)$. A graph is *empty* if it does not have any edges. A graph is *near-empty* if it has exactly one edge. A graph is *complete* if it has no nonedges. A component of a graph is a *largest component* if it has maximum number of vertices among all components of the graph. Similarly, a component of a graph is a *smallest component* if it has minimum number of vertices among all components of the graph. For a graph H which is not complete, the vertex connectivity of H is the minimum integer c such that there exists a set $S \subseteq V(H)$ such that $|S| = c$ and $H - S$ is disconnected. For a graph H with vertex connectivity 1, a vertex v in H is known as a cut vertex if $H - v$ is disconnected. A graph is k-connected, if

the vertex connectivity of it is at least k. An induced subgraph H' of H is known as a 2-connected component if H' is a maximal 2-connected induced subgraph of H. The adjectives "largest" and "smallest" can be applied to 2-connected components as done for components. A *twin-star* graph T_{ℓ_1,ℓ_2} for $\ell_1, \ell_2 \geq 0$ is defined as the tree with two adjacent vertices u and v such that $|N(u) \setminus \{v\}| = \ell_1, |N(v) \setminus \{u\}| = \ell_2$, and every vertex in $N(u) \cup N(v) \setminus \{u, v\}$ has degree 1. A graph G is H-free if G does not contain any induced copy of H. For two graphs G_1 and G_2, the disjoint union of G_1 and G_2 denoted by $G_1 \cup G_2$ (or $G_2 \cup G_1$) is the graph G such that $V(G) = V(G_1) \cup V(G_2)$ and $E(G) = E(G_1) \cup E(G_2)$. For two graphs G_1 and G_2, the join of G_1 and G_2 denoted by $G_1 \boxtimes G_2$ (or $G_2 \boxtimes G_1$), is the graph G such that $V(G) = V(G_1) \cup V(G_2)$ and $E(G) = E(G_1) \cup E(G_2) \cup \{(x, y) \mid x \in V(G_1), y \in V(G_2)\}$. A complete graph, a cycle, and a path with t vertices are denoted by K_t, C_t, and P_t respectively. By $K_t - e$, we denote the graph obtained by deleting an edge from a complete graph on t vertices. We call a graph *non-regular* if it is not regular. A *modular decomposition* $\mathcal{M}$ of a graph G is a partitioning of its vertices into maximal sets, known as *modules*, such that for every set $M \in \mathcal{M}$, every vertex in M has the same neighborhood outside M. Let $\mathcal{M}' \subseteq \mathcal{M}$. Let $V' = \bigcup_{M \in \mathcal{M}'} M$. Then we say that $\mathcal{M}'$ corresponds to V'. For a set $\mathcal{S}$ of graphs, by $\overline{\mathcal{S}}$ we denote the set of complements of graphs in $\mathcal{S}$. Figure 2 shows all graphs with at most four vertices which are neither empty nor complete.

For $t \geq 3$, let J_t be the graph obtained from $K_2 \boxtimes tK_1$ and C_4 by identifying an edge of C_4 with the edge between the highest degree vertices in $K_2 \boxtimes tK_1$. Let Q_t be the graph graph obtained from $K_{2,t}$, for some $t \geq 3$, by adding a path of length three between the highest degree vertices in $K_{2,t}$. Let $\mathcal{H}$, $\mathcal{A}$, $\mathcal{D}$, $\mathcal{B}$, $\mathcal{S}$ denote the graphs (H, A, D, B, S respectively) shown in Figures 1a, 1b, 1c, and 3a. Let $\mathcal{F}$ be the union of graphs in the classes of graphs shown in column $\mathcal{F}$ of Figure 3b. The graphs in $\mathcal{S}$ and $\mathcal{F}$ are handled in Section 4 and the graphs in $\mathcal{A}$ and $\mathcal{B}$ are handled in Section 5. For all these classes of graphs, we use subscripts to identify each graph/graph class. For example H_1 is $P_3 \cup 2K_1$ and $\mathcal{F}_1$ is the class of graphs $K_{1,t}$. Let $\mathcal{W}$ be the set $\mathcal{H} \cup \overline{\mathcal{H}} \cup \mathcal{A} \cup \overline{\mathcal{A}} \cup \mathcal{D} \cup \overline{\mathcal{D}} \cup \mathcal{B} \cup \overline{\mathcal{B}} \cup \mathcal{S} \cup \overline{\mathcal{S}} \cup \mathcal{F} \cup \overline{\mathcal{F}}$. We observe that $\overline{\mathcal{W}} = \mathcal{W}$.

Parameterized problems and transformations. A parameterized problem is a classical problem with an additional integer input known as the parameter. A parameterized problem admits a polynomial kernel if there is a polynomial-time algorithm which takes as input an instance (I, k) of the problem and outputs an instance (I', k') of the same problem, where $|I'|, k' \leq p(k)$, where $p(k)$ is a polynomial in k, such that (I, k) is a yes-instance if and only if (I', k') is a yes-instance. A parameterized problem is incompressible if it does not admit a polynomial kernel. A *Polynomial Parameter Transformation* (PPT) from one parameterized problem Q to another parameterized problem Q' is a polynomial-time algorithm which takes as input an instance (I, k) of Q and produces an instance (I', k') of Q' such that (I, k) is a yes-instance of Q if and only if (I', k') is a yes-instance of Q', and $k' \leq p(k)$, for some polynomial $p(.)$. It is known that if there is a PPT from Q to Q', then if Q is incompressible, then so is Q'. We refer to the book [11] for various concepts in parameterized algorithms and complexity.

The parameterized problems we deal with in this paper are listed below.

H-free Edge Editing: Given a graph G and an integer k, do there exist at most k edges such that editing (adding or deleting) them in G results in an H-free graph?
Parameter: k

H-free Edge Deletion: Given a graph G and an integer k, do there exist at most k edges such that, deleting them from G results in an H-free graph? **Parameter**: k

H-free Edge Completion: Given a graph G and an integer k, do there exist at most k edges such that, adding them in G results in an H-free graph? **Parameter**: k

Basic results. Proposition 4 follows from the observations that (G, k) is a yes-instance of H-free Edge Editing(Deletion) if and only if $(\overline{G}, k)$ is a yes-instance of $\overline{H}$-free Edge Editing(Completion). It enables us to focus only on H-free Edge Editing and H-free Edge Deletion.

▶ **Proposition 4** (folklore). *Let H be any graph. Then H-free Edge Deletion is incompressible if and only if $\overline{H}$-free Edge Completion is incompressible. Similarly, H-free Edge Editing is incompressible if and only if $\overline{H}$-free Edge Editing is incompressible.*

For graphs H and H', by "*H simulates H'*" and by "*H' is simulated by H*", we mean that, there is a PPT from H'-free Edge Editing to H-free Edge Editing, there is a PPT from H'-free Edge Deletion to H-free Edge Deletion, and there is a PPT from H'-free Edge Completion to H-free Edge Completion. We observe that this is transitive, i.e., if H simulates H' and H' simulates H'', then H simulates H''. A set of graphs $\mathcal{H}$ is called a *base* for a set $\mathcal{G}$ of graphs if for every graph $H \in \mathcal{G}$ there is a graph $H' \in \mathcal{H}$ such that H simulates H'. The objective of the rest of the paper is to find, for each of the problems, a base $\mathcal{H} \cup \mathcal{X}$ for all graphs with at least five vertices, except the trivial cases, such that the following conditions are satisfied: (i) $\mathcal{H}$ is finite and the incompressibility is not known for any graph in it; (ii) for every graph in $\mathcal{X}$, the problem is known to be incompressible.

Proposition 4 implies Corollary 5 and Proposition 6 can be deduced directly from the definitions.

▶ **Corollary 5.** *Let H and H' be graphs such that H simulates H'. Then $\overline{H}$ simulates $\overline{H'}$.*

▶ **Proposition 6.** *Let $\mathcal{H}$ be a base for a set $\mathcal{G}$ of graphs. Assume that for every graph $H' \in \mathcal{H}$, H'-free Edge Editing (Deletion) is incompressible. Then for every graph $H \in \mathcal{G}$, H-free Edge Editing (Deletion) is incompressible.*

Intuitively, if H' is an induced subgraph of H, then H-free Edge Editing (Deletion) seems harder than H'-free Edge Editing (Deletion). However, there is no general argument why this should be true: there does not seem to be a completely general reduction that would reduce H'-free Edge Editing (Deletion) to H-free Edge Editing (Deletion). There is, however, a fairly natural idea for trying to do such a reduction: we extend the graph by attaching copies of $H - H'$ at every place where a copy of H' can potentially appear. The following construction is essentially the same as the main construction used in [2].

▶ **Construction 1** (see [2]). *Let (G', k, H, V') be an input to the construction, where G' and H are graphs, k is a positive integer and V' is a subset of vertices of H. We construct a graph G from G' as follows. For every injective function $f : V' \longrightarrow V(G')$, do the following:*

- *Introduce $k+1$ sets of vertices $V_1, V_2, \ldots, V_{k+1}$, each of size $|V(H) \setminus V'|$, and $k+1$ bijective functions $g_i : V(H) \longrightarrow (f(V') \cup V_i)$, for $1 \leq i \leq k+1$, such that $g_i(v') = f(v')$ for every $v' \in V'$;*

- *For each set V_i, introduce an edge set $E_i = \{(u,v) \mid u \in (f(V') \cup V_i), v \in V_i, (g_i^{-1}(u), g_i^{-1}(v)) \in E(H)\}$.*

This completes the construction. Let the constructed graph be G.

For convenience, we call every set V_i of vertices introduced in the construction as a *satellite* and the vertices in it as *satellite vertices*. This reduction works correctly in one direction: it ensures that the operations that make the new graph G H-free should ensure that the copy of G' inside G is H'-free.

▶ **Proposition 7** (see Lemma 2.6 in [2]). *Let G be obtained by Construction 1 on the input (G', k, H, V'), where G' and H are graphs, k is a positive integer and $V' \subseteq V(H)$. Then, if (G, k) is a yes-instance of H-free Edge Editing (Deletion), then (G', k) is a yes-instance of H'-free Edge Editing (Deletion), where H' is $H[V']$.*

However, the other direction of the correctness of the reduction does not hold in general (this is easy to see for example for $H = K_{1,2}$ and $H' = K_2$). As we shall see, there are particular cases where we can prove the converse of Proposition 7, for example, when $H - H'$ consists of exactly the highest- or lowest-degree vertices. Application of such arguments will be our main tool in reducing the complexity of H-free Edge Editing (Deletion) to simpler cases. Propositions 8 to 11 summarize the major results on the incompressibility of H-free edge modification problems known so far.

▶ **Proposition 8** ([4]). *Assuming* NP $\not\subseteq$ coNP/poly, *H-free Edge Editing, H-free Edge Deletion, and H-free Edge Completion are incompressible if H is either of the following graphs.*

- **(i)** *C_ℓ for any $\ell \geq 4$;*
- **(ii)** *P_ℓ for any $\ell \geq 5$;*
- **(iii)** *$2K_2$.*

We observe that Proposition 8(iii) follows from Proposition 8(i) and Proposition 4.

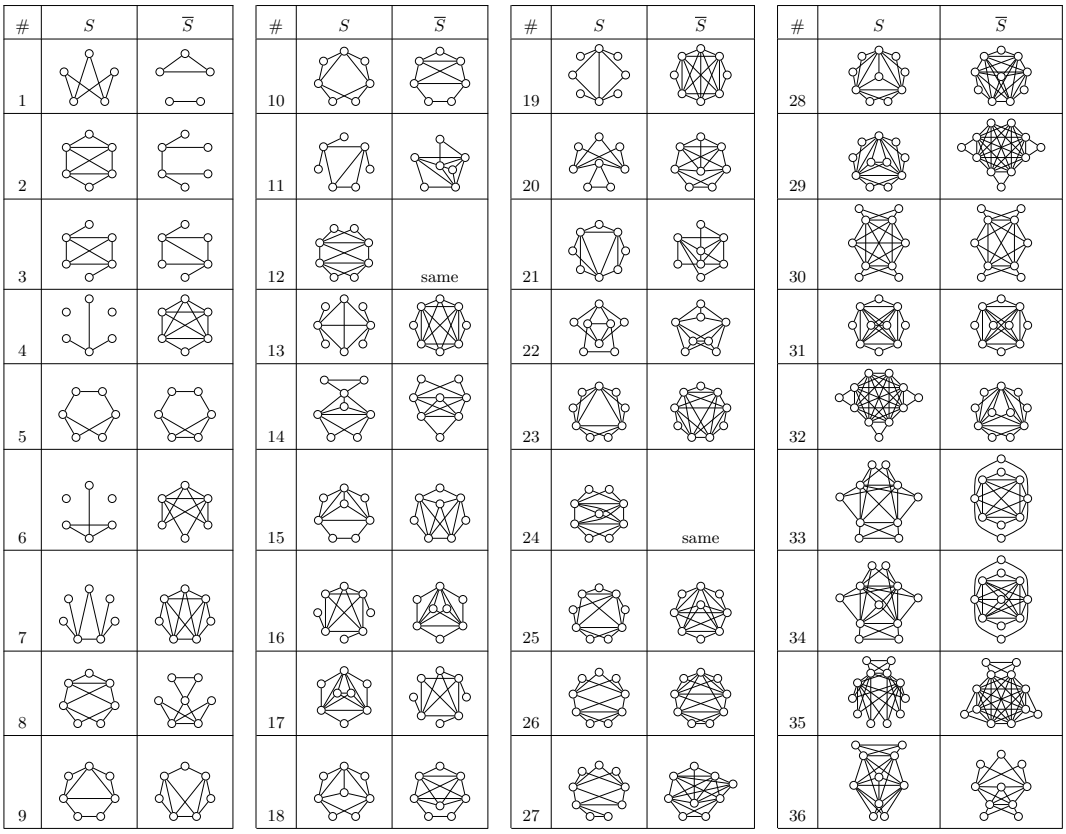
▶ **Proposition 9** ([4]). *Assuming* NP $\not\subseteq$ coNP/poly, *for 3-connected graphs H, H-free Edge Editing and H-free Edge Deletion are incompressible if H is not complete and H-free Edge Completion is incompressible if H has at least two nonedges.*

▶ **Proposition 10** ([4], folklore). *If H is a complete or empty graph, then H-free Edge Editing admits polynomial kernelization. If H is complete or has at most one edge then H-free Edge Deletion admits polynomial kernelization. If H is an empty graph or has at most one nonedge then H-free Edge Completion admits polynomial kernelization.*

▶ **Proposition 11.** *H-free Edge Editing, H-free Edge Deletion, and H-free Edge Completion admit polynomial kernels when H is a P_3 [6, 15], P_4 [16], paw [7, 13], or a diamond [5, 9].*

3 Churning

In this section, we introduce and analyze the churning procedure. The main result of the section is that assuming incompressibility for the class $\mathcal{W}$ of graphs defined in the previous section explains incompressibility for every graph with at least five vertices, except the trivial cases. Recall that $\mathcal{W}$ is not finite, as it contains the infinite families shown in Figure 3b. In Sections 4 and 5, we will further reduce $\mathcal{W}$ to a finite set.



(a) The set $\mathcal{S}$ of graphs.

(b) The set $\mathcal{F}$ of infinite sets of graphs.

Figure 3

▶ **Lemma 12.** *If H-free Edge Editing is incompressible for every $H \in \mathcal{W}$, then H-free Edge Editing is incompressible for every H having at least five vertices but is neither complete nor empty, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

▶ **Lemma 13.** *If H-free Edge Deletion is incompressible for every $H \in \mathcal{W}$, then H-free Edge Deletion is incompressible for every H having at least five vertices and at least two edges but not complete, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

Corollary 14 follows from Lemma 13, Proposition 4 and from the fact that $\overline{\mathcal{W}} = \mathcal{W}$.

▶ **Corollary 14.** *If H-free Edge Completion is incompressible for every $H \in \mathcal{W}$, then H-free Edge Completion is incompressible for every H having at least five vertices and at least two nonedges but not empty, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

By $\mathcal{X}_E$ we denote the set of all graphs (and their complements) listed in Proposition 8, Proposition 9, and Theorem 18 for which the incompressibility is known (assuming $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$) for H-free Edge Editing. By $\mathcal{Y}_E$, we denote the set of all graphs (and their complements) listed in Proposition 10 and 11 for which there exist polynomial kernels for H-free Edge Editing; additionally, we include into $\mathcal{Y}_E$ the claw and its complement (as we do not want to conjecture the incompressibility for these cases). Similarly, we define the set $\mathcal{X}_D$ of "hard" and the set $\mathcal{Y}_D$ of "nonhard" cases for H-free Edge Deletion. More formally,

$\mathcal{X}_D = \{C_\ell, \overline{C_\ell}$ for all $\ell \geq 4$,
$P_\ell, \overline{P_\ell}$ for all $\ell \geq 5$,
H such that H is regular but is neither complete nor empty,
H such that either H is 3-connected but not complete
or $\overline{H}$ is 3-connected with at least two nonedges$\}$

$\mathcal{X}_E = \mathcal{X}_D \cup \{H$ such that H has at most one edge and at least five vertices$\}$

$\mathcal{Y}_E = \{K_t, \overline{K_t}$ for all $t \geq 1$,
$P_3, \overline{P_3}, P_4$,
diamond, $\overline{\text{diamond}}$, paw, $\overline{\text{paw}}$, claw, $\overline{\text{claw}}\}$

$\mathcal{Y}_D = \mathcal{Y}_E \cup \{H$ such that H has at most one edge and at least five vertices$\}$

Additionally we define $\mathcal{Y}' = \{P_3, \overline{P_3}, P_4, \text{claw}, \overline{\text{claw}}, \text{paw}, \overline{\text{paw}}, \text{diamond}, \overline{\text{diamond}}\}$. We observe that $\mathcal{Y}' \subseteq \mathcal{Y}_E \cap \mathcal{Y}_D$ and the set of graphs with at most four vertices is a subset of $\mathcal{X}_E \cup \mathcal{Y}_E$ and $\mathcal{X}_D \cup \mathcal{Y}_D$. Further, we observe that near-empty graphs with at least five vertices are in $\mathcal{Y}_D$ but their complements are 3-connected and are in $\mathcal{X}_D$. We also note that both these graphs and their complements are in $\mathcal{X}_E$.

The main technical result of the section is the following lemma. It states that if a graph is not in the set $\mathcal{Y}_D$ of "easy" graphs, then it simulates a "hard" graph in $\mathcal{X}_\mathcal{D}$ or $\mathcal{W}$ (and there is a similar result for $\mathcal{X}_E$ and $\mathcal{Y}_E$).

▶ **Lemma 15.** *If $H \notin \mathcal{Y}_D$, then H simulates a graph in $\mathcal{X}_D \cup \mathcal{W}$. If $H \notin \mathcal{Y}_E$, then H simulates a graph in $\mathcal{X}_E \cup \mathcal{W}$.*

In the rest of the paper, integer ℓ and set V_ℓ denote the lowest degree and the set of lowest degree vertices in H respectively; integer h and set V_h denote the highest degree and the set of highest degree vertices in H respectively; and set V_m denotes the set $V(H) \setminus (V_\ell \cup V_h)$. By h^* we denote the degree of vertices of V_h in $\overline{H}$, i.e., $h^* = |V(H)| - h - 1$.

Now we introduce a procedure (Churn) which is similar to the one used to obtain dichotomy results on the polynomial-time solvable and NP-hard cases of these problems (see Section 5 in [2]). The basic observation is that H can simulate the graphs $H - V_\ell$ and $H - V_h$. This follows from proving that Construction 1 gives a PPT in these cases.

▶ **Proposition 16** (Corollary 2.9 in [2]). *Let H' be $H - V_\ell$ or $H - V_h$. Then H simulates H'.*

To deal with both H-free Edge Editing and H-free Edge Deletion in a uniform way, we define $\mathcal{X} = \mathcal{X}_E$ and $\mathcal{Y} = \mathcal{Y}_D$. We observe that $\overline{\mathcal{X} \cup \mathcal{Y}} = \mathcal{X} \cup \mathcal{Y}$ and $\mathcal{X} \cup \mathcal{Y} = \mathcal{X}_E \cup \mathcal{Y}_E = \mathcal{X}_D \cup \mathcal{Y}_D$.

Churn(H):
Step 1: If H is regular, then return H.
Step 2: If $H - V_\ell \notin \mathcal{Y}$, then return Churn($H - V_\ell$).
Step 3: If $H - V_h \notin \mathcal{Y}$, then return Churn($H - V_h$).
Step 4: Return H.

Proposition 16 implies Corollary 17.

▶ **Corollary 17.** *Let H' be the output of Churn(H). Then H simulates H'.*

We prove Lemma 15 by analyzing Churn() and showing that the graph returned by it always satisfies the requirements of the lemma. The procedure first handles the case when H is regular. In Section 3.1, we show that if H is regular, then it is safe to return H, as it is already in $\mathcal{X}_D \subseteq \mathcal{X}_E$. If H is not regular, then $H - V_\ell$ and $H - V_h$ are both defined. If one of these two graphs is not in $\mathcal{Y}$, then Proposition 16 allows us to proceed by recursion on that graph. Step 4 is reached when both $H - V_\ell$ and $H - V_h$ are in $\mathcal{Y}$. However, at this point the conditions on $H - V_\ell$ and $H - V_h$ give us important structural information about the graph H, which can be exploited to show that it is in $\mathcal{X}_D \cup \mathcal{W}$. Recall that $\mathcal{Y}$ is the union of complete, empty, near-empty, and the finite graphs in $\mathcal{Y}'$. This means we can split the problem into $4 \cdot 4$ different cases, with very strict structural restrictions on H in each case. These cases are analysed in a sequence of lemmas/corollaries (Lemma 19 to Lemma 34 in Sections 3.2–3.5).

3.1 Regular graphs

In this section, we handle the case when H is regular.

▶ **Theorem 18.** *Let H be a regular graph. Then H-free Edge Deletion, H-free Edge Completion, and H-free Edge Editing are incompressible if and only if H is neither complete nor empty, where the incompressibility assumes* NP $\not\subseteq$ coNP/poly.

3.2 Small graphs

If both $H - V_\ell$ and $H - V_h$ are in the in the finite set $\mathcal{Y}'$ of graphs, then H has bounded size. An exhaustive computer search showed the correctness of the procedure in this case.

▶ **Lemma 19.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that both $H - V_\ell$ and $H - V_h$ are in $\mathcal{Y}'$. Then $H \in \mathcal{W}$.*

3.3 Cliques and empty graphs

In this section, we consider the cases when both $H - V_\ell$ and $H - V_h$ are cliques or empty graphs. In this case, the structure of H is very limited. In principle, we need to consider four cases separately depending on the type of $H - V_\ell$ and $H - V_h$. However, a simple complementation argument shows that the case when both of them are cliques is equivalent to the case when both of them are empty.

▶ **Lemma 20.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that both $H - V_\ell$ and $H - V_h$ are complete graphs. Then $H \in \mathcal{W}$.*

Corollaries in this section and in Sections 3.4 and 3.5 use the facts that various sets we consider are self-complementary, i.e., $\mathcal{X} \cup \mathcal{Y} = \overline{\mathcal{X} \cup \mathcal{Y}}, \mathcal{W} = \overline{\mathcal{W}}, \mathcal{Y}' = \overline{\mathcal{Y}'}$.

▶ **Corollary 21.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that both $H - V_\ell$ and $H - V_h$ are empty graphs. Then $H \in \mathcal{W}$.*

▶ **Lemma 22.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell$ is a complete graph and $H - V_h$ is an empty graph. Then $H \in \mathcal{W}$.*

Our last case is when $H - V_\ell$ is empty and $H - V_h$ is complete. Let us observe that this case *does not* follow from Lemma 22 by complementation. If $\overline{V_\ell}$ and $\overline{V_h}$ are the lowest- and highest-degree vertices in $\overline{H}$, then $\overline{V_\ell} = V_h$, $\overline{V_h} = V_\ell$ and hence $\overline{H} - \overline{V_\ell}$ is empty and $\overline{H} - \overline{V_h}$ is a clique, that is, we have the same condition as for H. Fortunately, this last case is very simple to handle.

▶ **Lemma 23.** *There exists no graph $H \notin \mathcal{X} \cup \mathcal{Y}$ such that $H - V_\ell$ is an empty graph and $H - V_h$ is a complete graph.*

3.4 Cliques/empty graphs plus small graphs

Next we consider the cases when one of $H - V_\ell$ or $H - V_h$ is a clique or an empty graph, while the other is a graph from the finite set $\mathcal{Y}'$. Assuming that H is not too small, this means that H is essentially a clique or an empty graph, and intuitively it should follow that H or $\overline{H}$ is 3-connected, respectively. However, this requires a detailed proof considering several cases.

▶ **Lemma 24.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell \in \mathcal{Y}'$ and $H - V_h$ is a complete graph. Then $H \in \mathcal{W}$.*

▶ **Corollary 25.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell$ is an empty graph and $H - V_h \in \mathcal{Y}'$. Then $H \in \mathcal{W}$.*

▶ **Lemma 26.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell \in \mathcal{Y}'$ and $H - V_h$ is an empty graph. Then $H \in \mathcal{W}$.*

▶ **Corollary 27.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell$ is a complete graph and $H - V_h \in \mathcal{Y}'$. Then $H \in \mathcal{W}$.*

3.5 Near-empty graphs

Finally, we consider the cases when one of $H - V_\ell$ or $H - H_h$ is near empty. These cases are similar to the corresponding ones for empty graphs, but more technical and a higher number of corner cases need to be handled. Let us remark that this part of the proof is needed only for the H-free Edge Deletion problem: near-empty graphs are not in $\mathcal{Y}_E$, hence if our goal is to prove Theorem 1 for H-free Edge Editing, then the churning procedure can recurse on such graphs.

▶ **Lemma 28.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell$ is a complete graph and $H - V_h$ is a near-empty graph. Then $H \in \mathcal{W}$.*

▶ **Lemma 29.** *There exists no $H \notin \mathcal{X} \cup \mathcal{Y}$ such that $H - V_\ell$ is a near-empty graph and $H - V_h$ is a complete graph.*

▶ **Lemma 30.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ such that $H - V_\ell$ is an empty graph and $H - V_h$ is a near-empty graph. Then $H \in \mathcal{W}$.*

▶ **Lemma 31.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ such that $H - V_\ell$ is a near-empty graph and $H - V_h$ is an empty graph. Then $H \in \mathcal{W}$.*

▶ **Lemma 32.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that both $H - V_\ell$ and $H - V_h$ are near-empty graphs. Then $H \in \mathcal{W}$.*

▶ **Lemma 33.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell$ is a near-empty graph and $H - V_h \in \mathcal{Y}'$. Then $H \in \mathcal{W}$.*

▶ **Lemma 34.** *Let $H \notin \mathcal{X} \cup \mathcal{Y}$ be such that $H - V_\ell \in \mathcal{Y}'$ and $H - V_h$ is a near-empty graph. Then $H \in \mathcal{W}$.*

4 Reductions

Recall that we defined $\mathcal{W} = \mathcal{H} \cup \overline{\mathcal{H}} \cup \mathcal{A} \cup \overline{\mathcal{A}} \cup \mathcal{D} \cup \overline{\mathcal{D}} \cup \mathcal{B} \cup \overline{\mathcal{B}} \cup \mathcal{S} \cup \overline{\mathcal{S}} \cup \mathcal{F} \cup \overline{\mathcal{F}}$ and Section 3 reduced our main questions to assuming incompressibility for the set $\mathcal{W}$. In this section, we further refine the result and show that incompressibility needs to be assumed only for the finite set $\mathcal{W}' = \mathcal{H} \cup \overline{\mathcal{H}} \cup \mathcal{A} \cup \overline{\mathcal{A}} \cup \mathcal{B} \cup \mathcal{D}$. That is, we recall and introduce some further simple reductions and use them to prove that every graph in $\mathcal{W} \setminus \mathcal{W}'$ simulates a graph in $\mathcal{W}' \cup \mathcal{X}_D$. To begin with, we observe that deleting the lowest degree vertices in the graphs in $\overline{\mathcal{B}} \cup \overline{\mathcal{D}}$ results in 3-connected graphs which are not complete. Then by Proposition 16, we have:

▶ **Proposition 35.** *If $H \in \overline{\mathcal{B}} \cup \overline{\mathcal{D}}$, then H-free Edge Editing and H-free Edge Deletion are incompressible, assuming* NP $\not\subseteq$ coNP/poly.

The following reductions are based on Construction 1 and a few other similar constructions.

4.1 Reductions based on Construction 1

The following lemma can be proved using a straight-forward application of Construction 1.

▶ **Lemma 36.** *Let H be $J \cup K_t$, for some graph J and integer $t \geq 1$, where the K_t is induced by V_ℓ. Let V' be $V(H) \setminus \{v\}$, where v is any vertex in the K_t. Let H' be $H[V']$. Then H simulates H'. In particular, H simulates $J \cup K_1$.*

▶ **Corollary 37.**
- **(i)** *Let H be $K_t \cup K_2$, for $t \geq 4$ ($\in \overline{\mathcal{F}_1}$). Then H simulates $K_t \cup K_1$ ($\in \{\overline{H_5}\} \cup \overline{\mathcal{F}_2}$).*
- **(ii)** *Let H be $(K_t - e) \cup K_2$, for $t \geq 4$ ($\in \overline{\mathcal{F}_6}$). Then H simulates $(K_t - e) \cup K_1$ ($\in \{\overline{H_8}, \overline{D_2}\} \cup \overline{\mathcal{F}_8}$).*

Next we consider the removal of a path of degree-2 vertices. We can prove the correctness of the reduction only under a certain uniqueness condition on the path.

▶ **Lemma 38.** *Let H be a graph with minimum degree two and let $p \geq 2$ be an integer such that there is a unique induced path P of length p with the property that all the internal vertices of the path are having degree exactly two in H. Let H' be obtained from H by removing all internal vertices of P. Then H simulates H'.*

▶ **Corollary 39.** *Let H be J_t, for some $t \geq 3$ ($\in \mathcal{F}_9$). Then H simulates $K_2 \boxtimes tK_1$ ($\in \{\overline{H_3}\} \cup \mathcal{F}_3$).*

▶ **Corollary 40.** *Let H be Q_t, for some $t \geq 3$ ($\in \mathcal{F}_{10}$). Then H simulates $K_{2,t}$ ($\in \{S_1\} \cup \mathcal{F}_1$).*

▶ **Corollary 41.**
- **(i)** *S_5 simulates C_4.*
- **(ii)** *S_9 simulates $\overline{H_4}$.*
- **(iii)** *Let H be S_{15}. Then H simulates $\overline{H_9 \cup K_1}$. Further H simulates H_9 (Proposition 16).*
- **(iv)** *S_{22} simulates $\overline{diamond \cup K_2}$ ($\in \overline{\mathcal{F}_6}$).*

Lemma 42 essentially says the following: If H has vertex connectivity 1 and has a unique smallest 2-connected component which is a "leaf" in the tree formed by the 2-connected components, then H simulates a graph obtained by removing all vertices in the 2-connected component except the cut vertex.

▶ **Lemma 42.** *Let H be a graph with vertex connectivity 1 and be not a complete graph. Let $\mathcal{C}$ be the set of all 2-connected components of H having exactly one cut vertex of H. Assume that there exists a unique smallest (among $\mathcal{C}$) 2-connected component J in $\mathcal{C}$. Let v be the cut vertex of H in J. Let H' be $H - \{J \setminus \{v\}\}$. Then H' is simulated by H.*

▶ **Corollary 43.**

(i) *S_{20} simulates $K_{2,4}$ ($\in \mathcal{F}_1$).*

(ii) *S_{27} simulates $\overline{(K_5 - e) \cup K_2}$ ($\in \mathcal{F}_6$).*

▶ **Lemma 44.** *Let H be S_{35}. Then H simulates a 3-connected graph, which is not complete ($\in \mathcal{X}_D$).*

4.2 Reductions based on Construction 2

The following is a simplified version of Construction 1.

▶ **Construction 2.** *Let (G', k, ℓ) be an input to the construction, where G' is a graph and k and ℓ are positive integers. For every set S of ℓ vertices in G' introduce a clique C of $k+1$ vertices and make all the vertices in C adjacent to all the vertices in S.*

As before, we call every clique C introduced during the construction as a *satellite* and the vertices in it as *satellite vertices*. Lemma 45 can be proved using a straight-forward application of Construction 2. It says that if H satisfies some properties, then H simulates H' where H' is obtained by removing one vertex from each module of H contained within V_ℓ.

▶ **Lemma 45.** *Let H be a non-regular graph such that the following conditions hold true:*

(i) *$1 \leq \ell \leq 2, |V(H)| \geq 5$;*

(ii) *V_ℓ is an independent set, $V_h \cup V_m$ induces a connected graph, and every vertex in V_h is adjacent to at least one vertex in V_ℓ;*

(iii) *Every vertex in V_m has at least $\ell + 1$ neighbors outside V_m or there exists no pair u, v of adjacent vertices in V_m such that $N(u) \setminus \{v\} = N(v) \setminus \{u\}$.*

Consider a modular decomposition $\mathcal{M}$ of H. Let $\mathcal{M}' \subseteq \mathcal{M}$ corresponds to V_ℓ. Let H' be the graph obtained from H by removing one vertex from each module in $\mathcal{M}'$. Then H simulates H'.

The following corollary lists many graphs that can be handled by Lemma 45.

▶ **Corollary 46.**

(i) *S_7 simulates H_9.*

(ii) *S_8 simulates $\overline{A_1}$.*

(iii) *S_{10} simulates C_4.*

(iv) *S_{11} simulates $\overline{H_7}$.*

(v) *S_{12} simulates S_2.*

(vi) *S_{13} simulates S_3.*

(vii) *$\overline{S_{14}}$ simulates $\overline{B_1}$.*

(viii) *S_{18} simulates $\overline{A_1}$.*

(ix) *S_{19} simulates $\overline{S_3}$.*

(x) *S_{21} simulates $\overline{H_4}$.*

(xi) *S_{23} simulates $\overline{A_7}$.*

(xii) *S_{24} simulates $\overline{S_7}$.*

(xiii) *S_{25} simulates $\overline{H_1}$.*

(xiv) *S_{26} simulates S_8.*

(xv) *S_{28} simulates $\overline{A_9}$.*

(xvi) *S_{29} simulates S_{17}.*

(xvii) *S_{30} simulates $\overline{S_{19}}$.*

(xviii) *$\overline{S_{32}}$ simulates $\overline{S_{16}}$.*

(xix) *$\overline{S_{33}}$ simulates $\overline{K_{1,4} \cup K_2} \in \overline{\mathcal{F}_7}$.*

(xx) *$\overline{S_{34}}$ simulates $\overline{K_{1,5} \cup K_2} \in \overline{\mathcal{F}_7}$.*

(xxi) *$\overline{S_{36}}$ simulates $\overline{S_{14}}$.*

The following three corollaries are obtained by application of Lemma 45: they show that in certain families of graphs, every member simulates the simplest member. Corollary 47 deals with star graphs ($K_{1,t}$). For every graph H in this class, V_ℓ is a single module of the graph and H simulates a graph H', where H' is obtained by removing one vertex from V_ℓ. Corollary 48 handles $K_2 \boxtimes sK_1$, where V_ℓ forms a single module of the graph. As in the previous case, H' is obtained by removing one vertex from V_ℓ. Corollary 49 deals with the set of twin-star graphs (T_{t_1,t_2}). For every graph H in this class, there are two modules of H in V_ℓ : t_1 vertices adjacent to one vertex in $H - V_\ell$ and t_2 vertices adjacent to the other vertex in $H - V_\ell$. Then H simulates a graph H', where H' is obtained by removing one vertex each from the two modules.

▶ **Corollary 47** (see Lemma 6.4 in [2] for a partial result)**.** *Let H be $K_{1,t}$, for any $t \geq 5$ ($\in \mathcal{F}_2$). Let H' be $K_{1,t-1}$. Then H simulates H'. Furthermore, H simulates H_5 ($K_{1,4}$).*

▶ **Corollary 48** (see Lemma 4.5 in [1] for a partial result)**.** *Let H be $K_2 \boxtimes sK_1$, for any $s \geq 4$ ($\in \mathcal{F}_3$) and let H' be $K_2 \boxtimes (s-1)K_1$. Then H simulates H'. Furthermore, H simulates $\overline{H_3}$ ($K_2 \boxtimes 3K_1$).*

▶ **Corollary 49** (see Lemma 6.6 in [2] for a partial result)**.** *Let H be a twin-star graph T_{t_1,t_2}, such that $t_1, t_2 \geq 1$. Let H' be T_{t_1-1,t_2-1}. Then H simulates H'. In particular, if H is $T_{t,1}$, for some $t \geq 4$ ($\in \mathcal{F}_4$), then H simulates $K_{1,t}$ ($\in \{H_5\} \cup \mathcal{F}_2$).*

▶ **Lemma 50.** *$K_{2,3}$ ($= S_1$) simulates C_4.*

4.3 Reductions based on Construction 3

Now we give another construction that will be used in a few reductions.

▶ **Construction 3.** *Let (G', k, t) be an input to the construction, where G' is a graph and k and t are positive integers. For every set S of t vertices in G' introduce an independent set I_S of $k+2$ vertices such that every vertex in I_S is adjacent to every vertex in G' except those in S. Let $\bigcup_{S \subseteq V(G'), |S|=t} I_S = I$. Let the resultant graph be G.*

▶ **Lemma 51.** *Let H be a graph such that V_h forms a clique and for every pair of vertices $u, v \in V_h$, $H - u$ is isomorphic to $H - v$. Further assume that there exists no independent set S of size $s \geq 2$ where each vertex in S has degree at least $h - s + 1$ in H. Then H simulates $H - u$, where u is any vertex in V_h.*

Additional results used by Corollary 52 are shown in parenthesis.

▶ **Corollary 52.**

(i) *S_2 simulates $\overline{H_7}$.*
(ii) *S_3 simulates H_6.*
(iii) *S_{16} simulates S_3 (Proposition 16).*
(iv) *S_{17} simulates $\overline{H_1}$ (Proposition 16).*
(v) *S_{31} simulates S_3 (Proposition 16)*

▶ **Lemma 53.** *Let H be $(K_t - e) \cup K_1$ for $t \geq 6$ ($\overline{\mathcal{F}_8}$). Let H' be $K_{t-2} \cup K_1$ ($\in \{\overline{H_5}\} \cup \overline{\mathcal{F}_2}$). Then H simulates H'.*

4.4 Other reductions

To resolve graphs in $\mathcal{F}_7$ ($= K_{1,t} \cup K_2$), we resort to a known reduction. There is a PPT in [2] from H'-free Edge Editing to H-free Edge Editing, where H' is a largest component in H. It is a composition of two reductions: one from H'-free Edge Editing to H''-free Edge Editing and another from H''-free Edge Editing to H-free Edge Editing, where H'' is the union of all components in H isomorphic to H'. The first reduction uses a simple construction (take a disjoint union of the input graph and join of $k+1$ copies of H') and the second reduction uses Construction 1.

▶ **Proposition 54** (see Lemma 3.5 in [2]). *Let H' be a largest component of H. Then H simulates H'.*

▶ **Corollary 55.** *Let H be $K_{1,t} \cup K_2$, for $t \geq 4$ ($\in \mathcal{F}_7$). Then H simulates $K_{1,t}$ ($\in \{H_5\} \cup \mathcal{F}_2$).*

The following statement consider reduction that involve the removal of independent vertices.

▶ **Lemma 56.** *Let H be $J \cup tK_1$, for any $t \geq 2$ such that J has no component which is a clique. Let H' be $J \cup (t-1)K_1$. Then H simulates H'. In particular, H simulates $J \cup K_1$.*

▶ **Corollary 57.**

(i) *S_4 simulates H_2.*
(ii) *S_6 simulates H_6.*
(iii) *Let H be $(K_t - e) \cup 2K_1$, for $t \geq 4$ ($\in \overline{\mathcal{F}_5}$). Then H simulates $(K_t - e) \cup K_1$ ($\in \{\overline{H_8}, \overline{D_2}\} \cup \overline{\mathcal{F}_8}$).*

Summary of results in this section handling graphs in $\mathcal{S}$ and $\mathcal{F}$ are given in Figure 4a and 4b respectively. Lemma 58 follows from Corollary 5, Proposition 35, the transitivity of PPTs, and other results in this section (see Figures 4a and 4b) for details.

▶ **Lemma 58.** *Let $H \in \mathcal{W} \setminus \mathcal{W}'$. Then H simulates a graph in $\mathcal{W}' \cup \mathcal{X}_D$.*

5 Incompressibility results for the graphs in $\mathcal{A}$ and $\mathcal{B}$

In this section, we prove that for every graph $H \in \mathcal{A} \cup \overline{\mathcal{A}}$, all three problems H-free Edge Editing, H-free Edge Deletion, and H-free Edge Completion are incompressible, assuming NP $\not\subseteq$ coNP/poly. With the same assumption, we prove that H-free Edge Deletion is incompressible for every graph $H \in \mathcal{B}$; Proposition 4 then implies incompressibility of H-free Edge Completion for every $H \in \overline{\mathcal{B}}$.

▶ **Theorem 59.** *Assuming* NP $\not\subseteq$ coNP/poly*:*

(i) *Let $H \in \mathcal{A}$. Then H-free Edge Editing is incompressible.*
(ii) *Let $H \in \mathcal{A} \cup \overline{\mathcal{A}} \cup \mathcal{B}$. Then H-free Edge Deletion is incompressible.*
(iii) *Let $H \in \mathcal{A} \cup \overline{\mathcal{A}} \cup \overline{\mathcal{B}}$. Then H-free Edge Completion is incompressible.*

We apply the technique used by Cai and Cai [4] by which they obtained a complete dichotomy on the incompressibility of H-free edge modification problems on 3-connected graphs H. We will give a self-contained summary of their proof technique, with only a few references to proofs of formal statements. The reader is referred to [4] for a more detailed exposition of terminology and concepts discussed in this section.

The first step in the proof is to establish incompressibility for the *restricted* versions of H-free Edge Deletion and H-free Edge Completion, where only allowed edges can be deleted/added. Then deletion and completion *enforcer gadgets* can be used to reduce

Figure 4

the restricted problems to the original versions. Cai and Cai [4] presented constructions that were proved to work correctly when H is 3-connected. We show, by careful inspection, that the same technique works for certain graphs H that are not 3-connected. For certain graphs H, we can prove incompressibility of the restricted problem, but enforcer gadgets of the required form provably do not exist. In these cases, we use ad hoc ideas to reduce the restricted version to the original one. In yet further cases, we need even trickier reductions, where we reduce H'-free Edge Deletion to H-free Edge Deletion for some $H' \neq H$.

5.1 Incompressibility results for the restricted problems

A graph is called *edge-restricted* if a subset of its edges are marked as *forbidden*. All edges other than forbidden are *allowed*. A graph is called *nonedge-restricted* if a subset of its nonedges are marked as *forbidden*. All nonedges other than forbidden are *allowed*.

Restricted H-free Edge Deletion: Given a graph G, an integer k, and a set R of edges of G, do there exist at most k edges disjoint from R such that deleting them from G results in an H-free graph? **Parameter**: k

Restricted H-free Edge Completion: Given a graph G, an integer k, and a set R of nonedges of G, do there exist at most k nonedges disjoint from R such that adding them in G results in an H-free graph? **Parameter**: k

Propagational formula satisfiability. A ternary Boolean function $f(x, y, z)$ (where x, y, and z are either Boolean variables or constants 0 or 1) is *propagational* if $f(1, 0, 0) = 0, f(0, 0, 0) = f(1, 0, 1) = f(1, 1, 0) = f(1, 1, 1) = 1$. This has the meaning: if x is true then either y is true or z is true.

Propagational-f Satisfiability: Given a conjunctive formula φ of a propagational ternary function f with distinct variables in each clause of φ, find whether there exists a satisfying truth assignment with weight at most k. The parameter we consider is k.

▶ **Proposition 60** (Theorem 3.4 in [4]). *For any propagational ternary Boolean function f,* Propagational-f Satisfiability *on 3-regular conjunctive formulas (every variable appears exactly three times) admits no polynomial kernel, assuming* NP $\not\subseteq$ coNP/poly.

Satisfaction-testing components. For H-free Edge Deletion, a *satisfaction-testing component* $S_D(x, y, z)$ is a constant-size edge-restricted H-free graph with exactly three allowed edges $\{x, y, z\}$ such that there is a propagational Boolean function $f(x, y, z)$ such that $f(x, y, z) = 1$ if and only if the graph obtained from $S_D(x, y, z)$ by deleting edges in $\{x, y, z\}$ with value 1 is H-free. For H-free Edge Completion, a *satisfaction-testing component* $S_C(x, y, z)$ is a constant-size nonedge-restricted H-free graph with exactly three allowed nonedges $\{x, y, z\}$ such that there is a propagational Boolean function $f(x, y, z)$ such that $f(x, y, z) = 1$ if and only if the graph obtained from $S_C(x, y, z)$ by adding edges in $\{x, y, z\}$ with value 1 is H-free.

There is an easy construction (Lemma 4.3 in [4]) showing that $S_D(x, y, z)$ exists for every connected graph H with at least four vertices but not complete and $S_C\{x, y, z\}$ exists for every connected graph with at least four vertices and at least two nonedges. The construction for this is as follows. $S_D\{x, y, z\}$: Let x be a nonedge, and y and z be two edges in H. Then $H + x$ is a $S_D(x, y, z)$ where x, y, z are the only allowed edges. $S_C\{x, y, z\}$: Let x be an edge, and y and z be two nonedges in H. Then $H - x$ is a $S_C(x, y, z)$ where x, y, z are the only allowed nonedges.

Truth-setting components. For H-free Edge Deletion, a *truth-setting component* $(T_D(u))$ is a constant-sized, edge-restricted H-free graph such that it contains at least three allowed edges x, y, z without a common vertex and admits exactly two deletion sets $\emptyset$ and the set of all allowed edges. For H-free Edge Completion, a *truth-setting component* $(T_C(u))$ is a constant-sized, nonedge-restricted H-free graph such that it contains at least three allowed nonedges x, y, z without a common vertex and admits exactly two completion sets $\emptyset$ and the set of all allowed nonedges.

There is a construction given in [4] for $T_D(u)$ and $T_C(u)$ when H is 3-connected but not complete. The constructions are given below.

Construction of $T_D(u)$: Let e', e be a nonedge and an edge sharing no common vertex in H. Let the *basic unit* $U = H + e'$ and set all edges except e and e' in U as forbidden. Let p be the number of vertices in H. Take p copies $U_1, U_2, \ldots, U_p$ of U. Identify the edge e of U_i with the edge e' of U_{i+1} to form a chain of U's. This is a *basic chain* $B(u)$. Let us call the unidentified edge e' of U_1 as the *left-most allowed edge* of $B(u)$ and unidentified edge of U_p as the *right-most allowed edge* of $B(u)$. Take three basic chains B_0, B_1, and B_2. Attach them in a cyclic fashion: Identify the right-most allowed edge of B_i with the left-most allowed edge of B_{i+1}, where indices are taken mod 3. This is the claimed truth-setting component $T_D(u)$. Let us call the allowed edges thus identified as *variable edges*. We note that there are exactly three variable edges in $T_D(u)$.

It is easy to see that, for every H, there are only two possible deletion sets in $T_D(u)$: the empty set and the set of all allowed edges. To see this, observe that if we remove any of the allowed edges, then it creates a copy of H in one of the units, forcing us to remove the next allowed edge as well. However, it is not clear if these two deletion sets really make the graph H free. As Cai and Cai [4] show, this construction for $T_D(u)$ works correctly for 3-connected graphs H: Since the "cycle" of basic units is long enough, every subgraph having vertices from different basic units and having at most $|V(H)|$ vertices has vertex connectivity at most 2. In general, the construction may not give correct truth-setting components for 2-connected graphs H. But, as we shall see later, by carefully choosing e and e' in these constructions, we can obtain truth-setting components for many 2-connected graphs H.

Construction of $T_C(u)$: Let e', e be a nonedge and an edge sharing no common vertex in H. Let the *basic unit* $U = H - e$ and set all nonedges except e and e' in U as forbidden. Let p be the number of vertices in H. Take p copies $U_1, U_2, \ldots, U_p$ of U. Identify the nonedge e of U_i with the nonedge e' of U_{i+1} to form a chain of U's. This is a *basic chain* $B(u)$. Let us call the unidentified nonedge e' of U_1 as the *left-most allowed nonedge* of $B(u)$ and unidentified nonedge of U_p as the *right-most allowed nonedge* of $B(u)$. Take three basic chains B_0, B_1, and B_2. Attach them in a cyclic fashion: Identify the right-most allowed nonedge of B_i with the left-most allowed nonedge of B_{i+1}, where indices are taken mod 3. This is the claimed truth-setting component $T_C(u)$. Let us call the allowed nonedges thus identified as *variable nonedges*. We note that there are exactly three variable nonedges in $T_C(u)$. Similarly to $T_D(u)$, we can argue that for any H, there are only two potential completion sets (the empty set and the set of all allowed nonedges), and for 3-connected H, these two sets are indeed completion sets.

The following is the construction used in the reduction from Propagational-f Satisfiability to Restricted H-free Edge Deletion (Completion).

▶ **Construction 4.** *Let (φ, k, H) be an input to the construction, where φ is a 3-regular conjunctive formula on a propagational ternary Boolean function f, and k is a positive integer. The construction gives a graph G_φ, an integer k', and a set of restricted (non)edges in G_φ.*

- *For every clause in φ, introduce a satisfaction-testing component $S_D(x, y, z)$ ($S_C(x, y, z)$) for H-free Edge Deletion (Completion).*
- *If $c \in \{x, y, z\}$ is 1, then the corresponding allowed (non)edge is deleted(added) and if $c = 0$ then the corresponding allowed (non)edge is set as forbidden.*
- *For every variable u in f, introduce a truth-setting component $T_D(u)$ ($T_C(u)$) for H-free Edge Deletion (Completion)*
- *For every variable u, identify each of the variable (non)edges in $T_D(u)$ ($T_C(u)$) with an allowed (non)edge in a satisfaction-testing component corresponds to a different clause in which u appears – since φ is 3-regular, u appears in exactly three clauses.*

Let the graph obtained be G_φ and let $k' = 3|V(H)|k$. For the deletion problem the set R of forbidden edges is all the edges in G_φ except the allowed edges in the units. For the completion problem, the set R of forbidden nonedges contains every nonedge of G_φ except the allowed nonedges in the units.

Let H be a graph and (φ, k) be an instance of a Propagational-f Satisfiability problem. Let (G_φ, k', R) be the output of the Construction 4 applied on (φ, k, H). The construction works correctly in one direction: If (G_φ, k', R) is a yes-instance of Restricted H-free Edge Deletion (Completion), then (φ, k) is a yes-instance of Propagational-f Satisfiability. To see this, let F be a solution of (G_φ, k', R). By the definition of $T_D(u)$ ($T_C(u)$), if an allowed (non)edge is in F then so is every allowed (non)edge in it. Therefore,

since $|F| \leq k' = 3k|V(H)|$ and every truth-setting component has exactly $3|V(H)|$ many allowed (non)edges, only at most k (non)edges of satisfaction-testing components are in F. By the definition of $S_D(x,y,z)$ ($S_C(x,y,z)$), if $x \in F$ then either y or z is in F, otherwise there is an induced H in $G_\varphi + F$. Therefore, setting the variables to 1 corresponding to the (non)edges, which are part of F, in satisfaction-testing components, we obtain that (φ, k) is a yes-instance of Propagational-f Satisfiability. Thus we have the following Proposition.

▶ **Proposition 61** (see Lemma 5.1 in [4]). *Let (φ, k) be an instance of* Propagational-f Satisfiability. *For a graph H, let (G_φ, k', R) be obtained by applying Construction 4 on (φ, k, H). Then, if (G_φ, k', R) is a yes-instance of* Restricted H-free Edge Deletion *(Completion) then (φ, k) is a yes-instance of* Propagational-f Satisfiability.

We remark that the proof of Proposition 61 works even if we use a gadget for the truth-setting component which satisfies only a weak property: it has at most two deletion (completion) sets, the $\emptyset$ and the set of all allowed (non)edges. As we have seen, the construction of $T_D(u)$ and $T_C(u)$ discussed above satisfies this weak property. To prove the other direction, one needs to show that there is no induced H in the "vicinity" of a satisfaction-testing component after deleting (adding) the (non)edges corresponding to the variables being set to 1 in φ. This can be done very easily for 3-connected graphs H. Proving this direction for 2-connected graphs H (if provable) requires careful structural analysis of the constructed graph G_φ. In Figure 5, we give various gadgets required for the proofs of this section. We use *unit* as a general term to refer to a satisfaction-testing component or a basic unit.

▶ **Lemma 62.** *Let $H \in \{\overline{A_1}, \overline{A_2}, A_3, \overline{A_3}, A_4, A_5, \overline{A_7}, \overline{A_9}\}$. Then* Restricted H-free Edge Deletion *is incompressible, assuming* NP $\not\subseteq$ coNP/poly.

The following corollary follows from the fact that there is no subgraph isomorphic to a C_4 where all edges are allowed in the graph G_φ constructed in the proof of Lemma 62 for Restricted H-free Edge Deletion, when H is a $\overline{A_1}$. We will be using this result later to handle $\overline{A_7}$.

▶ **Corollary 63.** *Let H be $\overline{A_1}$. Then, assuming* NP $\not\subseteq$ coNP/poly, Restricted H-free Edge Deletion *is incompressible even if input graphs does not contain a subgraph (not necessarily induced) isomorphic to H where all the side-edges of the diamond (a side-edge of a diamond is an edge incident to a degree-2 vertex in the diamond) in the subgraph are allowed.*

▶ **Lemma 64.** *Let $H \in \{\overline{A_2}, \overline{A_7}, \overline{A_8}, \overline{A_9}, \overline{B_1}, \overline{B_2}, \overline{B_3}\}$. Then* Restricted H-free Edge Completion *is incompressible, assuming* NP $\not\subseteq$ coNP/poly.

5.2 Using enforcers to reduce to the unrestricted problems

If we want to reduce Restricted H-free Edge Deletion to H-free Edge Deletion, then there is a fairly natural idea to try: for each restricted edge $e' = x'y'$, we introduce a copy of H on set U of new vertices and identify $x'y'$ with xy, where $x, y \in U$ are nonadjacent vertices. Now U induces a copy of H plus an extra edge, but as soon as e' is deleted, it becomes a copy of H, effectively preventing the deletion of e'.

There are two problems with this approach. First, the solution could delete other edges from the new copy of H, and then it is not necessarily true that the removal of e' automatically creates an induced copy of H. However, this problem is easy to avoid by repeating this

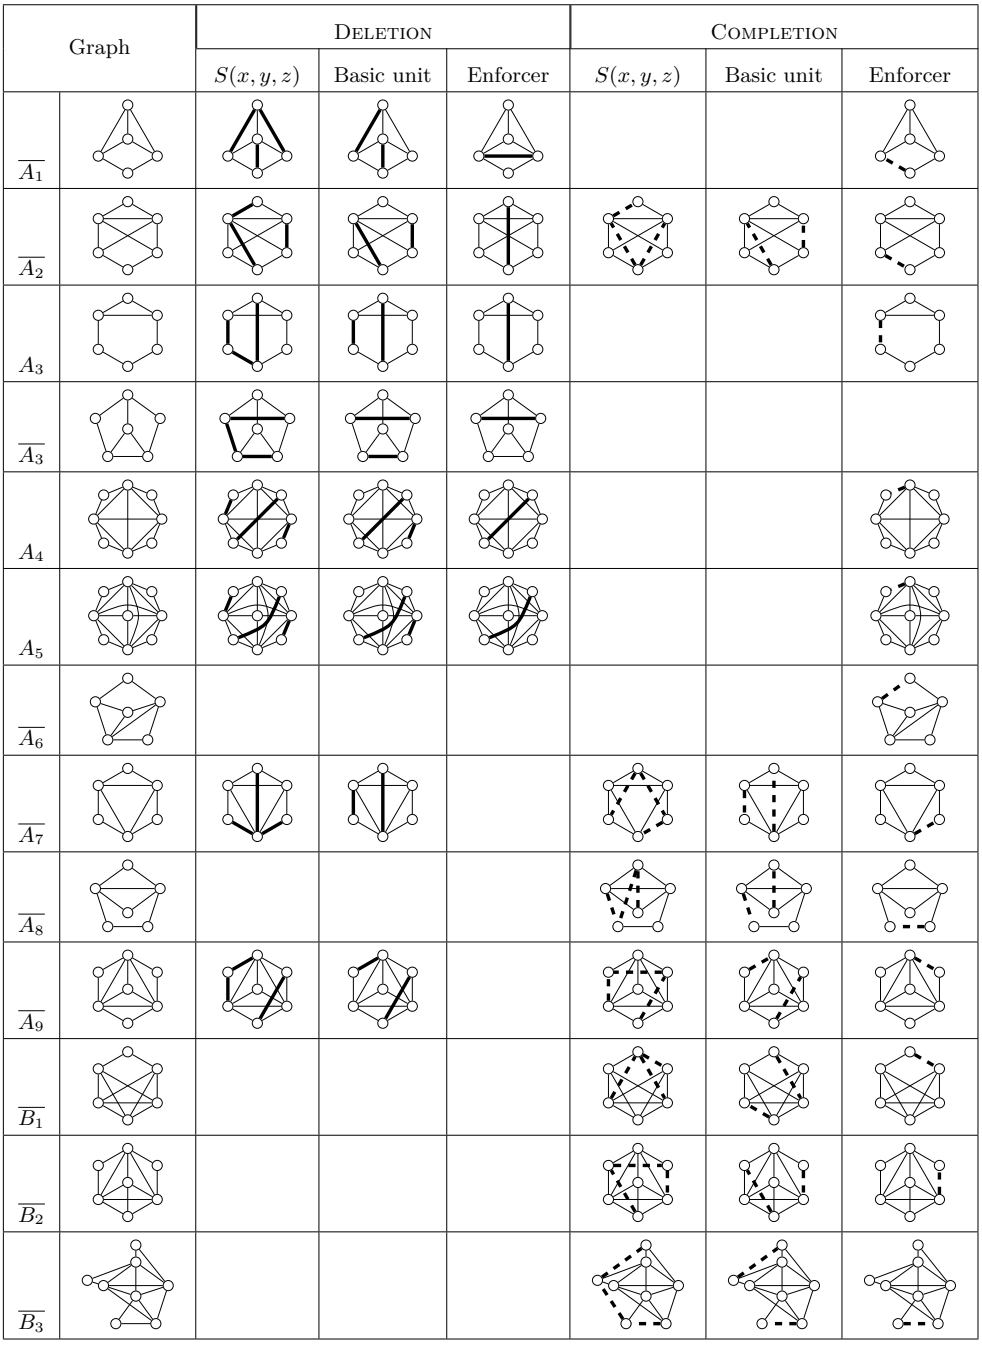

Figure 5 Various gadgets used in the proofs of this section. In a satisfaction-testing component $S_D(x,y,z)$ ($S_C(x,y,z)$), x is the darkened (non)edge added(deleted) in H to obtain the gadget, and y and z are the other two darkened (non)edges. Both the allowed (non)edges in basic units are darkened. The distinguished edge in a deletion enforcer and the distinguished nonedge in a completion enforcer are darkened.

gadget construction $k+1$ times: a solution of size at most k cannot interfere with all $k+1$ gadgets. The second problem is more serious: it is possible that attaching the new vertices creates a copy of H, even when e is not deleted. For certain graphs H, with a careful choice of x and y we can ensure that this does not happen: no induced copy of H can go through the separator x, y.

An *H-free deletion enforcer* (X, e) consists of an H-free graph X and a distinguished edge e in X such that (a) $X - e$ contains an induced H, and (b) for any graph G vertex disjoint with X, and any edge e' of G, all induced copies of H in the graph obtained by attaching X to G through identifying e with e' reside entirely inside G. Similarly, an *H-free completion enforcer* (X, e) consists of an H-free graph X and a distinguished nonedge e such that (a) $X + e$ contains an induced H, and (b) for any graph G vertex disjoint with X, and any nonedge e' in G, all induced copies of H in the graph obtained by attaching X to G through identifying e with e' reside entirely inside G. It can be shown that if we can come up with enforcer gadgets satisfying these conditions, then the ideas sketched above can be made to work, and we obtain a reduction from the restricted problem to the unrestricted version.

▶ **Proposition 65** (See Lemma 6.5 in [4]). *For a graph H:*

(i) *If* Restricted H-free Edge Deletion *is incompressible and there exists an H-free deletion enforcer, then H-*free Edge Deletion *is incompressible.*

(ii) *If* Restricted H-free Edge Completion *is incompressible and there exists an H-free completion enforcer, then H-*free Edge Completion *is incompressible.*

(iii) *If H-*free Edge Deletion *is incompressible and there exists an H-free completion enforcer, then H-*free Edge Editing *is incompressible.*

In the rest of the section, we establish the existence of enforcer gadgets for certain graphs H.

▶ **Lemma 66.** *Let $H \in \{\overline{A_1}, \overline{A_2}, A_3, \overline{A_3}, A_4, A_5\}$. Then the gadget X with a distinguished edge e shown in the corresponding cell in the column "Enforcer" (under* Deletion*) in Figure 5 is an H-free deletion enforcer.*

▶ **Lemma 67.** *Let $H \in \{\overline{A_1}, \overline{A_2}, A_3, A_4, A_5, \overline{A_6}, \overline{A_7}, \overline{A_8}, \overline{A_9}, \overline{B_1}, \overline{B_2}, \overline{B_3}\}$. Then the gadget X with a distinguished nonedge e shown in the corresponding cell in the column "Enforcer" (under* Completion*) in Figure 5 is an H-free completion enforcer.*

▶ **Lemma 68.** *Let $H \in \{\overline{A_1}, \overline{A_2}, A_3, \overline{A_3}, A_4, A_5\}$. Then H-*free Edge Deletion *and H-*free Edge Editing *are incompressible, assuming* NP $\not\subseteq$ coNP/poly.

Similarly, we can prove Lemma 69. The cases of H being A_4 or A_5 follows from the fact that H and $\overline{H}$ are isomorphic (see Proposition 4).

▶ **Lemma 69.** *Let $H \in \{\overline{A_2}, A_4, A_5, \overline{A_7}, \overline{A_8}, \overline{A_9}, \overline{B_1}, \overline{B_2}, \overline{B_3}\}$. Then H-*free Edge Completion *is incompressible, assuming* NP $\not\subseteq$ coNP/poly.

5.3 Further tricky reductions

There are graphs for which we can show that no completion/deletion enforcers, as defined in the previous section, exist (this can be checked by going through every pair x, y of (non)adjacent vertices). For some of these graphs, we can find a different way of enforcing that certain edges are forbidden; typically, we introduce some vertices that are used globally by every enforcer gadget. Furthermore, there are graphs H, where we were unable to obtain a reduction from Restricted H-free Edge Deletion (Completion), but could choose an induced subgraphs $H' \subseteq H$ and obtain a reduction from Restricted H'-free Edge Deletion (Completion), whose incompressibility was established earlier.

▶ **Lemma 70.** *Assuming* NP $\not\subseteq$ coNP/poly, H-free Edge Editing *and* H-free Edge Deletion *are incompressible, when* $H \in \{\overline{A_6}, \overline{A_7}, \overline{A_8}, \overline{A_9}\}$ *and* H-free Edge Completion *is incompressible when* $H \in \{\overline{A_1}, \overline{A_6}\}$.

Now, Theorem 59(i) follows from Lemma 68, Lemma 70, and Proposition 4. Similarly, Theorem 59(ii) follows from Lemma 68, 70, 69, and Proposition 4. Theorem 59(iii) follows from Theorem 59(ii) and Proposition 4. Theorem 1 follows from Lemma 12, 58, Theorem 59(i), and Proposition 6. Similarly, Theorem 2 follows from Lemma 13, 58, Theorem 59(ii), and Proposition 6.

Abstract

A subset S of nodes in a graph G is a **k-connected m-dominating set** (**(k,m)-cds**) if the subgraph $G[S]$ induced by S is k-connected and every $v \in V \setminus S$ has at least m neighbors in S. In the k-Connected m-Dominating Set ((k,m)-CDS) problem the goal is to find a minimum weight (k,m)-cds in a node-weighted graph. For $m \geq k$ we obtain the following approximation ratios. For general graphs our ratio $O(k \ln n)$ improves the previous best ratio $O(k^2 \ln n)$ of [26] and matches the best known ratio for unit weights of [34]. For unit disk graphs we improve the ratio $O(k \ln k)$ of [26] to $\min\left\{\frac{m}{m-k}, k^{2/3}\right\} \cdot O(\ln^2 k)$ – this is the first sublinear ratio for the problem, and the first polylogarithmic ratio $O(\ln^2 k)/\epsilon$ when $m \geq (1+\epsilon)k$; furthermore, we obtain ratio $\min\left\{\frac{m}{m-k}, \sqrt{k}\right\} \cdot O(\ln^2 k)$ for uniform weights. These results are obtained by showing the same ratios for the Subset k-Connectivity problem when the set of terminals is an m-dominating set.

1 Introduction

All graphs in this paper are assumed to be simple, unless stated otherwise. A (simple) graph is **k-connected** if it has k pairwise internally node disjoint paths between every pair of its nodes; in this case the graph has at least $k+1$ nodes. A subset S of nodes in a graph G is a **k-connected set** if the subgraph $G[S]$ induced by S is k-connected; S is an **m-dominating set** if every $v \in V \setminus S$ has at least m neighbors in S. If S is both k-connected and m-dominating set then S is a **k-connected m-dominating set**, or **(k,m)-cds** for short. A graph is a **unit disk graph** if its nodes can be located in the Euclidean plane such that there is an edge between u and v iff the Euclidean distance between u and v is at most 1. We consider the following problem for $m \geq k$ both in general graphs and in unit disk graphs.

k-Connected m-Dominating Set ((k,m)-CDS)
Input: A graph $G=(V,E)$ with node weights $\{w_v : v \in V\}$ and integers k, m.
Output: A minimum weight (k,m)-cds $S \subseteq V$.

The problem generalizes several classic problems including Set-Cover ($k=0, m=1$), Set-Multicover ($k=0$), and Connected Dominating Set ($k=m=1$). The Connected Dominating Set problem is closely related to the Node Weighted Steiner Tree problem, and both problems admit a tight ratio $O(\log n)$ [16, 12, 13]. In unit disk graphs, the problem is NP-hard [5], admits a PTAS for unit weights [3], and ratio $3+2.5\rho+\epsilon$ for arbitrary weights [33, 35], where ρ is the ratio for the edge-weighted Steiner Tree problem in general graphs. The (k,m)-CDS problem models (fault tolerant) virtual backbones in networks [7, 6], and it was studied extensively, c.f. [1, 3, 10, 12, 13, 21, 32, 26, 33, 31, 34, 35, 36] for the case $m \geq k$ and [2, 29] for the case $k=2, m=1$. For further motivation and history

survey we refer the reader to recent papers of Zhang, Zhou, Mo, and Du [31] and of Fukunaga [10], where they obtained in unit disk graphs ratios $O(k^3 \ln k)$ and $O(k^2 \ln k)$, respectively. This was improved to $O(k \ln k)$ in [26], where is also given ratio $O(k^2 \ln n)$ in general graphs.

Our main results is:

▶ **Theorem 1.** (k, m)-CDS *with* $m \geq k$ *admits the following approximation ratios:*

- $O(k \ln n)$ *in general graphs.*
- $\min\left\{\frac{m}{m-k}, k^{2/3}\right\} \cdot O(\ln^2 k)$ *in unit disk graphs.*
- $\min\left\{\frac{m}{m-k}, \sqrt{k}\right\} \cdot O(\ln^2 k)$ *in unit disk graphs with unit weights.*

For general graphs our ratio $O(k \ln n)$ improves the previous ratio $O(k^2 \ln n)$ of [26] and matches (while using totally different techniques) the best known ratio for unit weights of Zhang et. al. [34]. For unit disk graphs our ratio $\min\left\{\frac{k}{m-k}, k^{2/3}\right\} \cdot O(\ln^2 k)$ improves the previous best ratio $O(k \ln k)$ of [26]; this is the first sublinear ratio for the problem, and for any constant $\epsilon > 0$ and $m = k(1+\epsilon)$ the first polylogarithmic ratio $O(\ln^2 k)/\epsilon$.

Let us say that a graph with a set T of terminals and a root $r \in T$ is **k-(T, r)-connected** if it has k internally node disjoint rt-paths for every $t \in T \setminus \{r\}$. Similarly, a graph is **k-T-connected** if it has k internally node disjoint st-paths for every $s, t \in T$. A reason why the case $m \geq k$ is easier than the case $m < k$ is given in the following statement (a proof can be found in many papers, c.f. [31, 10, 26]).

▶ **Lemma 2.** *Let T be a k-dominating set in a graph $H = (U, F)$. If H is k-(T, r)-connected then H is k-(U, r)-connected; if H is k-T-connected then H is k-connected.*

The above lemma implies that in the case $m \geq k$ (k, m)-CDS has the property that the union $T \cup S$ of a partial solution T that is just m-dominating and a node set S such that $G[T \cup S]$ is T-k-connected, is a feasible solution – this enables to construct the solution iteratively. Specifically, most algorithms for the case $m \geq k$ start by computing just an m-dominating set T; the best ratios for m-Dominating Set are $\ln(\Delta + m)$ in general graphs [8] and $O(1)$ in unit disk graphs [10], where Δ is the maximum degree in G. By invoking just these ratios, Lemma 2 enables to reduce (k, m)-CDS with $m \geq k$ to following (node weighted) problem:

Subset k-Connectivity
Input: A graph $G = (V, E)$ with node-weights $\{w_v : v \in V\}$, a set $T \subseteq V$ of terminals, and an integer k.
Output: A minimum weight k-T-connected subgraph of G.

The ratios for this problem are usually expressed in terms of the best known ratio β for the following problem (in both problems we assume w.l.o.g. that $w_v = 0$ for all $v \in T$):

Rooted Subset k-Connectivity
Input: A graph $G = (V, E)$ with node-weights $\{w_v : v \in V\}$, a set $T \subseteq V$ of terminals, a root node $r \in T$, and an integer k.
Output: A minimum weight k-(T, r)-connected subgraph of G.

We refer the reader to recent surveys [28, 27] on approximation algorithm for node-connectivity problems and to [16, 22, 25, 9, 24] on approximation algorithm for various node-weighted connectivity problems and their generalizations. Currently, $\beta = O(k^2 \ln |T|)$ [22]. From previous work it can be deduced that Subset k-Connectivity with $|T| \geq k$

admits ratio $\beta + k^2$. Add a new root node r connected to a set $R \subseteq T$ of k nodes by edges of cost zero. Then compute a β-approximate solution to the obtained Rooted Subset k-Connectivity instance. Finally, augment this solution by computing for every $u, v \in R$ a min-weight set of k internally disjoint uv-paths. For the (k, m)-CDS problem with $m \geq k$ this already gives ratio $\beta + k^2 = O(k^2 \ln |T|)$ in general graphs. For the special case when T is a k-dominating set the ratio $\beta + k^2$ was improved in [26] to $\beta + k - 1$, since then in the final step it is sufficient to compute a min-weight set of k internally disjoint uv-paths only for pairs that form a forest on R (by the Critical Cycle Theorem of Mader [20]).

We now consider unit disk graphs. Zhang et al. [31] showed that any k-connected unit disk graph has a k-connected spanning subgraph of maximum degree $\leq 5k$. This implies that the node weighted case is reduced with a loss of factor $O(k)$ to the case of node induced edge costs – when $c_{uv} = w_u + w_v$ for every edge $e = uv \in E$. The edge costs version of Subset k-Connectivity admits ratio $O(k^2 \ln k)$, which gives ratio $O(k^3 \ln k)$ for (k, m)-CDS with $m \geq k$ in unit disk graphs. Independently, Fukunaga [10] obtained ratio $O(k^2 \ln k)$ using a different approach – he considered the Rooted Subset Connectivity Augmentation problem, when $G[T]$ is ℓ-(T, r)-connected and we seek a minimum weight $S \subseteq V \setminus T$ such that $G[T \cup S]$ is $(\ell + 1)$-(T, r)-connected. In [22] it is shown that the augmentation problem decomposes into $O(k)$ "uncrossable" subproblems (for precise definitions, see Definition 20 in Section 3), and Fukunaga [10] designed a primal-dual $O(1)$-approximation algorithm for such an uncrossable subproblem in unit disk graphs. This gives ratio $O(\ell)$ for Rooted Subset Connectivity Augmentation in unit disk graphs. Furthermore, using the so called "backward augmentation analysis" [11] Fukunaga showed that since his approximation is w.r.t. an LP, then sequentially increasing the T-connectivity by 1 invokes only a factor of $O(\ln k)$, thus obtaining ratio $O(k \ln k)$ for Rooted Subset Connectivity Augmentation. He then combined this result with a decomposition of the Subset k-Connectivity problem into k Rooted Subset k-Connectivity problems, and obtained ratio $O(k^2 \ln k)$. As was mentioned, in [26] it is proved that ratio β for Rooted Subset k-Connectivity implies ratio $\beta + k - 1$ for (k, m)-CDS with $m \geq k$, which improves the ratio to $O(k \ln k)$.

However, it seems that previous reductions and methods alone do not enable to obtain ratio better than $O(k^2 \ln |T|)$ in general graphs, or a sublinear ratio in unit disk graphs. These algorithm rely on the ratios and decompositions for the Rooted/Subset k-Connectivity problems from [22, 23, 19], but these do not consider the specific feature relevant to (k, m)-CDS with $m \geq k$ – that the set T of terminals is a k-dominating set; note that then Subset k-Connectivity is equivalent to the problem of finding the lightest k-connected subgraph containing T, by Lemma 2. Here we change this situation by asking the following question:

If the set T of terminals is an m-dominating set with $m \geq k$, what approximation ratio can be achieved for (node weighted) Subset k-Connectivity?

Our answer to this question is given in the following theorem, which is of independent interest, and note that it implies Theorem 1.

▶ **Theorem 3.** *The (node weighted)* Subset k-Connectivity *problem such that T is an m-dominating set with $m \geq k$ admits the following approximation ratios: $O(k \ln n)$ in general graphs, $O(\ln^2 k) \cdot \min\left\{\frac{m}{m-k+1}, k^{2/3}\right\}$ in unit disk graphs, and $O(\ln^2 k) \cdot \min\left\{\frac{m}{m-k+1}, \sqrt{k}\right\}$ in unit disk graphs with unit weights.*

In the proof of Theorem 3 we use several results and ideas from previous works [22, 23, 31, 10, 26]. As was mentioned, the best ratios for the Subset k-Connectivity are derived via reductions of [23, 26] from the ratios for the Rooted Subset k-Connectivity problem,

so we will consider the latter problem; the currently best known ratio for this problem is $O(k^2 \ln |T|)$ [22]. The algorithm of [22] has k iterations, where at iteration $\ell = 0, \ldots, k-1$ it considers the augmentation problem of increasing the connectivity from ℓ to $\ell + 1$. This is equivalent to "covering" a certain family $\mathcal{F}$ of "deficient sets" (see Section 2 for precise definitions), and the algorithm of [22] decomposes this problem into $O(\ell)$ uncrossable family covering problems; the ratio for covering each uncrossable family is $O(\ln n)$ in general graphs [22] and $O(1)$ in unit disk graphs [10].

However, a more careful analysis of the [22] algorithm reveals that in fact the number of uncrossable families is $O(\ell/q) + 1$, where q is the minimum number of terminals in a deficient set. Instances with $q \geq \ell + 1$ are often called "T-independence-free" (see Lemmas 6 and 7). In T-independence-free instances the entire family of deficient sets is uncrossable, hence such instances admit ratio $O(\ln n)$ in general graphs and $O(1)$ in unit disk graphs. The algorithm of [22] has an "inflation phase" that works towards reaching $q \geq \ell + 1$ – to make the instance T-independence-free, by repeatedly covering $O(\ell/q)$ uncrossable families to double q. Hence if q_0 is the initial value of q, the total number of uncrossable families that the algorithm covers is 1 plus order of $\frac{\ell}{q_0}\left(1 + \frac{1}{2} + \frac{1}{4} + \cdots\right) = O(\ell/q_0)$. Note that a large part of the uncrossable families are covered when q is small. One of our contributions is designing different "lighter" inflation algorithms for increasing the parameter q. These algorithms just aim to cover the inclusion minimal deficient sets (a.k.a. "cores" – for precise definition see Definition 14), by adding a light set S of nodes, and then add S to the set T of terminals; if T is a k-dominating set then adding any set S to T does not make the problem harder, by Lemma 2.

Our algorithms for covering inclusion minimal deficient sets reduce the problem to a set covering type problem. In the case of general graphs the reduction is to a special case considered in [18] of the Submodular Covering problem; the ratio invoked by this procedure is only $O(\ln n)$ and if we apply it $p = \max\{2k - m - 1, 1\}$ times then we get $q \geq m - \ell + p(k - \ell) \geq k$ for all $\ell = 0, \ldots, k-1$. In fact, we apply this procedure before considering the augmentation problems, but it guarantees that $q \geq k$ through all augmentation iterations. The same procedure applies in the case of unit disk graphs, but to avoid the dependence on n in the ratio we use a different procedure. Specifically, we use the result of Zhang et. al. [31] that a minimally k-connected unit disk graph has maximum degree $\leq 5k$, to reduce the problem of covering the family of deficient sets to the Set Cover problem with soft capacities. This approach gives ratio $\min\left\{\frac{m}{m-k}, k^{2/3}\right\} \cdot O(\ln^2 k)$.

Our algorithms are simple and combinatorial. We omit the running time analysis, but it is polynomial and dominated by that of finding k times an approximate solution to Rooted Subset k-Connectivity in T-independence-free instances [22, 10]. Apart from significantly improving approximation ratios for (k, m)-CDS and special instances of Subset/Rooted k-Connectivity, which are extensively studied important fundamental problems, we also have the following contribution. The framework of approximating k-connectivity problems via independence-free graphs was very successful in [22] and [4, 30] (see also [14] for the first paper that used this framework, for an exact algorithm), but these are the only papers that succeeded to apply it. In general, it is not clear how to find a cheap partial solution to make the residual instance independence-free. In [22] this was achieved by "merging" deficient sets, so that at each iteration the minimum number of terminals in a deficient set is doubled. The method used in [4, 30] constructs an independence free instance in just two iterations, but it is tailor made for the k-Connected Subgraph problem considered there. We use a different method that reaches an almost independence-free instance by just repeatedly solving

a Set Cover (or a Submodular Cover) problem. We believe that the method used here can be also applied for other problems, maybe for activation network design problems [24, 9], that generalize node weighted network design problems.

In the rest of the paper we prove Theorem 3; Section 2 considers general graphs and Section 3 considers unit disk graphs.

2 General graphs

In order to prove our results we need to characterize k-connectivity in terms of "cuts" rather than in terms of paths. While edge-cuts of a graph correspond to node subsets, a natural way to represent a node-cut of a graph is by a pair of sets called a "biset".

▶ **Definition 4.** *An ordered pair $\mathbb{A} = (A, A^+)$ of subsets of V with $A \subseteq A^+$ is called a* **biset***; the set $\partial\mathbb{A} = A^+ \setminus A$ is called the* **cut** *of $\mathbb{A}$. We say that $\mathbb{A}$ is a* **(T, r)-biset** *if $A \cap T \neq \emptyset$ and $r \in V \setminus A^+$. For an edge set/graph J let $d_J(\mathbb{A})$ denote the number of edges in J that have one end in A and the other in $V \setminus A^+$.*

Let $\kappa_G(t, r)$ denote the maximum number of pairwise internally disjoint tr-paths in G. In biset terms, the node connectivity version of Menger's Theorem (that applies also for non-simple graphs) says that $\kappa_G(t, r)$ equals $\min\{|\partial\mathbb{A}| : t \in A, r \in V \setminus A^+\}$ plus the number of tr-edges. Here $\partial\mathbb{A}$ is a node cut that separates t from r in the graph obtained from G by removing the tr-edges. It is not hard to verify that if J is an edge set that contains the tr-edges then $\kappa_G(t, r) = \min\{|\partial\mathbb{A}| : t \in A, r \in V \setminus A^+\} + d_J(\mathbb{A})$. In particular, we have:

▶ **Lemma 5.** *Let $G = (V, E)$ be a graph and let $\{t, r\} \subseteq T \subseteq V$. Then*

$$\kappa_G(t, r) = \min_{\mathbb{A}}\{|\partial\mathbb{A}| + d_{G[T]}(\mathbb{A}) : t \in A, r \in V \setminus A^+\} .$$

Here the nodes in $\partial\mathbb{A}$ and the edges in $G[T]$ that go from A to $V \setminus A^+$ form a "mixed" st-cut of G that contains both nodes and edges. The original Menger's Theorem is the case $T = \{r, t\}$, while the case $T = V$ is also widely used in the literature, c.f. [28].

From Lemma 5 we get that G is k-(T, r)-connected iff $|\partial\mathbb{A}| + d_{G[T]}(\mathbb{A}) \geq k$ holds for every (T, r)-biset $\mathbb{A}$. Given a Rooted Subset k-Connectivity instance, we say that a (T, r)-biset $\mathbb{A}$ is a **deficient biset** if $|\partial\mathbb{A}| + d_{G[T]}(\mathbb{A}) \leq k - 1$. We use the algorithm from [22] for Rooted Subset k-Connectivity. Two deficient bisets $\mathbb{A}, \mathbb{B}$ are ***T*-independent** if $A \cap T \subseteq \partial\mathbb{B}$ or $B \cap T \subseteq \partial\mathbb{A}$. A Rooted Subset k-Connectivity instance is ***T*-independence-free** if no pair of deficient bisets are T-independent. We have the following from previous work [22].

▶ **Lemma 6** ([22])**.** *T-independence-free Rooted Subset k-Connectivity instances admit ratio $O(k \ln |T|)$.*

Clearly, a sufficient condition for an instance to be T-independence-free is:

▶ **Lemma 7.** *If for a Rooted Subset k-Connectivity instance $|A \cap T| \geq k$ holds for every deficient biset $\mathbb{A}$, then the instance is T-independence-free.*

In the next two lemmas we show how to find an $O(k \ln n)$-approximate set $S \subseteq V \setminus T$ such that adding S to T result in a T-independence-free instance.

▶ **Lemma 8** (Inflation Lemma for general graphs)**.** *There exists a polynomial time algorithm that given an instance of Rooted Subset k-Connectivity finds $S \subseteq V \setminus T$ such that $|A \cap S| \geq k - (|\partial\mathbb{A}| + d_{G[T \cup S]}(\mathbb{A}))$ holds for any (T, r)-biset $\mathbb{A}$, and $w(S) = O(\ln \Delta) \cdot \mathsf{opt}$.*

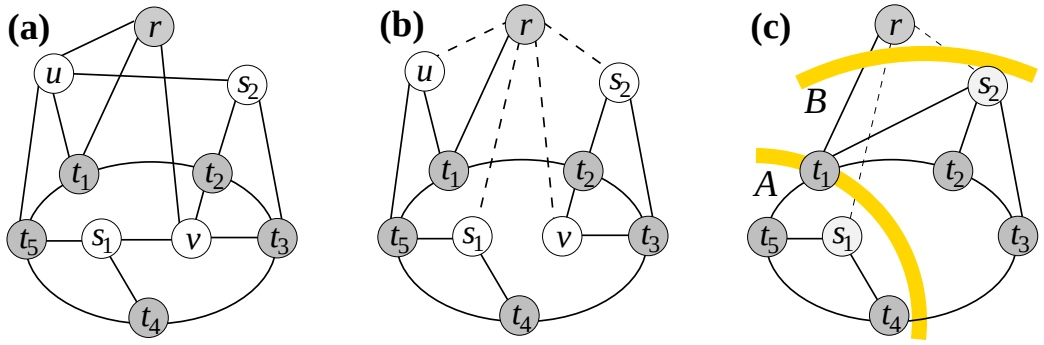

Figure 1 Illustration to Lemma 8 Algorithm 1 for $k = 3$. (a) Rooted Subset k-Connectivity instance; nodes in T are shown by gray circles. (b) Centered Rooted Subset k-Connectivity instance constructed in Algorithm 1; added edges are shown by dashed lines. (c) The set $S = \{s_1, s_2\}$ returned by the algorithm and two bisets $\mathbb{A}, \mathbb{B}$ in $G[T \cup S]$ (the dashed edges do not belong to $G[T \cup S]$), where $A = \{t_5, t_4, s_1\}, \partial\mathbb{A} = \{t_1\}$ and $B = (T \cup S) \setminus \{r\}, \partial\mathbb{B} = \emptyset$.

Proof. The Centered Rooted Subset k-Connectivity problem is a particular case of the Rooted Subset k-Connectivity problem when all nodes of positive weight are neighbors of the root. This problem admits ratio $O(\ln \Delta)$ [18], where here Δ is the maximum degree of a neighbor of the root. We use this in our algorithm as follows (see Fig. 1):

Algorithm 1 $(G = (V, E), w, r, T, k)$.

1 construct a Centered Rooted Subset k-Connectivity instance $(G' = (V, E'), w, T, r, k)$, where G' is obtained from G by removing edges in $G[(V \setminus T) \cup \{r\}]$ and adding an rv-edge for each $v \in V \setminus T$ (see Fig. 1(a,b))
2 compute an $O(\ln \Delta)$-approximate solution $S \subseteq V \setminus T$ for the obtained Centered Rooted Subset k-Connectivity instance (see Fig. 1(c))
3 **return** S

Let S^* and S^*_c be optimal solutions to Rooted Subset k-Connectivity and the constructed Centered Rooted Subset k-Connectivity instances, respectively. For every $t \in T$ fix some set of k internally disjoint rt-paths in the graph $G[T \cup S^*]$, and obtain a set P_t by picking for each path the node in S^* that is closest to t on this path, if such a node exists. Let $P = \cup_{t \in T} P_t$. Then P is a feasible solution to the constructed Centered Rooted Subset k-Connectivity instance, since for each $t \in T$, G' has $|P_t|$ internally disjoint rt-paths of length 2 each that go through P_t, and $k - |P_t|$ paths that have all nodes in T. Furthermore, since $P \subseteq S^*$, $w(P) \leq w(S^*)$. Thus $w(S^*_c) \leq w(P) \leq w(S^*)$, implying that $w(S) = O(\ln \Delta) \cdot w(S^*)$.

Now let $\mathbb{A}$ be a (T, r)-biset on $T \cup S$. Then:

- $d_{G'[T \cup S]}(\mathbb{A}) = |A \cap S| + d_{G[T \cup S]}(\mathbb{A})$ by the construction.
- $|\partial\mathbb{A}| + d_{G'[T \cup S]}(\mathbb{A}) \geq k$ since $G'[T \cup S]$ is k-(T, r)-connected.

Combining we get that $|\partial\mathbb{A}| + d_{G[T \cup S]}(\mathbb{A}) + |A \cap S| \geq k$, as claimed. ◀

Note that Lemma 8 does *not* assume that T has any domination properties, and it does *not* imply that $G[T \cup S]$ has higher (T, r)-connectivity than $G[T]$ – see the example in Fig. 1. The lemma just states that for every biset $\mathbb{A}$ in $G[T \cup S]$, $|A \cap S|$ is at least the "deficiency" $k - (|\partial\mathbb{A}| + d_{G[T \cup S]}(\mathbb{A}))$ of $\mathbb{A}$. E.g., in the example in Fig. 1(c) we have:

- $A \cap S = \{s_1\}$, $\quad k - (|\partial\mathbb{A}| + d_{G[T \cup S]}(\mathbb{A})) = 3 - (1 + 1) = 1$.
- $B \cap S = \{s_1, s_2\}$, $k - (|\partial\mathbb{B}| + d_{G[T \cup S]}(\mathbb{B})) = 3 - (0 + 1) = 2$.

Hence if we add S to T and $T \leftarrow T \cup S$ will become the new set of terminals, then the new Rooted Subset k-Connectivity instance will be "closer" to being T-independence-free than the original instance. And if also T is a k-dominating set (this is not the case in Fig. 1), then adding S to T does not increase the optimal solution value, by Lemma 2.

Our algorithms use the following simple procedure – Algorithm 2, that sequentially adds p sets $S_1, \ldots, S_p$ to an m-dominating set $T = T_0$ with $m \geq k$; in the case of general graphs considered in this section, each S_i is as in Lemma 8.

Algorithm 2 $(G = (V, E), c, r, T = T_0, k, 1 \leq p \leq k-1)$.

```
1 for i = 1 to p do
2 |  T ← T ∪ S_i
3 return T
```

▶ **Lemma 9.** *Suppose that we are given a Rooted Subset k-Connectivity instance such that T is an m-dominating set in G with $m \geq k$. If at each iteration i at step 2 of Algorithm 2 we add to T a set $S = S_i$ as in Lemma 8, then at the end of the algorithm $w(T \setminus T_0) = O(p \ln \Delta) \cdot \mathsf{opt}$, and $|A \cap T| \geq m - \ell + p(k - \ell)$ holds for any biset $\mathbb{A}$ on T with $|\partial\mathbb{A}| + d_{G[T]}(\mathbb{A}) = \ell \leq k - 1$. In particular, if $p \geq \max\{2k - m - 1, 1\}$ then the resulting instance is T-independence-free.*

Proof. The bound $w(T \setminus T_0) = O(p \ln \Delta) \cdot \mathsf{opt}$ follows from Lemma 2 and the bound $w(S) = O(\ln \Delta) \cdot \mathsf{opt}$ in Lemma 8.

Let $\mathbb{A}$ be a biset as in the lemma. Let $T_i = T_0 \cup S_1 \cup \cdots \cup S_i$ be the set stored in T at the end of iteration i, where T_0 is the initial set. Applying Lemma 8 on T_{i-1} and S_i we get

$$|A \cap S_i| \geq k - (|\partial\mathbb{A} \cap T_{i-1}| + d_{G[T_i]}(\mathbb{A})) \geq k - (|\partial\mathbb{A}| + d_{G[T]}(\mathbb{A})) = k - \ell \ .$$

In particular $A \cap S_1 \neq \emptyset$. Any $v \in A \cap S_1$ has in $G[T]$ at least m neighbors in T_0, and at most ℓ of them are not in A; thus v has at least $m - \ell$ neighbors in $A \cap T_0$, so $|A \cap T_0| \geq m - \ell$. Since $T_0, S_1, \ldots, S_p$ are pairwise disjoint we get $|A \cap T| \geq |A \cap T_0| + \sum_{i=1}^{p} |A \cap S_i| \geq m - \ell + p(k - \ell)$. If $p \geq \max\{2k - m - 1, 1\}$ then $m - \ell + p(k - l) \geq k$; thus, by Lemma 7, the resulting instance is T-independence-free. ◀

The proof of the following known statement can be found in [17], and the second part follows from Mader's Undirected Critical Cycle Theorem [20].

▶ **Lemma 10.** *Let $H_r = (U, F)$ be a k-(U, r)-connected graph and R the set of neighbors of r in H_r. The graph $H = H_r \setminus \{r\}$ can be made k-connected by adding a set J of new edges on R, and if J is inclusion minimal then J is a forest.*

Note that an inclusion minimal edge set J as in Lemma 10 can be computed in polynomial time, by starting with J being a clique on R and repeatedly removing from J an edge e if $H \cup (J \setminus e)$ remains k-connected.

Our algorithm for general graphs is as follows.

Algorithm 3 $(G=(V,E),w,T)$ **general graphs.**

1 construct a graph G_r by adding to G and to T a new node r connected to a set $R \subseteq T$ of k nodes by a set $F_r = \{rv : v \in R\}$ of new edges
2 apply the Lemma 9 algorithm with $p = \max\{2k-m-1, 0\}$
3 use the algorithm from Lemma 6 to compute an $O(k \ln n)$-approximate set $S \subseteq V \setminus T$ such that $H_r = G_r[T \cup S]$ is k-(T,r)-connected
4 let $H = H \setminus \{r\} = G[T \cup S]$ and let J be a forest of new edges on R as in Lemma 10 such that the graph $H \cup J$ is k-connected
5 for every $uv \in J$ find a minimum weight node set P_{uv} such that $G[T \cup S \cup P_{uv}]$ has k internally disjoint uv-paths; let $P = \bigcup_{uv \in J} P_{uv}$
6 return $T \cup S \cup P$

Except step 2, the algorithm is identical to the algorithm of [26] – the only difference is that step 2 improves the factor invoked by step 3. In [26] it is also proved that at the end of the algorithm $T \cup S \cup P$ is a k-connected set. The dominating terms in the ratio are invoked by steps 2 and 3, and they are both $O(k \ln n)$, while step 5 invokes just ratio $k-1$; thus the overall ratio is $O(k \ln n)$.

This concludes the proof of Theorem 3 for general graphs.

3 Unit disk graphs

Our goal in this section is to prove the following:

▶ **Lemma 11.** *Consider a* Subset k-Connectivity *instance on a unit disk graph $G=(V,E)$ where T is an (ℓ,m)-cds in G (so $G[T]$ is ℓ-connected and every $v \in V \setminus T$ has at least m neighbors in T), $m \geq k \geq \ell+1$. Then for any $1 \leq p \leq \ell+1$ there exists a polynomial time algorithm that computes $S \subseteq V \setminus T$ such that $G[T \cup S]$ is $(\ell+1)$-connected and*

$$\frac{w(S)}{\mathsf{opt}} = \frac{O(\ln k)}{k-\ell}\left(p + \frac{(m+p)^2}{(m+p-\ell)^2}\right) .$$

Furthermore, in the case of unit weights $\frac{w(S)}{\mathsf{opt}} = \frac{O(\ln k)}{k-\ell}\left(p + \frac{m+p}{m+p-\ell}\right)$.

Let us show that Lemma 11 implies the unit disk part of Theorem 3. We can apply the Lemma 11 algorithm sequentially, starting with an $O(1)$-approximate m-dominating set $T = T_0$, and at iteration $\ell = 0, \ldots, k-1$ add to T a set $S = S_\ell$ as in the lemma. In the case of arbitrary weights choosing $p=1$ if $m - \ell \geq \ell^{2/3}$ and $p = \ell^{2/3}$ otherwise gives $\frac{w(S_\ell)}{\mathsf{opt}} = \frac{O(\ln \ell)}{k-\ell} \min\left\{\frac{m}{m-\ell}, \ell^{2/3}\right\}$. Then denoting $S = S_0 \cup \cdots \cup S_{k-1}$ we get:

$$\frac{w(S)}{\mathsf{opt}} = \sum_{\ell=0}^{k-1} \frac{O(\ln \ell)}{k-\ell} \min\left\{\frac{m}{m-\ell}, \ell^{2/3}\right\} = O(\ln^2 k) \cdot \min\left\{\frac{m}{m-k+1}, k^{2/3}\right\}$$

In the case of unit weights, choosing $p=1$ if $m - \ell \geq \sqrt{\ell}$ and $p = \sqrt{\ell}$ otherwise gives $\frac{w(S_\ell)}{\mathsf{opt}} = \frac{O(\ln \ell)}{k-\ell} \min\left\{\frac{m}{m-\ell}, \sqrt{\ell}\right\}$, and then by a similar analysis we get that

$$\frac{w(S)}{\mathsf{opt}} = O(\ln^2 k) \cdot \min\left\{\frac{m}{m-k+1}, \sqrt{k}\right\} .$$

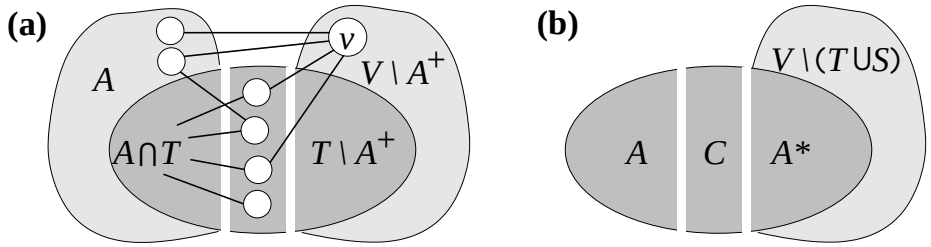

Figure 2 (a) Illustration to the definition of a biset $\mathbb{A} \in \mathcal{D}_T$ and a node v that covers $\mathbb{A}$. (b) Illustration to the proof that if $G[T \cup S]$ is not $(\ell+1)$-connected then S does not cover $\mathcal{D}_T$.

In the rest of this section we prove Lemma 11, so let G, T, and ℓ be as in the lemma; in particular, $G[T]$ is ℓ-connected. Define the following family of biset on V (see Fig. 2)

$$\mathcal{D}_T = \{\mathbb{A} : A \cap T \neq \emptyset \neq T \setminus A^+, d_{G[T]}(\mathbb{A}) = 0, |\partial\mathbb{A}| = \ell\} .$$

Let $\mathbb{A} \in \mathcal{D}_T$. Then $G[T] \setminus \partial\mathbb{A}$ is disconnected (since $d_{G[T]}(\mathbb{A}) = 0$), hence $\partial\mathbb{A} \cap T$ is a node cut of $G[T]$ that separates between the non-empty sets $A \cap T$ and $T \setminus A^+$. Since $|\partial\mathbb{A}| = \ell$ and since G is ℓ-connected, $\partial\mathbb{A}$ must be a minimum node cut of $G[T]$. Thus we have:

▶ **Corollary 12.** *A biset $\mathbb{A}$ on V belongs to $\mathcal{D}_T$ if and only if the following holds:*
- *$\partial\mathbb{A} \subseteq T$ and $\partial\mathbb{A}$ is a minimum node cut (of size ℓ) of the graph $G[T]$.*
- *$A \cap T$ is a union of some, but not all, connected components of $G[T] \setminus \partial\mathbb{A}$.*

We say that a **node v covers $\mathbb{A} \in \mathcal{D}_T$** (see Fig. 2(a)) if $v \in \Gamma(A) \setminus T$, where $\Gamma(A) \subseteq V \setminus A$ is the set of neighbors of A in G; $S \subseteq V \setminus T$ covers $\mathcal{F} \subseteq \mathcal{D}_T$ if every $\mathbb{A} \in \mathcal{F}$ is covered by some $v \in S$. Using Menger's Theorem and Lemma 2, one can see the following (see also [10, Section 5.2]).

▶ **Lemma 13.** *Let T be an $(\ell, \ell+1)$-cds in a graph $G = (V, E)$. Let $S \subseteq V \setminus T$. Then $G[T \cup S]$ is $(\ell+1)$-connected if and only if S covers $\mathcal{D}_T$.*

Proof. Let $\mathbb{A} \in \mathcal{D}_T$. Then $\partial\mathbb{A} \subseteq T$ is a node cut of size ℓ of the graph $G[T]$ that separates between the nonempty sets $A \cap T$ and $T \setminus A^+$. If S does not cover $\mathbb{A}$, then $S \cap \Gamma(A) = \emptyset$, and then $\partial\mathbb{A}$ is also a node cut of size ℓ of the graph $G[T \cup S]$ that separates between $A \cap T$ and $(T \setminus A^+) \cup S$; thus $G[T \cup S]$ is not ℓ-connected. Consequently, if $G[T \cup S]$ is $(\ell+1)$-connected then S must cover $\mathcal{D}_T$.

Suppose that $G[T \cup S]$ is not $(\ell+1)$-connected (see Fig. 2(b)). Then there is a node cut C of size ℓ of $G[T \cup S]$ that separates some $A \subseteq T \cup S$ from $A^* = (T \cup S) \setminus (A \cup C)$. Since T is an $(\ell+1)$-dominating set in $G[T \cup S]$ and since $|C| = \ell$, we must have $A \cap T \neq \emptyset$; otherwise, if $A \cap T = \emptyset$, then for any $u \in A$, there must exist $u' \in A^*$ with $uu' \in E$ since T is an $(\ell+1)$-dominating set, which contradicts that C is a node cut separating A from A^*. By a similar argument, $A^* \cap T \neq \emptyset$. Let $\mathbb{A} = (A, A \cup C)$. Then $A \cap T \neq \emptyset \neq T \setminus A^+$, $d_{G[T]}(\mathbb{A}) = 0$ (since $d_{G[T \cup S]}(\mathbb{A}) = 0$), and $|\partial\mathbb{A}| = |C| = \ell$. Thus $\mathbb{A} \in \mathcal{D}_T$. Furthermore, in $G[T]$, $C \cap T$ separates between the nonempty node sets $A \cap T$ and $T \setminus A^+$, hence $C = \partial\mathbb{A} = \Gamma(A) \subseteq T$, since $G[T]$ is ℓ-connected. Consequently, S does not cover $\mathbb{A}$, and the proof is complete. ◀

Thus we have the following LP-relaxation for the problem of finding a min-weight cover of $\mathcal{D}_T$ (a similar LP was used by Fukunaga in [10, Section 5.2]):

$$\begin{array}{lll} \tau(\mathcal{D}_T) = & \min & \sum_{v \in V \setminus T} w_v x_v \\ & \text{s.t.} & \sum_{v \in \Gamma(A) \setminus T} x_v \geq 1 \qquad \forall A \in \mathcal{D}_T \\ & & x_v \geq 0 \qquad\qquad\quad \forall v \in V \setminus T \end{array}$$

Note that if $\mathbb{A} \in \mathcal{D}_T$ then $\Gamma(A) \setminus T = \Gamma(A) \setminus \partial\mathbb{A}$, and thus the constraint $\sum_{v \in \Gamma(A)\setminus T} x_v \geq 1$ is equivalent to $\sum_{v \in \Gamma(A)\setminus \partial\mathbb{A}} x_v \geq 1$.

▶ **Definition 14.** *We say that* $\mathbb{A}$ ***contains*** $\mathbb{B}$ *and write* $\mathbb{A} \subseteq \mathbb{B}$ *if* $A \subseteq B$ *and* $A^+ \subseteq B^+$. *Inclusion minimal members of a biset family* $\mathcal{F}$ *are called* $\mathcal{F}$***-cores***. *The* ***intersection*** *and the* ***union*** *of two bisets* $\mathbb{A}, \mathbb{B}$ *are defined by*

$$\mathbb{A} \cap \mathbb{B} = (A \cap B, A^+ \cap B^+) \qquad \mathbb{A} \cup \mathbb{B} = (A \cup B, A^+ \cup B^+) \ .$$

▶ **Lemma 15.** *Let* $\mathcal{C}$ *be the family of* $\mathcal{D}_T$*-cores. Then* $C \cap C' = \emptyset$ *for any distinct* $\mathbb{C}, \mathbb{C}' \in \mathcal{C}$ *or* $|\mathcal{C}| \leq \ell(\ell+1)$.

Proof. let $\mathcal{F}$ be the family of "deficient bisets" of the ℓ-connected graph $G[T]$; namely, $\mathcal{F}$ is the family of those bisets $\mathbb{A}$ on T such that $\partial\mathbb{A}$ is a minimum node cut (of size ℓ) of the graph $G[T]$, and A is a union of some, but not all, connected components of $G[T] \setminus \partial\mathbb{A}$. Note that from Corollary 12 it follows that:

- $\mathcal{F} = \{\mathbb{A} \in \mathcal{D}_T : A \subseteq T\}$.
- Every $\mathcal{D}_T$-core belongs to $\mathcal{F}$, hence $\mathcal{C}$ coincides with the family of $\mathcal{F}$-cores.

Thus it is sufficient to prove the lemma with $\mathcal{D}_T$ replaced by $\mathcal{F}$. The family $\mathcal{F}$ has the following well known "symmetry" and "crossing" properties, c.f. [30].

(i) If $\mathbb{A} \in \mathcal{F}$ then $(V \setminus A^+, V \setminus A) \in \mathcal{F}$.
(ii) If $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ and $A \cap B, T \setminus (A^+ \cup B^+)$ are non-empty then $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B} \in \mathcal{F}$.

In [[15], Lemma 3.5, Case II] it is proved that if $C \cap C' \neq \emptyset$ for some distinct $\mathbb{C}, \mathbb{C}' \in \mathcal{C}$ then there is $P \subseteq V$ with $|P| \leq \ell + 1$ such that $P \cap C \neq \emptyset$ for every $\mathbb{C} \in \mathcal{C}$. In this case $\mathcal{F}$ has at most $\ell(\ell+1)$ distinct cores, since:

- For every $\mathbb{C} \in \mathcal{C}$, there is $s \in P \cap C$, and there is $t \in P \cap (V \setminus C^+)$, by (i).
- For each $(s,t) \in P \times P$ there is at most one such $\mathbb{C}$, by (ii).

Hence if $C \cap C' \neq \emptyset$ for some distinct $\mathbb{C}, \mathbb{C}' \in \mathcal{C}$ then $|\mathcal{C}| \leq |P|(|P|-1) \leq \ell(\ell+1)$. ◀

To obtain an approximation ratio that depends on k rather than on n, we will need the following result.

▶ **Theorem 16** (Zhang, Zhou, Mo, & Du [31])**.** *Any* k*-connected unit disk graph has a* k*-connected spanning subgraph of maximum degree* $\leq 5k$.

▶ **Lemma 17** (Inflation Lemma for unit disk graphs)**.** *There exists a polynomial time algorithm that computes* $S \subseteq V \setminus T$ *that covers the family* $\mathcal{C}$ *of cores of* $\mathcal{D}_T$ *and* $w(S) = O(\ln k) \cdot \frac{\mathsf{opt}}{k-\ell}$.

Proof. The problem of covering $\mathcal{C}$ is essentially a (weighted) Set Cover problem where for each $v \in V \setminus T$ the corresponding set has weight w_v and consists of the cores covered by v. Then the greedy algorithm for Set Cover computes a solution of weight $O(\ln |\mathcal{C}|)$ times the value of the standard Set Cover LP

$$\begin{array}{rlll} \tau(\mathcal{C}) = & \min & \sum_{v \in V\setminus T} w_v x_v & \\ & \text{s.t.} & \sum_{v \in \Gamma(A)\setminus T} x_v \geq 1 & \forall A \in \mathcal{C} \\ & & x_v \geq 0 & \forall v \in V \setminus T \end{array}$$

For any $S' \subseteq V \setminus T$ such that $G[T \cup S']$ is k-connected, any set A has at least $k - \ell$ neighbors in $G[T \cup S']$, hence if x' is a characteristic vector of S' then $\frac{x'}{k-\ell}$ is a feasible solution to the LP. Consequently, $\tau(\mathcal{C}) \leq \frac{\mathsf{opt}}{k-\ell}$.

In the case $|\mathcal{C}| \leq \ell(\ell+1)$ we get a solution of weight $O(\ln \ell) \cdot \tau(\mathcal{C}) = O(\ln \ell) \cdot \frac{\mathsf{opt}}{k-\ell}$.

In the case $|\mathcal{C}| > \ell(\ell+1)$, $C \cap C' = \emptyset$ for any $\mathbb{C}, \mathbb{C}' \in \mathcal{C}$, by Lemma 15. Then relying on Theorem 16 we modify this reduction such that every $v \in V \setminus T$ can cover at most $5k$ cores; this is essentially the Set Cover with (soft) capacities problem. Specifically, for each pair (v, J) where $v \in V \setminus S$ and J is a set of at most $5k$ edges incident to v, we add a new node v_J of weight w_v with corresponding copies of the edges in J. In the obtained Set Cover instance the maximum size of a set is at most $5k$, since the sets in $\{C : \mathbb{C} \in \mathcal{C}\}$ are pairwise disjoint. Note that we do not need to construct this Set Cover instance explicitly to run the greedy algorithm – we just need to determine for each $v \in V$ the maximum number of at most $5k$ not yet covered cores that can be covered by v. Since the sets in $\{C : \mathbb{C} \in \mathcal{C}\}$ are pairwise disjoint, this can be done in polynomial time. Note that during the greedy algorithm we may pick pairs (v, J) and (v, J') with distinct J, J' but with the same node v, but this only makes the solution lighter. Since in the Set Cover instance the maximum set size is $5k$, the computed solution has weight $O(\ln k) \cdot \tau$, where here τ is an optimal LP-value of the modified instance. Now we argue in the same way as before that $\tau \leq \frac{\mathsf{opt}}{k-\ell}$. Consider a feasible solution $S' \subseteq V \setminus T$ and an edge J' such that $G[T] \cup S' \cup J'$ is a spanning k-connected subgraph of $G[T \cup S']$ and $\deg_{J'}(v) \leq 5k$ for all $v \in S'$; such J' exists by Theorem 16. Let x' be the characteristic vector of the pairs (v, J'_v) where $v \in S'$ and J'_v is the set of edges in J' incident to v. Any set A has at least $k - \ell$ neighbors in $G[T] \cup S' \cup J'$, hence $\frac{x'}{k-\ell}$ is a feasible solution to the LP. Consequently, $\tau \leq \frac{\mathsf{opt}}{k-\ell}$. ◀

▶ **Corollary 18.** *If at step 2 of Algorithm 2 we add $S = S_i$ is as in Lemma 17, then at the end of the algorithm $w(T \setminus T_0) = O(p \ln k) \cdot \tau^*$ and $|A \cap T| \geq m - \ell + p$ holds for any $\mathbb{A} \in \mathcal{D}_T$.*

Proof. We have $|A \cap S_i| \geq 1$ for all i. In particular $A \cap S_1 \neq \emptyset$. Any $v \in A \cap S_1$ has in $G[T]$ at least m neighbors in T_0, and at most ℓ of them are not in A; thus v has at least $m - \ell$ neighbors in $A \cap T_0$, so $|A \cap T_0| \geq m - \ell$. Since $T_0, S_1, \ldots, S_p$ are pairwise disjoint we get $|A \cap T| \geq |A \cap T_0| + \sum_{i=1}^{p} |A \cap S_i| \geq m - \ell + p$. ◀

Now we decompose the problem of covering $\mathcal{D}_T$ into several subproblems. For $r \in T$ let $\mathcal{D}_{(T,r)} = \{\mathbb{A} \in \mathcal{D}_T : r \in T \setminus A^+\}$; we note the sets in $\{A : \mathbb{A} \in \mathcal{D}_{(T,r)}\}$ are called "demand cuts" by Fukunaga [10, Section 5.2].

▶ **Theorem 19** ([23]). *Given an ℓ-T-connected graph with $|T| \geq \ell + 1$, one can find in polynomial time $R \subseteq T$ of size $|R| = O\left(\frac{|T|}{|T|-\ell} \ln \ell\right)$ such that $\mathcal{D}_T = \cup_{r \in R} \mathcal{D}_{(T,r)}$.*

We now describe how to cover the family $\mathcal{D}_{(T,r)}$ for given $r \in T$.

▶ **Definition 20.** *The biset $\mathbb{A} \setminus \mathbb{B}$ is defined by $\mathbb{A} \setminus \mathbb{B} = (A \setminus B^+, A^+ \setminus B)$. We say that a biset family $\mathcal{F}$ is:*

- ***uncrossable*** *if $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B} \in \mathcal{F}$ or if $\mathbb{A} \setminus \mathbb{B}, \mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$ for all $\mathbb{A}, \mathbb{B} \in \mathcal{F}$.*
- ***T-intersecting*** *if $\mathbb{A} \cap \mathbb{B}, \mathbb{A} \cup \mathbb{B} \in \mathcal{F}$ for any $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ with $A \cap B \cap T \neq \emptyset$.*
- ***T-co-crossing*** *if $\mathbb{A} \setminus \mathbb{B}, \mathbb{B} \setminus \mathbb{A} \in \mathcal{F}$ for any $\mathbb{A}, \mathbb{B} \in \mathcal{F}$ with $A \cap B^* \cap T \neq \emptyset$ and $B \cap A^* \cap T \neq \emptyset$.*

▶ **Lemma 21** ([22, 10]). *$\mathcal{D}_{(T,r)}$ is T-intersecting and T-co-crossing for any $r \in T$.*

▶ **Theorem 22** ([22]). *There exists a polynomial time algorithm that given a T-intersecting T-co-crossing biset family $\mathcal{F}$ sequentially finds $O\left(\frac{q+\ell}{q}\right)$ T-intersecting uncrossable subfamilies of $\mathcal{F}$, such that the union of covers of these subfamilies covers $\mathcal{F}$, where $q = \min\{|A \cap T| : \mathbb{A} \in \mathcal{F}\}$ and $\ell = \max_{\mathbb{A} \in \mathcal{F}} |\partial \mathbb{A} \cap T|$.*

In [10, Theorem 3 and Proof of Corollary 3] Fukunaga proved the following.

▶ **Theorem 23** (Fukunaga [10]). *If $\mathcal{F}$ is a T-intersecting uncrossable subfamily of $\mathcal{D}_{(T,r)}$ then there exists a polynomial time algorithm that computes a cover S of $\mathcal{F}$ of weight $w(S) \leq \frac{15\mathsf{opt}}{k-\ell}$.*

Combining Lemma 21 with Theorems 22 and 23 we get:

▶ **Corollary 24.** *For any $r \in T$, there exists a polynomial time algorithm that computes a cover S_r of $\mathcal{D}_{(T,r)}$ such that if $q = \min\{|A \cap T| : \mathbb{A} \in \mathcal{D}_{(T,r)}\}$ then*

$$\frac{w(S_r)}{\mathsf{opt}} = O\left(\frac{q+\ell}{q(k-\ell)}\right) .$$

The algorithm for unit disk graphs is as follows.

Algorithm 4 $(G=(V,E), w, T, p)$ **unit disk graphs**.

1 apply Algorithm 2 where at step 2 each S_i is as in Lemma 17
2 **if** $G[T]$ is $(\ell+1)$ connected then $S \leftarrow \emptyset$
3 **else** {comment: now $|T| \geq m+p$ and $|A \cap T| \geq m+p-\ell$ for all $\mathbb{A} \in \mathcal{D}_T$}
4 find a set R of $O\left(\frac{|T|}{|T|-\ell} \ln \ell\right)$ roots as in Theorem 19
5 for each $r \in R$ compute a cover S_r of $\mathcal{D}_{(T,r)}$ as in Corollary 24
6 $S \leftarrow \cup_{r \in R} S_r$
7 **return** $T \cup S$

We bound the weight of each of the sets computed. Let T_0 denote the initial set stored in T. By Lemma 17, at the end of step 1 we have

$$\frac{w(T \setminus T_0)}{\mathsf{opt}} = \frac{O(\ln k)}{k-\ell} \cdot p$$

Now we bound the weight of the set S computed in steps 3 to 6:

$$\frac{w(S)}{\mathsf{opt}} = |R| \cdot O\left(\frac{q+\ell}{q(k-\ell)}\right) = \frac{O(\ln \ell)}{k-\ell} \frac{|T|}{|T|-\ell} \frac{q+\ell}{q} = \frac{O(\ln k)}{k-\ell} \frac{(m+p)^2}{(m+p-\ell)^2}$$

The last equation is since $q = \min\{|A \cap T| : \mathbb{A} \in \mathcal{F}\} \geq m-\ell+p$ by Corollary 18 and since $|T| \geq m+p$. The overall weight of the augmenting set computed is as claimed in Lemma 11.

In the case of unit weights, we add arbitrary ℓ nodes to T; this step invokes an additive term of $O(1)$ to the ratio, and $|T| \geq 2\ell+1$ holds after this step. Hence by Theorem 19 we will have $|R| = O\left(\frac{|T|}{|T|-\ell} \ln \ell\right) = O\left(\frac{2\ell+1}{\ell+1} \ln \ell\right) = O(\ln \ell)$ and thus

$$\frac{w(S)}{\mathsf{opt}} = |R| \cdot O\left(\frac{q+\ell}{q(k-\ell)}\right) = \frac{O(\ln \ell)}{k-\ell} \frac{q+\ell}{q} = \frac{O(\ln k)}{k-\ell} \frac{m+p}{m+p-\ell} .$$

The overall weight of the augmenting set computed is as claimed in Lemma 11.

This concludes the proof of Lemma 11, and thus also the proof of Theorem 3.

Abstract

A homomorphism from a graph G to a graph H is an edge-preserving mapping from $V(G)$ to $V(H)$. Let H be a fixed graph with possible loops. In the list homomorphism problem, denoted by LHOM(H), we are given a graph G, whose every vertex v is assigned with a list $L(v)$ of vertices of H. We ask whether there exists a homomorphism h from G to H, which respects lists L, i.e., for every $v \in V(G)$ it holds that $h(v) \in L(v)$.

The complexity dichotomy for LHOM(H) was proven by Feder, Hell, and Huang [JGT 2003]. The authors showed that the problem is polynomial-time solvable if H belongs to the class called *bi-arc graphs*, and for all other graphs H it is NP-complete.

We are interested in the complexity of the LHOM(H) problem, parameterized by the treewidth of the input graph. This problem was investigated by Egri, Marx, and Rzążewski [STACS 2018], who obtained tight complexity bounds for the special case of reflexive graphs H, i.e., if every vertex has a loop.

In this paper we extend and generalize their results for *all* relevant graphs H, i.e., those, for which the LHOM(H) problem is NP-hard. For every such H we find a constant $k = k(H)$, such that the LHOM(H) problem on instances G with n vertices and treewidth t

- can be solved in time $k^t \cdot n^{\mathcal{O}(1)}$, provided that G is given along with a tree decomposition of width t,
- cannot be solved in time $(k-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, for any $\varepsilon > 0$, unless the SETH fails.

For some graphs H the value of $k(H)$ is much smaller than the trivial upper bound, i.e., $|V(H)|$.

Obtaining matching upper and lower bounds shows that the set of algorithmic tools that we have discovered cannot be extended in order to obtain faster algorithms for LHOM(H) in bounded-treewidth graphs. Furthermore, neither the algorithm, nor the proof of the lower bound, is very specific to treewidth. We believe that they can be used for other variants of the LHOM(H) problem, e.g. with different parameterizations.

1 Introduction

A popular line of research in studying computationally hard problems is to consider restricted instances, in order to understand the boundary between easy and hard cases. For example, most of natural problems can be efficiently solved on trees, using a bottom-up dynamic programming. This observation led to the definition of *treewidth*, which, informally speaking, measures how much a given graph resembles a tree. The notion of treewidth appears to be very natural and it was independently discovered by several authors in different contexts [2, 8, 37, 13].

For many problems, polynomial-time algorithms for graphs with bounded treewidth can be obtained by adapting the dynamic programming algorithms for trees. Most of these straightforward algorithms follow the same pattern, which was captured by the seminal meta-theorem by Courcelle [11]: he proved that each problem expressible in *monadic second order logic* (MSO_2) can be solved in time $f(\mathrm{tw}(G)) \cdot n^{\mathcal{O}(1)}$ on graphs G with n vertices and treewidth $\mathrm{tw}(G)$, where f is some function, depending on the MSO_2 formula describing the particular problem. As a consequence of this meta-theorem, in order to show that some problem Π is *fixed-parameter tractable* (FPT), parameterized by the treewidth, it is sufficient to show that Π can be described in a certain way.

The main problem with using the meta-theorem as a black-box is that the function f it produces is huge (non-elementary). We also know that this bound cannot be improved, if we want to keep the full generality of the statement [23]. Because of this, as the area of the so-called *fine-grained complexity* gained popularity [32], researchers turned back to studying particular problems, and asking about the best possible dependence on treewidth, i.e., the function f. This led to many exciting algorithmic results which significantly improved the naive dynamic programming approach [40, 6, 31].

There is a little caveat that applies to most of algorithms mentioned above: Usually we assume that the input graph is given with its tree decomposition, and the running time is expressed in terms of the width of this decomposition. This might be a serious drawback, since finding an optimal tree decomposition is NP-hard [1]. However, finding a tree decomposition of given width (if one exists) can be done in FPT time [4, 7], which is often sufficient. Since we are interested in the complexity of certain problems, parameterized by the treewidth, we will not discuss the time needed to find a decomposition. Thus we will assume that the input graph is given with its tree decomposition.

In parallel to improving the algorithms, many lower bounds were also developed [33, 37, 13]. Let us point out that the main assumption from the classical complexity theory, i.e., $\mathrm{P} \neq \mathrm{NP}$, is too weak to provide any meaningful lower bounds in our setting. The most commonly used assumptions in the fine-grained complexity world, are the *Exponential-Time Hypothesis* (ETH) and the *Strong Exponential-Time Hypothesis* (SETH), both introduced by Impagliazzo and Paturi [27, 28]. Informally speaking, the ETH implies that 3-Sat with n variables cannot be solved in subexponential time, i.e., in time $2^{o(n)}$, and the SETH implies that CNF-Sat with n variables and m clauses cannot be solved in time $(2-\varepsilon)^n \cdot m^{\mathcal{O}(1)}$, for any $\varepsilon > 0$.

For example the straightforward dynamic programming algorithm for k-Coloring works in time $k^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$. As one of the first SETH-based lower bounds for problems parameterized by the treewidth, Lokshtanov, Marx, and Saurabh [33] proved that this bound is tight.

▶ **Theorem 1** (Lokshtanov, Marx, Saurabh [33]). *For any $k \geqslant 3$, there is no algorithm solving k-Coloring on a graph with n vertices and treewidth t in time $(k-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, unless the SETH fails.*

Graph homomorphisms. In this paper we are interested in extending Theorem 1 for one of possible generalizations of the k-Coloring problem. For graph G and H (both with possible loops on vertices), a *homomorphism* from G to H is a mapping $h\colon V(G) \to V(H)$, which preserves edges, i.e., for every edge xy of G it holds that $h(x)h(y) \in E(H)$. The graph H is called a *target*. If h is a homomorphism from G to H, we denote it by writing $h : G \to H$. We also write $G \to H$ to indicate that some homomorphism from G to H exists.

By $\textsc{Hom}(H)$ we denote the problem of deciding if an instance graph G admits a homomorphism to H (usually we consider H a fixed graph, but we might also treat it as a part of the input). Observe that if $H = K_k$, then $\textsc{Hom}(H)$ is equivalent to the k-Coloring problem. Because of that, homomorphisms to H are often called *H-colorings*. We will also refer to vertices of H as *colors*.

Let us briefly survey some results concerning the complexity of variants of the $\textsc{Hom}(H)$ problem. For more, we refer the reader to the monograph by Hell and Nešetřil [25]. The complexity dichotomy for $\textsc{Hom}(H)$ was shown by Hell and Nešetřil [26]: the problem is polynomial-time-solvable if H contains a vertex with a loop or is bipartite, and NP-complete for all other graphs H. Since then, many interesting results concerning the complexity of graph homomorphisms have appeared [22, 41, 38, 12, 14, 10]. The fine-grained complexity of the $\textsc{Hom}(H)$ problem, parameterized by the treewidth of the input graph, was recently studied by Okrasa and Rzążewski [35]. They found tight SETH-bounds, conditioned on two conjectures from algebraic graph theory from early 2000s. As these conjectures remain wide open, we know no graph, for which the bounds from [35] do not apply.

A natural and interesting extension of the $\textsc{Hom}(H)$ problem is its *list* version. In the *list homomorphism problem*, denoted by $\textsc{LHom}(H)$, the input consists of a graph G and a *H-lists* L, which means that L is a function which assigns to each vertex of G a subset of vertices of H. We ask whether there is a homomorphism h from G to H, which respects lists L, i.e., for each $x \in V(G)$ it holds that $h(x) \in L(x)$. If h is such a list homomorphism, we denote it by $h : (G, L) \to H$. We also write $(G, L) \to H$ to indicate that some homomorphism $h : (G, L) \to H$ exists.

The complexity of the $\textsc{LHom}(H)$ problem was shown in three steps. First, Feder and Hell [16] provided a classification for the case that H is *reflexive*, i.e., every vertex has a loop. They proved that if H is an interval graph, then the problem is polynomial-time solvable, and otherwise it is NP-complete. The next step was showing the complexity dichotomy for *irreflexive graphs* (i.e., with no loops). Feder, Hell, and Huang [17] proved that if H is bipartite and its complement is a circular-arc graph, then the problem is polynomial-time solvable, and otherwise it is NP-complete. Interestingly, bipartite graphs whose complement is circular-arc were studied independently by Trotter and Moore [39] in the context of some poset problems. Finally, Feder, Hell, and Huang [18] provided the full classification for general graph H: the polynomial cases appear to be *bi-arc graphs*, which are also defined in terms of some geometric representation. Let us now skip the exact definition of bi-arc graphs, and we will get back to it in Section 4.1.

Let us point out that in all three papers mentioned above, the polynomial-time algorithms for LHOM(H) exploited the geometric representation of H. On the other hand, all hardness proofs followed the same pattern. First, for each "easy" class $\mathcal{C}$ (i.e., interval graphs, bipartite co-circular-arc graphs, and bi-arc graphs), the authors provided an alternative characterization in terms of forbidden subgraphs. In other words, they defined a (non-necessarily finite) family $\mathcal{F}$ of graphs, such that $H \in \mathcal{C}$ if and only if H does not contain any $F \in \mathcal{F}$ as an induced subgraph. Then, for each $F \in \mathcal{F}$, the authors showed that LHOM(F) is NP-complete. Note that this is sufficient, as every "hard" graph H contains some $F \in \mathcal{F}$, and every instance of LHOM(F) is also an instance of LHOM(H), where no vertex from $V(H) - V(F)$ appears in any list.

If the input graph G is given with a tree decomposition of width $\mathrm{tw}(G)$, then the straightforward dynamic programming solves the LHOM(H) problem in time $|V(H)|^{\mathrm{tw}(G)} \cdot |V(G)|^{\mathcal{O}(1)}$. The study of the fine-grained complexity of LHOM(H), parameterized by the treewidth of the input graph, was initiated by Egri, Marx, and Rzążewski [15]. They provided the full complexity classification for reflexive graphs H, i.e., corresponding to the first step of the above-mentioned complexity dichotomy. The authors defined a new graph invariant, denoted by i^*, which is based on *incomparable sets* and the existence of a certain decomposition in H, and proved the following tight bounds.

▶ **Theorem 2** (Egri, Marx, Rzążewski [15]). *Let H be a fixed connected reflexive non-interval graph, and let $k = i^*(H)$. The LHOM(H) problem on instances (G, L) with n vertices,*

(a) *can be solved in time $k^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$, provided that an optimal tree decomposition of G is given,*

(b) *cannot be solved in time $(k-\varepsilon)^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, unless the SETH fails.*

Our results

In this paper we provide a full complexity classification of LHOM(H), parameterized by the treewidth of an instance graph. Our results heavily extend the ones of Egri, Marx, Rzążewski [15] and generalize Theorem 2 to all relevant graphs H. Let us point out that instead of designing ad-hoc algorithms and reductions that are fine-tailored for a particular problem, we rather build a general framework that allows us to provide tight bounds for a natural and important family of problems.

Bipartite graphs H. We first deal with the case that H is bipartite (in particular, irreflexive), with bipartition classes X and Y. Recall that we are interested in graphs H, for which the LHOM(H) problem is NP-hard, i.e., graphs that are not co-circular-arc graphs. Moreover, we consider only connected graphs H (as otherwise we can reduce to this case in polynomial time).

Let us present the high-level idea behind our algorithm for LHOM(H). Consider an instance (G, L), such that G is connected, and let $n = |V(G)|$. We may assume that G is bipartite, as otherwise (G, L) is clearly a no-instance. Furthermore, in any homomorphism from G to H, each bipartition class of G is mapped to a different bipartition class of H. We can assume that this is already reflected in the lists (we might have to solve two independent instances).

The algorithm is based on two main ideas. First, observe that if H contains two vertices u, v, which are in the same bipartition class, and each neighbor of u is a neighbor of v, then we can always use v instead of u, unless this is forbidden by lists. Thus we might always assume that each list is an *incomparable set*, i.e., it does not contain two vertices u, v as above. By $i(H)$ we denote the size of a largest incomparable set contained in one bipartition class.

The second idea is related to a certain decomposition of H. By a *bipartite decomposition* we mean a partition of the vertex set of H into three subsets D, N, R, such that:

- at least one of sets $(D \cap X)$ and $(D \cap Y)$ has at least 2 elements,
- N is non-empty, induces a biclique in H, and separates D and R,
- the sets $(D \cap X) \cup (N \cap Y)$ and $(D \cap Y) \cup (N \cap X)$ induce bicliques in H.

We show that if H has a bipartite decomposition, then we can reduce solving an instance (G, L) of LHom(H) to solving several instances of LHom(H_1) and LHom(H_2), where H_1 is the subgraph of H induced by D, and H_2 is obtained from H by collapsing $D \cap X$ and $D \cap Y$ to single vertices.

This leads to the definition of $i^*(H)$ as the maximum value of $i(H')$ over all connected undecomposable induced subgraphs H' of H, which are not complements of a circular-arc graph (a graph is undecomposable if it has no bipartite decomposition). As our first result, we show that the algorithm exploiting decompositions recursively runs in time $i^*(H)^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$.

One might wonder whether some additional observations could be used to improve the algorithm. As our second result, we show that this is not possible, assuming the SETH. This means that unless something unexpected happens in complexity theory, our algorithmic toolbox allows to solve LHom(H), parameterized by the treewidth, as fast as possible. More formally, we show the following theorem, which fully classifies the complexity of LHom(H) for bipartite graphs H.

▶ **Theorem 3.** *Let H be a connected bipartite graph, whose complement is not a circular-arc graph, and let $k = i^*(H)$. Let G be a bipartite graph with n vertices and treewidth* $\mathrm{tw}(G)$.

(a) *Even if H is given as an input, the LHom(H) problem with instance (G, L) can be solved in time $k^{\mathrm{tw}(G)} \cdot (n \cdot |H|)^{\mathcal{O}(1)}$ for any lists L, provided that G is given with an optimal tree decomposition.*

(b) *Even if H is fixed, there is no algorithm that solves LHom(H) for every G and L in time $(k - \varepsilon)^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, unless the SETH fails.*

Note that for Theorem 3 a), if H is not considered to be a constant, $n \cdot |H|$ is a natural measure of the size of an instance, as it is an upper estimate on the sum of sizes of all lists.

The main tool used in the proof of Theorem 3 b) is the following technical lemma.

▶ **Lemma 4** (Constructing a NEQ(S)-gadget)**.** *Let H be a connected, bipartite, undecomposable graph, whose complement is not a circular-arc graph. Let S be an incomparable set of $k \geqslant 2$ vertices of H, contained in one bipartition class. Then there exists a* NEQ(S)*-gadget, i.e., a graph F with H-lists L and two special vertices $x, x' \in V(F)$, such that $L(x) = L(x') = S$ and*

- *for any list homomorphism $h : (F, L) \to H$, it holds that $h(x) \neq h(x')$,*
- *for any distinct $s, s' \in S$ there is $h : (F, L) \to H$, such that $h(x) = s$ and $h(x') = s'$.*

Let us point out that the graph constructed in Lemma 4 can be seen as a *primitive-positive definition* of the inequality relation on S (see e.g. Bulatov [9, Section 2.1]). However, we prefer to present our results using purely combinatorial terms.

The proof of Lemma 4 is technically involved, but as soon as we have it, the proof of Theorem 3 b) is straightforward. Consider an instance G of k-Coloring, where $k = i^*(H)$. Let H' be a connected, undecomposable, induced subgraph of H, whose complement is not a circular-arc graph, and contains an incomparable set S of size k. We construct a graph G^* by replacing each edge uv of G with a copy of the NEQ(S)-gadget, given by Lemma 4 (invoked for H' and S), so that u is identified with x and v is identified with x'. By the properties of the gadget, we observe that G^* has a list homomorphism to H if and only if

G is a yes-instance of k-Coloring. Furthermore, the construction of the NEQ(S)-gadget depends on H only, and H is assumed fixed, so we conclude that $\mathrm{tw}(G^*) = \mathrm{tw}(G) + \mathcal{O}(1)$. Therefore the statement of Theorem 3 b) follows from Theorem 1.

General graphs H. Next, we move to the general case. We aim to reduce the problem to the bipartite case. The main idea comes from Feder, Hell, and Huang [18] who showed a close connection between the LHom(H) problem and the LHom(H^*) problem, where H^* is the *associated bipartite graph* of H, i.e., the bipartite graph with bipartition classes $\{v' \colon v \in V(H)\}$ and $\{v'' \colon v \in V(H)\}$, where $u'v'' \in E(H^*)$ if and only if $uv \in E(H)$. Let us point out that we can equivalently define H^* as a categorical (direct) product of H and K_2 [24].

We extend the definition of i^* to non-bipartite graphs by setting $i^*(H) := i^*(H^*)$. Let us point out that this is consistent with the definition for bipartite graphs, and with the definition of i^* for reflexive graphs, introduced by Egri, Marx, and Rzążewski [15]. We show the following theorem, fully classifying the complexity of LHom(H), parameterized by the treewidth of the instance graph[1].

▶ **Theorem 5.** *Let H be a connected non-bi-arc graph (with possible loops), and let $k = i^*(H)$. Let G be a graph with n vertices and treewidth* $\mathrm{tw}(G)$.

(a) *Even if H is given as an input, the LHom(H) problem with instance (G, L) can be solved in time $k^{\mathrm{tw}(G)} \cdot (n \cdot |H|)^{\mathcal{O}(1)}$ for any lists L, provided that G is given with an optimal tree decomposition.*

(b) (♠) *Even if H is fixed, there is no algorithm that solves LHom(H) for every G and L in time $(k-\varepsilon)^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}$ for any $\varepsilon > 0$, unless the SETH fails.*

As we mentioned before, both statements of Theorem 5 follow from the corresponding statements in Theorem 3. For the algorithmic part, we define certain decompositions of general graphs H and show that they coincide with bipartite decompositions H^*. This lets us reduce solving an instance (G, L) of LHom(H) to solving some instances of LHom(H^*). On the complexity side, the reduction is even more direct: we show that an algorithm solving the LHom(H) problem on instances with treewidth t in time $(i^*(H) - \varepsilon)^t \cdot n^{\mathcal{O}(1)}$ could be used to solve the LHom(H^*) problem on instances with treewidth t in time $(i^*(H^*) - \varepsilon)^t \cdot n^{\mathcal{O}(1)}$, thus contradicting Theorem 3 b).

We also analyze the complexity of LHom(H) for *typical* graphs H, and prove the following.

▶ **Corollary 6 (♠).** *For almost all graphs H with possible loops the following holds. Even if H is fixed, there is no algorithm that solves LHom(H) for every instance (G, L) in time $\mathcal{O}\left((|V(H)| - \varepsilon)^{\mathrm{tw}(G)} \cdot n^{\mathcal{O}(1)}\right)$ for any $\varepsilon > 0$, unless the SETH fails.*

Finally, we show how to generalize our approach of reducing instances of LHom(H) to instances of LHom(H'), where H' is undecomposable. We believe that this idea could be exploited to study the complexity of LHom(H) in various regimes, e.g., for different parameterizations of input instances.

Comparison to the previous work. Let us briefly discuss similarities and differences between our work and previous, closely related results by Egri, Marx, and Rzążewski [15] (about the complexity of the LHom(H) problem for reflexive H), and by Okrasa and Rzążewski [35] (about the complexity of the Hom(H) problem).

[1] The proofs of results marked with ♠ can be found in the full version of the paper [34].

At the high level, we follow the direction used by Egri *et al.* [15], but since we generalize their result to *all* relevant graphs H, the techniques become much more involved. The crucial idea was to reduce the problem to the bipartite case, and to define decompositions of general graphs that correspond to the decompositions of H^*. On the contrary, the case of reflexive graphs H is much more straightforward. In particular, there is just one type of decomposition that could be exploited algorithmically. Also, the structure of "hard" subgraphs is much simpler in this case, so the necessary gadgets are significantly easier to construct.

On the other hand, in order to prove hardness for the HOM(H) problem, Okrasa and Rzążewski [35] used mostly *algebraic tools* that are able to capture the global structure of a graph. In contrast, our proofs are purely combinatorial. Furthermore, we are able to provide the full complexity classification for all graphs H, while the results of [35] are conditioned on two twenty-year-old conjectures.

Notation

Let H be a graph. By $\mathrm{comp}(H)$ we denote the set of connected components of H. For a vertex v, by $N(v)$ we denote the *open neighborhood* of v, i.e., the set of vertices adjacent to v (note that $v \in N(v)$ if and only if v has a loop). For a set $U \subseteq V(H)$, we define $N(U) := \bigcup_{u \in U} N(u) - U$ and $N[U] := \bigcup_{u \in U} N(u) \cup U$. If $U = \{u_1, \ldots, u_k\}$, we omit one pair of brackets and write $N(u_1, \ldots, u_k)$ (respectively $N[u_1, \ldots, u_k]$) instead of $N(\{u_1, \ldots, u_k\})$ (respectively $N[\{u_1, \ldots, u_k\}]$).

We say that two vertices x, y are *comparable* if $N(y) \subseteq N(x)$ or $N(x) \subseteq N(y)$. If two vertices are not comparable, we say that they are *incomparable*. A set of vertices is *incomparable* if all vertices are pairwise incomparable.

We say that a set $A \subseteq V(H)$ is *complete* to a set $B \subseteq V(H)$ if for every $a \in A$ and $b \in B$ the edge ab exists. On the other hand, A is *non-adjacent* to B if there are no edges with one endvertex in A and the other in B.

Let H be a bipartite graph, whose bipartition classes are denoted by X and Y. For a set $S \subseteq V(H)$ and $Z \in \{X, Y\}$, by S_Z we denote $S \cap Z$. For $A, B \subseteq V(H)$, we say that A is *bipartite-complete* to B if A_X is complete to B_Y and A_Y is complete to B_X.

A *walk* $\mathcal{P}$ is a sequence $\mathcal{P} = p_1, \ldots, p_\ell$ of vertices of H, such that $p_i p_{i+1} \in E(H)$, for every $i \in [\ell - 1]$.

2 Algorithm for bipartite target graphs

Observe that we might always assume that H is connected, as otherwise we can solve the problem for each connected component of H separately. Furthermore, without losing the generality we may assume certain properties of instances of LHOM(H) that we need to solve.

▶ **Observation 7 (♠).** *Let (G, L) be an instance of LHOM(H), where H is connected and bipartite with bipartition classes X, Y. Without loss of generality, we might assume the following.*

1. *The graph G is connected and bipartite, with bipartition classes X_G and Y_G,*
2. *$\bigcup_{x \in X_G} L(x) \subseteq X$ and $\bigcup_{y \in Y_G} L(y) \subseteq Y$,*
3. *for each $x \in V(G)$, the set $L(x)$ is incomparable.*

An instance of LHOM(H) that respects conditions in Observation 7 is called *consistent*. From now on we will restrict ourselves to consistent instances. Let us introduce a graph parameter, which will play a crucial role in our investigations.

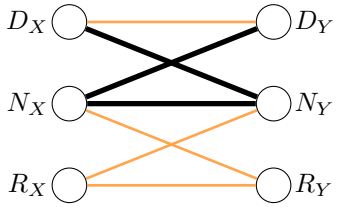

Figure 1 A schematic view of a bipartite decomposition. Disks correspond to independent sets of vertices. Thick black lines indicate that all possible edges between two sets exist, and thin orange lines depict edges that might exist, but do not have to. The lack of a line means that there are no edges between two sets.

▶ **Definition 8** ($i(H)$). *For a bipartite graph H, by $i(H)$ we denote the maximum size of an incomparable set in H, which is fully contained in one bipartition class.*

Clearly for every H we have $i(H) \leqslant |H|$. Note that by Observation 7 we obtain the following.

▶ **Corollary 9.** *Let (G, L) be a consistent instance of LHOM(H), where H is bipartite. Then $\max_{v \in V(G)} |L(v)| \leqslant i(H)$.*

2.1 Decomposition of bipartite graphs

Throughout this section we assume that the target graph H is bipartite with bipartition classes X and Y. In particular, it has no loops. Our algorithm for LHOM(H) is based on the existence of a certain decomposition of H.

▶ **Definition 10** (Bipartite decomposition). *A partition of $V(H)$ into an ordered triple of sets (D, N, R) is a* bipartite decomposition *if the following conditions are satisfied (see Figure 1).*

1. *N is non-empty and separates D and R,*
2. *$|D_X| \geqslant 2$ or $|D_Y| \geqslant 2$,*
3. *N induces a biclique in H,*
4. *D is bipartite-complete to N.*

Since so far we only consider bipartite decompositions, we will just call them decompositions. Later on we will introduce other types of decompositions and then the distinction will be important. If H admits a decomposition, then it is *decomposable*, otherwise it is *undecomposable*.

For a graph H with a decomposition (D, N, R), the *factors of the decomposition* are two graphs H_1, H_2 defined as follows. The graph H_1 is the subgraph of H induced by the set D. The graph H_2 is obtained in the following way. For $Z \in \{X, Y\}$, if D_Z is non-empty, then we contract it to a vertex d_Z. If there is at least one edge between the sets D_X and D_Y, we add the edge $d_X d_Y$.

Note that both H_1 and H_2 are proper induced subgraphs of H. For H_1 is follows directly from the definition and H_2 can be equivalently defined as a graph obtained from H by removing all but one vertex from D_X (if $D_X \neq \emptyset$) and all but one vertex from D_Y (if $D_Y \neq \emptyset$). We leave the vertices that are joined by an edge, provided that such a pair exists.

Now let us show how the bipartite decomposition can be used algorithmically. Let $T(H, n, t)$ denote an upper bound for the complexity of LHOM(H) on instances with n vertices, given along a tree decomposition of width t. In the following lemma we do not assume that $|H|$ is a constant.

▶ **Lemma 11** (Bipartite decomposition lemma). *Let H be a bipartite graph with bipartition classes X and Y, whose complement is not a circular-arc graph, and suppose H has a bipartite decomposition with factors H_1, H_2. Assume that there are constants $\alpha \geqslant 1$, $c \geqslant 1$, and $d > 2$, such that $T(H_1, n, t) \leqslant \alpha \cdot c^t \cdot (n \cdot |H_1|)^d$ and $T(H_2, n, t) \leqslant \alpha \cdot c^t \cdot (n \cdot |H_2|)^d$. Then $T(H, n, t) \leqslant \alpha \cdot c^t \cdot (n \cdot |H|)^d$, if n is sufficiently large.*

Proof. Consider an instance (G, L) of LHOM(H), recall that without loss of generality we may assume that it is consistent. Let the bipartition classes of G be X_G and Y_G and assume that $\bigcup_{x \in X_G} L(x) \subseteq X$ and $\bigcup_{y \in Y_G} L(y) \subseteq Y$.

Let (D, N, R) be a bipartite decomposition of H. We observe that for $Z \in \{X, Y\}$, and any two vertices $v \in D_Z, s \in N_Z$, we have $N(v) \subseteq N(s)$. Thus we may assume that no list contains both s and v. Let Q be the set of vertices of G which have at least one vertex from N in their lists.

▷ Claim 12. If there exists a list homomorphism $h\colon (G, L) \to H$, the image of each $C \in \mathrm{comp}(G - Q)$ is entirely contained either in D or in R.

Proof. By the definition of $\mathrm{comp}(G - Q)$, the image of C is disjoint with N. Suppose there exist $a, b \in C$, such that $h(a) = u \in D$ and $h(b) = r \in R$. Since C is connected, there exists an a-b-path P in C. The image of P is an u-r-walk in H. But since N separates D and R in H, there is a vertex of P, which is mapped to a vertex of N, a contradiction. ◁

Let us define lists L_1 as $L_1(x) := L(x) \cap D$, for every $x \in V(G) - Q$. For each $C \in \mathrm{comp}(G - Q)$, we check if there exists a homomorphism $h_C\colon (C, L_1) \to H_1$. Let $\mathbb{C}_1$ be the set of those $C \in \mathrm{comp}(G - Q)$, for which h_C exists. By Claim 12, we observe that if $C \notin \mathbb{C}_1$, then we can safely remove all vertices from D from the lists of vertices of C.

Now consider the graph H_2. Let $Z \in \{X, Y\}$ and let d_Z be the vertex to which the set D_Z is collapsed (if it exists). Let us define an instance (G, L_2) of the LHOM(H_2) problem, where the lists L_2 are as follows. If $v \in Z_G$ is a vertex from some component of $\mathbb{C}_1$, then $L_2(v) := L(v) - D_Z \cup \{d_Z\}$ (note that in this case d_Z must exist). If v is a vertex from some component of $\mathrm{comp}(G - Q) - \mathbb{C}_1$, then $L_2(v) := L(v) - D_Z$. Finally, if $v \in Q$, then $L_2(v) := L(v)$. Note that the image of each list is contained in $V(H_2)$. Moreover, note that $\bigcup_{x \in X_G} L_2(x) \subseteq R_X \cup N_X \cup \{d_X\}$ and $\bigcup_{y \in Y_G} L_2(y) \subseteq R_Y \cup N_Y \cup \{d_Y\}$.

▷ Claim 13. There is a list homomorphism $h : (G, L) \to H$ if an only if there is a list homomorphism $h' : (G, L_2) \to H_2$.

Proof. First, assume that $h : (G, L) \to H$ exists. Define $h' : V(G) \to V(H_2)$ in the following way:

$$h'(v) = \begin{cases} d_X & \text{if } h(v) \in D_X, \\ d_Y & \text{if } h(v) \in D_Y, \\ h(v) & \text{otherwise.} \end{cases}$$

Clearly h' is a homomorphism from G to H_2, we need to show that it also respects lists L_2. Suppose otherwise and let v be a vertex of G, such that $h'(v) \notin L_2(v)$. By symmetry, assume that $v \in X_G$, and thus $h'(v) \in X$. If $h'(v) \neq d_X$, then $h'(v) = h(v) \in (L(v) - D_X) \subseteq L_2(v)$. So suppose $h'(v) = d_X$ (and thus $h(v) \in D_X$) and $d_X \notin L_2(v)$. Observe that v cannot be a vertex from Q, since h maps v to a vertex of D_X and vertices from Q do not have any vertices of D in their lists. So the only case left is that v belongs to some connected component C of $G - Q$, which cannot be mapped to H_1. But then, by Claim 12, no vertex of C is mapped to any vertex of D, so $h(v) \notin D_X$, a contradiction.

Now suppose there exists a list homomorphism $h' : (G, L_2) \to H_2$. Define the following mapping h from $V(G)$ to $V(H)$. If $h'(v) \notin \{d_X, d_Y\}$, then we set $h(v) := h'(v)$. Otherwise, if $h'(v) \in \{d_X, d_Y\}$, then v is a vertex of some connected component $C \in \mathbb{C}_1$, and we define $h(v) := h_C(v)$. Clearly h preserves lists L: if $h(v) \notin D$, then $h(v) = h'(v) \in L_2(v) - \{d_X, d_Y\} \subseteq L(v)$; otherwise we use h_C, which preserves lists L by the definition.

Now suppose h does not preserve edges, so there are vertices $u \in X_G$ and $v \in Y_G$, such that uv is an edge of G and $h(u)h(v)$ is not an edge of H. If $h'(u) = d_X, h'(v) = d_Y$, or $h'(u) \neq d_X, h'(v) \neq d_Y$, then $h(u)h(v)$ must be an edge of H, otherwise we get a contradiction by the definitions of h_C (as since x and y are neighbors, they belong to the same C) and h', respectively. So, by symmetry, suppose $h'(u) = d_X$ and $h'(v) \neq d_Y$. But then we observe that $h(u) \in D_X$ and $h(v) = h'(v) \in N_Y$, since h' is a homomorphism. And because N_Y is complete to D_X, so $h(u)h(v)$ is an edge – a contradiction. ◁

Computing $\mathrm{comp}(G - Q)$ can be done in time $\mathcal{O}(n \cdot |H| + n^2) = \mathcal{O}((n \cdot |H|)^2)$. Note that given a tree decomposition of G of width at most t, we can easily obtain a tree decomposition of each $C \in \mathrm{comp}(G - Q)$ of width at most t. Computing h_C for all $C \in \mathrm{comp}(G - Q)$ requires time at most

$$\sum_{C \in \mathrm{comp}(G-Q)} T(H_1, |C|, t) \leqslant \sum_{C \in \mathrm{comp}(G-Q)} \alpha \cdot c^t \cdot (|H_1| \cdot |C|)^d \leqslant \alpha \cdot c^t \cdot (|H_1| \cdot n)^d.$$

The estimation follows from the facts that $\sum_{C \in \mathrm{comp}(G-Q)} |C| \leqslant n$, and n^d is superadditive with respect to n, i.e., $n_1^d + n_2^d \leqslant (n_1 + n_2)^d$. Computing lists L_2 can be performed in time $\mathcal{O}(|H| \cdot n)$. Finally, computing h' requires time $T(H_2, n, t) \leqslant \alpha \cdot c^t \cdot (|H_2| \cdot n)^d$. The total running time is therefore bounded by:

$$\mathcal{O}\left((n \cdot |H|)^2\right) + \alpha \cdot c^t \cdot (|H_1| \cdot n)^d + \mathcal{O}(|H| \cdot n) + \alpha \cdot c^t \cdot (|H_2| \cdot n)^d.$$

With a careful analysis one can verify that the above expression is bounded by $\alpha \cdot c^t \cdot (|H| \cdot n)^d$, provided that n is sufficiently large. ◀

2.2 Solving LHom(H) for bipartite targets

Let us define the main combinatorial invariant of the paper, $i^*(H)$:

▶ **Definition 14** ($i^*(H)$ for bipartite H). *Let H be a connected bipartite graph, whose complement is not a circular-arc graph. Define*

$$i^*(H) := \max\{i(H') \colon H' \text{ is an undecomposable, connected, induced subgraph of } H, \text{ whose complement is not a circular-arc graph}\}.$$

Observe that if H' is an induced subgraph of H, then $i(H') \leqslant i(H)$ and $i^*(H') \leqslant i^*(H)$, and thus $i^*(H) = i(H)$ for undecomposable H. Furthermore, we always have $i^*(H) \leqslant i(H) \leqslant |H|$.

Now we are ready to present an algorithm solving LHom(H), note that again we do not assume that $|H|$ is a constant. We present the following, slightly more general variant of Theorem 3 a), where we also do not assume that the tree decomposition of G is optimal.

▶ **Theorem 3' a).** *Let H be a connected bipartite graph (given as an input) and let (G, L) be an instance of LHom(H), where G has n vertices and is given along a tree decomposition of width t. Then there is an algorithm which decides whether $(G, L) \to H$ in time $\mathcal{O}\left(i^*(H)^t \cdot (n \cdot |H|)^{\mathcal{O}(1)}\right)$.*

Proof. Clearly we can assume that n is sufficiently large, as otherwise we can solve the problem in polynomial time by brute-force.

Observe that with H we can associate a *recursion tree* $\mathcal{R}$, whose nodes are labeled with induced subgraphs of H. The root, denoted by $node(H)$ corresponds to the whole graph H. If H is undecomposable or is a complement of a circular-arc graph, then the recursion tree has just one node. Otherwise H has a decomposition with factors H_1 and H_2, and then $node(H)$ has two children, $node(H_1)$ and $node(H_2)$, respectively. Recall that each factor has strictly fewer vertices than H, so we can construct $\mathcal{R}$ recursively. Clearly, each leaf of $\mathcal{R}$ is either the complement of a circular-arc graph (and thus the corresponding problem is polynomial-time solvable), or is an undecomposable induced subgraph of H. Note that a recursion tree may not be unique, as a graph may have more than one decomposition. However, the number of leaves is bounded by $\mathcal{O}(|H|)$ (actually, with a careful analysis we can show that it is at most $|H|-2$), so the total number of nodes is $\mathcal{O}(|H|)$. Furthermore, it can be shown that in time polynomial in H we can check if H is undecomposable, or find a decomposition (we show this in the full version of the paper). Since recognizing circular-arc graphs (and therefore of course their complements) is also polynomial-time solvable, we conclude that $\mathcal{R}$ can be constructed in time polynomial in $|H|$.

If H is the complement of a circular-arc graph, then we solve the problem in polynomial time [17]. If H is undecomposable, we run a standard dynamic programming algorithm on a tree decomposition of G (see [8, 5]). For each bag of the tree decomposition, and every partial list homomorphism from the graph induced by this bag to H we indicate whether this particular partial homomorphism can be extended to a list homomorphism of the graph induced by the subtree rooted at this bag. By Corollary 9, the size of each list $L(x)$ for $x \in V(G)$ is at most $i(H)$, thus the complexity of the algorithm is bounded by $\alpha \cdot i(H)^t \cdot (n \cdot |H|)^d$ for some constants α, d. We can assume that $d > 2$, as otherwise we can always increase it.

So suppose H is decomposable and let us show that we can solve the problem in time $\alpha \cdot i^*(H)^t \cdot (n \cdot |H|)^d$. Let $\mathcal{R}$ be a recursion tree of H and recall that its every leaf corresponds to an induced subgraph of H with strictly fewer vertices. Therefore, for any leaf node of $\mathcal{R}$, corresponding to the subgraph H' of H, we can solve every instance of LHom(H') with n vertices and a tree decomposition of width at most t in time $\alpha \cdot i(H')^t \cdot (n \cdot |H'|)^d \leqslant \alpha \cdot i^*(H)^t \cdot (n \cdot |H'|)^d$. Now, applying Lemma 11 in a bottom-up fashion, we conclude that we can solve LHom(H) in time $\alpha \cdot i^*(H)^t \cdot (n \cdot |H|)^d = \mathcal{O}(i^*(H)^t \cdot (n \cdot |H|)^{\mathcal{O}(1)})$. ◀

3 Hardness for bipartite target graphs

In this section we aim to prove Theorem 3 b). Actually we will show a version, which gives the lower bound parameterized by the pathwidth of G. Clearly such a statement is be stronger, as $\mathrm{pw}(G) \geqslant \mathrm{tw}(G)$. This corresponds to the pathwidth variant of Theorem 1, also shown by Lokshtanov, Marx, Saurabh [33].

▶ **Theorem 1'** (Lokshtanov, Marx, Saurabh [33]). *For any $k \geqslant 3$, there is no algorithm solving k-Coloring on a graph with n vertices and pathwidth t in time $(k-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, unless the SETH fails.*

Thus we show the following strengthening of Theorem 3 b).

▶ **Theorem 3' b).** *Let H be a fixed bipartite graph, whose complement is not a circular-arc graph. Unless the SETH fails, there is no algorithm that solves the LHom(H) problem on instances with n vertices and pathwidth t in time $(i^*(H)-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, for any $\varepsilon > 0$.*

In order to prove Theorem 3' b), it is sufficient to show the following.

▶ **Theorem 15.** *Let H be a fixed connected bipartite undecomposable graph, whose complement is not a circular-arc graph. Unless the SETH fails, there is no algorithm that solves the* LHOM*(H) problem on instances with n vertices and pathwidth t in time $(i(H)-\varepsilon)^t \cdot n^{\mathcal{O}(1)}$, for any $\varepsilon > 0$.*

Let us show that Theorem 3' b) and Theorem 15 are equivalent.

(Theorem 15 → Theorem 3' b)). Assume the SETH and suppose that Theorem 15 holds and Theorem 3' b) fails. So there is a bipartite graph H, whose complement is not a circular-arc graph, and an algorithm A that solves LHOM(H) in time $(i^*(H)-\varepsilon)^{\mathrm{pw}(G)} \cdot n^{\mathcal{O}(1)}$ for every input (G, L), assuming that G is given along with its optimal path decomposition.

Let H' be an undecomposable connected induced subgraph of H, whose complement is not a circular-arc graph, and $i(H') = i^*(H)$. Let (G, L') be an arbitrary instance of LHOM(H'). Since H' is an induced subgraph of H, the instance (G, L') can be seen as an instance of LHOM(H), where no vertex from $V(H) - V(H')$ appears in any list. The algorithm A solves this instance in time $(i^*(H)-\varepsilon)^{\mathrm{pw}(G)} \cdot n^{\mathcal{O}(1)} = (i(H')-\varepsilon)^{\mathrm{pw}(G)} \cdot n^{\mathcal{O}(1)}$, contradicting Theorem 15.

(Theorem 3' b) → Theorem 15). Assume the SETH and suppose Theorem 3' b) holds and Theorem 15 fails. So there is a connected bipartite undecomposable graph H, whose complement is not a circular-arc graph, and an algorithm A that solves LHOM(H) in time $(i(H)-\varepsilon)^{\mathrm{pw}(G)} \cdot n^{\mathcal{O}(1)}$ for every input (G, L). But since H is connected, bipartite, and undecomposable, we have $i^*(H) = i(H)$, so algorithm A contradicts Theorem 3' b).

3.1 Hardness reduction

Let H be an undecomposable, bipartite graph, whose complement is not a circular-arc graph. First, we will show that the structure of H is sufficiently rich to express some basic relations.

For a k-ary relation $\mathrm{R}_k \subseteq V(H)^k$, by an R_k-gadget we mean a graph F with H-lists L and k specified vertices $v_1, v_2, \ldots, v_k$, called *interface*, such that for every $i \in [k]$ it holds that

$$\{f(v_1)f(v_2)\ldots f(v_k) \mid f : (F, L) \to H\} = \mathrm{R}_k.$$

In other words, the set of all possible colorings of the interface vertices that can be extended to a list H-coloring of the whole gadget is precisely the relation we are expressing. In the definition of an R_k-gadget we do not insist that interface vertices are pairwise different.

Let (α, β) be a fixed pair of vertices of H. First, we need to express a k-ary relation $\mathrm{OR}_k = \{\alpha, \beta\}^k - \{\alpha^k\}$ and a binary relation $\mathrm{NAND}_2 = \{\alpha\alpha, \alpha\beta, \beta\alpha\}$ for (α, β). To make the definitions more intuitive, note that we can assign logic values to vertices α, β in the following way: α is interpreted as false, and β is interpreted as true. Note that the relations OR_k and NAND_2 are symmetric with respect to interface vertices.

The other type of gadget which we need to introduce is distinguisher.

▶ **Definition 16** (Distinguisher). *Let S be an incomparable set in H and let (α, β) be a fixed pair of vertices of H, such that $\{\alpha, \beta\} \cup S$ is contained in one bipartition class of H. Let $a, b \in S$. A* distinguisher *gadget for (α, β) is a graph $D_{a/b}$ with two specified vertices x (called* input*) and y (called* output*), and H-lists L such that:*

(D1) *$L(x) = S$ and $L(y) = \{\alpha, \beta\}$,*

(D2) *there is a list homomorphism $\varphi_a : (D_{a/b}, L) \to H$, such that $\varphi_a(x) = a$ and $\varphi_a(y) = \alpha$,*

(D3) *there is a list homomorphism* $\varphi_b : (D_{a/b}, L) \to H$*, such that* $\varphi_b(x) = b$ *and* $\varphi_b(y) = \beta$*,*

(D4) *for any* $c \in \mathcal{S} - \{a, b\}$ *there is* $\varphi_c : (D_{a/b}, L) \to H$*, such that* $\varphi_c(x) = c$ *and* $\varphi_c(y) \in \{\alpha, \beta\}$*,*

(D5) *there is no list homomorphism* $\varphi : (D_{a/b}, L) \to H$*, such that* $\varphi(x) = a$ *and* $\varphi(y) = \beta$*.*

The existence of the OR_k-gadget, the NAND_2-gadget, and the distinguisher gadgets follows from the lemma.

▶ **Lemma 17 (♠).** *Let* H *be an undecomposable bipartite graph, whose complement is not a circular-arc graph and let* S *be an incomparable set in* H*,* $|S| \geqslant 2$*. Then there exists a pair of vertices* (α, β)*, such that* $S \cup \{\alpha, \beta\}$ *is contained in one bipartition class of* H *and:*

1. *for every* $k \geqslant 2$ *there exists an* OR_k*-gadget for* (α, β)*,*
2. *there exists a* NAND_2*-gadget for* (α, β)*,*
3. *for every pair* (a, b) *of distinct elements of* S *there exists a distinguisher* $D_{a/b}$ *for* (α, β)*.*

With Lemma 17 in hand we proceed to the construction of the $\mathrm{NEQ}(S)$-gadget.

▶ **Lemma 4** (Constructing a $\mathrm{NEQ}(S)$-gadget)**.** *Let* H *be a connected, bipartite, undecomposable graph, whose complement is not a circular-arc graph. Let* S *be an incomparable set of* $k \geqslant 2$ *vertices of* H*, contained in one bipartition class. Then there exists a* $\mathrm{NEQ}(S)$*-gadget, i.e., a graph* F *with* H*-lists* L *and two special vertices* $x, x' \in V(F)$*, such that* $L(x) = L(x') = S$ *and*

- *for any list homomorphism* $h : (F, L) \to H$*, it holds that* $h(x) \neq h(x')$*,*
- *for any distinct* $s, s' \in S$ *there is* $h : (F, L) \to H$*, such that* $h(x) = s$ *and* $h(x') = s'$*.*

Proof. We denote the vertices of S by $v_1, v_2, \ldots, v_k$. We call Lemma 17 for S, let (α, β) be a pair of vertices given by this lemma. We will construct the $\mathrm{NEQ}(S)$-gadget in three steps.

Step I. In this step we will show that for every $i \in [k]$ we can construct a graph I_i with two special vertices x_i and c_i and H-lists L, satisfying the following properties.

- $L(x_i) = S$ and $L(c_i) = \{\alpha, \beta\}$,
- for every list homomorphism $\varphi : (I_i, L) \to H$, if $\varphi(x_i) = v_i$, then $\varphi(c_i) = \beta$,
- for every $j \neq i$ there exists a list homomorphism $\varphi_j : (I_i, L) \to H$ such that $\varphi_j(x_i) = v_j$ and $\varphi_j(c_i) = \alpha$.

Let us fix any $i \in [k]$. For every $j \in [k] - \{i\}$ we take a distinguisher D_{v_i/v_j} given by Lemma 17 for $a = v_i, b = v_j$ with the input $x_{i,j}$ and the output $y_{i,j}$. We identify the vertices $x_{i,j}$, for all feasible j, to a single vertex x_i, and introduce a new vertex c_i. Then we add to our construction a copy of the OR_k gadget and identify its k interface vertices with distinct elements of $\{c_i\} \cup \{y_{i,j}\}_{j \neq i}$. This completes the construction of I_i (see Figure 2, left).

Recall that the properties of the OR_k-gadget imply that every list homomorphism from I_i to H maps at least one of vertices in $\{c_i\} \cup \{y_{i,j}\}_{j \neq i}$ to β. By the property (D5) in Definition 16, for any $\varphi : (I_i, L) \to H$ with $\varphi(x_i) = v_i$, and for every $j \neq i$ it holds that $\varphi(y_{i,j}) = \alpha$. This in turn forces $\varphi(c_i) = \beta$.

On the other hand, by properties (D2), (D3), and (D4), for any $j \neq i$ there is a homomorphism $\varphi_j : (I_i, L) \to H$, such that $\varphi_j(x_i) = v_j$ and $\varphi(y_{i,j}) = \beta$, which allows us to set $\varphi_j(c_i) = \alpha$. So I_i satisfies all desired properties.

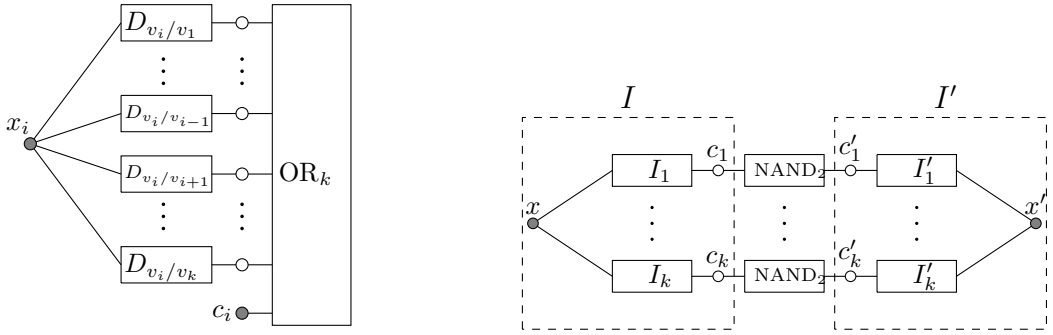

Figure 2 The graph I_i with special vertices x_i and c_i (left) and NEQ(S)-gadget with interface vertices x, x' (right).

Step II. In this step we will construct a graph I with H-lists L and special vertices $x, c_1, \ldots, c_k$, satisfying the following properties.

- $L(x) = S$ and $L(c_i) = \{\alpha, \beta\}$ for every $i \in [k]$,
- for every list homomorphism $\varphi : (I, L) \to H$, if $\varphi(x) = v_i$, then $\varphi(c_i) = \beta$.
- for every $i \in [k]$ there exists a list homomorphism $\varphi_i : (I, L) \to H$, such that $\varphi_i(x) = v_i$ and $\varphi_i(c_i) = \beta$, and $\varphi_i(c_j) = \alpha$ for every $j \in [k] - \{i\}$.

The graph I is constructed by introducing k gadgets $I_1, \ldots, I_k$, and identifying the vertices $x_1, \ldots, x_k$ into a single vertex x (see Figure 2, right). The desired properties of I follow directly from properties of I_i's.

Step III. Finally, we can construct a NEQ(S)-gadget. We introduce two copies of the gadget from the previous step, call them I and I' (we will use primes to denote the appropriate vertices of I'). For each $i \in [k]$, we introduce a NAND_2-gadget and identify its interface vertices with vertices c_i and c'_i (see Figure 2, right). Let us call such constructed graph F. We claim that F is a NEQ(S)-gadget, whose interface vertices are x and x'.

Clearly, $L(x) = L(x') = S$. Suppose that $\varphi : (F, L) \to H$ is a list homomorphism such that $\varphi(x) = \varphi(x') = v_i$. Then, by definition of I, we have $\varphi(c_i) = \varphi(c'_i) = \beta$, but this is impossible due to the properties of the NAND_2-gadget joining c_i and c'_i.

On the other hand, let us choose any distinct $v_i, v_j \in S$. We can color I according to the homomorphism φ_i, and I' according to the homomorphism φ_j (both φ_i and φ_j are defined in Step II). In particular this means that x is mapped to v_i, x' is mapped to v_j, c_i and c'_j are mapped to β, and all other vertices in $\{c_1, \ldots, c_k\} \cup \{c'_1, \ldots, c'_k\}$ are mapped to α. Since $i \neq j$, by the definition of a NAND_2-gadget, we can extend such defined mapping to all vertices of F. This completes the proof of the lemma. ◀

Now, equipped with Lemma 4, we can easily prove Theorem 15.

Proof of Theorem 15. Recall that H is an undecomposable bipartite graph, whose complement is not a circular-arc graph. Let S be the largest incomparable set in H, contained in one bipartition class. Let $k = |S|$, i.e., $k = i(H)$.

Observe that since the complement of H is not a circular-arc graph, we have that $k \geqslant 3$. Indeed, recall that H contains an obstruction, which is either an induced C_6, an induced C_8, or an asteroidal subgraph. Observe that all vertices from one bipartition class of C_6 or C_8 form an incomparable set of size at least 3. On the other hand, recall that a special edge asteroid contains at least three independent edges, so their appropriate endvertices form the desired incomparable set.

We reduce from k-Coloring, let G be an instance. Clearly we can assume that G is connected and has at least 3 vertices. We will construct a graph G^* with H-lists L and the following properties:

- $(G^*, L) \to H$ if and only if G is k-colorable,
- the number of vertices of G^* is at most $g(H) \cdot |E(G)|$ for some function g of H,
- the pathwidth of G^* is at most $g(H) + \mathrm{pw}(G)$,
- G^* can be constructed in time $(|V(G)|)^{\mathcal{O}(1)} \cdot g'(H)$ for some function g'.

Observe that this will be sufficient to prove the theorem. Indeed, suppose that for some $\varepsilon > 0$ we can solve LHom(H) in time $\mathcal{O}^*((k-\varepsilon)^t)$ on instances of pathwidth t. Let us observe that applying this algorithm to G^* gives an algorithm solving the k-Coloring problem on G in time

$$(k-\varepsilon)^{\mathrm{pw}(G^*)} \cdot |V(G^*)|^{\mathcal{O}(1)} \leqslant (k-\varepsilon)^{\mathrm{pw}(G)+g(H)} \cdot (g(H) \cdot |E(G)|)^{\mathcal{O}(1)} = (k-\varepsilon)^{\mathrm{pw}(G)} \cdot |V(G)|^{\mathcal{O}(1)},$$

where the last step follows since $|H|$ is a constant. Recall that by Theorem 1', the existence of such an algorithm for k-Coloring contradicts the SETH.

We start the construction of G^* with the vertex set of G. The lists of these vertices are set to S. Then, for each edge uv of G, we introduce a copy F_{uv} of the NEQ(S)-gadget introduced in Lemma 4. We identify the interface vertices of this gadget with u and v, respectively. This completes the construction of G^*. Let us show that it satisfies the properties (a)–(d).

Note that (a) follows directly from Lemma 4. Indeed, consider an edge uv of G. On one hand, for every list homomorphism $f : (G^*, L) \to H$ we have that $f(u) \neq f(v)$. On the other hand, mapping u and v to any distinct vertices from S can be extended to a homomorphism of the whole graph F_{uv}.

To show (b), recall that the number of vertices of each F_{uv} depends only on H, let it be $g(H)$. Every original vertex of G belongs to some gadget in G^*, so G^* contains at most $g(H) \cdot |E(G)|$ vertices.

Next, consider a path decomposition $\mathcal{T}$ of G of width $\mathrm{pw}(G)$, let the consecutive bags be $X_1, X_2, \ldots, X_\ell$. We extend $\mathcal{T}$ to a path decomposition $\mathcal{T}^*$ of G^* as follows: for every edge uv in G we choose one bag X_i such that $u, v \in X_i$, and we add a new bag $X_i' = X_i \cup V(F)$, which becomes the immediate successor of X_i. We repeat this for every edge, making sure that for X_i we can only choose the original bags coming from $\mathcal{T}$. Note that it might happen that we will insert several new bags in a row, if the same X_i was chosen for different edges, but this is not a problem. Is it straightforward to observe that $\mathcal{T}^*$ is a path decomposition of G^*, and the width of $\mathcal{T}^*$ is at most $g(H) + \mathrm{pw}(G)$. This proves (c).

Finally, it is straightforward to observe that the construction of G^* was performed in time polynomial in G (recall that we treat H as a constant-size graph). ◀

4 Algorithm for general target graphs

In this section we will generalize the invariant $i^*(H)$ and extend Theorem 3' a) to all relevant target graphs H. Let us start with a simple observation, which is an analogue of Observation 7.

▶ **Observation 18 (♠).** *Let (G, L) be an instance of LHom(H). Without loss of generality we might assume the following.*

1. *The graph G is connected,*
2. *for each $x \in V(G)$, the set $L(x)$ is incomparable,*
3. *for each edge $xy \in E(G)$, for every $u \in L(x)$ there is $v \in L(y)$, such that $uv \in E(H)$.*

The high-level idea is to reduce the general case of LHOM(H) to the case, when the target is bipartite, and then use Theorem 3' a). For this, we will consider the so-called *associated instances*, introduced by Feder, Hell, and Huang [18] (see Section 4.1).

We will also separately consider some special graphs that we call *strong split graphs*. A graph H is a *strong split graph*, if its vertex set can be partitioned into two sets B and P, where B is independent and P induces a reflexive clique. We call (B, P) *the partition of* H. Note that the partition is unique: all vertices without loops must be in B and all vertices with loops must be in P.

4.1 Associated instances and clean homomorphisms

For a graph $G = (V, E)$, by G^* we denote the *associated bipartite graph*, defined as follows. The vertex set of G^* is the union of two independent sets: $\{x' : x \in V\}$ and $\{x'' : x \in V\}$. The vertices x' and y'' are adjacent if and only if $xy \in E$. Note that the edges of type $x'x''$ in G^* correspond to loops in G. The vertices x' and x'' are called *twins*. For any $W \subseteq V(G)$, we define two subsets of $V(G^*)$ as follows: $W' := \{x' : x \in W\}$ and $W'' := \{x'' : x \in W\}$.

Let (G, L) be an instance of LHOM(H). An *associated instance* is the instance (G^*, L^*) of LHOM(H^*), where L^* are *associated lists* defined as follows. For $x \in V(G)$, we set $L^*(x') = \{u' : u \in L(x)\}$ and $L^*(x'') = \{u'' : u \in L(x)\}$. Note that in the associated lists, the vertices appearing in the list of x' are precisely the twins of the vertices appearing in the list of x''. A homomorphism $f : (G^*, L^*) \to H^*$ is *clean* if it maps twins to twins, i.e., $f(x') = u'$ if and only if $f(x'') = u''$. The following simple observation was the crucial step of the proof of the complexity dichotomy for list homomorphisms, shown by Feder, Hell, and Huang [18]. We state it using slightly different language, which is more suitable for our purpose.

▶ **Proposition 19** (Feder, Hell, Huang [18]). *Let (G, L) be an instance of LHOM(H). Then it is a yes-instance if and only if (G^*, L^*) admits a clean homomorphism to H^*.*

Let us point out that the restriction to clean homomorphisms is necessary for the equivalence. Indeed, consider for example $G = K_3$, $H = C_6$ and $L(v) = V(H)$ for every $v \in V(G)$. Clearly $(G, L) \not\to H$, however, we have $G^* \simeq C_6$ and $H^* \simeq 2C_6$, so $(G^*, L^*) \to H^*$.

Recall that if H is bipartite, then LHOM(H) is polynomial-time solvable if H is the complement of a circular-arc graph [17], and NP-complete otherwise. Feder, Hell, and Huang [18] proved the following dichotomy theorem.

▶ **Theorem 20** (Feder, Hell, Huang [18]). *Let H be an arbitrary graph (with loops allowed).*
1. *The LHOM(H) problem is in P if H is a bi-arc graph, and NP-complete otherwise.*
2. *The graph H is a bi-arc-graph if and only if H^* is the complement of a circular-arc graph.*

So for our problem the interesting graphs H are those, for which H^* is not the complement of a circular-arc graph. In the observation below we summarize some properties of associated instances.

▶ **Observation 21 (♠).** *Consider an instance (G, L) of LHOM(H) and the associated instance (G^*, L^*) of LHOM(H^*). Suppose that G is given along with a tree decomposition of width t.*
1. *For each $v \in V(G)$ and $u \in V(H)$, we have $u \in L(v)$ if and only if $u' \in L^*(v')$ if and only if $u'' \in L^*(v'')$. In particular, each list is contained in one bipartition class of H^*.*
2. *In polynomial time we can construct a tree decomposition $\mathcal{T}^*$ of G^* of width at most $2t$ with the property that for each $x \in V(G)$, each bag of $\mathcal{T}$ either contains both x', x'' or none of them.*

Observe that for bipartite H, the graph H^* consists of two disjoint copies of H, so clearly $i^*(H) = i^*(H^*)$. This motivates the following definition, generalizing Definition 14.

▶ **Definition 22** ($i^*(H)$). *For a connected non-bi-arc graph H, we define $i^*(H) := i^*(H^*)$.*

4.2 Decompositions of generals target graphs

In this section we generalize the notion of decompositions of bipartite graphs, introduced in Section 2.1, to all graphs (with possible loops). The high-level idea is to define decompositions of H, so that they will correspond to bipartite decompositions of H^*. We consider the following three types of decompositions of a graph H. Note that unless stated explicitly, we do not insist that any of the defined sets is non-empty.

▶ **Definition 23** (F-decomposition). *A partition of $V(H)$ into an ordered triple of sets (F, K, Z) is an* F-decomposition *if the following conditions are satisfied (see Figure 3, left).*

1. *K is non-empty and it separates F and Z,*
2. *$|F| \geqslant 2$,*
3. *K induces a reflexive clique,*
4. *F is complete to K.*

▶ **Definition 24** (BP-decomposition). *A partition of $V(H)$ into an ordered five-tuple of sets (B, P, M, K, Z) is a* BP-decomposition *if the following conditions are satisfied (see Figure 3, middle).*

1. *$K \cup M$ is non-empty and separates $(P \cup B)$ and Z,*
2. *$|P| \geqslant 2$ or $|B| \geqslant 2$,*
3. *$K \cup P$ induces a reflexive clique and B is an independent set,*
4. *M is complete to $P \cup K$ and B is complete to K,*
5. *B is non-adjacent to M.*

▶ **Definition 25** (B-decomposition). *A partition of $V(H)$ into an ordered six-tuple of sets $(B_1, B_2, K, M_1, M_2, Z)$ is a* B-decomposition *if the following conditions are satisfied (see Figure 3, right).*

1. *$K \cup M_1 \cup M_2$ is non-empty and it separates $(B_1 \cup B_2)$ and Z,*
2. *$|B_1| \geqslant 2$ or $|B_2| \geqslant 2$,*
3. *K induces a reflexive clique and each of B_1, B_2 is an independent set,*
4. *K is complete to $M_1 \cup M_2 \cup B_1 \cup B_2$, M_2 is complete to $M_1 \cup B_1$, and M_1 is complete to B_2,*
5. *B_1 is non-adjacent to M_1 and B_2 is non-adjacent to M_2.*

Observe that a graph H can have more than one decomposition: for example, if (B, P, M, K, Z) is an BP-decomposition of H, but $M = \emptyset$, then $(B \cup P, K, Z)$ is an F-decomposition of H.

For each kind of decomposition, we define its *factors* as the following pair of graphs (H_1, H_2).

for an F-decomposition: $H_1 = H[F]$ and H_2 is obtained from H by contracting F to a vertex f. It has a loop if and only if F is not an independent set.

for a BP-decomposition: $H_1 = H[B \cup P]$ and H_2 is obtained from H by contracting P and B respectively (if they are non-empty), to vertices p and b, such that p has a loop and b does not. Also, $pb \in E(H_2)$ if and only if there is any edge between P and B in H.

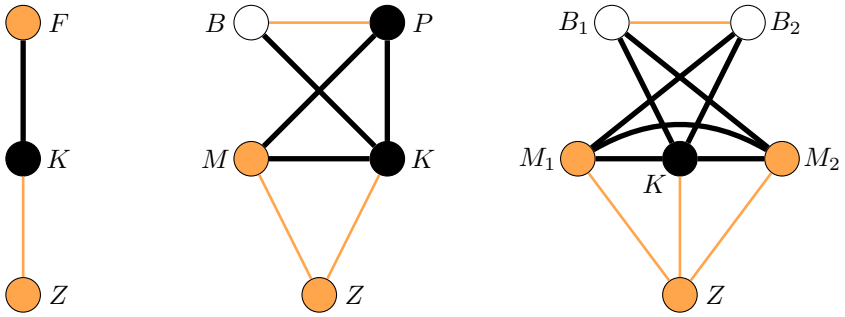

Figure 3 A schematic view of an F-decomposition (left), a BP-decomposition (middle), and a B-decomposition of H (right). Disks correspond to sets of vertices: white ones depict independent sets, black ones depict reflexive cliques, and orange ones depict arbitrary subgraphs. Similarly, thick black lines indicate that all possible edges between two sets exist, and thin orange lines depict edges that might exist, but do not have to. The lack of a line means that there are no edges between two sets.

for a B-decomposition: $H_1 = H[B_1 \cup B_2]$ and H_2 is obtained from H by contracting B_1 and B_2 respectively (if they are non-empty), to vertices b_1 and b_2 (without loops). Also, $b_1b_2 \in E(H_2)$ if and only if there is any edge between B_1 and B_2 in H.

It appears that if H is not a strong split graph, then the three types of decompositions defined above precisely correspond to bipartite decompositions of the associated bipartite graph H^*.

▶ **Lemma 26 (♠).** *Let H be be a connected, non-bi-arc graph, which is not a strong split graph. Then H^* admits a bipartite decomposition if and only if H admits a B-, a BP-, or an F-decomposition.*

Let us point out that one application of a BP-decomposition or a B-decomposition corresponds to two consecutive applications of a bipartite decomposition in H^*. Consider the case of a BP-decomposition and the bipartite decomposition $(B' \cup P'', K' \cup M' \cup P' \cup K'', Z' \cup M'' \cup B'' \cup Z'')$ of H'. Note that after contracting B' to b' and P'' to p'', we still have a decomposition $(P' \cup B'', K' \cup K'' \cup M'' \cup \{p''\}, M' \cup \{b'\} \cup Z' \cup Z'')$ of the second factor $(H^*)_2$ of H^*. Similarly, in the case of a B-decomposition, we still have another bipartite decomposition of $(H^*)_2$, where the new set D is $B_1'' \cup B_2'$.

Note that in a BP-decomposition, a B-decomposition, and an F-decomposition, when F is an independent set or contains a vertex with a loop, the factors are always induced subgraphs of H. Indeed, we can equivalently obtain H_2 by removing certain vertices from H. In the last case of an F-decomposition, when F contains at least one edge and has only vertices without loops, H_2 is not an induced subgraph of H. We can equivalently define H_2 as the graph obtained by removing from F all but two adjacent vertices, and then replacing them with a vertex with a loop.

In the next lemma we consider a graph H' that was obtained from H by a series of decompositions (i.e., it is a factor of H, or a factor of a factor of H etc.). We show that even if H' is not an induced subgraph of H, the associated bipartite graph H'^* is still an induced subgraph of H^*.

▶ **Lemma 27 (♠).** *Let H' be a graph obtained from H by a series of decompositions. Then H'^* is an induced subgraph of H^*.*

Finally, let us show an analogue of Lemma 11 for general graphs. Recall that $T(H, n, t)$ denotes an upper bound for the complexity of LHOM(H) on instances with n vertices, given along with a tree decomposition of width t. Note that we do not assume that $|H|$ is a constant [2].

▶ **Lemma 28** (♠ General decomposition lemma). *Let H be a connected, non-bi-arc graph, and let Γ be a decomposition of H (i.e., Γ is either an F-, a BP-, or a B-decomposition) with factors H_1, H_2. If there exist constants $c \geqslant 1$ and $d > 2$ such that $T(H_1, n, t) = \mathcal{O}\left(c^t \cdot (n \cdot |H_1|)^d\right)$ and $T(H_2, n, t) = \mathcal{O}\left(c^t \cdot (n \cdot |H_2|)^d\right)$, then $T(H, n, t) = \mathcal{O}\left(c^t \cdot (n \cdot (|H| + 2))^d\right)$.*

4.3 Solving LHom(H) for general target graphs

By Lemma 26, it is straightforward to observe the following.

▶ **Observation 29.** *If H is a connected, undecomposable, non-bi-arc graph, then $i^*(H)$ is the size of the largest incomparable set in H.*

In this section we sketch the proof of the following, slightly stronger version of Theorem 5 a), where the input tree decomposition is not assumed to be optimal.

▶ **Theorem 5' a).** *Let H be non-bi-arc graph. Even if H is given as an input, the LHOM(H) problem with instance (G, L) can be solved in time $\mathcal{O}\left(i^*(H)^t \cdot (n \cdot |H|)^{\mathcal{O}(1)}\right)$ for any lists L, provided that G is given with its tree decomposition of width t.*

The main idea is similar to the one in the proof of Theorem 3' a): given an instance of LHOM(H), we recursively decompose H into smaller subgraphs and reduce the initial instance to a number of instances of list homomorphism to these smaller subgraphs. Finally, we solve the problem for leaves of the recursion tree, and then, using Lemma 28 in a bottom-up fashion, we will compute the solution to the original instance. The only thing missing is how to solve the instances corresponding to leaves of the recursion tree. We describe this in the following results.

▶ **Corollary 30** (♠). *Let $\widehat{H}$ be a graph and let H be a strong split graph, which was obtained from $\widehat{H}$ by a series of decompositions. The LHOM(H) problem with instance (G, L) with n vertices, given along with a tree decomposition of width t, can be solved in time $\mathcal{O}(i^*(\widehat{H})^t \cdot (n \cdot |H|)^{\mathcal{O}(1)})$.*

▶ **Lemma 31.** *For any graph H, any n-vertex instance (G, L) of LHOM(H) can be solved in time $\mathcal{O}\left(i(H^*)^t \cdot (n \cdot |H|)^{\mathcal{O}(1)}\right)$, assuming a tree decomposition of G with width at most t is given.*

Proof. Let (G^*, L^*) be the associated instance of LHOM(H^*). By Proposition 19, we know that $(G, L) \to H$ if and only if there is a clean homomorphism $(G^*, L^*) \to H^*$. We will focus on finding such a clean homomorphism.

First, recall that by Observation 18 (2) and Observation 21 (1), the instance (G^*, L^*) is consistent. So, by Corollary 9, the size of each list in L^* is at most $i(H^*)$. Moreover, by Observation 21 (1), for every $x \in V(G)$, the vertices in $L^*(x')$ are precisely the twins

[2] Let us point out that in the full version of the paper we actually prove three variants of Lemma 28, one for each type of decomposition. Furthermore, in the statements of these three lemmas we are more explicit about the constants, to make sure that they do not increase multiplicatively. This is necessary to avoid introducing factors exponential in $|H|$ in the proof of Theorem 5 a).

of vertices in $L^*(x'')$. Finally, by Observation 21 (2), in polynomial time we can obtain a tree decomposition $\mathcal{T}^*$ of G^* with width at most $2t$, in which vertices of G^* come in pairs: whenever any bag contains x', it also contains x''.

Consider the straightforward dynamic programming algorithm for LHOM(H^*), using the tree decomposition $\mathcal{T}^*$ of G^*. We observe that since we are looking for a clean homomorphism, we do not need to remember partial solutions, in which the colors of twins do not agree. Thus, even though the size of each bag of $\mathcal{T}^*$ is at most $2t$, the number of partial colorings we need to consider is bounded by $(\max_{x \in V(G^*)} |L^*(x)|)^t \leqslant i(H^*)^t$. So the claim follows. ◀

Finally, let us wrap everything up and prove Theorem 5' a).

Proof of Theorem 5' a). Let (G, L) be an instance of LHOM(H), where G has n vertices and is given with its tree decomposition of width at most t. Again, we can assume that n is sufficiently large, as otherwise we can solve the problem by brute-force. We proceed as in the Theorem 3' a). We consider a recursion tree $\mathcal{R}$, obtained by decomposing H recursively. For each node corresponding to some graph H', we construct its children recursively, unless none of the following happens (i) H' is a bi-arc graph, (ii) H' is bipartite, (iii) H' is a strong split graph, or (iv) H' is undecomposable.

We compute the solutions in a bottom-up fashion. First, consider a leaf of the recursion tree, let the corresponding target graph for this node of $\mathcal{R}$ be H'. If H' is a bi-arc graph, we can solve the problem in polynomial time. If H' is bipartite, we solve the problem in time $\beta \cdot i^*(H') \cdot (n \cdot |H'|)^{d_1} \leqslant \beta \cdot i^*(H) \cdot (n \cdot |H'|)^{d_1}$ for some constants β and d_1, using the algorithm from Theorem 3' a). If H' is a strong split graph, we can solve the problem in time $\gamma \cdot i^*(H) \cdot (n \cdot |H'|)^{d_2}$, for constants γ, d_2, using the algorithm from Corollary 30.

So finally consider the remaining case, i.e., that H' is connected, non-bi-arc, non-bipartite, undecomposable, which is not a strong split graph. Furthermore we know that H' was obtained from H by a sequence of decompositions. Recall that by Lemma 31, we can solve the instances of LHOM(H') in time $\delta \cdot i(H'^*)^t \cdot (n \cdot |H'|)^{d_3}$, for some constants δ, d_3. Let us consider the graph H'^*, by Lemma 27 we know that H'^* is an induced subgraph of H^*. Also, H'^* is either connected (if H' is non-bipartite), or consists of two disjoint copies of H' (if H' is bipartite). Moreover, by Lemma 26, we observe that H'^* is undecomposable. Thus, by the definition of $i^*(H)$, we observe that

$$i(H'^*) \leqslant \max\{i(H'') \colon H'' \text{ is an undecomposable, connected, induced subgraph of } H^*, \text{ whose complement is not a circular-arc graph}\} = i^*(H).$$

So the algorithm from Lemma 31 solves the instances corresponding to leaves of $\mathcal{R}$ in time $\delta \cdot i^*(H)^t \cdot (n \cdot |H'|)^{d_3}$. Define $\alpha := \max(2\beta, \gamma, \delta)$ and $d := \max(d_1, d_2, d_3, 3)$ [3]. By applying Lemma 28 for every non-leaf node of $\mathcal{R}$ in a bottom-up fashion, we conclude that we can solve LHOM(H) in time $\alpha \cdot i^*(H)^t \cdot (n \cdot |H|)^d = \mathcal{O}\left(i^*(H)^t \cdot (n \cdot |H|)^{\mathcal{O}(1)}\right)$, which completes the proof. ◀

[3] The choice of these constants follows from the full statement of Lemma 28, refined for each of the decompositions.

5 Conclusion

Let us conclude the paper with some side remarks and pointing out several open problems.

5.1 Special cases: reflexive and irreflexive graphs

Recall that the crucial tool for our algorithmic results were the decompositions of a connected graph H, introduced in Section 2.1 (for bipartite graphs H) and in Section 4.2 (for general graphs H). Let us analyze how the general decompositions behave in two natural special cases: if H is either a reflexive or an irreflexive graph. We use the notation introduced in Definition 23, Definition 24, and Definition 25.

First we consider the case that H is reflexive, i.e., every vertex of H has a loop. Let us point out that a B-decomposition cannot occur in this case, as the sets B_1, B_2 are empty. In case of an F-decomposition we obtain exactly the decomposition defined by Egri et al. [15, Lemma 8]. Finally, in the case of a BP-decomposition, note that the set B is empty and therefore each vertex in P has exactly the same neighborhood. Thus the total contribution of the vertices in P to $i^*(H)$ is at most 1. Therefore the only type of decomposition that can be algorithmically exploited in reflexive graph is the F-decomposition, as observed by Egri et al. [15].

Now let us consider the case that H is irreflexive, i.e., no vertex of H has a loop. Observe that the sets K and P are reflexive cliques, so they are empty in our case. Thus BP-decompositions and F-decompositions do not occur in this case (recall that H is connected). Therefore the only possibility left is a B-decomposition, in which the set K is empty. Let us point out that this decomposition is very similar to the bipartite decomposition, in particular, the graph H_1 is bipartite (while H_2 might be non-bipartite). This gives even more evidence that the case of bipartite graphs H is a crucial step to understanding the complexity of the LHom(H) problem. Actually, if H is bipartite, then the B-decomposition turns out to be equivalent to the bipartite decomposition introduced in Section 2.1.

5.2 Generalized algorithm

We believe that the decompositions that we discovered can be used for many problems concerning the complexity of variants of the LHom(H) problem, e.g., for various other parameterizations. Let us point out that in the proofs of Lemma 11 and Lemma 28, we did not really require that the running time is of the form $\mathcal{O}(c^{\mathrm{tw}(G)} \cdot (n \cdot |H|)^d)$, for a constant c.

Moreover, recall that in each variant of the decomposition lemma, all instances for which we computed partial results were induced subgraphs of G, the original instance. This motivates the following, generalized statement. For a graph G, and a graph H, let $T(G, H, n)$ be an upper bound for the complexity of the LHom(H) problem for instances of size n, which are induced subgraphs of G.

▶ **Corollary 32.** *Let H be a connected, non-bi-arc graph. Let $\mathcal{R}$ be its recursion tree and let $\mathcal{H}$ be the set of graphs associated with leaves of $\mathcal{R}$. Consider an instance (G, L) of LHom(H) with n vertices. Suppose that that for each $H' \in \mathcal{H}$ it holds that $T(G, H', n') \leqslant f(n', H')$, where f is superadditive with respect to its first argument. Then (G, L) can be solved in time $\mathcal{O}\left(\sum_{H' \in \mathcal{H}} f(n, H') + n^2 \cdot |H|^3\right)$.*

Sketch of proof. The proof is analogous to the proofs of Theorem 3' a) and Theorem 5' a). Recall that we can compute the instances associated with the leaves of $\mathcal{R}$, and then proceed in a bottom-up fashion. Even though there might be more than one instance associated with a leaf node, we observe that their numbers of vertices sum up to n , so by the superadditivity of f we can bound the running time related to each leaf node, associated with H', by $f(n, H')$.

Now let us consider an internal node of $\mathcal{R}$, it is associated with some subgraph H' of H. Recall that the computation for this node consists of the computations for child nodes and $\mathcal{O}(n^2|H'|^2)$ additional steps. Since the total number of nodes of $\mathcal{R}$ is $\mathcal{O}(|H|)$, we can bound the total running time for the root node (i.e., time needed to solve (G, L)) by $\mathcal{O}\left(\sum_{H' \in \mathcal{H}} f(n, H') + n^2 \cdot |H|^3\right)$. ◀

5.3 Further research directions

In this paper we have shown tight complexity bounds for the list homomorphism problem, parameterized by the treewidth of the instance graph.

A very natural question, mentioned also in [15], is to provide analogous results for the non-list variant of the problem, denoted by $\textsc{Hom}(H)$. As we already mentioned, Okrasa and Rzążewski were able to provide tight bounds for the complexity of $\textsc{Hom}(H)$, assuming two conjectures from algebraic graph theory from early 2000s [35]. It would be very interesting to strengthen these results, either by proving the mentioned two conjectures, or by providing a different reduction.

Another interesting direction is to consider one of many other variants of the graph homomorphism problem. Let us mention one, i.e., *locally surjectve homomorphism*, denoted by $\textsc{LSHom}(H)$. In this problem we ask for a homomorphism from an instance graph G to the target graph H, which is surjective on each neighborhood. In other words, if we map some vertex $x \in V(G)$ to some vertex $v \in V(H)$, then every neighbor of v must appear as a color of some neighbor of x [21, 19, 20, 36]. We believe that it is interesting to show tight complexity bounds for this problem. One of the reasons why this problem is challenging is that the natural dynamic programming runs in time $2^{\mathcal{O}(|H| \cdot \mathrm{tw}(G))} \cdot (n + |H|)^{\mathcal{O}(1)}$. Thus in order to show that this bound is tight, it is not sufficient to design edge gadgets encoding inequality and substitute all edges of the instance of k-Coloring with these edge gadgets, as we did in this paper. Since the number of colors needs to be exponential in H, one should also design some *vertex gadgets*, which will encode the exponential number of possible states.

Finally, instead of changing the problem, we can consider changing the parameter. We believe that an exciting question is to find tight bounds for $\textsc{Hom}(H)$ and $\textsc{LHom}(H)$, parameterized by the *cutwidth* of the instance graph, denoted by $\mathrm{cw}(G)$. Quite recently Jansen and Nederlof showed that the chromatic number of a graph can be found in time $2^{\mathcal{O}(\mathrm{cw}(G))} \cdot n^{\mathcal{O}(1)}$ [30], i.e., the base of the exponential factor does not depend on the number of colors. Jansen [29] asked whether the same is possible for $\textsc{Hom}(H)$ and $\textsc{LHom}(H)$, if the target H is not complete? Note that while the chromatic number of a graph can be found in time $2^n \cdot n^{\mathcal{O}(1)}$ [3], for the $\textsc{Hom}(H)$ and $\textsc{LHom}(H)$ problems the $|H|^{\mathcal{O}(n)}$-time algorithm is essentially best possible, assuming the ETH [12]. We believe that a similar phenomenon might occur if the cutwidth is a parameter.

Abstract

Even though Delaunay originally introduced his famous triangulations in the case of infinite point sets with translational periodicity, a software that computes such triangulations in the general case is not yet available, to the best of our knowledge. Combining and generalizing previous work, we present a practical algorithm for computing such triangulations. The algorithm has been implemented and experiments show that its performance is as good as the one of the CGAL package, which is restricted to cubic periodicity.

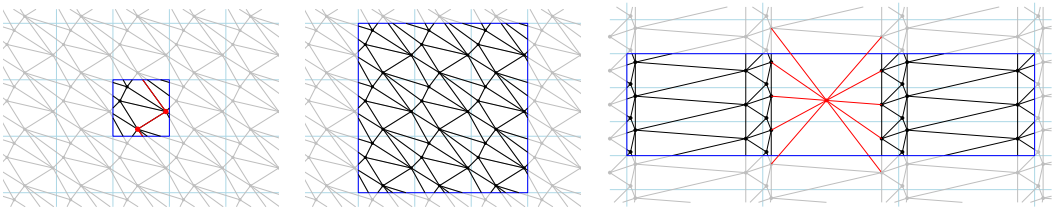
1 Introduction

Delaunay triangulations are one of the most prominent structures in computational geometry. While nowadays many applications use Delaunay triangulations of finite point sets in Euclidean space, Delaunay originally introduced the notion in the context of infinite point sets with translational periodicity [9]. Such periodic point sets are abundant in fields such as crystallography and material sciences; thus their communities would benefit from software that computes Delaunay triangulations of infinite periodic point sets in Euclidean space. Specifically, given a d-dimensional lattice and its associated translation group, the orbits of a given finite point set in $\mathbb{R}^d$ with respect to this translation group define a periodic point set. Our aim is to compute a finite representation of the periodic Delaunay triangulation of such a periodic point set, specifically a projection of the triangulation onto the flat d-torus that is the quotient space of $\mathbb{R}^d$ under the action of the translation group.

The first algorithm for this problem was already outlined in 1997 [12], yet a robust and efficient implementation for this problem does not exist to date as far as we know. The Voro++ library [18] is focused on crystallographic applications in 3 dimensions; however it is

limited to orthogonal lattices. Zeo++ [22] extends its functionality to arbitrary 3-dimensional lattices. Both libraries compute the Voronoi cell of a given input point as an intersection of half-spaces, by searching for other points around it that have an influence on its Voronoi cell. The combinatorics of the Delaunay triangulation cannot be easily accessed. The CGAL library [17] provides packages for periodic Euclidean Delaunay triangulations in 2D and 3D, which currently are limited to the integer lattice, referred to as the square and cubic setting and 2 and 3 dimensions, respectively [15, 6, 5]. We propose an addition to CGAL that extends this functionality to arbitrary lattices.

The algorithm by Dolbilin and Huson [12] creates 3^d copies of each input point and computes their finite Delaunay triangulation, from which a representation of the periodic Delaunay triangulation is extracted. The CGAL algorithm [4, 7] computes the triangulation in a finitely-sheeted covering space of the d-torus. It is based on the classical incremental algorithm by Bowyer and Watson [3, 21], and requires that the triangulation be a simplicial complex at any given time. Let us quickly recall that a triangulation is a simplicial complex, or is *simplicial* for short, if each of its simplices consists of a set of distinct vertices, and the intersection of any two simplices is either empty or a simplex. Operating directly on the d-torus does not guarantee this, see Figure 1a. Thus, in the cubic setting, a 3^d-sheeted cover is used (Figure 1b) until sufficiently many points have been inserted to guarantee that the triangulation in the 1-sheeted cover is a simplicial complex. Unfortunately, a 3^d-sheeted cover is not sufficient for more general periodic point sets: As the 3^d copies of each point have to be inserted iteratively into the 3^d-sheeted cover, simpliciality can be violated in the intermediate stages of point insertion, see Figure 1c. While there always exists a finitely-sheeted covering space [7] that ensures simpliciality, the number of sheets might be prohibitively large. Thus, we propose a different approach.



(a) The intersection of the two red edges is not a simplex but a set of two vertices. Thus the triangulation is not simplicial.

(b) The 9-sheeted cover guarantees a simplicial triangulation in the square setting.

(c) In the non-square setting, incremental point insertion of the 9 copies into the 9-sheeted cover can violate simpliciality. Here, the first of 9 copies is being inserted.

Figure 1 Representation of the projections of the periodic Delaunay triangulation into the 1-sheeted (left) and 9-sheeted cover (middle, right) of the 2-torus.

Overview. After formally defining the problem in Section 2, we propose an algorithm (Section 3) for periodic Delaunay triangulations that combines two different approaches and consists of two phases, both of which use Bowyer-Watson's algorithm. While for 2-dimensional spaces algorithms based on flips circumvent the simpliciality requirement [10], we stick to Bowyer-Watson's algorithm as it easily generalizes to 3 (and higher) dimensions. Furthermore it enables an efficient, clean, and easily maintainable implementation. The first phase of our algorithm (Section 3.2) refines the algorithm by Dolbilin and Huson [12], and its implementation details are based on some new results. It uses 3^d copies of each input point, regardless of the lattice, and computes a finite Euclidean Delaunay triangulation on this point set, from which a representation of the Delaunay triangulation on the d-torus is obtained. Once a simpliciality criterion is met, our algorithm switches to the second phase

(Section 3.4), which conceptually follows the CGAL implementation of the cubic case [4]. It operates directly on the d-torus, maintaining only one copy of each input point, and thus provides better insertion running times than phase 1. A first version of our open-source implementation in 2D and 3D is publicly available.[1] This implementation is expected to be an integral part of CGAL in a near future release. Experiments (Section 4) show similar performances as the CGAL implementation restricted to cubic lattices [5]. We close with a discussion of future extensions in Section 5.

2 Preliminaries

Let us recall various notions [13, 8] that are employed throughout the algorithm. Let $B = \{b_1, b_2, \dots, b_d\}$ be a basis of $\mathbb{R}^d$. The point set $\Lambda := \{\sum_{i=1}^{d} z_i b_i \colon z \in \mathbb{Z}^d\}$ is called a *lattice*, and B is its *lattice basis*. The lattice Λ is associated with the translation group Γ consisting of the translations $\phi_\lambda \colon \mathbb{R}^d \to \mathbb{R}^d$ mapping the origin to λ, for each $\lambda \in \Lambda$. The group Γ acts on $\mathbb{R}^d$ and each translation of Γ maps Λ onto itself. We denote the length of the shortest non-zero lattice vector as $\mathrm{sv}(\Lambda)$. For a given lattice basis B, we call $B_{\mathrm{sup}} := B \cup \{b_0\}$ with $b_0 = -\sum_{i=1}^{d} b_i$ its *superbase*. A superbase is *obtuse* if for any pair b_i and b_j, $\langle b_i, b_j \rangle \leq 0$. A basis is *reduced* if its superbase is obtuse [13, Definition 4.4]. This notion is defined in such a way that we can easily compute $\mathrm{sv}(\Lambda)$ and Dirichlet domains. The *Dirichlet domain* of a lattice point $\lambda \in \Lambda$ is the region of λ in the Voronoi tesselation of Λ, or more formally $\mathrm{dom}(\lambda, \Lambda) := \{p \in \mathbb{R}^d \colon \|p - \lambda\| \leq \|p - \nu\| \ \forall \nu \in \Lambda\}$. It is a convex polytope, and we call the lattice Λ *generic* if each vertex of $\mathrm{dom}(0, \Lambda)$ is incident to the Dirichlet domains of exactly d other lattice points. For 2-dimensional generic lattices the Dirichlet domains are hexagons, for 3-dimensional generic lattices they are combinatorially equivalent to truncated cubes.

For a lattice vector λ, $\mathrm{str}(\lambda) = \{p \in \mathbb{R}^d \colon -0.5 \leq \frac{\langle p, \lambda \rangle}{\langle \lambda, \lambda \rangle} < 0.5\}$ is an infinite half-open strip that contains the subspace orthogonal to λ through the origin. Then $\mathrm{dom}(0, \Lambda)$ is the closure of the intersection of these strips for all non-zero lattice vectors. However, as $\mathrm{dom}(0, \Lambda)$ only has a finite number of facets, there must be a finite subset of strips whose closed intersection yields $\mathrm{dom}(0, \Lambda)$. Let $\mathcal{V}$ be the minimal set of lattice vectors (together with their negates) such that the closure of $\bigcap_{v \in \mathcal{V}} \mathrm{str}(v)$ is $\mathrm{dom}(0, \Lambda)$. The vectors in $\mathcal{V}$ are commonly called *Voronoi-relevant vectors*. Each of them is a normal vector of a facet of the Dirichlet domain of 0, and thus there are at most $2(2^d - 1)$ Voronoi relevant vectors [13, Theorem 3.6]. Let $\mathcal{V}^+ \sqcup \mathcal{V}^-$ be a partition of $\mathcal{V}$ such that if $v \in \mathcal{V}^+$, then $-v \in \mathcal{V}^-$, and vice versa. For a fixed choice of $\mathcal{V}^+$ (and implicitly $\mathcal{V}^-$), we define the *canonical* domain $\mathrm{dom}^{\mathbin{\rotatebox{90}{)}}}(0, \Lambda) := \bigcap_{v \in \mathcal{V}^+} \mathrm{str}(v)$ (Figure 2). Its closure is $\mathrm{dom}(0, \Lambda)$, and its images under Γ, denoted $\mathrm{dom}^{\mathbin{\rotatebox{90}{)}}}(\lambda, \Lambda) := \phi_\lambda(\mathrm{dom}^{\mathbin{\rotatebox{90}{)}}}(0, \Lambda))$ for $\lambda \in \Lambda$, form a partition of $\mathbb{R}^d$. With $k\Lambda$ for $k \in \mathbb{Z}$ referring to the lattice with basis $\{kb_1, \dots, kb_d\}$, we note that $\mathrm{dom}^{\mathbin{\rotatebox{90}{)}}}(0, k\Lambda)$ is $\mathrm{dom}^{\mathbin{\rotatebox{90}{)}}}(0, \Lambda)$ scaled by a factor of k.

For $d \leq 3$, if we have a reduced lattice basis B with its superbase B_{sup}, then $\mathcal{V}$ is a subset of $\{\sum_{v \in S} v \colon S \subset B_{\mathrm{sup}}, S \neq \emptyset, S \neq B_{\mathrm{sup}}\}$ [8, Theorems 3 and 8], with equality if the lattice is generic. Note that $\mathrm{sv}(\Lambda)$ can be obtained as the length of the shortest vector in $\mathcal{V}$.

Delaunay triangulations. The *Delaunay triangulation* $\mathrm{Del}(X)$ of an input point set $X \subset \mathbb{R}^d$ is a collection of simplices up to dimension d whose vertex set is X and each d-simplex (which we refer to as a *cell*) corresponds to a set of $d + 1$ points whose open circumscribing ball does not contain any other points of X. We call the $(d - 1)$-simplices of $\mathrm{Del}(X)$ its *facets*.

(b) $\mathrm{dom}^{\mathrm{C}}(0,\Lambda)$ of a 3-dimensional lattice (blue). Lattice basis B in black, $\mathcal{V}^+ \supset B$ in orange.

Figure 2 Canonical domains and Voronoi relevant vectors for lattices in 2D and 3D.

Given a lattice Λ and a finite set of points X, we get the *periodic point set* $\Gamma X := \{\phi_\lambda(x) \colon x \in X \text{ and } \lambda \in \Lambda\}$ consisting of the elements of the orbits of X under Γ. ΓX is globally invariant under Γ. Then $\mathrm{Del}(\Gamma X)$ is the *periodic Delaunay triangulation* of the infinite point set ΓX. Note that we can ignore degeneracies in ΓX by using the symbolic perturbation provided by CGAL [11]: it is translation-invariant, so, degeneracies are triangulated in a consistent way, which ensures that the computed $\mathrm{Del}(\Gamma X)$ is actually invariant under Γ. The orbit space $\mathbb{R}^d/\Gamma$ is a *flat torus*, and we denote its projection map as $\pi \colon \mathbb{R}^d \to \mathbb{R}^d/\Gamma$. The *torus triangulation* $\mathrm{Del}(\Gamma X)/\Gamma$ is the projection of $\mathrm{Del}(\Gamma X)$ into $\mathbb{R}^d/\Gamma$. Using $\mathrm{dom}^{\mathrm{C}}(0,\Lambda)$ as a geometric representation of the torus, we can use $X_0 := \Gamma X \cap \mathrm{dom}^{\mathrm{C}}(0,\Lambda)$ as *canonical* representatives of the vertex set of $\mathrm{Del}(\Gamma X)/\Gamma$. While $\mathrm{Del}(\Gamma X)/\Gamma$ gives us a finite representation of $\mathrm{Del}(\Gamma X)$, unlike $\mathrm{Del}(\Gamma X)$ it is not necessarily simplicial (see Figure 1a).

3 Algorithm

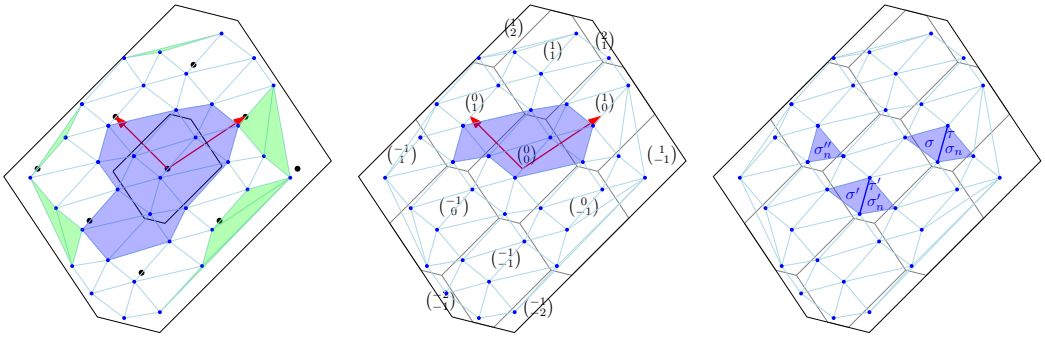
The input to our algorithm is a lattice basis B' for Λ and a set of points X defining the periodic point set. The output is an object representing $\mathrm{Del}(\Gamma X)/\Gamma$. This object provides a uniform interface that, regardless of the internal state of our algorithm, allows the user to access the properties of Λ as well as the torus triangulation $\mathrm{Del}(\Gamma X)/\Gamma$. For Λ this includes the reduced basis $B = \{b_1, \ldots, b_d\}$. For $\mathrm{Del}(\Gamma X)/\Gamma$ this includes the set X_0 of canonical representatives for its vertex set, and its cells. Cells are not solely defined by their vertex set, but have additional geometric information attached. Specifically, each vertex of a cell is represented as a point x from X_0 with an associated offset $o = (o_1, \ldots, o_d)$, which is an integer vector. The geometric location of the vertex then is $x + \sum_{i=1}^{d} o_i b_i$. In alignment with other CGAL triangulations, we also provide access to simplices of lower dimensions, represented with associated vertex offsets akin to cells, as well as neighborhood relations. These include querying a cell for its adjacent cells, or querying a vertex for its incident cells or lower dimensional simplices. While many steps generalize, we restrict our focus to 2- and 3-dimensional triangulations, which are the most widely used.

Internally, our algorithm operates in two phases, which use two different data structures, respectively: The first phase maintains a finite Euclidean Delaunay triangulation while the second phase maintains a triangulation of $\mathrm{Del}(\Gamma X)/\Gamma$.

Let us now recall the result that is crucial to the first phase of our algorithm. For a point set X, let $X_3 := \mathrm{dom}^{\square}(0, 3\Lambda) \cap \Gamma X$, i.e. all periodic copies of X that lie within the Dirichlet domain of 0 scaled by a factor of 3. We call a cell of $\mathrm{Del}(X_3)$ a *periodic cell* if it is also a cell of the periodic triangulation $\mathrm{Del}(\Gamma X)$ (see Figure 3a).

▶ **Proposition 1** ([12, Lemma 3.4]). *Given a point set X, each cell of $\mathrm{Del}(X_3)$ that has at least one vertex in $\mathrm{dom}^{\square}(0, \Lambda)$ is a periodic cell. Furthermore the set of these cells contains at least one periodic copy of each cell of $\mathrm{Del}(\Gamma X)/\Gamma$.*

After some preprocessing that essentially consists in computing the canonical domain, the first phase internally maintains $\mathrm{Del}(X_3)$ using the CGAL packages for Euclidean Delaunay triangulations [14, 23]. For this we need to develop a systematic way of computing X_3 and obtaining the interface for $\mathrm{Del}(\Gamma X)/\Gamma$ from the internal data structure $\mathrm{Del}(X_3)$.



(a) Cells in blue are guaranteed to be periodic cells by Proposition 1. Green: non-periodic cells. Black vertices: Λ.

(b) The set of canonical cells in blue. Each copy of $\mathrm{dom}(0, \Lambda)$ is labeled with its offset.

(c) Finding the periodic neighbor of σ across the edge τ, which is σ''_n, the canonical representative of σ'_n.

Figure 3 In blue, the points X_3 with their Delaunay triangulation $\mathrm{Del}(X_3)$. The large hexagon is $\mathrm{dom}(0, 3\Lambda)$, while the smaller ones are $\mathrm{dom}(0, \Lambda)$ and (middle, right) its periodic copies. The reduced lattice basis is drawn in red (left, middle).

Once we can guarantee that $\mathrm{Del}(\Gamma X)/\Gamma$ is simplicial and will remain so for any future point insertions, we switch to the second phase. Simpliciality guarantees that the Bowyer-Watson algorithm can be used directly on $\mathrm{Del}(\Gamma X)/\Gamma$. For this purpose we leverage the CGAL machinery for periodic triangulations from the cubic setting [15, 5] and enhance its underlying data structures to work for the generic setting. As we keep only one representative for each vertex, inserting points in this phase is more efficient than in the first phase.

The remainder of this section describes the two phases and the transition between them, as well as the preprocessing of the lattice.

3.1 Lattice preprocessing

We first compute the reduced lattice basis B, which allows us to compute $\mathcal{V}$, the face normals of the canonical domain. We use $\mathcal{V}$ to represent $\mathrm{dom}^{\square}(0, \Lambda)$ and check for containment of a point within $\mathrm{dom}^{\square}(0, \Lambda)$, which helps obtaining the canonical copy of each input point. To find all periodic copies of a canonical point x that lie within $\mathrm{dom}^{\square}(0, 3\Lambda)$, it is sufficient to find all points λ such that the domain $\mathrm{dom}^{\square}(\lambda, \Lambda)$ intersects $\mathrm{dom}^{\square}(0, 3\Lambda)$, and then check $\phi_\lambda(x)$ for containment within $\mathrm{dom}^{\square}(0, 3\Lambda)$ for these points. As the set of these points λ is independent of x, we compute it before phase 1.

Lattice reduction

Many lattice related problems, such as the shortest non-zero vector problem (SVP), are believed to be hard in general [20, 2]. However in low dimensions, we can use two classical iterative algorithms to solve lattice reduction. Let B' be a lattice basis and ${B'}_{\text{sup}} = \{b'_0, \ldots, b'_d\}$ its superbase, as defined in Section 2. Define $c_{ij} := \langle b'_i, b'_j \rangle$.

2-dimensional reduction. A 2-dimensional lattice basis is Lagrange-reduced [13, Section 4.2] if $0 \leq 2|c_{12}| \leq c_{11} \leq c_{22}$. We can negate b'_2 if necessary so that $c_{12} \leq 0$. Then $\{b'_1, b'_2, b'_0 := -b'_1 - b'_2\}$ form an obtuse superbase, because $c_{01} = \langle b'_1, -b'_1 - b'_2 \rangle = -c_{11} - c_{12} \leq 0$ due to $2|c_{12}| \leq c_{11}$, and similarly $c_{02} \leq 0$. If a basis is not Lagrange-reduced with $2|c_{12}| > c_{11}$, we exchange b'_2 for a shorter vector that forms a basis with b'_1: Let $b''_2 := b'_2 - sb'_1$, with $s = 1$ if $c_{12} > 0$ and $s = -1$ otherwise. Vector b''_2 is shorter than b'_2 since $c'_{22} = c_{22} + c_{11} - 2sc_{12}$. Since there are only finitely many pairs of lattice vectors within a ball of any given radius, a finite number of applications of this procedure will yield a Lagrange-reduced basis.

3-dimensional reduction. We outline Selling's algorithm [13, Section 4.4], an iterative algorithm that obtains an obtuse superbase in 3 dimensions. In each step of the algorithm, if there is a $c_{ij} > 0$, the algorithm returns a new superbase ${B''}_{\text{sup}}$ defined via $b''_i := -b'_i$, $b''_j := b'_j$, $b''_h := b'_h + b'_i$ and $b''_k := b'_k + b'_i$ where h and k are the remaining two indices different from i and j. For any basis B, let $\sigma(B) := \sum_{b \in B_{\text{sup}}} ||b||^2$. Notice that in each step, $\sigma(B'') = \sigma(B') - 2c_{ij}$. In particular, $\sigma(B'') < \sigma(B')$. This fact, together with the fact that there are only finitely many lattice points in a ball of radius $\sqrt{\sigma(B')}$ (and thus only finitely many quadruplets of vectors whose square magnitudes sum up to at most $\sigma(B')$) guarantees termination of the algorithm.

Intersecting domains

For a given canonical point $x \in X_0$, each of its periodic copies $y \in \Gamma x$ can be obtained as $\phi_\lambda(x)$ for some translation $\phi_\lambda \in \Gamma$. The corresponding lattice point λ can be uniquely written as $\sum_{i=1}^{d} o_i b_i$ for some $o \in \mathbb{Z}^d$ and we write and $\lambda(o) := \lambda$. We then call $o =: o(y)$ the *offset* of y and $\phi_{\lambda(o)}$ the *translation* associated with o. For each point $x \in X_0$ we need to determine the 3^d offsets for which $\phi_{\lambda(o)}(x)$ is within $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$. Fortunately, these offsets have to come from a fixed set of offsets that only depends on the lattice basis. Notice that if $\phi_{\lambda(o)}(\text{dom}^{\mathbb{Q}}(0, \Lambda))$ does not intersect $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$, then $\phi_{\lambda(o)}(x)$ cannot be in $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$ for $x \in X_0$. Thus we only need to check those offsets for which $\phi_{\lambda(o)}(\text{dom}^{\mathbb{Q}}(0, \Lambda)) \cap \text{dom}^{\mathbb{Q}}(0, 3\Lambda) \neq \emptyset$.

▶ **Lemma 2.** *There are at most* $4^d - 2^d + 1$ *translates of* $\text{dom}^{\mathbb{Q}}(0, \Lambda)$ *that have non-empty intersection with* $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$.

Proof. If $\text{dom}^{\mathbb{Q}}(\lambda, \Lambda)$ intersects $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$ for some $\lambda \in \Lambda$, then λ must be inside $\text{dom}^{\mathbb{Q}}(0, 4\Lambda)$. There are 4^d lattice points within $\text{dom}^{\mathbb{Q}}(0, 4\Lambda)$. For each $v \in \mathcal{V}^+$, the lattice vectors $-2v$ and $2v$ are on the boundary of $\text{dom}^{\mathbb{Q}}(0, 4\Lambda)$, however only $-2v$ is one of those 4^d points within $\text{dom}^{\mathbb{Q}}(0, 4\Lambda)$. For these lattice points $-2v$ on the boundary however the intersection between $\text{dom}^{\mathbb{Q}}(-2v, \Lambda)$ and $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$ is empty. Thus only $4^d - |\mathcal{V}^+| = 4^d - (2^d - 1)$ translates of $\text{dom}^{\mathbb{Q}}(0, \Lambda)$ intersect $\text{dom}^{\mathbb{Q}}(0, 3\Lambda)$. ◀

In general, we can find this set of offsets via a breadth-first search: We define a graph on Λ with each lattice point λ connected to $\lambda + v$ for $v \in \mathcal{V}$. We start the search at lattice point 0 and terminate once we have found $4^d - 2^d + 1$ offsets, or in the case of non-generic lattices once all 4^d lattice points inside $\text{dom}^{\mathbb{Q}}(0, 4\Lambda)$ have been reached (with the ones on the boundary being discarded).

In 2 dimensions, there is in fact a fixed set S of 13 offsets such that for any lattice, $\mathrm{dom}^{\square}(\lambda(o), \Lambda)$ only intersects $\mathrm{dom}^{\square}(0, 3\Lambda)$ when $o \in S$ (Figure 3b).

▶ **Lemma 3.** *Given a 2-dimensional lattice with basis B and an offset o, if $o \notin \{$(0, 0), (-1, -1), (0, 1), (1, 0), (-1, 0), (0, -1), (1, 1), (-1, -2), (1, 2), (-2, -1), (2, 1), (-1, 1), (1, -1)$\}$, then $\mathrm{dom}^{\square}(\lambda(o), \Lambda) \cap \mathrm{dom}^{\square}(0, 3\Lambda) = \emptyset$.*

Proof. Each $\mathrm{dom}^{\square}(\lambda, \Lambda)$ adjacent to $\mathrm{dom}^{\square}(0, \Lambda)$ has all but one of its facets in the interior of $\mathrm{dom}^{\square}(0, 3\Lambda)$. Except for those adjacent via one of those facets, all $\mathrm{dom}^{\square}(\lambda, \Lambda)$ at graph distance 2 from 0 intersect $\mathrm{dom}^{\square}(0, 3\Lambda)$. The ones that don't are exactly the 6 domains $\mathrm{dom}^{\square}(2v, \Lambda)$ for $v \in \mathcal{V}$. As there are 19 domains at distance at most 2, we have found 13 domains that intersect $\mathrm{dom}^{\square}(0, 3\Lambda)$. As this is the maximum possible number by Lemma 2, we have found all of them. ◀

In 3 dimensions, the same argument yields a set of 51 fixed offsets. However, by Lemma 2, the total number of domains that intersect $\mathrm{dom}^{\square}(0, 3\Lambda)$ is 57. Fortunately, the remaining 6 offsets come from a fixed set of 24 offsets that is independent of the lattice.

▶ **Lemma 4.** *There is a set $O_{\leq 2}$ of 51 offsets and a set O_3 of 24 offsets such that for any 3-dimensional lattice with basis B, there is a subset S of O_3 of size 6 such that if $o \notin O_{\leq 2} \cup S$, then $\mathrm{dom}^{\square}(\lambda(o), \Lambda) \cap \mathrm{dom}^{\square}(0, 3\Lambda) = \emptyset$.*

Proof. We use the observation that $|\langle v, w\rangle| \leq \langle v, v\rangle$ for any two Voronoi relevant vectors $w, v \in \mathcal{V}$ [13, Section 3.5]. Then the following claim holds:

▷ Claim. Domains $\mathrm{dom}^{\square}(\nu, \Lambda)$ of graph-distance at most $(k-2)$ from some $\lambda = kv$ for an integer $k \geq 2$ and $v \in \mathcal{V}$ cannot intersect $\mathrm{dom}^{\square}(0, 3\Lambda)$.

Proof. We have $\nu = kv + v_1 + \cdots + v_{k-2}$ for some $v_i \in \mathcal{V}, i = 1, \ldots, k-2$. Then $\langle w, v\rangle = k\langle v, v\rangle + \langle v, v_1\rangle + \cdots + \langle v, v_{k-2}\rangle \geq k\langle v, v\rangle - (k-2)\langle v, v\rangle = 2\langle v, v\rangle$ due to the observation above. This means that ν is not in the interior of $\mathrm{str}(4v)$ and thus the interior of the 4-scaled domain. Therefore $\mathrm{dom}^{\square}(\nu, \Lambda) \cap \mathrm{dom}^{\square}(0, 3\Lambda) = \emptyset$. ◁

For a generic 3-dimensional lattice, the Voronoi relevant vectors correspond to the non-empty subsets of B_{sup} of size at most 3, independent of the actual vectors of B_{sup}. Thus the graph we defined on Λ is isomorphic for all generic lattices. For non-generic lattices it is isomorphic to a subgraph of the graph for generic lattices; thus it is sufficient to restrict our attention to generic lattices.

We enumerate all lattice points at graph distance 3 from the origin. For a generic lattice, this yields 110 points, however all but 24 of them can be written as $3v$ or $3v + w$ for Voronoi relevant vectors v and w. The set of the 24 corresponding offsets is O_3, while $O_{\leq 2}$ are those 51 offsets that the argument from Lemma 3 yields. All lattice points at graph distance 4 can be written as $4v + kw$ for $k \leq 2$ and Voronoi relevant vectors v and w, and thus their domains and consequently any domains at higher distances cannot intersect $\mathrm{dom}^{\square}(0, 3\Lambda)$. ◀

3.2 Phase 1

Phase 1 maintains the Euclidean Delaunay triangulation of X_3. For each new point to be inserted, we first find its canonical copy. Then we can compute its periodic copies that are contained within $\mathrm{dom}^{\square}(0, 3\Lambda)$ using Lemmas 3 and 4. These are then inserted into $\mathrm{Del}(X_3)$. To provide user access to the cells of $\mathrm{Del}(\Gamma X)/\Gamma$, we define a notion of canonical cell in $\mathrm{Del}(X_3)$ to get a representative for each cell of $\mathrm{Del}(\Gamma X)/\Gamma$.

Canonical points

For each point of X, finding its periodic copy that lies in $\text{dom}^{\square}(0, \Lambda)$ is equivalent to solving the closest vector problem (CVP), i.e. given $x \in X$, determining the lattice point that is closest to x. For arbitrary dimensions this problem is known to be NP-hard [20]. For the exact version of CVP, various iterative algorithms have been described [1, 19, 16]. As we are only operating in 2 and 3 dimensions, any of them would suffice for us in practice in terms of running time, and we will describe the algorithm by Sommer et al [19] due to its simplicity.

For a real number r, define $\text{round}(r)$ to be the closest integer to r. If this integer is not unique, then it is the one with the smallest absolute value. This definition ensures convergence in cases where x is on the boundary of a Dirichlet domain of the lattice [19]. Recall that $\mathcal{V}^+$ is a set of normals of the facets of the canonical domain, and can be obtained from a reduced basis B (see Section 2). We first sort the vectors of $\mathcal{V}^+$ by their magnitude. As $\text{dom}^{\square}(0, \Lambda)$ is the intersection of the strips $\text{str}(v)$ for $v \in \mathcal{V}^+$, we need to find the periodic copy of x that is in all these $\text{str}(v)$. We loop through the vectors v of $\mathcal{V}^+$ and for each of them perform the following operations: Compute $c := \frac{\langle x,v \rangle}{\langle v,v \rangle}$. If $-0.5 \leq c < 0.5$, then already $x \in \text{str}(v)$. If not, then we subtract $\text{round}(c) \cdot v$ from x. Note that after such a step, it is guaranteed that $x \in \text{str}(v)$. However after modifying x for a longer vector v, it might happen that x is moved outside of $\text{str}(v')$ for some shorter vector v' again. Therefore we need to repeatedly loop through $\mathcal{V}^+$ and perform this operation until $x \in \text{str}(v)$ for all $v \in \mathcal{V}^+$.

Notice that in each step where x is modified, the magnitude of x strictly decreases. Therefore this algorithm terminates in finite time, as the number of lattice vectors within a ball of given radius $||x||$ is finite.

Extracting representative cells

Recall that our interface specifies access to the cells (and lower-dimensional simplices) of $\text{Del}(\Gamma X)/\Gamma$. Thus for each of its cells we have to provide one representative from $\text{Del}(X_3)$. For a cell σ of either $\text{Del}(\Gamma X)$ or $\text{Del}(X_3)$, with $V(\sigma) = \{x_1, \ldots, x_d\}$, we define its offset as the vector $o(\sigma) = \min_{x \in V(\sigma)}\{o(x)\}$ where the minimum is taken lexicographically. Note that this definition differs from [4, Convention 3.3.1] where the coordinate-wise minimum is taken. If the offset of a cell is the 0-vector, we call it a *canonical cell*. Note that due to our definition a canonical cell always has a vertex with offset 0. Therefore by Proposition 1 a canonical cell of $\text{Del}(X_3)$ is also periodic , see Figure 3b. For $\sigma \in \text{Del}(\Gamma X)$, the translated cell $\sigma - \sum_{i=1}^{d} o_i b_i$ is called its *canonical representative*. This means that for each class of cells in $\text{Del}(\Gamma X)$ (or equivalently each cell of $\text{Del}(\Gamma X)/\Gamma$), there is a unique canonical representative in $\text{Del}(X_3)$. Therefore we can get a set of representative cells by iterating over the cells of $\text{Del}(X_3)$ and selecting those that are canonical.

Neighborhood relations

In accordance with our interface, we need to provide neighborhood relations for the vertices and cells of $\text{Del}(\Gamma X)/\Gamma$. These vertices and cells are represented by the canonical vertices and cells of $\text{Del}(X_3)$, whose neighbors in $\text{Del}(X_3)$ (which we have access to) may differ from the neighbors in $\text{Del}(\Gamma X)/\Gamma$ (which we want to find). We outline how to get the neighors of a cell of $\text{Del}(\Gamma X)/\Gamma$ from $\text{Del}(X_3)$, and note that other neighborhood relations work in a conceptually similar way. Note that we do not store these relations explicity, but we compute them upon request and may cache them for future access.

Consider a canonical cell σ of $\text{Del}(X_3)$ and a neighboring cell σ_n. If σ_n is canonical, it is the neighbor of σ in $\text{Del}(\Gamma X)$. If σ_n is not canonical but has a vertex in $\text{dom}^{\square}(0, \Lambda)$, then it is periodic and we return the canonical representative of this cell. However, it is possible that

all vertices of σ_n are outside $\mathrm{dom}^{\lozenge}(0,\Lambda)$, and thus σ_n might not be a periodic cell at all. In that case, we need to consider the facet τ separating σ and its neighbor σ_n. As τ is a facet of a canonical cell, it is also a periodic facet (i.e. a facet of $\mathrm{Del}(\Gamma X)$). We compute τ's offset $o := o(\tau)$. Then $\tau' := \phi_{\lambda(-o)}(\tau)$ is the canonical representative of τ and $\sigma' := \phi_{\lambda(-o)}(\sigma)$ as well as its neighbor σ'_n across τ' are periodic cells because they share τ', which has a vertex in $\mathrm{dom}^{\lozenge}(0,\Lambda)$. If σ'_n is canonical, then is it the canonical representative of the neighbor of σ in $\mathrm{Del}(\Gamma X)$; if not, then its canonical representative is. Figure 3c illustrates this process.

In practice, we store the canonical representative of each vertex of X_3. To obtain the canonical representative of a cell (or facet) σ, we need to choose a vertex x whose offset is minimal (lexicographically) among its vertices. This ensures that the periodic copy x' of x in the canonical version of the cell is inside $\mathrm{dom}^{\lozenge}(0,\Lambda)$. Then one of the cells (or facets) incident to x' in $\mathrm{Del}(X_3)$ is the canonical representative of σ.

3.3 Transition

Phase 2 is more efficient than phase 1 as it directly operates on $\mathrm{Del}(\Gamma X)/\Gamma$; however, we cannot use it from the start as the Bowyer-Watson algorithm [3, 21] comes with some constraints. The Bowyer-Watson algorithm is an incremental algorithm inserting points one by one. For each new point x, it determines the *conflict zone*, which is the set of cells whose circumsphere contains x. All these cells are removed, and all boundary facets of the resulting hole are connected to x to fill in the hole with new cells. The algorithm requires this hole to be a topological d-ball, which is not always guaranteed for $\mathrm{Del}(\Gamma X)/\Gamma$. However the following criterion is a sufficient condition for the Bowyer-Watson algorithm to work [7].

▶ **Lemma 5** ([7, Criterion 3.11]). *If for every cell in* $\mathrm{Del}(\Gamma X)/\Gamma$ *the circumradius is smaller than* $\frac{1}{4}\mathrm{sv}(\Lambda)$*, then* $\mathrm{Del}(\Gamma X')/\Gamma$ *is simplicial for every* $X' \supseteq X$*.*

If this criterion is fulfilled, we can safely switch to phase 2. To detect at which point in phase 1 the criterion is fulfilled, we maintain a set S_{big} of *big* cells, which are canonical cells whose circumradius is larger than or equal to $\frac{1}{4}\mathrm{sv}(\Lambda)$. We update S_{big} during each point insertion.

Assume we wish to insert a new point x into the periodic triangulation of some point set X. On a high level, we need to remove the big cells in the conflict zone of x from S_{big}, and then add the newly created big cells to S_{big}. In practice, we have already computed the triangulation $\mathrm{Del}(X_3)$ and have to insert the periodic copies of x that are within $\mathrm{dom}^{\lozenge}(0,3\Lambda)$, i.e. $\Gamma x \cap \mathrm{dom}^{\lozenge}(0,3\Lambda)$, into $\mathrm{Del}(X_3)$. We first detect the conflict zone of x_0, the canonical copy of x. For each big cell in the conflict zone we check if it has a canonical copy in S_{big}, and remove that copy from S_{big} if it does. While the conflict zone may contain non-periodic cells, Lemma 6 guarantees that we capture a representative of each cell from $\mathrm{Del}(\Gamma X)$ that is in conflict with x. Next we insert all the copies $\Gamma x \cap \mathrm{dom}^{\lozenge}(0,3\Lambda)$ into $\mathrm{Del}(X_3)$. Finally, for each big cell incident to x_0 in the resulting triangulation, we add its canonical copy to S_{big}. Note that all these cells have a canonical copy by Proposition 1 as they have a vertex inside $\mathrm{dom}^{\lozenge}(0,\Lambda)$.

▶ **Lemma 6.** *Let* C *be the conflict zone of some point* $x \in \mathrm{dom}^{\lozenge}(0,\Lambda)$ *with respect to* $\mathrm{Del}(\Gamma X)$*. Then the conflict zone of* x *with respect to* $\mathrm{Del}(X_3)$ *contains at least one periodic copy of each cell from* C*.*

Proof. First observe that if a cell of $\mathrm{Del}(\Gamma X)$ has its circumcenter at the origin, then all its vertices must be within $\mathrm{dom}(0,\Lambda)$, because if the circumsphere contains a point outside $\mathrm{dom}(0,\Lambda)$, then it also contains its canonical copy. Via translation it follows that if a cell has

its circumcenter in $\mathrm{dom}^{\mathrm{D}}(0, 2\Lambda)$, then its vertices are in $\mathrm{dom}^{\mathrm{D}}(0, 3\Lambda)$ and thus it is a cell of $\mathrm{Del}(X_3)$. So assume we have a cell σ in C whose circumcenter c is not within $\mathrm{dom}^{\mathrm{D}}(0, 2\Lambda)$. Then there is a facet of $\mathrm{dom}^{\mathrm{D}}(0, 2\Lambda)$ with respect to which c is outside. Let f be its face normal. Then $x + f$ is also contained in the circumsphere of σ. Reversely, $\sigma - f$ is a cell whose circumsphere contains x, and furthermore its circumcenter is closer to 0 than c, see Figure 4. As there are only finitely many periodic copies of c within a given distance from 0, after

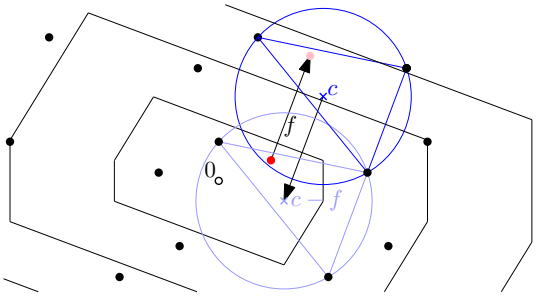


Figure 4 The red point x is in the conflict zone of the blue cell σ, which is not a cell of $\mathrm{Del}(X_3)$ and whose circumcenter c is outside $\mathrm{dom}^{\mathrm{D}}(0, 2\Lambda)$. However the light blue cell $\sigma - f$ is a periodic copy of σ that is in $\mathrm{Del}(X_3)$ and x is in its conflict zone.

applying this process a finite number of times we eventually obtain a cell whose circumsphere contains x and whose circumcenter is in $\mathrm{dom}^{\mathrm{D}}(0, 2\Lambda)$. This cell is a periodic copy of σ, is contained in $\mathrm{Del}(X_3)$ and thus also part of the conflict zone of x with respect to $\mathrm{Del}(X_3)$. ◀

Once S_{big} is empty, the criterion of Lemma 5 is fulfilled, and we can internally convert our triangulation from $\mathrm{Del}(X_3)$ to $\mathrm{Del}(\Gamma X)/\Gamma$, which is maintained in phase 2. We initialize the periodic triangulation data structure with the set of canonical vertices X_0 and canonical cells obtained from $\mathrm{Del}(X_3)$, as well as the adjacency and incidence relations outlined earlier.

3.4 Phase 2

Phase 2 operates directly on the torus triangulation $\mathrm{Del}(\Gamma X)/\Gamma$. Thus it maintains only one copy of each cell and vertex and point insertion is faster than in phase 1. The data structure it uses to represent $\mathrm{Del}(\Gamma X)/\Gamma$ is akin to the one used in CGAL for the cubic case, and closely resembles the interface we defined for our algorithm: Only X_0 is stored as vertex set, and each cell is represented by its vertices, with a vertex encoded as a pair (x, o) of a point $x \in X_0$ and an offset so that its geometric location is $\phi_{\lambda(o)}(x)$. While in the cubic case each offset coordinate either takes the value 0 or 1 and offsets can be encoded in d bits, in our more general setting offsets can take any of the lattice-specific values from Lemma 2. Unlike in phase 1, most neighborhood relations for $\mathrm{Del}(\Gamma X)/\Gamma$ are already stored explicitly in the data structure: For each cell its adjacent cells are stored, and for each vertex one incident cell is stored. The remaining neighborhood relations required by our interface are obtained implicitly from the explicitly stored ones. With each point insertion, all stored neighborhood relations have to be updated accordingly.

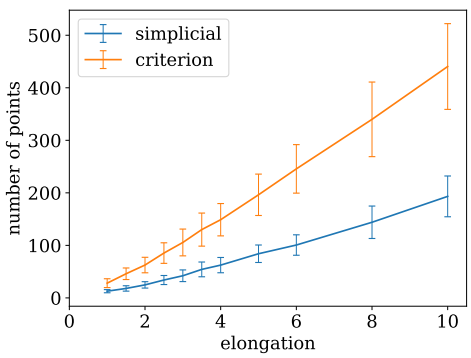
Point insertion. To insert a new point x into $\mathrm{Del}(\Gamma X)/\Gamma$ using the Bowyer-Watson algorithm, first we compute the canonical copy x_0. Then we locate the cell containing x_0, via a traversal starting from an arbitrary cell. The conflict zone is computed via a search starting in the cell containing the point x_0. Whenever we are traversing cells, care has to be taken to maintain the correct offset of the affected cells relative to x_0, and similarly when creating

new cells to fill in the hole left by the deleted conflict zone. For the cubic case the details are described in [4, Section 3.3], and we omit the technical adjustments needed to make these steps work in the more general case.

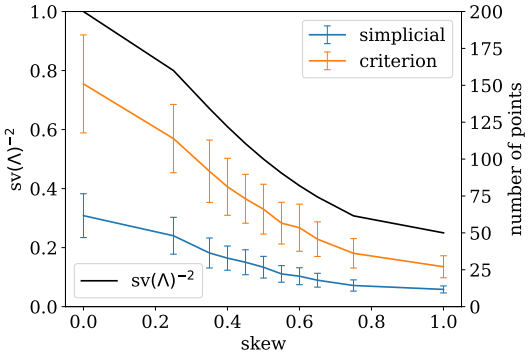
4 Experimental results

Points until transition. We experimentally evaluated the number of points required until the criterion of Lemma 5 is fulfilled and the transition to phase 2 occurs. Lemma 5 requires all of $\mathbb{R}^d/\Gamma$ to be covered by the balls of radius $\frac{1}{4}\mathrm{sv}(\Lambda)$ around X_0. As the volume of the torus equals the volume of the Dirichlet domain of 0, denoted as $\mathrm{vol}(\mathrm{dom}(0,\Lambda))$, we expect the number of points until switching to phase 2 to be roughly proportional to $\mathrm{vol}(\mathrm{dom}(0,\Lambda))/\mathrm{sv}(\Lambda)^d$, assuming the points are sampled uniformly at random.

To investigate this in 2 dimensions, we parametrize a 2-dimensional space of lattices. We call the parameters the elongation ℓ and the skew s. The basis of the lattice with elongation ℓ and skew s is $b_1 = (\ell, 0)$ and $b_2 = (s \cdot \ell/2, 1)$. With $\ell \geq 1$ and s between 0 and 1 we can parametrize all 2-dimensional lattices up to symmetry and scaling. Note that the skew affects $\mathrm{sv}(\Lambda)$ but not $\mathrm{vol}(\mathrm{dom}(0,\Lambda))$, while the elongation is proportional to $\mathrm{vol}(\mathrm{dom}(0,\Lambda))$ but does not affect the $\mathrm{sv}(\Lambda)$. Fixing the skew at 0 and varying the elongation (Figure 5a), we see that the number of random points needed until the phase switch appears to be proportional to the elongation. The same applies to the number of points until the resulting triangulation is simplicial for the first time. Figure 5b shows the same statistics for lattices of fixed area but varying skew. In addition we plot the inverse of $\mathrm{sv}(\Lambda)^2$ for comparison, and observe that it behaves similarly albeit not entirely proportionally.



(a) Results for fixed skew $s = 0$ and varying elongation ℓ.



(b) Results for $\ell = 4$ and varying s. The inverse of the square length of the shortest non-zero lattice vector in black, with its y-axis on the right.

Figure 5 For different lattices, the number of points inserted into a periodic triangulation until (blue) $\mathrm{Del}(\Gamma X)/\Gamma$ is simplicial for the first time, and (orange) $\mathrm{Del}(\Gamma X)/\Gamma$ fulfills Lemma 5. Each data point is the mean of 200 trials, and the bars represent the standard deviation.

In 3-dimensions, a parametrization of lattices up to symmetry and scaling needs 5 parameters, and thus an analysis like in 2D is impractical. As mentioned before, we expect that the number of points until the switch to phase 2 is proportional to $\mathrm{vol}(\mathrm{dom}(0,\Lambda))/\mathrm{sv}(\Lambda)^3$. By comparing the two, Figure 6 confirms this relationship for 182 lattices whose basis vectors have randomly sampled direction and a random magnitude between 1 and 100.

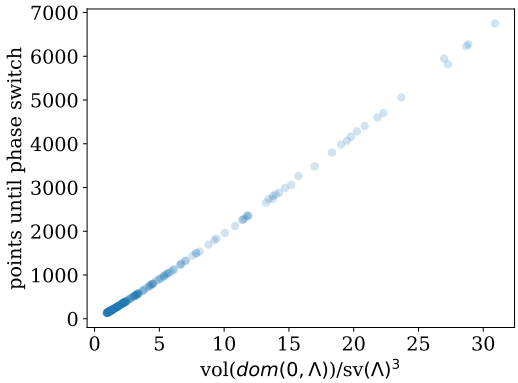


Figure 6 Phase switching in 3D: Each point in the plot represents a lattice, with $\mathrm{vol}(\mathrm{dom}(0,\Lambda))/\mathrm{sv}(\Lambda)^3$ on the x-axis and the number of points inserted until the switch to phase 2 occurred on the y-axis. Each y-value is obtained as the average over 200 point sets, each distributed uniformly at random.

Running times. We evaluate the running times of our algorithm for different 3-dimensional lattices, and compare them to the existing CGAL implementations. The data points collected are from Delaunay triangulations of 10^k uniformly sampled random points for k up to 7. Each data point is an average of 300 trials (10 trials for 10^7 points). The experiments were conducted on a laptop running Fedora 30 64-bits, with two 6-core Intel(R) i9-8950HK CPU clocked at 2.90GHz, and with 32GB of RAM. The CGAL kernel used was CGAL::Exact_predicates_inexact_constructions_kernel and CPU time was measured using CGAL's timer tools. The code was compiled using clang 8.0.0 with compilation flags -O3 and -DNDEBUG.

Table 1 shows a comparison between the CGAL implementation of Euclidean Delaunay triangulations [14] (with random points uniformly sampled in the unit cube), periodic Delaunay triangulations in the cubic setting [5] and our algorithm for various lattices, including the cubic lattice. For each lattice, we also measured the average number of points until the switch to phase 2. As our algorithm and the one for the cubic setting are based on the same code base when operating directly on the torus triangulation, their runtimes are comparable for large point sets. It should be noted that when similar experiments were conducted in 2010 to compare the Euclidean and cubic periodic algorithms [4, Section 3.6.2], both were performing comparably. Since then, Euclidean Delaunay triangulations in CGAL have seen significant optimizations, which were not applied to periodic triangulations. This also explains why our algorithm is faster than the cubic periodic algorithm for point sets where phase 1 takes up a significant portion of the running time, as internally we use a Euclidean rather than a periodic triangulation.

5 Discussion

Weighted points. Phase 1 of our algorithm readily generalizes to weighted point sets. In particular, Proposition 1 still holds for weighted point sets (see Appendix A for a proof). Phase 2 only works for weighted points under additional restrictions because $\mathrm{Del}(\Gamma X)/\Gamma$ can not be guaranteed to remain simplicial, in particular after inserting points with large weights. Such point insertions that break simpliciality can be prevented by requiring points to be inserted in decreasing order of weight, or like in the cubic implementation in CGAL by severely restricting the range of weights a point can have. Thus an implementation is subject to a tradeoff between flexibility (phase 1) and performance (phase 2).

Table 1 Running time (in seconds) of various Delaunay triangulation algorithms on random point sets of different sizes. Our algorithm ("Lattice") is evaluated for different lattices including the cubic lattice, face-centered cubic (FCC) lattice and two other lattices Λ_1 and Λ_2 with bases $B_1 = \{(0.5, -0.5, 0.1), (-0.5, 0.5, 0.1), (0.5, 0.5, -0.1)\}$ and $B_2 = \{(1, 0, 0), (-0.5, \sqrt{3}/2, 0), (0, 0, 0.05)\}$. For each lattice we also record the average number of points until the switch to phase 2 (n_{switch}).

Algorithm	Euclidean [14]	Cubic [5]	Lattice

Higher dimensions. Conceptually, our algorithm generalizes to higher dimensions. The only step that is dimension-dependent and therefore requires significant adjustments is obtaining a representation of $\text{dom}^{\complement}(0, \Lambda)$. While up to 3 dimensions every lattice has an obtuse superbase, this does not hold in higher dimensions. Therefore we would need to find a different way of obtaining the set of Voronoi relevant vectors. Complexity-wise, computing the canonical representative of a point is believed to be hard. Furthermore, the number of copies that we compute of each input point in phase 1 is 3^d. Therefore we expect the runtime of our algorithm to be exponential in the dimension, but still feasible in practice as long as the dimension is not too large.

Dummy points. For best performance, transition from phase 1 to phase 2 should occur as soon as possible. Intuitively, this happens when the input point distribution does not have large gaps. We can achieve this by first inserting additional *dummy points*, which are removed at the end (if possible) [7]. In practice, we can choose these points from a sufficiently fine hexagonal lattice (or body-centered cubic in 3 dimensions), such that the open spheres of radius $\frac{1}{4}\text{sv}(\Lambda)$ around the points cover the entire torus.

Software distribution. We aim to provide a CGAL package for periodic Delaunay triangulations for arbitrary lattices in 2 and 3 dimensions. The current state of our implementation is available online (see Footnote 1). Both the 2- and 3-dimensional implementations have been integrated into the CGAL codebase and only require some additional refactoring and optimizing to adhere to CGAL's quality standards. Automated tests and documentation still have to be produced. An extension to weighted Delaunay triangulations, referred to as regular triangulations in CGAL, is planned for the future.

A Generalization to weighted points

For a weighted point x, we denote its weight with w_x. For weighted points $x, y \in X$, their power distance is $\text{dist}(x,y) := \|x-y\| - w_x - w_y$. For an arbitrary point $p \in \mathbb{R}$ that is not part of X we define the power distance from x to p as $\text{dist}(x,p) := \|x-p\| - w_x$ (as if the weight of p was 0).

We call two points x and y orthogonal if $\text{dist}(x,y) = 0$. For $d+1$ points $Q \subseteq X$ (if in general position) there is a unique point z with weight w_z that is orthogonal to all points of Q. This point is called the orthocenter or power sphere of Q. If Q is a set of points forming a cell (simplex) in the Delaunay triangulation, then for all points $x \in Q$ and $y \in X \setminus Q$ it holds that $\text{dist}(y,z) > \text{dist}(x,z) = 0$. We call this the empty-sphere property. The converse holds as well. The perpendicular bisector of two weighted points x and y is the set of points p with $\text{dist}(x,p) = \text{dist}(y,p)$.

▶ **Proposition 7** (Generalization of Lemma 3.2–3.4 from [12]). *Given a set X of representatives for our point set, let $X_3 := \text{dom}^{\mathbb{C}}(0, 3\Lambda) \cap \Gamma X$, i.e. all periodic copies of these points that lie within the Dirichlet domain of 0 scaled by a factor of 3. Let T_0 be those cells of $\text{Del}(X_3)$ that have at least one vertex in $\text{dom}^{\mathbb{C}}(0,\Lambda)$. Then the cells of T_0 are all part of the triangulation of ΓX. Furthermore, these cells contain at least one representative of each class of cells from $\text{Del}(\Gamma X)$.*

Proof. We will prove the proposition in 3 steps.

▷ Claim 1. Assume one of our points is $x_0 = 0$ (with arbitrary weight). Then the orthocenter c_T of any Delaunay cell that has x_0 as a vertex is within $\text{dom}(0,\Lambda)$.

Proof. Assume not. Then there is a face F_i of $\text{dom}(0,\Lambda)$ such that F_i separates x_0 from c_T. Let f_i be the corresponding translation lattice vector orthogonal to F_i. Then $x_0 + f_i$ is strictly closer to c_T than x_0 because it has the same weight as x_0. This is a contradiction to the empty-sphere property. ◁

▷ Claim 2. For a cell containing x_0 as a vertex, all vertices are in $\text{dom}(0, 2\Lambda)$.

Proof. Assume some vertex x is not. Consider the perpendicular bisector between x and $x - f_i$ where f_i is the face normal vector orthogonal to the face F_i of $\text{dom}(0,\Lambda)$ with respect to which x is outside of $\text{dom}(0, 2\Lambda)$. This bisector is separated from x_0 and the orthocenter c_T by F_i, the face of $\text{dom}(0,\Lambda)$ that is parallel to this bisector. In particular, it follows from Claim 1 that c_T is (strictly) on the $x - f_i$ side of the perpendicular bisector. So $x - f_i$ is closer to c_T than x and thus the empty-sphere property is violated. See Figure 7 for reference. ◁

▷ Claim 3. All cells σ having a vertex in $\text{dom}^{\mathbb{C}}(0,\Lambda)$ are entirely contained in $\text{dom}^{\mathbb{C}}(0, 3\Lambda)$.

Proof. Let x be a vertex of σ that is within $\text{dom}^{\mathbb{C}}(0,\Lambda)$. Shift the entire point set ΓX and its triangulation by the vector $-x$ so that x now coincides with 0. Now from Claim 2 it follows that the other vertices of the shifted cell are within $\text{dom}(0, 2\Lambda)$. Adding the vector $+x$ to these shifted vertices we get back to the original setting, but because $x \in \text{dom}^{\mathbb{C}}(0,\Lambda)$ we also know now that these vertices are within $\text{dom}^{\mathbb{C}}(0, 3\Lambda)$, as $\text{dom}^{\mathbb{C}}(0, 3\Lambda)$ is the Minkowski sum of $\text{dom}^{\mathbb{C}}(0,\Lambda)$ and $\text{dom}(0, 2\Lambda)$. ◁

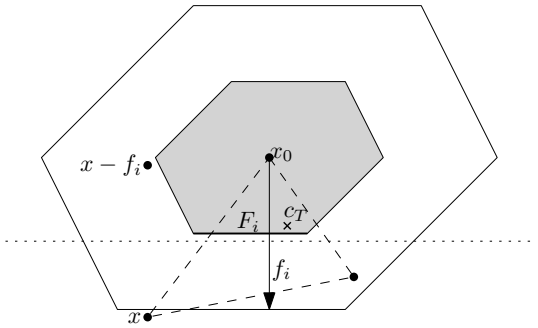

Figure 7 A cell (dashed) with a vertex x that is outside of $\mathrm{dom}(0, 2\Lambda)$. The dotted line is the perpendicular bisector between x and $x - f_i$.

Every cell of $\mathrm{Del}(\Gamma X)$ that has a vertex in $\mathrm{dom}^{\mathbb{Q}}(0, \Lambda)$ has all its vertices in X_3. Furthermore, because it fulfils the empty-sphere property in ΓX, then it also fulfils this property in $X_3 \subset \Gamma X$, and thus is present in $\mathrm{Del}(X_3)$. As every point from X has a representative in $\mathrm{dom}^{\mathbb{Q}}(0, \Lambda)$, also each cell from $\mathrm{Del}(\Gamma X)$ has a representative in T_0, proving the statement. ◀

B Detailed proof of Lemma 4

▶ **Lemma 4** (extended version). *Let* $O_3 := \{$`(3, 2, 1), (2, 1, -1), (3, 1, 2), (2, -1, 1), (1, -1, -2), (1, -2, -1), (2, 3, 1), (1, 2, -1), (1, 3, 2), (-1, 2, 1), (-1, 1, -2), (-2, 1, -1), (2, 1, 3), (1, -1, 2), (1, 2, 3), (-1, 1, 2), (-1, -2, 1), (-2, -1, 1), (-1, -2, -3), (-1, -3, -2), (-2, -1, -3), (-3, -1, -2), (-2, -3, -1), (-3, -2, -1)`$\}$ *and* $O_{\leq 2} := \{$`(0, 0, 0), (-1, -1, -1), (0, 0, 1), (0, 1, 0), (1, 0, 0), (1, 1, 0), (1, 0, 1), (0, -1, -1), (0, 1, 1), (-1, 0, -1), (-1, -1, 0), (1, 1, 1), (0, 0, -1), (0, -1, 0), (-1, 0, 0), (1, 2, 0), (1, 0, 2), (-1, -2, -2), (2, 1, 0), (2, 0, 1), (1, -1, -1), (0, 1, 2), (-2, -1, -2), (0, 2, 1), (-1, 1, -1), (-2, -2, -1), (-1, -1, 1), (1, 1, 2), (-1, -1, -2), (1, 2, 1), (0, 1, -1), (-1, -2, -1), (0, -1, 1), (2, 1, 1), (1, 0, -1), (1, -1, 0), (-2, -1, -1), (-1, 0, 1), (-1, 1, 0), (1, 2, 2), (-1, 0, -2), (-1, -2, 0), (2, 1, 2), (0, -1, -2), (2, 2, 1), (1, 1, -1), (0, -2, -1), (1, -1, 1), (-2, -1, 0), (-2, 0, -1), (-1, 1, 1)`$\}$.

Given a 3-dimensional lattice and an offset o, there is a subset S of size 6 of O_3 such that if $o \notin O_{\leq 2} \cup S$, then $\mathrm{dom}^{\mathbb{Q}}(\lambda(o), \Lambda) \cap \mathrm{dom}^{\mathbb{Q}}(0, 3\Lambda) = \emptyset$.

Proof. As mentioned in the proof of Theorem 3.5 from [13], $\frac{v}{2}$ is on the boundary of $\mathrm{dom}^{\mathbb{Q}}(0, \Lambda)$ for every Voronoi-relevant vector v.

▷ Claim 1. The orthogonal projection of v into the 1-dimensional subspace spanned by another Voronoi relevant vector $w \in \mathcal{V}^+$ has magnitude less than w.

Proof. All facets of $\mathrm{dom}^{\mathbb{Q}}(0, \Lambda)$ are contained in $\mathrm{str}(w)$ for all $w \in \mathcal{V}^+$, so because $\frac{v}{2}$ is on the boundary of $\mathrm{dom}^{\mathbb{Q}}(0, \Lambda)$, it is contained in $\mathrm{str}(w)$. By definition of $\mathrm{str}(w)$ this implies $|\langle \frac{1}{2}v, w\rangle / \langle w, w\rangle| \leq \frac{1}{2}$, from which it follows that $|\langle v, w\rangle| \leq \langle w, w\rangle$. ◁

▷ Claim 2. Domains $\mathrm{dom}^{\mathbb{Q}}(\nu, \Lambda)$ of graph-distance $(k-2)$ from some $\lambda = kv$ for an integer k and $v \in \mathcal{V}$ cannot intersect $\mathrm{dom}^{\mathbb{Q}}(0, 3\Lambda)$.

Proof. We have $\nu = kv + v_1 + \cdots + v_{k-2}$ for some $v_i \in \mathcal{V}$. Then $\langle w, v\rangle = k\langle v, v\rangle + \langle v, v_1\rangle + \cdots + \langle v, v_{k-2}\rangle \geq k\langle v, v\rangle - (k-2)\langle v, v\rangle = 2\langle v, v\rangle$ due to Claim 1. This means that ν is not in the interior of $\mathrm{str}(4v)$ and thus the interior of the 4-scaled domain. Therefore $\mathrm{dom}^{\mathbb{Q}}(\nu, \Lambda) \cap \mathrm{dom}^{\mathbb{Q}}(0, 3\Lambda) = \emptyset$. ◁

Let $B_{\text{sup}} = \{b_0, b_1, b_2, b_3\}$. Note that because $b_0 = -(b_1 + b_2 + b_3)$, every lattice point λ can be written as a non-negative integer combination of three of these extended basis vectors, i.e. $\lambda = c_1 a + c_2 b + c_3 c$ with $c_i \in \mathbb{Z}, c_1 \geq c_2 \geq c_3 \geq 0$ and $a, b, c \in B_{\text{sup}}$. This representation is unique up to permutation of basis vectors with the same coefficient.

Enumerating all $\text{dom}^{\text{◹}}(\lambda, \Lambda)$ at graph distance 3 from $\text{dom}^{\text{◹}}(0, \Lambda)$, we get lattice points λ with non-negative integer combinations of the following types:

$$
\begin{aligned}
&3a \\
&3a + \ \ b \ \ &&= 3a \ \ &&+ b \\
&3a + \ \ b + \ \ c \ &&= 3a \ \ &&+ (b + c) \\
&3a + 2b \ \ &&= 3(a + b) \ \ &&- b \\
&3a + 2b + \ \ c \\
&3a + 2b + 2c \ &&= 3(a + b + c) \ &&- (b + c) \\
&3a + 3b \\
&3a + 3b + \ \ c \ &&= 3(a + b) \ \ &&+ c \\
&3a + 3b + 2c \ &&= 3(a + b + c) \ &&- c \\
&3a + 3b + 3c
\end{aligned}
$$

All of these, except for type $3a + 2b + c$, can be written as $3v$ or $3v + w$ for some Voronoi relevant vectors $v, w \in \mathcal{V}$. This means that they are, or are adjacent to, a domain centered at $3v$, and from Claim 2 it follows that they cannot intersect $\text{dom}^{\text{◹}}(0, 3\Lambda)$. A similar argument shows that none of the domains at graph distance 4 from $\text{dom}^{\text{◹}}(0, \Lambda)$ can intersect $\text{dom}^{\text{◹}}(0, 3\Lambda)$, and therefore also none at higher graph distance.

Now the 51 offsets from $O_{\leq 2}$ are those that the argument from Lemma 3 yields, while O_3 contains the offsets corresponding to type $3a+2b+c$. As by Lemma 2 there are 57 intersecting domains, only 6 of the offsets from O_3 can correspond to intersecting domains. ◀

Engineering Fast Almost Optimal Algorithms for Bipartite Graph Matching

CNRS and LIP, ENS Lyon, France
bora.ucar@ens-lyon.fr

Abstract

We consider the maximum cardinality matching problem in bipartite graphs. There are a number of exact, deterministic algorithms for this purpose, whose complexities are high in practice. There are randomized approaches for special classes of bipartite graphs. Random 2-out bipartite graphs, where each vertex chooses two neighbors at random from the other side, form one class for which there is an $O(m + n \log n)$-time Monte Carlo algorithm. Regular bipartite graphs, where all vertices have the same degree, form another class for which there is an expected $O(m + n \log n)$-time Las Vegas algorithm. We investigate these two algorithms and turn them into practical heuristics with randomization. Experimental results show that the heuristics are fast and obtain near optimal matchings. They are also more robust than the state of the art heuristics used in the cardinality matching algorithms, and are generally more useful as initialization routines.

1 Introduction

A matching in a graph is a set of edges, such that no two of them share a common vertex. We consider the *maximum cardinality problem* in bipartite graphs which asks for a matching with maximum cardinality. There are a number of exact algorithms for this problem. The best known algorithms [21] run in $O(m\sqrt{n})$ time for a graph with n vertices and m edges. Such complexity can be prohibiting for large instances. For this reason, there is significant interest in algorithms which can find large matchings in linear or near linear time [37]. The practical use of approximate matchings in applications [33] and as an initialization to exact algorithms [30] are well known.

We investigate two randomized algorithms by Karp et al. [22] and Goel et al. [18], both of which run in $O(m + n \log n)$ time. The former algorithm finds, almost surely, maximum cardinality matchings on random graphs formed by allowing each vertex to select two vertices from the other side uniformly at random. The latter algorithm finds maximum cardinality matchings in regular bipartite graphs, where all vertices have equal degree. In both of these classes of graphs, the bipartite graphs have equal number of vertices in each part, and the maximum cardinality matchings cover all vertices (such matchings are called perfect). We investigate these two theoretical algorithms for very special cases of bipartite graphs and convert them to efficient heuristics for general bipartite graphs. We discuss our implementations and investigate the performance of the resulting heuristics in terms of run time and the matching cardinality. Both heuristics run in near linear time and obtain matchings whose cardinality is more than 0.99 of the maximum, even in cases where the current state of the art approaches have difficulties.

The rest of the paper is organized as follows. In Section 2, we give the necessary background. In Sections 3.1 and 3.2 we review the existing randomized algorithms and then discuss how we adapt them. Section 4 contains the experimental results, and Section 5 concludes the paper. Appendices A–D provide some additional results and discussion.

2 Background and notation

Let $G = (R \cup C, E)$ be a bipartite graph, where R and C are two disjoint set of vertices, and E is the set of edges. The bipartite graph G can be represented with a matrix $\mathbf{A}_G$. The vertex $r_i \in R$ corresponds to the ith row, and the vertex $c_j \in C$ corresponds to the jth column, so that $\mathbf{A}_G(i,j) = 1$ if and only if $(r_i, c_j) \in E$. We will refer to vertices of R as *rows* and to those of C as *columns* from this point on, and use $\mathbf{A}$ to refer to $\mathbf{A}_G$.

Let $\mathcal{M}$ be a matching. For $(u,v) \in \mathcal{M}$, the vertices u and v are matched, and they are each other's mate. A vertex is called free if it is not matched by $\mathcal{M}$. If there are no free vertices in R or in C, then $\mathcal{M}$ is called perfect. An augmenting path with respect to $\mathcal{M}$ is a path which starts with a free vertex and ends at another free vertex, where every second edge is in $\mathcal{M}$. A matching is maximum if and only if there are no augmenting paths [7].

A square matrix is called doubly stochastic if the sum of entries in each row and column is equal to one. An $n \times n$ matrix $\mathbf{A}$ has *support* if there is a perfect matching in the associated bipartite graph G. $\mathbf{A}$ is said to have *total support* if each edge in G is used in a perfect matching. A square matrix is fully indecomposable, if it has total support and cannot be permuted into a block diagonal matrix. Any nonnegative matrix $\mathbf{A}$ with total support can be scaled with two positive diagonal matrices $\mathbf{D_R}$ and $\mathbf{D_C}$ such that $\mathbf{A_S} = \mathbf{D_R A D_C}$ is doubly stochastic, and if $\mathbf{A}$ is fully indecomposable, then the matrices $\mathbf{D_R}$ and $\mathbf{D_C}$ are unique. The Sinkhorn–Knopp algorithm [38] is a well-known method for finding such $\mathbf{D_R}$ and $\mathbf{D_C}$ for a given matrix. This is an iterative algorithm, where at each iteration each row is normalized to have unit length, and then each column is normalized to have unit length. If a given matrix $\mathbf{A}$ has total support, then Sinkhorn–Knopp algorithm finds the unique scaling matrices. If $\mathbf{A}$ has support but not total support, then entries that cannot be put into a perfect matching tend to zero. The method converges with an asymptotical convergence rate depending on the second singular value of the final doubly stochastic matrix. There are other iterative, faster converging methods [1, 10, 28], whose iterations are more sophisticated than that of Sinkhorn–Knopp's.

A k-out subgraph G_k of a host graph G is defined by allowing each vertex in G to randomly select uniformly k of its neighbors, and the union of all selections forms the edge set of G_k. Walkup [40] shows that in the pure random k-out setting, where the host graph is the complete bipartite graph, the resulting G_k has a perfect matching with high probability for $k \geq 2$. We do not know any general result about properties of G_2 sampled from any arbitrary host graph. Frieze and Johansson [17] investigate some other properties of G_ks on host graphs where the minimum degree of a vertex is at least $n/2$. Dufossé et al. [16] propose using the doubly stochastic matrix $\mathbf{A_S}$ (scaled version of the matrix representation) for sampling and show an approximation result for G_1, when $\mathbf{A}$ has total support. We give some experiments in which G_2s generated using the same probabilities have perfect matchings in majority of the cases.

Two popular classes of randomized algorithms are *Las Vegas* and *Monte Carlo* algorithms. *Las Vegas* algorithms always return a correct answer, but their run time can depend on random choices, whereas Monte Carlo algorithms can fail with small probability, but their complexity is independent of the random choices made (see for example [34, p. 70]).

There are a number of heuristics for the cardinality matching problem [30, 37] (see Appendix A for a relevant discussion). Among those, that by Karp and Sipser [23] is very well known and widely used. This heuristic eliminates vertices of degree at most two in the following way. It matches any degree-1 vertices with their neighbors (and discards both), or merges the neighbors of a degree-2 vertex (which is then discarded) to a single node, and removes any parallel edges that occur. If neither operation can be done, it matches a pair of vertices randomly.

3 Two heuristics

We describe the original Monte Carlo algorithm [22] for finding perfect matchings in 2-out bipartite graphs in Section 3.1 and the original Las Vegas algorithm [18] for finding perfect matchings in d-regular bipartite graphs in Section 3.2. These two algorithms are based on uniform sampling. We generalize these two algorithms to general bipartite graphs within a common framework. The framework we propose scales the adjacency matrix of the input bipartite graph and uses the nonzero values of the scaled matrix for sampling. We also identify and fix an oversight in the description of the Monte Carlo algorithm, and describe efficient implementations of the two heuristics.

3.1 2outMC: Monte Carlo on 2-out graphs

3.1.1 Description of the algorithm

The Monte Carlo algorithm by Karp et al. [22] finds a perfect matching, with high probability, in a random 2-out bipartite graph, sampled from the complete bipartite graph. A random 2-out bipartite graph B_{2o} is constructed by selecting uniformly at random two row vertices for each column, and two column vertices for each row. These selections form the edges of B_{2o}. Given the edges of B_{2o}, Karp et al. define two multigraphs. The *Column-Graph* (CG) is the multigraph whose vertices are the rows, and whose edges are the choices of the columns. That is, there is an edge in CG for a column vertex in B_{2o}. Parallel edges occur if two columns select the same rows. The *Row-Graph* (RG) is defined similarly. The main idea to show that B_{2o} has a perfect matching is the following. In a component of CG that contains a cycle, it is possible to match all rows (vertices in CG) with one of the columns that have selected them (edges in CG). On the other hand in a tree component of CG, in any matching (pairing of edges with vertices) there will always be a free row vertex. As a consequence, when one or more trees appear in CG, the choices of the columns alone do not suffice to find a perfect matching, and those of the rows must be used. The algorithm thus keeps track of the tree components of CG and tries to identify one row vertex per tree component whose selections should be taken into account. The columns selected by such a row could be used for a set of rows belonging in tree components. Thus one should go back and forth identifying trees in CG and analyzing components in RG. Karp et al.'s algorithm, which is described in Algorithm 1, formalizes this approach.

The algorithm operates on H_1, a copy of CG, and H_2, a copy of RG initially devoid of edges. It furthermore uses two arrays `checked` for columns and `marked` for rows. These two arrays together signal whether a vertex will be matched with one of its two selections or not. More specifically, if a row vertex r is marked (i.e., `marked`[r]=true), then the algorithm will match r with one of its two selections. On the other hand, if a column c is checked (i.e., `checked`[c]=true), then the algorithm will match c with one of the marked row vertices that have selected it.

Initially, all row vertices are unmarked and all column vertices are unchecked. The algorithm at each step picks a tree from H_1 and marks one of its vertices x. This signifies that x can only be matched with one of its choices. Then, the edge of x is inserted in H_2. The algorithm then finds the component Q_x in H_2 containing the edge x, and selects an unchecked column y from Q_x. Column y is checked, which means that it can only be matched with a marked vertex. As y's choices are rendered useless now, the corresponding edge is removed from H_1 upon which new trees can arise. For each tree vertex x identified in H_1, one should be able to find a vertex in the associated component Q_x, so that x can be matched in that component. Otherwise, Q_x has more edges than vertices, and any matching of vertices with edges in Q_x will hence leave some edges unpaired. In other words, Algorithm 1 has decided that all columns that correspond to edges in Q_x should be matched with one of their two selections. However, the union of the rows denoted by these selections has cardinality strictly smaler than the number of such columns, and that is why a column is always left unmatched by the algorithm if this scenario occurs. The algorithm returns failure upon detecting this case (Line 10). The algorithm terminates successfully if all trees have a marked vertex. If this happens, each component in H_1 will have as many edges as unmarked vertices. Likewise, each component in H_2 will have as many edges as checked vertices. It is therefore possible to orient the edges in either H_1 or H_2 such that each vertex (excluding marked rows or unchecked columns) is matched with a unique adjacent edge. This gives a perfect matching in B_{2o}, which can be found by the Karp–Sipser heuristic in linear time. Algorithm 1 finds a perfect matching with probability $1 - O(n^{-\alpha})$, where α is a positive constant.

Algorithm 1 2OUTMC: Monte Carlo on 2-out graphs.

1: $H_1 \leftarrow CG$, $H_2 \leftarrow$ empty graph with columns as vertices;
2: All vertices in H_1 are unmarked, all vertices in H_2 are unchecked;
3: CORE $\leftarrow$ edges in cycles of CG
4: **while** there exists a tree T in H_1 with no marked vertex **do**
5: Let x be a random vertex of T ▶ x is a column vertex
6: `marked`$[x] \leftarrow$ true ▶ x must be matched with one of its choices
7: Add the edge of x in H_2
8: Let Q_x be the component in H_2 containing the edge of x
9: **if** Q_x has no unchecked vertices **then**
10: Return Fail ▶ Q_x has more edges than vertices (no 1-1 pairing possible)
11: **else**
12: Select an unchecked vertex y of Q_x. In case of ties, prefer one from CORE
13: `checked`$[y] \leftarrow$ true ▶ y will be matched with a row that selected it
14: delete y in H_1 ▶ The algorithm forgets y's choices
15: Create B'_{2o} from B_{2o} by keeping only edges between marked rows and checked columns (edges in H_2) or unmarked rows and unchecked columns (edges in H_1)
16: Apply Karp–Sipser on B'_{2o} to find a perfect matchin

The authors then describe how to efficiently implement the algorithm such that it runs in $O(n \log n)$ worst case time. They identify two main tasks:

- **Task A**: Keep track of the tree components during edge deletions in H_1.
- **Task B**: Keep track of the connected components during edge insertions in H_2, and the single unchecked vertex in each component.

Task B can be efficiently done in amortized near linear time (over the course of the algorithm) by using a union-find data-structure and keeping the identity of the single unchecked vertex in a component of H_2 at the root of the component. For Task A, Karp

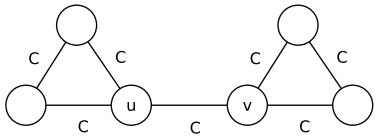

Figure 1 Algorithm 1 does not recognize new trees, if another edge is deleted after (u, v).

et al. propose the following. In the beginning, the edges of CG are labeled as $\mathcal{F}$, if their deletion creates a tree; $\mathcal{T}$, if they belong to a tree component; and $\mathcal{C}$ otherwise. Let c-degree of a vertex v be the number of $\mathcal{C}$ edges incident on v. During deleting the edge (u, v) from H_1, one of the following is performed depending on the label of (u, v).

- **Case 1**: (u, v) is $\mathcal{C}$: The c-degrees of u and v are decreased by one. Then, while there is a vertex with a single $\mathcal{C}$ edge; its $\mathcal{C}$ edge is relabeled as $\mathcal{F}$.
- **Case 2**: (u, v) is $\mathcal{F}$: Using a dove-tailed depth-first search, where depth-first searches from u and v are interleaved, the tree component created can be found in time proportional to its size. One then changes the labels of all edges in this tree from $\mathcal{F}$ to $\mathcal{T}$.
- **Case 3**: (u, v) is $\mathcal{T}$: Deleting (u, v) creates two trees. As in the previous case, a dove-tailed DFS is used to find these two trees in time proportional to the size of the smaller one. The new trees are to be examined by the algorithm.

We identify an oversight in this procedure, where the algorithm fails to keep track of some trees in H_1. We demonstrate this by an example. In Figure 1, if the edge between vertices u and v gets deleted, then the connected component is split into two triangles. The c-degree of both u and v decreases to two, and as both are greater to one, the deletion procedure stops without any action. However, both triangles are unicylic. If an edge is deleted from either triangle, then Case-1 does not recognize that the remaining edges should be relabeled as $\mathcal{T}$ not $\mathcal{F}$.

If Algorithm 1 is not able to keep track of all the trees in H_1, then it can exit the loop of Line 4 prematurely. As a consequence Karp–Sipser in Line 16 will return a suboptimal matching. We propose a fix for this oversight in Lemma 1.

▶ **Lemma 1.** *Let u be an endpoint of a deleted edge (u, v) with label $\mathcal{C}$. Apply the procedure of Case-1 until we arrive at a vertex p with* c-degree$[p] \neq 1$. *If* c-degree$[p] = 0$, *then u's component has become a tree.*

Proof. We claim that if c-degree$[p] = 0$, then p and v are the same vertex. Each vertex on the path from u to p had its c-degree affected twice (from 2 to 0), except p. Hence for p to become 0, its c-degree must have been equal to 1. If $p \neq v$, then p should had its $\mathcal{C}$ edge relabeled during another deletion process. Therefore, prior to the deletion of (u, v), there was a cycle on H_1 with all vertices having c-degree equal to 2, and both their $\mathcal{C}$ edges participated in the cycle. Any outgoing edges from vertices of the cycle therefore were labeled $\mathcal{F}$ and by definition, their deletion led to a tree being formed. The component was hence unicyclic before. ◀

Case 1-continuation is therefore as follows:

- Once there are no vertices with c-degree equal to 1, take the last vertex v whose c-degree was reduced. If c-degree$[v] = 0$, then relabel all edges in vs component from $\mathcal{F}$ to $\mathcal{T}$.

This addition has overall $O(n)$ cost, because each edge can change label at most twice.

3.1.2 Conversion to an efficient general heuristic

Algorithm 1 works well when the random 2-out graph is sampled from $K_{n,n}$. However, in the case of an arbitrary host graph, the underlying theory is not shown to hold, and the algorithm can make erroneous decisions. Here we discuss how to turn Algorithm 1 into a general heuristic. Apart from the aim of obtaining a practical heuristic for bipartite matching, there is another reason to investigate the matching problem in 2-out bipartite graphs. We show in Appendix D that an $O(f(n,m))$ time algorithm to find a maximum cardinality matching in a 2-out bipartite graph can be used to find a maximum cardinality matching in any bipartite graph with m edges in $O(f(m,m))$ time, where f is a function on the number of vertices n and edges m. Such a reduction is important because it shows that an algorithm for finding maximum cardinality matchings in 2-out graphs with similar complexity to 2OUTMC can be used to obtain an $O(m \log m)$ algorithm for matchings in general bipartite graphs.

If the algorithm reaches Line 10 during execution, it quits immediately before examining all trees in H_1. We instead propose to continue with the execution of the algorithm to make the returned matching as large as possible. To achieve this efficiently, we keep for each tree T a list L_T of unmarked vertices. At Line 5 we randomly sample x from L_T and discard it from L_T. Contrary to Algorithm 1, we neither mark x nor insert it in H_2 yet. Instead, we examine first whether the component in H_2 of either of the two choices of x has an unchecked column y. If y exists, we mark x, insert it to H_2 and continue by deleting y from H_1. Otherwise, we perform the same set of actions with another randomly sampled vertex from L_T. If L_T becomes empty, and no vertex was marked, we abandon T and proceed to another tree. Each such tree in the final state of H_1 decreases the cardinality of the returned matching by one, as a row is left free. If T is split into two trees, the lists of unmarked vertices for the new trees contain only those vertices still inside L_T at the moment of splitting. This is necessary to avoid sampling vertices more than once.

The overall algorithm 2OUTMC is as follows. It takes the matrix representation of the given bipartite graph and scales it with a few steps of the Sinkhorn–Knopp algorithm to obtain $\mathbf{A_S}$. It then chooses two random neighbors for each column and row using their respective probability distributions in the corresponding row and column of $\mathbf{A_S}$, which are given as input to Algorithm 1. Then, the auxiliary graph B_{2o} is constructed and Karp–Sipser is run on this graph to retrieve a maximum cardinality matching in B_{2o}. If one allows vertices to choose neighbors uniformly, then there are no guarantees on the maximum cardinality of a matching in B_{2o}. As an example, consider the graph where the ith row and ith column are connected for $i = 1, \ldots, n$, and additionally the first ℓ rows and columns are connected with every vertex on the opposite side. Then, in expectation $O(\frac{\ell-1}{\ell+1} \cdot n)$ rows (resp. columns) make both choices from the first ℓ columns (resp. rows), such that in the generated B_{2o} the maximum cardinality matching is of size $O(\frac{n}{\ell} + \ell)$. Using $\mathbf{A_S}$'s values to perform the random choices spreads the choices so that the maximum cardinality of the matching in the subgraph increases (see Theorem 2 and Lemmas 6–8 in [16] that examines the 1-out subgraph model).

In Appendix B we describe two heuristics for 2OUTMC which can lead to an increase in the cardinality of the returned matching. The main idea of both heuristics is to reduce the chance that an edge deletion in H_1 creates a new tree.

3.2 TruncRW: Truncated random walk with nonuniform sampling

3.2.1 Description of the algorithm for regular bipartite graphs

Goel et al. [18] propose a randomized algorithm (of the Las Vegas type) that finds a perfect matching in a d-regular bipartite graph with n vertices in each side in $O(n \log n)$ time in expectation. This algorithm starts a random walk from a randomly chosen free column-vertex.

At a column vertex c, the algorithm selects uniformly at random one of the row-vertices that are not matched to c, and goes to the chosen row vertex r. If r is free, then an augmenting path is obtained by removing possible loops from the walk. If r is matched, then the random walk goes to the mate of r. Goel et al. show that the total length of the random walks is $O(n \log n)$ in expectation, and thus the algorithm obtains a perfect matching in the stated time [18, Theorem 4]. They also show that one can obtain a Monte Carlo-type algorithm by truncating the random walks. The expected length of an augmenting path with respect to a given matching of cardinality j is $2(4 + 2n/(n - j))$, and the random walks could be truncated at this length to obtain near optimal matchings in $O(n \log n)$ time.

A random walk is easy to implement for d-regular bipartite graphs. At a column vertex c, one can create a random number between 1 and d in $O(1)$ time and choose the neighbor at that position, and repeat the experiment if the mate of c is chosen. This will take $O(1)$ time in expectation for each step of the walk, and the run time bound of $O(n \log n)$ is maintained.

Goel et al. show that the random-walk based algorithm will work for finding perfect matchings in the bipartite graph representation of a doubly stochastic matrix. They also suggest using an existing data structure [20] when the row and column sums are constant with nonnegative integer entries bounded by a polynomial in n, to attain an $O(n \log n)$ run time bound. A more recent paper [32] removes the restriction on the entries, and obtains an expected constant time per update and sampling. Further investigations and a careful implementation are necessary to apply the mentioned sampling approaches in our context. Instead, for general doubly stochastic matrices without any bound on the entries, Goel et al. propose an augmented binary search tree with which each selection step of the random walk can be implemented in $O(\log n)$ time, and obtain a run time of $O(m + n \log^2 n)$ in expectation, with a total of $O(m)$ preprocessing time.

3.2.2 Conversion to an efficient general heuristic

Let c be a free column vertex with respect to a given matching of cardinality j. Assuming there is a perfect matching, one can find an augmenting path to match c, and a random walk can find it. The $O(\frac{n}{n-j})$ bound on the expected length of such a path will not hold if the bipartite graph is not regular. One may perform more than m steps, which is the worst case time complexity of deterministically finding an augmenting path starting from a free vertex. We propose two methods to make the random walks more useful and to sample efficiently in a random walk. We also discuss an efficient implementation of the whole approach.

The first proposed method is to scale the matrix representation $\mathbf{A}$ of a given bipartite graph to obtain a doubly stochastic matrix $\mathbf{A_S}$ for random selections. The expected length of a random walk to find an augmenting path holds when $\mathbf{A_S}$ has bounded nonzero entries. In general, ones does not have any bound on the entries of $\mathbf{A_S}$. Consider the matrix $\mathbf{A}$ associated with an upper Hessenberg matrix of size n. $\mathbf{A}$ has a full lower triangular part, and additional $n - 1$ entries $\mathbf{A}(i - 1, i) = 1$ for $i = 2, \ldots, n$, and fully indecomposable. The 4×4 example along with its unique scaling matrices are shown in Fig. 2. In the resulting scaled matrix $\mathbf{A_S}(n, 1) = 1/2^{n-1}$ whose inverse is not bounded polynomially in n.

As highlighted at the end of Section 3.2, one needs an $O(\log n)$ time algorithm to select a row vertex randomly from a given column vertex. The second proposed method is a simple yet efficient algorithm for this purpose, rather than a sophisticated augmented tree. The main components of the proposed sampling method are as follows. For each column vertex c, with d_c neighbors, we have:

$$\begin{pmatrix} \sqrt{2} & & & \\ & \frac{1}{\sqrt{2}} & & \\ & & \frac{1}{\sqrt{8}} & \\ & & & \frac{1}{\sqrt{8}} \end{pmatrix} \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \end{pmatrix} \begin{pmatrix} \frac{1}{\sqrt{8}} & & & \\ & \frac{1}{\sqrt{8}} & & \\ & & \frac{1}{\sqrt{2}} & \\ & & & \sqrt{2} \end{pmatrix} = \begin{pmatrix} 1/2 & 1/2 & 0 & 0 \\ 1/4 & 1/4 & 1/2 & 0 \\ 1/8 & 1/8 & 1/4 & 1/2 \\ 1/8 & 1/8 & 1/4 & 1/2 \end{pmatrix}$$

Figure 2 The matrix $\mathbf{A}$ associated with a 4×4 Hessenberg matrix, the scaling matrices $\mathbf{D_R}$ and $\mathbf{D_C}$, and the resulting doubly stochastic matrix $\mathbf{A_S} = \mathbf{D_R A D_C}$. In general, $\mathbf{A_S}(n, 1) = 1/2^{n-1}$.

- $\mathsf{adj}_c[1, \ldots, d_c]$: an array keeping the neighbors of c.
- $\mathsf{wghts}_c[1, \ldots, d_c]$: the weight of the edges incident on c. This array is parallel to the first one so that the weight of the edge $(c, \mathsf{adj}_c[i])$ is $\mathsf{wghts}_c[i]$.
- $\mathsf{medge}[c]$: the position of the mate of c in the array adj_c, or -1 if c is not matched.

At the beginning, we compute the prefix sum of $\mathsf{wghts}_c[1, \ldots, d_c]$. After this operation, the total weight of the edges incident on c is $\mathsf{wghts}_c[d_c]$, and the weight of the edge $(c, \mathsf{mate}[c])$ is $\mathsf{wghts}_c[\mathsf{medge}[c]] - \mathsf{wghts}_c[\mathsf{medge}[c] - 1]$, assuming that $\mathsf{wghts}_c[0]$ signifies zero.

Given the prefix sums in $\mathsf{wghts}_c[1, \ldots, d_c]$, the position of the mate of c at $\mathsf{medge}[c]$, we can choose a random neighbor (which is not equal to $\mathsf{mate}[c]$) as shown in Algorithm 2. We use a binary search function, binSearch, which takes an array, the array's start and end positions, a target value, and returns the smallest index of an array element which is larger than the given value with binary search (we skip the details of this search function). At Line 5, since c does not have a mate, we search in the whole list. At Line 8, since the prefix sum just before $\mathsf{medge}[c]$ is larger than the target value, we search in the first part of wghts_c until the current mate located at $\mathsf{medge}[c]$. At Line 10, we search on the right of $\mathsf{medge}[c]$, by a modified target value. This last part is the gist of the algorithm's efficiency as it avoids updating the prefix sums when the mate changes.

Algorithm 2 Sampling a random neighbor of the column vertex c with d_c neighbors.

Require: $\mathsf{adj}_c[1, \ldots, d_c]$, $\mathsf{wghts}_c[1, \ldots, d_c]$, and $\mathsf{medge}[c]$.
1: mwght $\leftarrow \mathsf{wghts}_c[\mathsf{medge}[c]] - \mathsf{wghts}_c[\mathsf{medge}[c] - 1]$ if $\mathsf{medge}[c] \neq -1$, otherwise 0
2: totalW $\leftarrow \mathsf{wghts}_c[d_c] -$ mwght ▶ The total weight of the edges that can be sampled
3: create a random value rv between 0 and totalW
4: **if** $\mathsf{medge}_c = -1$ **then**
5: **return** binarySearch($\mathsf{wghts}_c[1, \ldots, d_c], rv$)
6: **else**
7: **if** $\mathsf{wghts}_c[\mathsf{medge}_c] -$mwght $\geq rv$ **then**
8: **return** binSearch($\mathsf{wghts}_c[1, \ldots, \mathsf{medge}[c] - 1], rv$)
9: **else**
10: **return** binSearch($\mathsf{wghts}_c[\mathsf{medge}[c] + 1, \ldots, d_c], rv +$ mwght$) + \mathsf{medge}_c$

The sampling algorithm returns the index of the neighbor in adj_c different from the current mate in time $O(\log d_c)$, independent of the values of the edges. It thus respects the required run time bound. If we were to apply the rejection sampling (as discussed before for the regular bipartite graphs), the run time would depend on the value of the matching edge that we want to avoid. This could of course lead to an expected run time of more than $O(n)$.

There are two key components of Algorithm 2. The first one is the prefix sum, which is computed once before the random walks start and does not change. The second one is $\mathsf{medge}[c]$, the position of $\mathsf{mate}[c]$ in adj_c. The value $\mathsf{medge}[c]$ changes and needs to be updated when we perform an augmentation. We handle this update as follows. We keep the random walk in a stack by storing only the column vertices, as the row vertices direct the walk to their mate, or terminate the walk if not matched. We discard the cycles from the random

walk as soon as they arise – this way we only store a path on the stack, and its length can be at most n. Storing a path also enables keeping the $\mathsf{medge}[\cdot]$ up-to-date. Every time we sample an outgoing edge from a column vertex c, we assign the location of the sampled row vertex in adj_c to a variable $\mathsf{nmedge}[c]$. When we find a free row, the stack contains the column vertices of the corresponding augmenting path, whose new mates' locations are in $\mathsf{nmedge}[\cdot]$ and thus can be used to update $\mathsf{medge}[\cdot]$.

The described procedure will work gracefully in expected $O(m + n \log n)$ time for regular bipartite graphs and for doubly stochastic matrices where the nonzero values do not differ by large. On the other hand, when there are large differences in edge weights, a random walk can get stuck in a cycle. That is why truncating the long walks is necessary to make the algorithm work for any given doubly stochastic matrix. Furthermore, such a truncation is necessary with the proposed matrix scaling approach for defining random choices. For the overall approach to be practical, we should not apply the scaling algorithms until convergence. As in the previous approaches [15, 16], we allot a linear time of $O(m + n)$ for scaling. Applying Sinkhorn–Knopp algorithm for a few iterations will thus be allowable. The known convergence bounds for the Sinkhorn–Knopp algorithm [27, Thm. 4.5] apply asymptotically, therefore we do not have any bounds on the error after a few iterations; it can be large. That is why truncation makes the random walk based augmenting path search practical.

The overall algorithm TruncRW is thus as follows. It takes the matrix representation of the given bipartite graph and scales it with a few steps of the Sinkhorn–Knopp algorithm. Then for $j = 0$ to $n - 1$, it uniformly at random picks a free column vertex, and starts a random walk starting from that column, for at most $2(4 + 2n/(n - j))$ steps, after which the walk is truncated. Some follow discussion and experiments with different parameters for TruncRW may be found in Appendix C.

4 Experiments

We implemented 2outMC and TruncRW in C/C++, and the codes are accessible from `https://gitlab.inria.fr/bora-ucar/fast-matching`. The codes, all are sequential, were compiled with "-O3" and run on a machine with 2 x Intel Xeon CPU Gold 6136 CPUs and 187 GB RAM. We evaluate 2outMC and TruncRW both on real-life and synthetic bipartite graphs with equal number of vertices in each side. We compared the two algorithms against KaSi, the widely used version of Karp–Sipser which applies degree-1 reduction (own implementation), and KaSi2, the original version of Karp–Sipser with both reduction rules. We use a publicly available implementation of KaSi2 (`https://gitlab.inria.fr/bora-ucar/karp--sipser-reduction`) which is the fastest of recent implementations [26, 29]. We note that there are other heuristics (a short summary and further references are in Appendix A) which deliver very good results in practice. For most of these heuristics, especially for those based on vertex degree, there are known worst case upper bounds close to 1/2. We therefore restrict the focus on KaSi and KaSi2, which are efficient and very effective in practice [14, 25, 30]. We also investigated if random 2-out bipartite graphs of a general host graph have perfect matchings if rows and columns select neighbors with the probabilities in the scaled matrix representation. The quality of a matching refers to the ratio of the cardinality of the matching to the maximum cardinality of a matching in a given graph. The practical version of Sinkhorn-Knopp is referred to as SK-t, where t is the number of allowed iterations. All run times are reported in seconds.

Table 1 We divide the real-life graphs into five groups. The ith group consists of graphs whose $\frac{m}{n}$ ratio is between $10(i-1)$ and $10i$. For each group, we give the number of instances in which a 2-out graph built using the models M_1 and M_2 has a perfect matching and the largest difference from the maximum cardinality of a matching.

$\frac{m}{n}$	[0,10)		[10,20)		[20,30)		[30,40)		[40,50)	
#Instances	27		5		5		1		1	
	#PM	deficiency	#PM	deficiency	#PM	deficiency	#PM	deficiency	#PM	deficiency
Model M_1	0	223	0	8	1	20	0	2	1	0
Model M_2	27	0	3	3	1	10	0	1	0	1

4.1 Investigation of perfect matchings in 2-out graphs

Here, we investigate the claim that G_2 will likely have a perfect matching for G, if created with the probabilities in the scaled matrix. We used a set of 39 large sparse square matrices from the SuiteSparse Collection [12], whose bipartite graphs have perfect matchings. These matrices are automatically selected from all square matrices available at the collection with $10^6 \leq n \leq 28 \times 10^6$, and with at least two nonzeros per row or column.

We consider two different models to create G_2. In the model M_1, row choices are independent of the column choices. Under this model, a row and a column can select each other resulting in parallel edges – only one of them is kept. The model M_2 tries to avoid parallel edges. In this model, all columns perform their selections. Then, each row r attempts to randomly choose two columns, only from those that did not select r. These selections again are based on the scaled matrix. In this model, parallel edges can arise (and be discarded) only when a vertex v is connected in the 2-out graph with all of its neighbors in G, because it is impossible for v to select otherwise. We experimented three times with each real-life graph. M_i's result is the maximum of those three experiments. In each test, we first created the choices of all columns. Then we allowed the two models to generate the choices of the rows accordingly.

The results are shown in Table 1 for the 39 real-life graphs and are with SK-5. As seen in this table, the random G_2 graphs generated with the model M_1 have near perfect matchings, but they do not contain perfect matchings in most cases. In contrast, the random G_2 graphs generated by M_2 in many cases contain a perfect matching. In only a few graphs this does not hold true, and in these cases the deficiency is no more than 10.

4.2 On synthetic graphs

In Table 2, we give results with a synthetic family $\mathcal{I}$ of graphs from literature [16], whose matrix representations do not have total support. To create a member of $\mathcal{I}$, we separate the vertex set R into $R_1 = \{r_1, \ldots, r_{n/2}\}$ and $R_2 = \{r_{n/2+1}, \ldots, r_n\}$ and likewise for C. All vertices of R_1 are connected to all vertices of C_1. Edges $(r_i, c_{n/2+i})$ and $(r_{n/2+i}, c_i)$ for $i = 1, \ldots, n/2$ are added to introduce a perfect matching. A parameter h is used to connect h vertices from R_1, and h vertices from C_1 to every vertex on the opposite side.

As seen in Table 2, KaSi and KaSi2 have more and more difficulty with increasing h. The matching quality drops over 30% between $h = 2$ and $h = 512$ for KaSi and almost 40% for KaSi2. On the contrary, 2outMC and TruncRW both obtain a near perfect matching, with SK-5. Even though the matrices associated with the graphs of $\mathcal{I}$ lack total support, SK-5 sufficed to obtain near optimal matchings. We notice the effect of scaling: if vertices select without scaling (Uniform), the matching quality reduces. This is particularly true for 2outMC, which exhibits the worst overall performance with uniform selection. Family

Table 2 Average quality of the matchings found by the algorithms on graphs from the synthetic family $\mathcal{I}$ for $n = 30000$ and various values of h.

			2OUTMC		TRUNCRW	
h	KASI	KASI2	Uniform	SK-5	Uniform	SK-5
2	0.93	1.00	0.78	0.99	0.88	0.99
8	0.80	0.85	0.59	0.99	0.91	0.99
32	0.69	0.72	0.52	0.99	0.83	0.99
128	0.64	0.65	0.51	0.99	0.78	0.99
512	0.61	0.63	0.52	0.99	0.76	0.99

Table 3 Average quality of the matchings found by the algorithms on graphs from the synthetic family $\mathcal{J}$ for $n \in \{10000, 20000, 30000\}$.

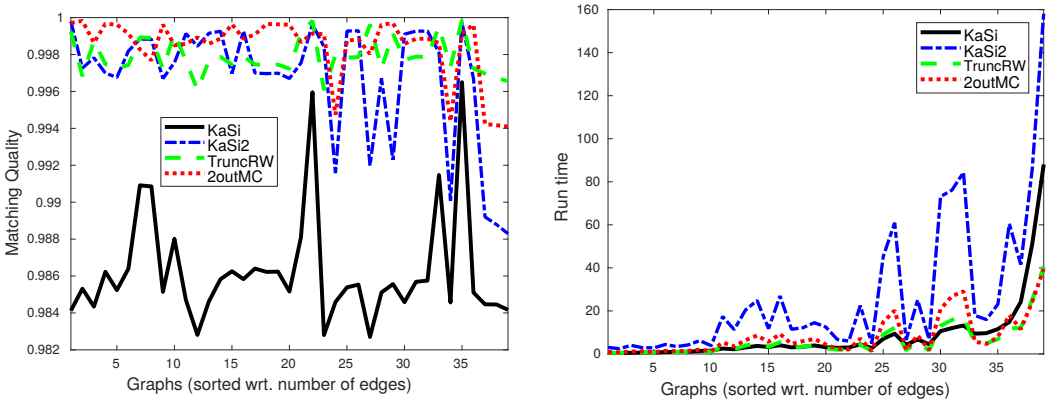
$\mathcal{I}$ shows the importance of scaling, and more importantly highlights the robustness of the proposed methods. An adversary can create graphs which make degree-based randomized approaches lose quality – some of those heuristics are briefly mentioned in Appendix A, and the full details including negative results on KASI2 can be found elsewhere [9]. On the other hand, the use of scaling helps to avoid such cases for 2OUTMC and TRUNCRW.

We now discuss another synthetic family of graphs $\mathcal{J}$ in which the proposed approaches obtain matchings of much higher quality than KASI and KASI2. A bipartite graph with n vertices per side belonging to $\mathcal{J}$ contains the following edges: (r_i, c_j) for all $i \leq j$; (r_2, c_1), (r_n, c_{n-1}); (r_3, c_1), (r_3, c_2), (r_n, c_{n-2}); and (r_{n-1}, c_{n-2}). The graphs in $\mathcal{J}$ are hard for Karp–Sipser-based heuristics because only few of the edges participate in a perfect matching, the deterministic rules do not apply, and hence they resort to multiple suboptimal random decisions. Likewise, due to the large number of entries without support in the matrix representation, Sinkhorn–Knopp will take many iterations to properly scale the matrix.

In Table 3, we give results of the algorithms for a few graphs from this family. In the table, we also show the effects of scaling on 2OUTMC and TRUNCRW by showing results without scaling (under column "uniform", in which a column vertex chooses a neighbor uniformly at random), with SK-5, and with SK-20. As can be seen, despite the lack of total support, both 2OUTMC and TRUNCRW obtain matchings whose cardinality is more than 0.92 of the maximum, when SK-5 or SK-20 is used. TRUNCRW in particular is nearly optimal. These results are always better than that of KASI and KASI2, with the difference in matching quality being about 20–25% for the former, and 10–15% for the latter. With increased iterations of Sinkhorn–Knopp, 2OUTMC increases the cardinality of its matchings by 3%. If we do not use scaling ("uniform"), while there's no noticeable effect on TRUNCRW's matchings, 2OUTMC matchings decrease by roughly 10%. Even so, its results remain better than KASI's and on par with those of KASI2.

4.3 On real-life graphs

We compared TRUNCRW and 2OUTMC with KASI and KASI2 on all 39 real-life graphs from Section 4.1. Figure 3a and Figure 3b present the high level picture. For the experiments, we did not permute the matrices randomly, which generally increases the experimentation time.



(a) Quality results. **(b)** Run time results.

Figure 3 Quality (left) and run time (right) results for all 39 graphs from Section 4.1.

The results for matching quality can be seen in Figure 3a, where we plot the ratio of the cardinality of the matchings found by different algorithms to the maximum cardinality of the matching. The graphs are indexed in nondecreasing number of edges. 2OUTMC and TRUNCRW use SK-3 for scaling. As can be observed, both 2OUTMC and TRUNCRW obtain near perfect matchings. The average matching quality obtained by 2OUTMC is 0.9979 and that obtained by TRUNCRW is 0.9984. Both algorithms never drop below 0.9900 in any of the 39 cases.

Figure 3a also shows the matching quality of KASI2 and KASI. KASI obtains matchings of quality 0.9862 on average, with always smaller cardinality than TRUNCRW and 2OUTMC. KASI2 fares better and its average quality is 0.9968. Even so, in the majority of cases, it obtains matchings that are inferior quality-wise to both TRUNCRW and 2OUTMC.

While all algorithms obtain matchings of high quality, the absolute different is remarkable in some cases. For example, the largest difference observed between the matching cardinalities obtained by 2OUTMC and KASI was 346577, in favor of 2OUTMC.

Figure 3b shows the run time of all examined heuristics, where the graphs are again indexed in nondecreasing number of edges. KASI is in general the fastest of these four algorithms when there are not too many edges. TRUNCRW and 2OUTMC are close run-time wise to KASI and in some instances faster than it. This is especially true in instances with many edges because KASI depends more on m. KASI2 has the slowest performance overall.

For a detailed study, we show results on the five largest graphs from the mentioned dataset and `Circuit5M`, which was identified as a challenging instance in earlier work [25]. Degree-1 vertices from `Circuit5M` are removed by applying Rule-1 of KASI2 as a preprocessing step – this is without loss of generality of the heuristics. For each graph we relabeled its row-vertices randomly and executed five tests with each algorithm.

Table 4 shows the matching quality and the run time of the four heuristics. 2OUTMC and TRUNCRW used SK-3 for this set of experiments for speed. For each graph, we give the minimum, maximum, and averages over five runs. As already discussed, all heuristics obtain high quality matchings. On a closer look, we see that TRUNCRW, on average, matched 158410 more edges than KASI, and 50847 more edges than KASI2. Similarly 2OUTMC matched 139220 more edges than KASI on average, and 31652 more edges than KASI2. Interestingly, on graph `Channel-500` TRUNCRW was able to find the maximum matching.

Table 4 Full run time comparisons with heuristics for the graphs of Section 4.3. The run time of SK-3 should be added to TruncRW and 2outMC. For each instance we give the minimum, the average, and the maximum of five runs for all columns regarding the quality and the run time. The number of vertices n per side is in the order of millions. `Hugebub-20` stands for `Hugebubbles-0020`.

Concerning run time, as KaSi is a linear time heuristic it is expected to be the fastest. Surprisingly, TruncRW even with the scaling time added is faster than KaSi in three instances. This is due to the fact that each iteration of the scaling algorithm takes linear time with small constants. As an algorithm on its own (without scaling time), TruncRW becomes the fastest one, thanks to its run time not depending on m after the initialization. 2outMC, though slower, also exhibits good behavior, except in `nlpkkt240`. KaSi2 has the worst run time overall. Its initialization takes more time, and its implementation is more involved. SK-3 is fast except for `nlpkkt240` where it requires about 30 seconds. The reason that SK-3 requires 30 seconds for this particular graph is due to the random permutation of its rows, which is not cache-friendly (if SK-3 is run on `nlpkkt240` using the initial ordering of rows, it finishes in less than 10 seconds). In the other cases and despite the large size of the graphs, scaling finishes in less than seven seconds. Table 4 additionally shows that TruncRW and 2outMC's run time performance does not seem to be affected by their random decisions. The largest difference between the result of the minimum, and the maximum run is no more than two seconds for both of these algorithms.

Combined with the results in the previous section, we conclude thus that (i) 2outMC and TruncRW always obtain near perfect matchings, while KaSi and KaSi2 are not as robust; (ii) 2outMC and TruncRW are nearly as fast as the linear time algorithm KaSi, and are much faster than KaSi2.

Next, we consider the impact of our heuristics as initialization to an exact algorithm for finding a maximum cardinality matching. We first run the heuristics to obtain an initial matching, then call an exact algorithm to augment the initial matchings for maximum cardinality. We consider three different exact algorithms MC21, PR, and PF+ for the augmentation steps. MC21 [13] from `mmaker` [14, 25] visits free vertices one by one and tries to match the visited vertex with a depth-first search, and hence is closely related to TruncRW. In this setting, differences among the qualities of initial matchings should

be observable while computing an exact matching. PR [25] is based on the Push-Relabel method [19], and PF+ which is a depth-first search based method [14, 36]. The last two algorithms are more elaborate than MC21, and the cardinality difference between two different initial matchings does not necessarily correlate with the run time.

The statistics of five runs with MC21 are given in Table 5. In this table, the time spent in augmentations is given in column "augment.". The overall time to compute a maximum cardinality matching is given in column "overall', which includes the time spent in heuristics – in case of 2OUTMC and TRUNCRW it includes the scaling time as well. The runs on `nlpkkt240` did not finish within an hour and are not presented. As seen in the table, the overall time to obtain a maximum cardinality matching is always the smallest with TRUNCRW initialization. 2OUTMC is usually competitive with the faster of KASI2 and KASI, without a clear winner. It is also interesting to note that in all graphs the worst behavior of TRUNCRW is better than the best behavior of KASI2 and KASI and in some cases (see `cage15` or `Channel-500`) significantly so. The same is almost true for 2OUTMC as well except for graphs `Delaunay_24` and `Hugebbubles-0020` where 2OUTMC's worst result is only a few seconds slower than KASI's best result, or `cage15` versus KASI2.

In Table 6, we observe the behavior of the heuristics when used for initializing the PF+ algorithm. The table shows the minimum, average, and maximum time over the five runs. As can be observed, TRUNCRW exhibits the best overall behavior. TRUNCRW has the fastest performance in four out of six instances, and in the remaining two instances it is very close to KASI. The largest difference between the two can be observed in `nlpkkt240` where KASI is overall almost 50 seconds slower. The total run time with KASI2 is never better than that with TRUNCRW. It roughly takes the same amount of time for PF+ to augment 2OUTMC's initial matching, as it takes for it to augment the matching of TRUNCRW. Therefore, when 2OUTMC has a run time similar to TRUNCRW their overall run times are similar. In the largest of instances 2OUTMC's and TRUNCRW's performance diverge, but 2OUTMC's overall behavior is superior to KASI2 and competitive with that of KASI.

In Table 7, we observe the behavior of the heuristics when used for initializing the PR algorithm. The behavior of KASI in `Circuit5M` demonstrates the robustness of our approaches. The average behavior of PR initialized with KASI is 339 seconds with the maximum run time exceeding 500 seconds. In stark contrast, PR with TRUNCRW's input never needs more than 25 seconds, whereas with 2OUTMC it never surpasses 150 seconds. In the remaining instances, the proposed algorithms are competitive with KASI or even faster.

In summary, the effects of the proposed methods as an initialization routine are more observable with MC21 on all instances. With PF+, we see that the augmentations take less time on average with 2OUTMC and TRUNCRW, but the overall time with KASI can be sometimes better than that of TRUNCRW slightly thanks to KASI being faster. When PR is used, the augmentations take less time with KASI in three instances compared to TRUNCRW; and in four instances compared to 2OUTMC. When 2OUTMC and TRUNCRW serve better than KASI as an initialization to PR, the difference is more significant. The above results with three different algorithms demonstrate the merits of the two proposed algorithms for use as initialization routines in exact matching algorithms.

5 Conclusions

We have examined two randomized algorithms for the maximum cardinality matching problem in bipartite graphs. These algorithms originally were designed for two very special classes of bipartite graphs. We have discussed how to convert them into efficient and effective heuristics.

Table 5 Detailed run times when MC21 is used for augmentations on the graphs described in Section 4.3. The quality of heuristics are in Table 4. We have omitted graph `nlpkkt240` for which MC21 did not finish within a reasonable amount of time. For each instance we give the minimum, the average, and the maximum run time of five runs. `Hugebub-20` stands for `Hugebubbles-0020`.

Our experimental results show that these approaches obtain near perfect matchings in real-life and synthetic instances and have a near linear time run time. The two approaches are also shown to be more robust than the state of the art heuristics used in the cardinality matching algorithms, and are generally more useful as initialization routines.

Our adaptation of 2outMC is based on the premise that 2-out graphs sampled from a host graph have perfect matchings, assuming that the matrix representation of the host graph have total support. We showed evidence that this may be true and even if not, the sampled graphs have close to perfect matchings. A proof or the disproof of such 2-out graphs having perfect matchings is certainly welcome. Furthermore, this was the first attempt to implement 2outMC, and there is room for improved performance.

A Other heuristics for bipartite matching and recent work

In the main text, we compared the proposed heuristics with KaSi and KaSi2. There are a few other effective heuristics, which we briefly review here (see a recent survey [37]).

Hopcroft and Karp's original algorithm [21] proceeds in phases. At each phase, it finds shortest augmenting paths, and augments the current matching along a maximal set of disjoint such paths, where each phase runs in $O(n+m)$ time. Stopping when the shortest augmenting paths is of length $2k+1$ at a phase no larger than k results in an $1-1/(k+1)$ approximate matching in $O(k(m+n))$ time in the worst case. Greedy [39] chooses a random edge and matches the two endpoints and discards both vertices and the edges incident on them. Modified Greedy [39] chooses a free vertex and then randomly matches it to one of the available neighbors. MinGreedy [39] (see also Magun [31] and Langguth et al. [30] for related algorithms) improves upon Modified Greedy by selecting a random vertex with the minimum degree at the first step. The Greedy-like algorithms obtain maximal matchings and therefore are $1/2$ approximate. Slight improvements in the form of $1/2+\varepsilon$ are shown for these algorithms [2, 35], but there are theoretical bounds in the same vicinity [9]. Duff et al. [14] and Langguth et al. [25, 30] compare these algorithms for initialization in maximum cardinality matching algorithms and suggest using KaSi as initialization for general problems especially with the push-relabel based algorithms.

Another class of heuristics use randomization for breaking the 1/2 barrier. RANKING [24] algorithm achieves an approximation ratio of $1 - 1/e$, where e is the base of the natural logarithm. The same approximation ration is also achieved by a very simple parallel algorithm [16] whose most involved step is the application of a matrix scaling algorithm. This last paper also proposes an algorithm based on sampling 1-out subgraphs of a general bipartite graph (as we did in this paper) to obtain matchings of size about 0.86 times the maximum cardinality.

Matching has stirred some recent interest in the theoretical computer science community, with works focusing on parallel and distributed settings [4, 5, 11, 3] or on the fully dynamic version [6, 8] among others. Among the recent work, a method by Assadi et al. [4] shares similarities with the 2OUTMC algorithm. Their approach similarly sparsifies a given graph G to produce a subgraph with some approximation guarantees for the maximum cardinality matching. A detailed experimentation with this sparsification approach will reveal useful.

B Further comments on 2outMC

As demonstrated in the experiments in Section 4, 2OUTMC obtains matchings of very high cardinality. We can improve its matching quality by the following two heuristics. These two heuristics are not used in the given experiments. We plan to improve their run time.

B.1 Heuristic 1: Delayed tree vertex selection during Line 5

The ideal case at Line 5 of Algorithm 1 is to select an x such that x's insertion as an edge to H_2 does not lead to a new tree in H_1 after the deletion of the edge corresponding to the unchecked vertex of the connected component Q_x. This is only possible if Q_x contains an unchecked column labeled as $\mathcal{C}$ in H_1. Otherwise, a new tree will be created in H_1, and the algorithm will have to process it in a future step. For the first heuristic, we greedily select an x such that, if possible, the creation of a tree in H_1 is avoided.

We replace L_T is with two lists L_T^1 and L_T^2. The lists L_T^1 contains those unmarked vertices of T whose insertion in H_2 leads to a new tree; L_T^2 contains all other L_T vertices that have not been tried yet. At first, we sample x from L_T^2 and see whether the components of x's choices in H_2 have an unchecked vertex of type $\mathcal{C}$ in H_1. If they have, x is marked and inserted to H_2. Otherwise, x is inserted in L_T^1, and we consider another random vertex of L_T^2. If L_T^2 becomes empty, we start sampling from L_T^1.

With the union-find data structure, this heuristic requires constant amortized time per sample and each vertex can be sampled at most twice. Therefore the overhead associated with this heuristic is almost linear in n.

B.2 Heuristic 2: Online creation of the RG multigraph

In this heuristic, the decisions of the rows are not given as input, but are instead defined during the course of the algorithm. Similar to the previous idea, this heuristic aims to reduce the possibility that a tree in H_1 gets created following an edge insertion into H_2.

More specifically, consider a vertex x randomly chosen at Line 5. In this heuristic, x has not picked its two choices yet, and we let x choose them at this point, in the way that benefits the algorithm the most. This is done as follows. Initially, we iterate over all of x's neighbors in the host graph G. Let c be one of x's neighbors and c^* be the sole unchecked vertex in c's connected component in H_2, or $c^* = -1$ if no unchecked vertices exist. We assign values to x's neighbors to classify them. If c^* is equal to -1, c's value is 0. If c^* has

label $\mathcal{F}$ or $\mathcal{T}$ in H_1, c's value is 1. Otherwise, c's value is 2. Based on these assigned values, we partition the neighbors of x in G into three disjoint sets C_0, C_1 and C_2 such that C_i contains all neighbors of x with value equal to i. Selecting columns from C_2 is preferred, as they can avoid creating a tree in H_1. Vertex x will attempt to sample first from C_2, and if needed from C_1 or C_0, with a preference for C_1 over C_0. The sets C_0, C_1 and C_2 are kept implicitly, and each vertex x requires amortized $O(d_x)$ to make its choices, where d_x is its degree. Hence, the overhead associated with this heuristic is almost linear in m.

B.3 Comparison with 2outMC

Here, we briefly discuss the effects that the above two heuristics have on the performance of the 2OUTMC algorithm. Since 2OUTMC obtains high quality results, the two heuristics can only yield a relatively small improvement. When they are enabled and used with SK-5 2OUTMC finds matchings with average quality of 0.9997 for the real-world graphs from Section 4.3 for which 2OUTMC obtained matchings of quality 0.9983. This difference corresponds to about 13113 additionally matched edges, and hence signals that 13113 augmentations are avoided.

It is also interesting to consider the effects that these heuristics can have on cases where 2OUTMC did not deliver near-optimal matchings. As an example, we consider the synthetic family $\mathcal{J}$ from Section 4.2. When scaling was not enabled, 2OUTMC found matchings of average cardinality $0.80 - 0.81\%$ of the maximum. If however one uses the two heuristics proposed in this section, then there is a significant improvement in performance, and 2OUTMC finds matchings of cardinality 0.89 of the maximum.

C Further comments on TruncRW

We incorporated a known heuristic called look-ahead [13, 14] for speeding up the augmenting path search in practice. All our experiments with TRUNCRW in Section 4 were with the look-ahead approach. In this heuristic, before sampling an arbitrary row-vertex from a column-vertex c, we check if there is a free row vertex in the adjacency list of c. If so, such a row is returned, and the random walk terminates. The implementation of this heuristic has a total overhead of $O(m)$ for the whole course of the algorithm [13, 14]. We note that the look-ahead technique trades the quality of TRUNCRW with run time. In our experiments, the look-ahead heuristic reduced the run time significantly; it interferes with the randomization though.

We can easily apply TRUNCRW to bipartite graphs with different number of vertices in each side. This is based on the fact that we can scale a rectangular $n_1 \times n_2$ matrix (say $n_1 \geq n_2$) so that all columns have sum of 1, and all rows have equal sum of n_2/n_1, if there is matching covering all columns, and all entries can be put in such a matching. Then, all components of TRUNCRW work without any change.

If there is no total support, then Sinkhorn–Knopp works in such a way that the entries that cannot put into a perfect matching tend to zero. This is helpful in TRUNCRW's context, as the corresponding edges will not likely be selected in a random walk. If there is no perfect matching, then little is known about scaling. It is our experience that the Sinkhorn–Knopp iterations tend to zero out entries that cannot be put into a maximum cardinality matching. Therefore, in this case again, scaling, random selection, and truncation should help. We present some experiments to support this observation and leave the question of showing this theoretically as an open problem.

We experimented with bipartite graphs without total support which correspond to square (10000×10000) and rectangular matrices (12000×10000) with a uniform nonzero distribution. These matrices are generated with `sprand` command of Maltab and have about $d \times 10000$

Table 8 The quality of TruncRW on bipartite graphs without perfect matchings.

	10000 × 10000		12000 × 10000	
d	sprank	TruncRW	sprank	TruncRW
2	7787	0.9888	8724	0.9919
3	9266	0.9697	9667	0.9958
4	9761	0.9828	9899	0.9995
5	9918	0.9922	9973	1.0000

nonzeros for $d = 2, 3, 4, 5$. The matrix representation of the bipartite graphs were scaled with 10 iterations of SK. For each d, we created five random matrices and ran TruncRW on the corresponding five instances. We report the worst quality of the five instances in Table 8. As seen in this table, TruncRW works just fine for this case. We did not report in the table but with increased SK iterations, the results improve, which is in accordance with earlier work [16].

C.1 Engineering TruncRW

The experiments here are on real-life instances from Subsection 4.3 and with SK-5.

Recall that TruncRW tries to find an augmenting path starting from a column vertex a certain number of times before giving up and moving to the next column vertex. When we allowed TruncRW just a single attempt, it was unable to find a perfect matching in any of the cases, and its average matching quality was 0.9984. When we allowed five attempts, TruncRW found a perfect matching for 13 graphs, and its average matching quality was 0.9999. With 10 attempts, it managed to find a perfect matching in 5 additional graphs. This verifies that allowing more attempts indeed improves the performance of the algorithm. The drawback, however, was the increased run time, which we did not think worth. That is why our implementation of TruncRW starts a random walk from a vertex only once.

We also test the effects of the look-ahead mechanism. Let us define the walk efficiency of TruncRW as the ratio of the cardinality of the matching found to the total length of the random walks. The higher this ratio, the more useful the random walks are. We evaluate the walk efficiency on a set of seven instances (real-life instances having at most 10000000 edges). We test both with and without scaling and report the results of the 14 tests. In 13 cases, the look-ahead mechanism improved the walk efficiency. The geometric mean (of 14 cases) of the ratios of walk efficiencies with look-ahead to that of without was 1.37. In the case where the look-ahead did not help (ratio was 0.71 in an instance named `Hamrle3`), the maximum deviation of a row or column sum from one after SK-5 was 0.28, which is high. We conclude that the look-ahead mechanism is very helpful.

Finally we test the effects that the length of the augmenting walk has on TruncRW. We doubled the allowed length of a random walk to $4(4 + 2n/(n - j))$. On average, the matching quality rose from 0.9984 to 0.9998. This modification was not able to find a perfect matching in any of the 39 instances. This led to an increase in the run time, which we deemed too large. We therefore keep $2(4 + 2n/(n - j))$ as the truncation length.

D Reducing bipartite graph matching to matching on 2-out graphs

Here, we prove our claim in Section 3.1 that bipartite matching can be reduced to matching on a 2-out bipartite graph. Let $G = (V_G, E_G)$, with be a graph with minimum degree at least two. If G's minimum degree is one, we can apply the first deterministic rule of Karp–Sipser to match degree-1 vertices with their neighbors and consider as G the resulting graph.

We produce a new graph G' from G in the following way. For any edge $e = (a, b) \in E$ we add edges $e' = (a, a_e)$, $e'' = (a_e, b_e)$, and $e''' = (b_e, b)$ to G'. We hence introduce two new vertices a_e, b_e s.t $d_{G'}(a_e) = d_{G'} = 2$ for each edge $e \in E_G$. The degree of nodes in V_G remains unchanged in G'.

▶ **Lemma 2.** *Let H be a random 2-out subgraph G'. Then $H = G'$.*

Proof. The added vertices a_e, b_e have degree two and will select both neighbors, hence no edge will remain unpicked. ◀

In what follows, we refer to the second reduction rule of Karp–Sipser which merges the neighbors of a degree-2 vertex, which is then discarded, as a degree-2 reduction.

▶ **Lemma 3.** *It is possible to obtain G by doing only degree-2 reductions on G'.*

Proof. Let a_e be a vertex of G', introduced due to the edge $e = (a, b)$. Since $d_{G'}(a_e) = 2$ we can apply a degree-2 reduction which will merge a with b_e to create a single node ab_e. As a consequence of this merge, the edge (ab_e, b) will be created and edges $(a, a_e), (a_e, b_e), (b_e, b)$ will be erased. We simply relabel ab_e to a again. The proof then follows similarly by applying degree-2 reduction for all a_e corresponding to $e \in E$ until we obtain G. ◀

Now we show that maximum matchings in G' are related to those on G and vice versa.

▶ **Lemma 4.** *Any maximum cardinality matching M' on G' corresponds to a maximum cardinality matching M on G.*

Proof. Let M' be a maximum cardinality matching on G'. A matching M for G can be generated in the following way: If both (a, a_e) and (b_e, b) appear in M', e is added to M. Hence it suffices to show that any maximum cardinality matching M' in G' necessarily contains $|M|$ pair of matched edges (a, a_e) and (b, b_e).

First, we have that $|M'| = |E_G| + |M|$. To see this, note that per Lemma 2 we perform $|E_G|$ degree-2 reductions, and result in G. Each of this reductions corresponds with a matched edge in M'. Then, we only need to find the maximum cardinality on G which is $|M|$.

Let S_a contain all indices e such that (a, a_e) is in M' and (b_e, b) is not in M'. Set S_b is defined similarly. Set $S_\emptyset$ contains all indices e such that (a_e, b_e) appears in M'. Finally, S_{ab} contains all indices e such that (a, a_e) and (b, b_e) are matched together in M'. Then, since M' is a maximum cardinality matching we have

$$|S_a| + |S_b| + |S_\emptyset| + 2 \cdot |S_{ab}| = |E_G| + |M| \ .$$

This is true because of the fact that for each edge e exactly one matched edge appears in M' in case $e \in S_a \cup S_b \cup S_\emptyset$ and two edges are added if $e \in S_{ab}$.

However, $|S_a| + |S_b| + |S_\emptyset| + |S_{ab}| = |E_G|$, since each edge e must appear in one of those sets and there exist exactly $|E_G|$ of them.

Hence, $|S_{ab}| = |M|$ necessarily. As they define a matching in G and their cardinality is $|M|$, the matching is maximum. ◀

Using the above lemma, we can prove Theorem 5 below.

▶ **Theorem 5.** *Assume there is an algorithm* `ALG` *working in $O(f(n, m))$ time for finding a maximum cardinality matching in a 2-out graph. Then we can find a maximum cardinality matching in $O(f(m, m))$ time for any given graph.*

Proof. Let G be any bipartite graph without degree-1 vertices and $m = |E_G|$. In $O(m)$ time we generate G'. By Lemma 2, the 2-out subgraph of G' corresponds to G' itself. In addition $|E_{G'}|, |V_{G'}| \in O(m)$. Using `ALG`, we can find a maximum cardinality M' for G' in $O(f(m, m))$ time. By Lemma 4 then, we can convert M' to a maximum cardinality matching M for G in $O(m)$ time. ◀

As a byproduct of Lemma 4, we observe that the transformation of G to G' also eliminates the need to perform SK as a preprocessing step. We briefly experimented with this method on the real-world graphs of Section 4.3. For each graph G of the test-set, we generated its extension G' and executed the 2OUTMC algorithm on 2-out graphs sampled from G', with uniform selections. The behavior of 2OUTMC was similar with that of the previous experiments. It was not able to obtain a perfect matching in G' (and consequently G), but it always returned near-optimal matchings of quality over 0.99. These matchings, when converted into matchings of G (following the idea in Lemma 4) yielded also near-optimal matchings with quality over 0.99.

Efficient Computation of 2-Covers of a String

Abstract

Quasiperiodicity is a generalization of periodicity that has been researched for almost 30 years. The notion of cover is the classic variant of quasiperiodicity. A cover of a text T is a string whose occurrences in T cover all positions of T. There are several algorithms computing covers of a text in linear time. In this paper we consider a natural extension of cover. For a text T, we call a pair of strings a 2-cover if they have the same length and their occurrences cover the text T. We give an algorithm that computes all 2-covers of a string of length n in $\mathcal{O}(n \log n \log\log n + \mathsf{output})$ expected time or $\mathcal{O}(n \log n \log^2 \log n / \log\log\log n + \mathsf{output})$ worst-case time, where output is the size of output.

If (X, Y) is a 2-cover of T, then either X is a prefix and Y is a suffix of T, in which case we call (X, Y) a ps-cover, or one of X, Y is a border (that is, both a prefix and a suffix) of T, and then we call (X, Y) a b-cover. A string of length n has up to n ps-covers; we show an algorithm that computes all of them in $\mathcal{O}(n \log\log n)$ expected time or $\mathcal{O}(n \log^2 \log n / \log\log\log n)$ worst-case time. A string of length n can have $\Theta(n^2)$ non-trivial b-covers; our algorithm can report one b-cover per length (if it exists) or all shortest b-covers in $\mathcal{O}(n \log n \log\log n)$ expected time or $\mathcal{O}(n \log n \log^2 \log n / \log\log\log n)$ worst-case time. All our algorithms use linear space.

The problem in scope can be generalized to $\lambda > 2$ equal-length strings, resulting in the notion of λ-cover. Cole et al. (2005) showed that the λ-cover problem is NP-complete. Our algorithms generalize to λ-covers, with (the first component of) the algorithm's complexity multiplied by $n^{\lambda-2}$.

1 Introduction

Identifying repetitive structure of a string is one of the key research areas of text algorithms, with applications to computational biology; see e.g. the books [19, 28]. Processing of a string that has a regular structure can be performed more efficiently, be it for pattern matching or for data compression.

The most elementary notion that grasps repetitiveness is *periodicity*. If a string can be generated by repeated concatenation of its smaller piece, then we say that it is periodic. The field of periodicity has been expanded upon by allowing not only concatenation, but also superpositions, which resulted in the introduction of *quasiperiodicity* by Apostolico and Ehrenfeucht [6].

The basic terms of quasiperiodicity are the notions of *cover* and *seed*. A cover of a text T is a string whose occurrences in T cover all positions of T, while a seed of T is a cover of some superstring of T. An $\mathcal{O}(n)$-time algorithm for computing the shortest cover of a text of length n was presented by Apostolico et al. [7]. Moore and Smyth showed that all the covers of a string can be computed in $\mathcal{O}(n)$ time [43, 44, 45]. Moreover, $\mathcal{O}(n)$-time algorithms for computing covers of all prefixes of a string were shown [13, 41]. Seeds were introduced by Iliopoulos et al. [33] who showed an algorithm for finding a representation of all seeds of a string in $\mathcal{O}(n \log n)$ time. The majority of these classic algorithms were developed in the 1990s. It was not until many years later that an $\mathcal{O}(n)$-time algorithm for computing seeds was found [36, 37]. Various approximate variants of covers and seeds were studied – see e.g. [3, 4, 16, 25, 38, 39] – as well as covers in other models of computation [10, 14, 26], in non-standard stringology [1, 9, 20, 31, 32] and in 2-dimensional texts [21, 47].

We consider *2-covers* which are a natural generalization of covers. A 2-cover of a text T is a pair of equal-length strings whose occurrences in T cover all positions of T; see Figure 1. A yet more general notion of a λ-*cover*, that is, a λ-tuple of strings whose occurrences cover the whole text T, was introduced by Iliopoulos et al. in [27, 49]. Unfortunately, the authors' $\mathcal{O}(n^2)$ time algorithm for finding all λ-covers under fixed λ and constant-size alphabet has been proven to be faulty. In reality, the algorithm has, at worst, exponential runtime [23].

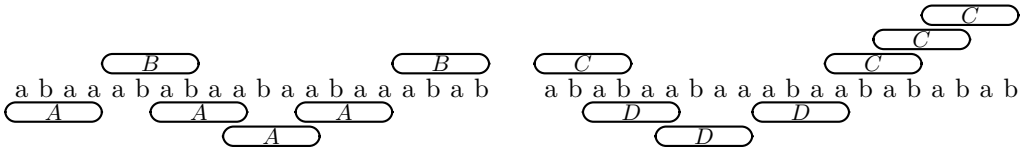

Figure 1 Two examples of a 2-cover of a string: a ps-cover (left) and a b-cover (right). Note that none of these strings has a proper cover.

In this paper, we present an $\mathcal{O}(n \log n \log\log n + \mathtt{output})$ time algorithm for finding all 2-covers of a text of length n. Each string from a 2-cover in the output is represented by giving endpoints of its sample occurrence. Our algorithm can compute a 2-cover of each length or all shortest 2-covers in $\mathcal{O}(n \log n \log\log n)$ time. The complexities show the expected running time of the algorithms; they can be made worst-case at a cost of an additional $\log\log n / \log\log\log n$ factor. The space complexities of the algorithms are $\mathcal{O}(n)$. We assume the standard word-RAM model of computation.

In the case of previously mentioned seeds and covers, the input text is generated by concatenations and superpositions of a single string. However, in our problem, we need to check if the text can be generated by two strings of equal length. This alone suggests that the problem is computationally harder than its original counterpart. Intuitively, to find all covers of a string we need to check only $\mathcal{O}(n)$ candidates, i.e. all prefixes. This is not the case with 2-covers, because a text of length n can have up to $\Theta(n^2)$ different non-trivial 2-covers. (A simple example $T = \mathtt{a}^m\mathtt{ba}^m\mathtt{ba}^m$ of such a text was shown in [23].) The general λ-cover problem was shown to be NP-hard by Cole et al. [17].

There are two types of 2-cover of a text T, as shown in Figure 1: a *ps-cover* (X, Y) that is composed of a prefix X and a suffix Y of T and a *b-cover* (X, Y) in which one of the strings, let us say X, is a border of T. (2-covers (X, Y) in which X is actually a cover of T are considered to be trivial and can be ignored.) Our main result consists of two algorithms, one for each of the types.

The first algorithm finds ps-covers. This is the easier type and for it, we propose an $\mathcal{O}(n \log\log n)$ expected time algorithm. It iterates over all possible candidates (there are $\mathcal{O}(n)$ of them) and maintains a set of *gaps*, that is, parts of the text that are not covered yet. There, we exploit locality of changes in coverage between consecutive lengths by using a predecessor data structure [5, 48]. Secondly, we efficiently express the dynamics of the gaps by storing linear functions.

The remaining, harder algorithm, finds b-covers (X, Y). In this case there are significantly more candidates to consider (up to $\mathcal{O}(n^2)$ [23]). For each length ℓ we use string periodicity to compute a set of $\mathcal{O}(n/\ell)$ positions in T, called *anchors*, that implies all non-redundant occurrences of any string Y in a b-cover of length ℓ. This set is computed using Internal Pattern Matching [40]. Finally our algorithm forms a set of constraints on Y based on the anchors and finds all strings that satisfy these constraints in $\mathcal{O}(n \log\log n/\ell + \mathsf{output})$ expected time using predecessor queries.

Our algorithms easily generalize to the λ-covers problem, achieving $\mathcal{O}(n^{\lambda-1}\mathrm{polylog}\, n + \mathsf{output})$ time.

▶ Remark 1. "String cover" is also used to describe a different notion that should not be confused with the one studied in this work. Namely, a string cover C of a set of strings S is a set of factors of strings from S such that every string in S can be written as a concatenation of the strings in C; see [12, 15, 30, 46].

2 Preliminaries

By $[i\,..\,j]$ we denote the integer interval $\{i, \ldots, j\}$; we use a round bracket if the interval does not contain one of its ends. For a set S of integers and integer a, by $S \oplus a$ and $S \ominus a$ we denote the sets $\{s + a : s \in S\}$ and $\{s - a : s \in S\}$, respectively, and by $\mathit{intervals}_k(S)$ we denote the set $\{[i\,..\,i + k) : i \in S\}$.

A string T is a sequence of letters from a given alphabet. The length of string T is denoted by $|T|$. We assume that the positions in T are numbered 1 through $|T|$, with letter at position i denoted as $T[i]$. By $T[i\,..\,j]$ we denote the string $T[i] \ldots T[j]$ that is called a *factor* of T (the same notation is used for open intervals of positions). A factor $T[i\,..\,j]$ is called a *prefix* if $i = 1$ and a *suffix* if $j = |T|$.

For a string X, by $\mathit{Occ}_T(X)$ we denote the set of starting positions of occurrences of X in T and by $\mathit{Cov}_T(X)$ the set of positions that are covered by occurrences of X in T, i.e.,

$$\mathit{Cov}_T(X) = \bigcup \mathit{intervals}_{|X|}(\mathit{Occ}_T(X)).$$

We omit the subscript T when it is clear from the context. We say that a set of strings $\mathcal{S}$ is a *λ-cover of length ℓ* of T if the following conditions hold:

- $|\mathcal{S}| = \lambda$
- $|X| = \ell$ for all $X \in \mathcal{S}$
- $\bigcup_{X \in \mathcal{S}} \mathit{Cov}(X) = [1\,..\,|T|]$

Periodicity of strings. We say that string S has *period* p (for $p \in [1\,..\,|S|]$) if $S[i] = S[i + p]$ for all $i \in [1\,..\,|S| - p]$.

▶ **Fact 2** (Periodicity lemma; Fine and Wilf [24]). *If string S has periods p and q such that $p + q \le |S|$, then it has a period* $\gcd(p, q)$.

A string is called *periodic* if it has a period that is at most a half of its length and *aperiodic* otherwise. Moreover, a string is called *$\frac{1}{4}$-periodic* if it has a period that is at most a quarter of its length.

▶ **Fact 3** (Folklore; see [2]). *If S is periodic and S' is a string of length $|S|$ that differs from S at exactly one position, then S' is aperiodic.*

In particular, if S is periodic with smallest period p and the letter c is different from $S[|S|-p+1]$, then Sc, i.e., S concatenated with c, is aperiodic.

String B is called a *border* of string S if B is a prefix and a suffix of S. String S has a period p if and only if it has a border of length $n-p$. In particular, this implies the following.

▶ **Observation 4.** *If string S is not periodic, then $|Occ_T(S)| = \mathcal{O}(|T|/|S|)$.*

A string S is *primitive* if $S = V^k$ for a string V and positive integer k implies that $k = 1$.

▶ **Fact 5** (Synchronization property; [19, Lemma 1.11]). *A primitive string S has exactly two occurrences in S^2.*

PREF table. The table $PREF$ over a length-n string T stores, as $PREF[i]$, the length of the longest common prefix of T and $T[i\,..\,n]$. Let $PREF^R[i]$ denote the length of the longest common suffix of T and $T[1\,..\,i]$. Both arrays can be computed in $\mathcal{O}(n)$ time by a classical comparison-based algorithm, as in the Main-Lorentz algorithm [42]; see also the book [22].

Longest Common Extension (LCE) queries. Assume that string T is over an integer alphabet $[1\,..\,n^{\mathcal{O}(1)}]$. A longest common prefix (longest common suffix) query on T, given indices $i, j \in [1\,..\,n]$, returns the length of the longest common prefix of suffixes $T[i\,..\,n]$ and $T[j\,..\,n]$ (the length of the longest common suffix of $T[1\,..\,i]$ and $T[1\,..\,j]$, respectively). Both types of queries are often referred to as LCE queries. It is well-known that after $\mathcal{O}(n)$-time preprocessing, one can answer LCE queries for T in $\mathcal{O}(1)$ time using the suffix array [34] and range minimum queries [11]. Moreover, we use the inverse suffix array that gives, for each suffix, its position in the sorted list of suffixes.

Assume that $T[i\,..\,j]$ is periodic with smallest period p. A position $j' > j$ ($i' < i$) is said to *break the periodicity* of $T[i\,..\,j]$ if $j' = \min\{k > j \,:\, T[k] \neq T[k-p]\}$ ($i' = \max\{k < i \,:\, T[k] \neq T[k+p]\}$, respectively). We set $i' = 0$ and $j' = n+1$ if the respective position does not exist. One can use LCE queries to compute the positions breaking periodicity of a given factor $T[i\,..\,j]$, if they exist, in $\mathcal{O}(1)$ time.

Internal Pattern Matching (IPM) queries. Again assume that T is over an integer alphabet $[0\,..\,n^{\mathcal{O}(1)}]$. The IPM problem requires one to preprocess a text T of length n so that one can efficiently compute the occurrences of a factor of T in another factor of T. An $\mathcal{O}(n)$-sized data structure, with $\mathcal{O}(n)$ expected time construction, that answers IPM queries in $\mathcal{O}(1)$ time when the ratio between the lengths of the two factors is at most 2 was presented in [40]. The set of occurrences is returned as a single arithmetic sequence. Moreover, if the sequence contains at least three elements, then its difference equals the smallest period of the pattern factor. A deterministic version of this data structure can be found in [35]. This data structure can also be used to answer in $\mathcal{O}(1)$ time so-called *two-period queries*, in which we are asked to find the smallest period of a given factor of T if this factor is periodic (an alternative data structure was proposed in [8]).

Predecessor data structures. For a set of integers A, by $pred(x, A)$ and $succ(x, A)$ we denote the predecessor and successor of x in A, that is, $\max\{a \in A \,:\, a < x\}$ and $\min\{a \in A \,:\, a > x\}$, respectively. (We assume that $\max\emptyset = -\infty$ and $\min\emptyset = \infty$.) We use the following known efficient dynamic predecessor data structures. A collection $A \subseteq [1\,..\,n]$ can be maintained

under insertions and deletions and can answer predecessor and successor queries in $\mathcal{O}(\log\log n)$ expected time per operation using a y-fast trie [48] or in $\mathcal{O}(\log^2 \log n/\log\log\log n)$ worst-case time using an exponential search tree [5]. Below by τ_n we denote the time complexity of an operation on a predecessor data structure. Moreover, we use Han's deterministic algorithm [29] to sort n numbers in $\mathcal{O}(n \log\log n)$ time.

3 Computing ps-covers

Let T be a string of length n. Let us start with a simpler but less efficient approach for computing ps-covers. For each length ℓ we would like to check if there is a ps-cover (X, Y) of length ℓ of T. We aim at $\mathcal{O}(n/\ell)$ time complexity after linear-time preprocessing. In the preprocessing phase we compute the data structures for LCE-queries [11, 34] and IPM queries [35, 40] in T. If T has a ps-cover (X, Y) of length ℓ, then $X = T[1\,..\,\ell]$ and $Y = T[n-\ell+1\,..\,n]$. We apply IPM queries to compute the sets of occurrences $Occ(X)$ and $Occ(Y)$, represented as unions of $\mathcal{O}(n/\ell)$ of arithmetic sequences, in $\mathcal{O}(n/\ell)$ time. This lets us compute the sets $Cov(X)$ and $Cov(Y)$, represented as unions of $\mathcal{O}(n/\ell)$ maximal intervals, sorted left-to-right. Then we need to check if $Cov(X) \cup Cov(Y) = [1\,..\,n]$, which can be done in linear time w.r.t. to the sizes of the representations of these sets by merging the sorted lists of intervals. Thus we have shown the following result.

▶ **Lemma 6.** *Let T be a string of length n over an integer alphabet. After $\mathcal{O}(n)$-time and space preprocessing, one can compute a ps-cover of T of a given length ℓ, if it exists, in $\mathcal{O}(n/\ell)$ time.*

Let us note that Lemma 6 applied for all lengths $\ell = 1, \ldots, n$ allows us to compute all ps-covers in $\mathcal{O}(n \log n)$ time. However, there is a more efficient approach that does not involve the intricate technique of IPM queries and also works for strings over any alphabet. We will use the lemma when computing λ-covers in Section 5.

Let P_ℓ be the prefix of length ℓ of T and S_ℓ be the suffix of length ℓ of T. For each length ℓ there is only one candidate for a ps-cover, that is, (P_ℓ, S_ℓ). Furthermore, the set of positions of the text T that are covered by $Cov(P_\ell) \cup Cov(S_\ell)$ does not change much when ℓ is incremented.

The idea is to iterate over increasing values of ℓ and check whether occurrences of P_ℓ and S_ℓ cover the entire text. We are going to maintain a set of *gaps*, that is, parts of the text that are covered by occurrences of neither the prefix nor the suffix.

First, let us identify an occurrence of a prefix P_ℓ with the index of its leftmost character and an occurrence of a suffix S_ℓ with the index of its *rightmost* character. In this way, when the length ℓ is incremented, some occurrences persist and get their length increased by one and other occurrences disappear. Specifically, occurrences of the prefix extend to the right and, respectively, occurrences of the suffix extend to the left. As a result, some gaps shrink or disappear and some other gaps are created. For an example, see Figure 2. Because of the way how joint occurrences of the prefix and the suffix affect the sizes of gaps, we will refer to these occurrences as the *pressing factors*.

We will iterate over subsequent $\ell = 1, \ldots, n$ and observe the set of gaps. If for some ℓ the set of gaps is empty, then (P_ℓ, S_ℓ) is a ps-cover. We track the following data:

- length ℓ
- the set $\triangleright_\ell$ of left endpoints of occurrences of P_ℓ
- the set $\triangleleft_\ell$ of right endpoints of occurrences of S_ℓ
- a set of pairwise disjoint gaps and an expiration time (value of ℓ) for each of them.

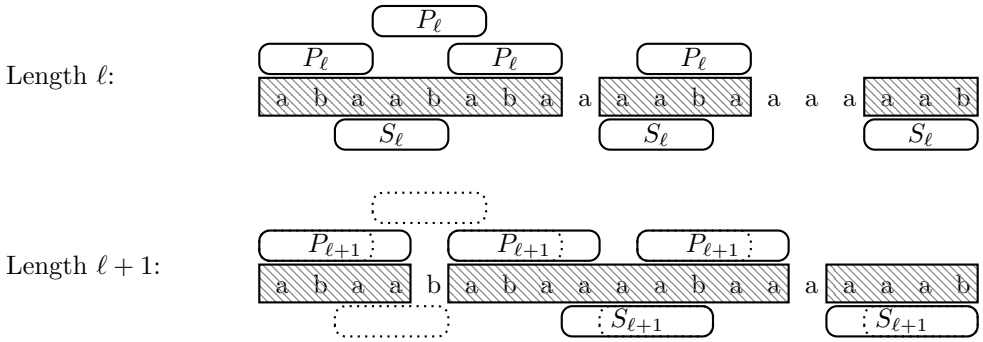

Figure 2 Illustration of gap dynamics. After incrementation of ℓ, a gap `b` was created, a gap `a` disappeared, and a gap `aaa` shrunk to `a`.

The sets will be maintained using predecessor data structures, which allow to perform predecessor/successor queries in τ_n time. Using the aforementioned data, the outline of the algorithm is as follows:

Algorithm 1 Outline of the algorithm for computing ps-covers.

```
pressing_factors := Occurrences of P_1 and S_1 in T;
gaps := Gaps between pressing_factors;
for ℓ := 1 to n do
    to_remove := Expired pressing_factors;
    Remove to_remove from pressing_factors;
    foreach expired_factor in to_remove do
        Recalculate elements of gaps around expired_factor;
```

An occurrence $i \in \triangleright_\ell$ ($i \in \triangleleft_\ell$) persists as long as $\ell \leq PREF[i]$ ($\ell \leq PREF^R[i]$, respectively). Therefore, for $\ell = PREF[i] + 1$ ($\ell = PREF^R[i] + 1$), we consider that occurrence as expired. In conclusion, the $PREF$ arrays allow us to compute expiration times of every prefix and suffix. This allows us to efficiently compute expired pressing factors in amortized $\mathcal{O}(1)$ time by precomputing a list of factors to expire for each moment of time in $\mathcal{O}(n)$ time.

Now let us simulate gap dynamics. Incrementations of ℓ successively get a gap increasingly covered (by occurrences of a prefix and/or suffix) until it expires completely. Assuming that none of the relevant pressing factors disappears, a gap expiration depends on the closest prefix occurrence to the left and the closest suffix occurrence to the right of the gap. If we know that some position p belongs to a gap, we would like to know the following:

- $L_\triangleright = \max\{a : a \in \triangleright_\ell, a < p\}$ and $L_\triangleleft = \max\{a : a \in \triangleleft_\ell, a < p\}$
- $R_\triangleright = \min\{b : b \in \triangleright_\ell, b > p\}$ and $R_\triangleleft = \min\{b : b \in \triangleleft_\ell, b > p\}$.

Unfortunately, this is too much to maintain. One factor that expires might influence many gaps. Let us analyze it further. Let us fix some prefix occurrence, i.e. pressing factor that extends to the right. It might influence expiration time of many gaps to the right. On the other, hand we can safely note this exclusively in the closest gap to the right. This is because the pressing factor won't reach other gaps before closing the immediate gap. When the gap closes, we can propagate the information to neighbouring gaps. Therefore, in a gap we only take into consideration pressing factors whose immediate neighbour is this gap and ignore them otherwise. We can easily check for this and compute all these values in τ_n time. If the gap initially covers the interval $[i\,..\,j]$, then it can expire in two ways:

- it can close on one boundary by a single opposing pressing factor, so the gap will close no later than $\ell = \min(R_\triangleleft - i + 1, j - L_\triangleright + 1)$, or

- it can close in the middle of the gap, by both pressing factors simultaneously, at $\ell = \lceil \frac{R_\triangleleft - L_\triangleright + 1}{2} \rceil$.

  The endpoints of a gap at moment ℓ can be computed using the formulas:

  $i = \max(L_\triangleright + \ell,\, L_\triangleleft + 1)$ and $j = \min(R_\triangleleft - \ell,\, R_\triangleright - 1)$.

When a gap is created or its neighbouring pressing factors are altered, we use these formulas to recompute the gap boundaries. The predecessor data structure that stores gaps uses, for each gap, its recently computed left boundary for comparison. It is sufficient since the left-to-right order of gaps is never changed.

Thus we can recompute the expiration moment of a single gap given at least one position belonging to the gap. The remaining issue is to know which gaps need to be updated. Note that each expired factor can affect at most two existing neighbouring gaps and possibly introduce a new one. We can find the neighbouring gaps via predecessor/successor queries. Positions that were not covered will still not be covered after removing the expired factor, so we can pick an arbitrary position from this gap and recalculate its boundaries.

Now, we need to check if some new gap was created in the boundaries of the expired factor. In this case we have some intervals of length ℓ, representing the set $Cov(P_\ell) \cup Cov(S_\ell)$, and we would like to know if removing one interval creates a gap in coverage. Thanks to the fact that all intervals are of the same length, if the expired factor is $[i\,..\,j]$, we only need to find the last interval ending at most at j and the first interval starting at least at i. If found intervals do not cover the entirety of $[i\,..\,j]$, we have at least one position of the gap and we are able to calculate its boundaries. Otherwise, removing the factor did not change the coverage, so no new gap was created. All of this can be performed using the predecessor data structures in τ_n time.

In conclusion, the entire computation of ps-covers takes $\mathcal{O}(n\tau_n)$ time and $\mathcal{O}(n)$ space. We obtain the following result.

▶ **Theorem 7.** *Let T be a string of length n over any alphabet that allows $\mathcal{O}(1)$-time checking of letter equality. One can compute a ps-cover of T of every possible length in $\mathcal{O}(n\tau_n)$ time and $\mathcal{O}(n)$ space.*

4 Computing b-covers

Let T be a string of length n. Our goal in this section is, given a length ℓ, to check if there is a b-cover (X, Y) of length ℓ of T. We aim at $\mathcal{O}(n\tau_n/\ell)$ time complexity after linear-time preprocessing. In the preprocessing phase we compute the data structures for LCE-queries [11, 34] and IPM queries [35, 40] in T.

Let $X = T[1\,..\,\ell]$. We apply IPM queries to compute the set $Occ(X)$, represented as a union of $\mathcal{O}(n/\ell)$ of arithmetic sequences, and the set $Cov(X)$, represented as a union of $\mathcal{O}(n/\ell)$ maximal intervals, in $\mathcal{O}(n/\ell)$ time. If $n - \ell + 1 \notin Occ(X)$, there is no b-cover of length ℓ, and if $Cov(X) = [1\,..\,n]$, we skip this length since we have the trivial case of a 2-cover containing a cover. Henceforth we assume that X is a border of T whose occurrences do not cover the whole string T.

Our goal is to find all strings Y for which (X, Y) is a b-cover of T. We start by building up some intuition. We have $|Y| = \ell$, so in order for Y to cover all positions from the set $Cov(Y)$, it suffices to use $\mathcal{O}(n/\ell)$ occurrences of Y (instead of, potentially, $\Theta(n)$ occurrences). Let P_Y be a set of starting positions of such a set of occurrences. We will compute $t = \mathcal{O}(1)$ sets $\Gamma_1, \ldots, \Gamma_t$, each of size $\mathcal{O}(n/\ell)$, that contain information about all (Y, P_Y), for every Y that can form a b-cover with X. In each set Γ_i we will select an element $\gamma_i \in \Gamma_i$ and consider only length-ℓ factors Y starting at positions $\gamma_i - a$ for $a \in [0\,..\,\ell)$.

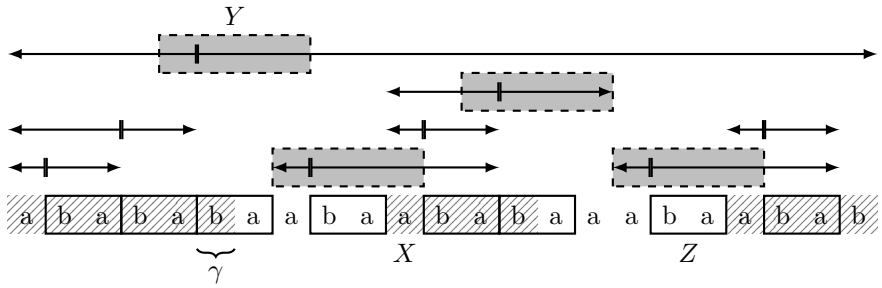

Figure 3 This string has a b-cover ($X = abab, Y = abaa$). The sets $Cov(X)$ and $Cov(Y)$ are shown in gray. We have $Z = ba$, $\Gamma = Occ_T(Z)$, and γ is the position of the occurrence of Z that ends at the first position that is not covered by $Cov(X)$. The set P_Y of occurrences of Y that is generated by $(\Gamma, \gamma, 1)$ is shown. For the meaning of arrows, see Section 4.3.

In particular, for every such (Y, P_Y) we would like to have $P_Y \subseteq (\Gamma_i \ominus a)$ and $Y = T[\gamma_i - a \,..\, \gamma_i - a + \ell)$ for some $i \in [1\,..\,t]$ and $a \in [0\,..\,\ell)$. We then say that (Y, P_Y) is *generated* by (Γ_i, γ_i, a). Moreover, for each set Γ_i we will provide an interval $J_i \subseteq [0\,..\,\ell)$ such that for every Y that forms a b-cover with X, the factor Y is generated by (Γ_i, γ_i, a) for just a constant number of $a \in J_i$. This will allow us to report each sought factor Y a constant number of times and filter out repetitions in the end.

In the algorithm we first compute a constant number of factors $Z_1, \ldots, Z_t$ of T length $z = \lceil \ell/2 \rceil$ such that if (X, Y) is a b-cover, then Y contains at least one of $Z_1, \ldots, Z_t$ as a factor. Let Z be a factor of Y such that $a+1 \in Occ_Y(Z)$. If $i \in Occ_T(Z)$ and $i - a \in Occ_T(Y)$, then we say that the occurrence i of Z *a-anchors* the occurrence $i - a$ of Y and that the latter is *a-anchored* at the former. If Z_i is aperiodic, by Observation 4, we have $|Occ_{Z_i}(T)| = \mathcal{O}(n/\ell)$ and $|Occ_{Z_i}(Y)| = \mathcal{O}(1)$ for any length-ℓ string Y. In this case we will take $\Gamma_i = Occ_{Z_i}(T)$ and $J_i = [0\,..\,\ell - z]$. If Z_i is periodic with period p, we will only be interested in factors Y that are periodic with the same period. In this case we will take as Γ_i a sufficient subset of $Occ_{Z_i}(T)$ and set $J_i = [0\,..\,p)$. See Figure 3 for an example.

Formally, we reduce computing a b-cover of a given length to a constant number of instances of the following problem.

Positioned Cover of Length ℓ
Input: A factor Z of T, a set of positions $\Gamma \subseteq Occ_T(Z)$, its element $\gamma \in \Gamma$, and an interval $J \subseteq [0\,..\,\ell)$.
Output: Report all $a \in J$ such that $Cov_T(X) \cup (\bigcup intervals_\ell(P_Y)) = [1\,..\,n]$ for (Y, P_Y) that is generated by (Γ, γ, a), with $|Y| = \ell$.

In Section 4.3 we show how to solve this problem efficiently if $|\Gamma| = \mathcal{O}(n/\ell)$. Clearly:

▶ **Observation 8.** *If an instance of Positioned Cover of Length ℓ for any Γ, γ, J has a solution (X, Y) for some $a \in J$, then (X, Y) is a b-cover of T.*

Let i be the first position of T that is not covered by occurrences of X. Hence, i has to be covered by the second string Y of the b-cover. Let us denote

$$z = \lceil \ell/2 \rceil, \quad Z_1 = T[i - z + 1\,..\,i], \quad Z_2 = T[i\,..\,i + z).$$

▶ **Observation 9.** *If (X, Y) is a b-cover of length ℓ of T, then Z_1 or Z_2 is a factor of Y.*

Proof. Let $T[j\,..\,j+\ell)$ be an occurrence of Y that covers the position i. If $j \le i-z+1$, then it covers the factor Z_1. Otherwise, $j+\ell-1 \ge i+z$ and $j \le i$, so it covers Z_2. ◀

We will consider as Z each of the two factors Z_1, Z_2 and denote by i_Z the starting position of the occurrence of Z mentioned in the definition. We can ask a two-period query [8, 35, 40] to check if Z is periodic and, if so, compute its smallest period.

▶ **Observation 10.** *If Z is aperiodic, then Y is not 4-periodic. If Z is periodic, then either Y is 4-periodic with the same period, or Y is not 4-periodic.*

Proof. Assume that Z is aperiodic. If Y was 4-periodic with period p, i.e., $4p \le \ell$, then p would also be a period of its factor Z and $2p \le z$, so Z would be periodic.

Assume now that Z is periodic. Let p be the smallest period of Z; we have $2p \le z$. Assume to the contrary that Y is 4-periodic with smallest period p' such that $p' \ne p$. We have $4p' \le \ell$, so $2p' \le z$. Then p' is not a multiple of p, since otherwise p would have been a period of Y. By the periodicity lemma (Fact 2), Z has period $\gcd(p,p') < p$, a contradiction. ◀

In the remainder of the reduction we consider two cases depending on if Y is 4-periodic.

4.1 Reduction for non-4-periodic Y

If Z is periodic, then we try two ways of substituting it with a string that is not periodic.

▶ **Observation 11.** *Assume that Z is periodic with smallest period p, Y is not 4-periodic and an occurrence $T[i\,..\,i+\ell)$ of Y contains $T[i_Z\,..\,i_Z+z)$. Let $i' < j'$ be the positions that break the periodicity of $T[i_Z\,..\,i_Z+z)$. Then $T[i\,..\,i+\ell)$ contains at least one of the fragments $T[i'\,..\,i'+z)$, $T[j'-z+1\,..\,j']$.*

We denote the fragments in the conclusion of the observation by Z' and Z'', respectively. Let us recall that if Z is periodic, the positions breaking the periodicity can be computed using LCE queries. Hence, Z' and Z'' can be computed in $\mathcal{O}(1)$ time. By Fact 3, if Z' or Z'' exists, it is aperiodic. If Z is periodic, we try replacing it by Z' or Z'' (and redefine the occurrence i_Z).

In total we obtain up to four aperiodic strings Z such that if Y is not 4-periodic, its occurrence contains the occurrence $T[i_Z\,..\,i_Z+z)$ for at least one of them. We have $|Occ(Z)| = \mathcal{O}(n/\ell)$ (Observation 4) and all the occurrences can be found in $\mathcal{O}(n/\ell)$ time using IPM queries. The following lemma summarizes the above argument.

▶ **Lemma 12.** *If T has a b-cover (X,Y) of length ℓ with non-4-periodic Y, then (Y,P_Y) is generated by (Γ,γ,a) where $\Gamma = Occ(Z)$, $\gamma = i_Z$ and $a \in [0\,..\,\ell-z]$, for one of up to four aperiodic strings Z. We have $|\Gamma| = \mathcal{O}(n/\ell)$ and Γ, γ can be computed in $\mathcal{O}(n/\ell)$ time.*

4.2 Reduction for 4-periodic Y

By Observation 10, in this case Z is necessarily periodic with the same smallest period as Y. If we used the same reduction as in Lemma 12, we could unfortunately have $|\Gamma| = |Occ(Z)| = \Theta(n)$. We deal with this problem by choosing the first occurrence of Z in Y as an anchor and selecting only some of the occurrences of Z in T to the set Γ that are sufficient for Y to cover all positions in $Cov(Y)$; see Figure 4.

▶ **Lemma 13.** *If T has a b-cover (X,Y) of length ℓ with 4-periodic Y, then (Y,P_Y) is generated by (Γ,γ,a) where $\Gamma \subseteq Occ(Z)$ and $a \in [0\,..\,p)$, for one of up to two periodic strings Z with smallest period p and one of up to two positions γ. We have $|\Gamma| = \mathcal{O}(n/\ell)$ and Γ, γ, p can be computed in $\mathcal{O}(n/\ell)$ time.*

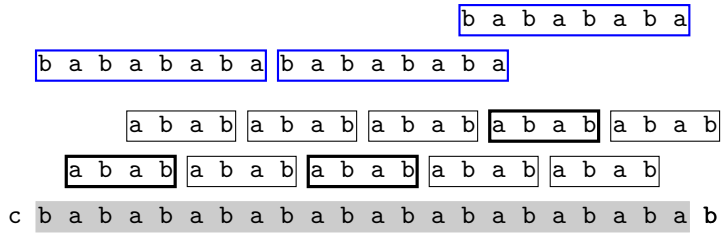

Figure 4 $Z = \texttt{abab}$ (black rectangles), $Y = \texttt{bababababa}$ (blue rectangles); gray color shows $Cov(Y)$. The occurrences of Y that are 1-anchored at marked occurrences of Z are shown and cover $Cov(Y)$.

Proof. Let $p = \mathsf{per}(Z)$. We apply IPM queries to compute the set $Occ(Z)$, represented as a union of $\mathcal{O}(n/\ell)$ arithmetic sequences with difference p. Let us further merge these arithmetic sequences into maximal sequences with difference p, that we denote as $S_1, \ldots, S_k$. We note that $Z[1\,..\,p]$ is primitive, since otherwise Z would have a smaller period. By the synchronization property (Fact 5) for $Z[1\,..\,p]$, we can assume that $\max(S_i) + p < \min(S_{i+1})$ for $i = 2, \ldots, k$, so $\sum_{i=1}^{k} |S_i| = \mathcal{O}(n/p)$. Initially let $\Gamma = Occ(Z)$. We will show how to prune Γ by leaving $\mathcal{O}(|S_i|p/\ell)$ elements in each of the sequences S_i. This will indeed give $|\Gamma| = \mathcal{O}(n/\ell)$.

The set $Occ_Y(Z)$ is an arithmetic sequence with difference p and first element $t \in [1\,..\,p)$. Let $m = |Occ_Y(Z)|$; we have $2 \le m \le \ell/p$. An occurrence of Y in T implies a subsequence of length m of consecutive elements in one of the sequences S_i. Moreover, any arithmetic sequence $j, j+p, \ldots, j+(m+1)p$ of $m+2$ occurrences of Z in T implies an occurrence of Y in T at position $j + p - t + 1$. (Note that a difference-p arithmetic sequence of $m+1$ occurrences of Z in T does not have to imply an occurrence of Y, e.g. if $T = \texttt{abababab}$, $Z = \texttt{abab}$ and $Y = \texttt{bababa}$.)

We can now construct the pruned set Γ' as follows. Let us consider $S_i = \{j, j+p, \ldots, j+(w-1)p\}$. If $w + 1 < m$, then we can ignore S_i. Otherwise we insert to Γ':

- the elements j and $j + p$;
- all elements $j + m \cdot p \cdot t \in S_i$ for positive integer t;
- the elements $j + (w - m - 1)p$ and $j + (w - m)p$.

This way $\mathcal{O}(w/m) = \mathcal{O}(|S_i|p/\ell)$ elements are inserted to Γ', so indeed $|\Gamma'| = \mathcal{O}(n/\ell)$.

Finally, let S_b be the arithmetic sequence that contains the position i_Z. Then we have two choices for γ: $\min(S_b)$ or $\min(S_b) + p$. ◀

4.3 Solution to Positioned Cover problem

Let us recall the problem statement.

Positioned Cover of Length ℓ
Input: A factor Z of T, a set of positions $\Gamma \subseteq Occ_T(Z)$, its element $\gamma \in \Gamma$, and an interval $J \subseteq [0\,..\,\ell)$.
Output: Report all $a \in J$ such that $Cov_T(X) \cup (\bigcup intervals_\ell(P_Y)) = [1\,..\,n]$ for (Y, P_Y) that is generated by (Γ, γ, a), with $\lvert Y\rvert = \ell$.

▶ **Lemma 14.** *After $\mathcal{O}(n)$ time and space preprocessing, assuming that $|\Gamma| = \mathcal{O}(n/\ell)$, Positioned Cover of Length ℓ over an integer alphabet can be solved in $\mathcal{O}(n\tau_n/\ell + \mathsf{output})$ time and $\mathcal{O}(n/\ell)$ space.*

Proof. Let $A = Cov(X)$, $A' = [1\,..\,n] \setminus A$, and $\mathcal{A} \subseteq [1\,..\,n]^2$ be the set of maximal intervals of A. We have $|\mathcal{A}| \leq n/\ell$ and $\mathcal{A}$ can be computed in $\mathcal{O}(n/\ell)$ time. Then the Positioned Cover problem can be solved with the following Claim 15 for

$$S = \{(i,\, \mathsf{lcs}(T[1\,..\,i), T[1\,..\,\gamma)),\, \mathsf{lcp}(T[i\,..\,n], T[\gamma\,..\,n])) \,:\, i \in \Gamma\},$$

where lcp and lcs is the length of the longest common prefix and the longest common suffix, respectively. Intuitively, if $(i, x, y) \in S$, then there is an occurrence of a length-ℓ factor Y a-anchored at $i \in Occ(Z)$ if and only if $a \leq x$ and $|Z| \leq \ell - a \leq y$. See the arrows in Figure 3.

▷ Claim 15. In $\mathcal{O}(n\tau_n/\ell + \mathsf{output})$ time and $\mathcal{O}(n/\ell)$ space one can report all $a \in J$ such that

$$A \cup \bigcup intervals_\ell(S'_a \ominus a) = [1\,..\,n], \tag{1}$$

where $S'_a = \{i \,:\, (i, x, y) \in S,\, a \leq x,\, \ell - a \leq y\}$.

Proof. In the algorithm we store $\mathcal{A}$ in a predecessor data structure $D_{\mathcal{A}}$ sorted by the left endpoints of intervals. We will consider all $a \in J$ in a decreasing order and store the current set S'_a in a predecessor data structure D_S. However, we will only consider values of a for which $S'_a \neq S'_{a+1}$. Let us note that $(i, x, y) \in S$ contributes to $i \in S'_a$ for $a \in [\ell - y\,..\,x]$. Hence, if this interval is non-empty, we will insert i to S'_a for $a = x$ and remove it for $a = \ell - y - 1$. We have $|S| = \mathcal{O}(n/\ell)$, so all events of insertion and deletion to D_S can be precomputed and sorted in $\mathcal{O}(n \log\log n/\ell)$ time using Han's algorithm [29].

Assume that D_S is the data structure that stores S'_a for all a in an interval $J_0 \subseteq J$. Let $i \in D_S$ and $i' = succ(i, D_S)$. We can observe that:

- If $K = [i\,..\,i') \setminus A$ is non-empty and (1) holds for some $a \in J_0$, then $K \subseteq [i - a\,..\,i - a + \ell) \cup [i' - a\,..\,i' - a + \ell)$.

Hence, if $[i\,..\,i')$ is to be covered by the left hand side of (1) for some $a \in J_0$, we have the following set $C(i, i')$ of constraints on a (see Figure 5 in the appendix):

(a) If $i' - i \leq \ell$ or $[i\,..\,i') \subseteq A$, no constraints are imposed. If there are at least two intervals from $\mathcal{A}$ that are fully contained in $[i\,..\,i')$, then there is no such a.

(b) Otherwise, if no interval in $\mathcal{A}$ is a subset of $[i\,..\,i')$, then $a \geq i' - j$ or $\ell - a \geq j' - i + 1$, where $j = succ(i, A')$ and $j' = pred(i' - 1, A')$.

(c) Otherwise, if there is an interval $[u\,..\,v] \in \mathcal{A}$ such that $[u\,..\,v] \subseteq [i\,..\,i')$, then $a \geq i' - v - 1$ and $\ell - a \geq u - i$.

The respective cases can be checked and $C(i, i')$ can be constructed in τ_n time using $D_{\mathcal{A}}$. A similar set of conditions can be stated for the left hand side of (1) to contain all elements of $[1\,..\,\min D_S)$ and $[\max D_S\,..\,n]$; we denote the resulting constraints by $C(0, \min D_S)$ and $C(\max D_S, n + 1)$, respectively, and insert 0 and $n + 1$ to S'_a.

Let us note that each of the constraints from the set $C(i, i')$ is a conjunction of at most two constraints of the form $a \notin I$ for some interval I. Indeed,

$$(a \geq x) \vee (a \leq y) \Leftrightarrow a \notin (y\,..\,x), \quad (a \geq x) \wedge (a \leq y) \Leftrightarrow (a \notin [0\,..\,x)) \wedge (a \notin (y\,..\,\ell)).$$

When i is inserted to D_S, we remove the constraints $C(i', i'')$ imposed by the pair $i' = pred(i, D_S)$ and $i'' = succ(i, D_S)$ and insert the constraints $C(i', i)$ and $C(i, i'')$. For every constraint $a \notin I$, we will retain the value a_1 of a for which it is inserted and the value a_2 for which it is removed. If $I' = [a_1\,..\,a_2)$, the constraint imposes a constraint $a \notin (I \cap I')$ on values of a that satisfy (1).

Overall we obtain $\mathcal{O}(n/\ell)$ constraints of the form $a \notin I$ for (1) to hold. Our goal is to report all $a \in J$ that satisfy all the constraints, i.e., all a in the complement of the union of the $\mathcal{O}(n/\ell)$ intervals from the constraints. This task can be completed by a classic 1d sweep algorithm if the endpoints of intervals from the constraints are sorted [29].

The data structure $D_{\mathcal{A}}$ takes $\mathcal{O}(n\tau_n/\ell)$ time to construct since $|\mathcal{A}| = \mathcal{O}(n/\ell)$ and admits $\mathcal{O}(n/\ell)$ queries. The data structure D_S admits $\mathcal{O}(n/\ell)$ operations. Additional sorting takes $\mathcal{O}(n\tau_n/\ell)$ time. Finally, all values of a for which (1) is satisfied are reported in $\mathcal{O}(\mathsf{output})$ time. The complexity follows. ◁

This concludes the solution to Positioned Cover problem. ◀

A single string Y can be generated by (Γ, γ, a) with $a \in J$ from Lemma 12 a constant number of times because Z is aperiodic, and a constant number of times from Lemma 13 because of the synchronization property. By combining Lemma 14 with Observation 8 and the reductions of Lemmas 12 and 13, we obtain the following result and its corollary.

▶ **Lemma 16.** *Let T be a string of length n over an integer alphabet. After $\mathcal{O}(n)$-time and space preprocessing, one can report all b-covers of T of a given length ℓ, each of them $\mathcal{O}(1)$ times, in $\mathcal{O}(n\tau_n/\ell + \mathsf{output})$ time.*

▶ **Theorem 17.** *Let T be a string of length n over any ordered alphabet. All b-covers of T can be computed in $\mathcal{O}(n\tau_n \log n + \mathsf{output})$ time and $\mathcal{O}(n)$ space.*

Proof. Let us sort and renumber letters in T so that they are in $[1\,..\,n]$. This takes $\mathcal{O}(n \log n)$ time. Then we apply Lemma 16 for every possible length ℓ of a b-cover. Apart from the time to report the output, the complexity becomes $\sum_{\ell=1}^{n} \mathcal{O}(n\tau_n/\ell) = \mathcal{O}(n\tau_n \log n)$.

Finally, we need to make sure that each b-cover is reported only once. We can use the inverse suffix array to sort all factors Y of a given length in the lexicographic order. The sorting is performed globally, across all lengths, using radix sort. We can then iterate over length-ℓ strings Y in the sorted order and remove duplicates using LCE-queries. ◀

5 Computation of 2-covers and λ-covers

We summarize the results of Theorems 7 and 17 and use efficient predecessor data structures [5, 48] to obtain the following result.

▶ **Theorem 18.** *Let T be a string of length n over any ordered alphabet. All 2-covers of T can be computed in $\mathcal{O}(n \log n \log\log n + \mathsf{output})$ expected time or $\mathcal{O}(n \log n \log^2 \log n / \log\log\log n + \mathsf{output})$ worst-case time and $\mathcal{O}(n)$ space.*

Let us recall that there are up to n ps-covers. Moreover, the algorithm behind Lemma 16 allows one to generate as many b-covers of a given length as one requires. This shows that indeed one can compute a 2-cover of each possible length or all the shortest 2-covers in $\mathcal{O}(n\tau_n \log n)$ time.

Theorem 19 extends Theorem 18 to λ-covers for any $\lambda \geq 2$. As in the case of 2-covers, we are only interested in computing λ-covers of lengths for which T does not have a $(\lambda-1)$-cover.

▶ **Theorem 19.** *Let T be a string of length n over any ordered alphabet. For any $\lambda \geq 2$, all λ-covers of T can be computed in $\mathcal{O}(n^{\lambda-1} \log n \log\log n + \mathsf{output})$ expected time or $\mathcal{O}(n^{\lambda-1} \log n \log^2 \log n / \log\log\log n + \mathsf{output})$ worst-case time and $\mathcal{O}(n)$ space.*

Proof. It suffices to give a proof for $\lambda \geq 3$. Similarly as in the case of 2-covers, we classify λ-covers $\mathcal{S} = (X_1, \ldots, X_\lambda)$ into ps-λ-covers, for which X_1 is a prefix and X_2 is a suffix of T, and b-λ-covers, for which X_1 is a border of T. (Formally, in order to compute all λ-covers, in case of ps-λ-covers in the end we need to generate all tuples where the prefix and suffix of T are not the first two respective elements of the tuple, and similarly for b-λ-covers.) The two cases are handled similarly as ps-covers and b-covers, respectively. The number of ps-λ-covers is upper bounded by $n^{\lambda-1}$, whereas the number of b-λ-covers can be $\Theta(n^\lambda)$; see [23].

Let us show how to compute all ps-λ-covers of a given length $\ell \in [1\,..\,n]$. First we use IPM queries to compute $Cov(X_1) \cup Cov(X_2)$, represented as a union of $\mathcal{O}(n/\ell)$ maximal intervals, as in Lemma 6. We LCE-queries on suffixes of the suffix array of T to partition positions of T into classes $C_1, \ldots, C_m$ such that positions i, j belong to the same class if and only if $T[i\,..\,i+\ell) = T[j\,..\,j+\ell)$. This could be also done in $\mathcal{O}(n \log n)$ total time using Crochemore's partitioning [18]. For each of the $\binom{m}{\lambda-2}$ choices of $\lambda - 2$ classes $C_{i_1}, \ldots, C_{i_{\lambda-2}}$, if none of them corresponds to X_1 or X_2, we compute their union B. The sets B are computed simultaneously for several choices containing $\Theta(n)$ elements in total using radix sort in order to achieve $\mathcal{O}(|C_{i_1}| + \cdots + |C_{i_{\lambda-2}}|)$ amortized time per choice. Within the same time complexity we can compute the set $\bigcup \mathit{intervals}_\ell(B)$ represented as a union of maximal intervals. Finally, we merge this set with $Cov(X_1) \cup Cov(X_2)$ and check if their union is $[1\,..\,n]$. The time complexity for a given choice of classes is $\mathcal{O}(|C_{i_1}| + \cdots + |C_{i_{\lambda-2}}| + n/\ell)$.

Over all choices, the running time is proportional to

$$\sum_{1 \leq i_1 \leq \ldots \leq i_{\lambda-2} \leq m} \left(|C_{i_1}| + \cdots + |C_{i_{\lambda-2}}| + \frac{n}{\ell} \right) = \binom{m-1}{\lambda-3} \sum_{i=1}^{m} |C_i| + \binom{m}{\lambda-2} \frac{n}{\ell} \leq \frac{2n^{\lambda-1}}{\ell}. \quad (2)$$

The total cost of computing all classes C_i, over all $\ell \in [1\,..\,n]$, is $\mathcal{O}(n^2)$ (or $\mathcal{O}(n \log n)$), and the other preprocessing (LCE and IPM) takes $\mathcal{O}(n)$ time. Thus the overall cost of computing all ps-λ-covers is $\mathcal{O}(n^{\lambda-1} \log n)$.

Computation of b-λ-covers is a similar adjustment to the computation of b-covers of a given length. Recall that X_1 is a length-ℓ border of T. We iterate over all $\binom{m}{\lambda-2}$ choices of $\lambda - 2$ classes $C_{i_1}, \ldots, C_{i_{\lambda-2}}$ which corresponds to selecting factors $X_2, \ldots, X_{\lambda-1}$ from the b-λ-cover. A selection for which $X_i = X_1$ for some $i > 1$ is discarded. The set $\mathcal{C} := Cov(X_1) \cup \cdots \cup Cov(X_{\lambda-1})$ can be expressed as a union of $\mathcal{O}(n/\ell)$ maximal intervals in $\mathcal{O}(|C_{i_1}| + \cdots + |C_{i_{\lambda-2}}| + n/\ell)$ time, which is $\mathcal{O}(n^{\lambda-1}/\ell)$ overall by (2).

In order to compute X_λ, we we make a reduction to a generalization of Positioned Cover of Length ℓ in which we take $\mathcal{C}$ instead of $Cov_T(X)$. The factors Z_1 and Z_2 are computed as in Observation 9, by setting i to the first position in T that is not covered by $\mathcal{C}$. This allows us to compute Z depending on if X_λ is 4-periodic, as in Sections 4.1 and 4.2, in $\mathcal{O}(1)$ time. The solution of the general Positioned Cover of Length ℓ is the same as the one given in Lemma 14, but using $\mathcal{C}$ instead of $Cov_T(X)$. The time complexity of the solution is $\mathcal{O}(n\tau_n/\ell)$ plus the time needed to output b-λ-covers. These steps need to be performed for each of the $\binom{m}{\lambda-2} \leq n^{\lambda-2}$ choices of classes, which gives $\mathcal{O}(n^{\lambda-1}\tau_n/\ell)$ for the given length ℓ, and $\mathcal{O}(n^{\lambda-1}\tau_n \log n)$ in total (plus output).

The complexity follows by summing the complexities of computing ps-λ-covers and b-λ-covers and using efficient predecessor data structures [5, 48]. ◀

6 Conclusions and open problems

We presented quasi-linear time algorithms (plus the time to report the output) for computing 2-covers of a string. One could ask if a shortest 2-cover can be computed in linear time. A further problem is to check if the general λ-cover problem parameterized by λ is fixed-parameter tractable.

One could also consider alternative definitions of 2-covers (and λ-covers) in which the factors that are to cover the text need not to be of the same length. Efficient computation of such covers seems to be an interesting open problem. In particular, under this alternative definition, there can be $\Theta(n^4)$ candidates for a 2-cover (every pair of factors).

Abstract

In the Set Multicover problem, we are given a set system $(X, \mathcal{S})$, where X is a finite ground set, and $\mathcal{S}$ is a collection of subsets of X. Each element $x \in X$ has a non-negative demand $d(x)$. The goal is to pick a smallest cardinality sub-collection $\mathcal{S}'$ of $\mathcal{S}$ such that each point is covered by at least $d(x)$ sets from $\mathcal{S}'$. In this paper, we study the set multicover problem for set systems defined by points and non-piercing regions in the plane, which includes disks, pseudodisks, k-admissible regions, squares, unit height rectangles, homothets of convex sets, upward paths on a tree, etc.

We give a polynomial time $(2+\epsilon)$-approximation algorithm for the set multicover problem $(P, \mathcal{R})$, where P is a set of points with demands, and $\mathcal{R}$ is a set of non-piercing regions, as well as for the set multicover problem $(\mathcal{D}, P)$, where $\mathcal{D}$ is a set of pseudodisks with demands, and P is a set of points in the plane, which is the hitting set problem with demands.

1 Introduction

The Set Cover problem and its variants are central problems in Computer Science. For general set systems, tight results are known - there is an $O(\log n)$ approximation algorithm [32] and this is tight under standard complexity assumptions [18]. Over the last decade, significant progress has been on these problems for geometric set systems in the plane and in low dimensions. There are broadly two approaches that have been successful in the geometric setting, *viz.*, LP-rounding based algorithms and local-search. The LP-rounding approach relies on the existence of small ϵ-nets, which exist whenever the *VC-dimension* of the set system is bounded. Set systems with VC-dimension at most d have ϵ-nets of size $O(d/\epsilon \log 1/\epsilon)$ [22], and this leads to an $O(\log |\textsc{Opt}|)$-approximation algorithm [5, 17], that holds even in the *weighted setting*[1]. Smaller ϵ-nets are known when the *union complexity* of the set system is *small* [13], leading to algorithms with better approximation factors, though not in the weighted setting. Varadarajan [31] showed via the *quasi-uniform* sampling technique how these results can be made to work in the weighted setting. His technique was optimized by Chan, et al. [7] who also introduced the notion of *shallow cell complexity* generalizing the notion of union complexity to abstract set systems. Chekuri, et al. [11] extended the LP-based techniques for set cover to set multicover obtaining an $O(\log |\textsc{Opt}|)$

[1] In the weighted setting, the sets have non-negative weights, and the goal is to find a minimum weight feasible sub-collection, as opposed to the minimum cardinality.

approximation when the VC dimension is bounded, and better bounds in the case where the union complexity is bounded. In particular, they obtain $O(1)$-approximation algorithms when union complexity is linear. However, their results only hold in the unweighted setting. Bansal and Pruhs [3] extended the approach based on shallow cell complexity and quasi-uniform sampling [31, 7] to work for the weighted set multicover problem. The main weakness of these LP-rounding techniques is that the approximation factor obtained is at least as large as the integrality gap, which is often large. Furthermore, the constants gained in the approximation factor during the rounding process is often large. For instance, [11] uses *shallow cuttings*, which involves large constants.

A second approach that has been effective for fundamental geometric packing and covering problems, albeit in the unweighted setting [8, 28, 21, 25, 4, 30] is Local Search. Besides packing and covering problems, Local Search has also been remarkably successful for several clustering problems (See [20, 19, 14, 15], and references therein). A drawback of the Local Search approach is that the running time of the algorithms are prohibitive. In particular, Mustafa and Jartoux [23] showed that to obtain a $(1+\epsilon)$-approximation for the Set Cover problem with disks, the local search algorithm takes $n^{\Omega(1/\epsilon^2)}$ time.

The analysis of local search for most of the geometric packing and covering problems relies on showing the existence of a graph with desired characteristics which is problem specific, and this is usually the challenging part of the analysis. In [30], Raman and Ray gave a unified method to obtain such graphs for several packing and covering problems. While the techniques in [30] can be extended to *packing problems* with bounded capacities as was shown in [4], it was not clear how to extend them to the set multicover problem - even with bounded demands.

Obtaining approximation algorithms that run fast, while simultaneously guaranteeing small approximation factors is a challenging research direction. Recently, Chekuri et al. [12], and Chan and He [10], building on the work of Agarwal and Pan [1] have improved the running times of the LP based algorithms for both packing and covering problems via the multiplicative weights update framework. In this work, we improve the approximation factor, but we do not improve the running times of the algorithms. We give a polynomial time $(2+\epsilon)$-approximation algorithm for the Set Multicover problem for non-piercing regions in the unweighted setting. We obtain the same approximation factor for the multi-hitting set problem for pseudodisks. Our key observation is that even if the LP relaxation has a large integrality gap, we can round it without losing more than a $(1+\delta)$ factor so that it meets all demands with only a constant deficit which depends on the parameter δ. This yields a problem with low demands for which a PTAS can be obtained via local search. Note that even the second part of our approach - PTAS for multihitting set problems with bounded demands, is non-trivial, and builds on tools developed by Raman and Ray [30].

2 Preliminaries

The set multicover problem is defined by a set system $(X, \mathcal{S})$ and a demand function $d : X \mapsto \mathbb{R}$. The task is to select the smallest cardinality subset $\mathcal{S}'$ of $\mathcal{S}$ such that each $x \in X$ is contained in at least $d(x)$ subsets of $\mathcal{S}'$. We refer to the set X as the *ground set* and the elements of $\mathcal{S}$ as *ranges*. For any subset $\mathcal{S}' \subseteq \mathcal{S}$ and any $x \in X$, we denote by $\mathcal{S}'(x)$ the set of elements in $\mathcal{S}'$ containing x and we refer to $|\mathcal{S}'(x)|$ as the *depth* of x in $\mathcal{S}'$.

We require the notion of *shallow-cell complexity* defined by Chan et al. [7]. A *cell* in the set system $(X, \mathcal{S})$ is a maximal subset $X' \subseteq X$ such that the elements of X' are contained in the same collection of ranges in $\mathcal{S}$. We say that a range $S \in \mathcal{S}$ contains a cell C if S contains

the elements in C. The depth of a cell C is the number of ranges in $\mathcal{S}$ containing C. A set system has shallow-cell complexity $f(n,k)$ if for any subset $\mathcal{S}' \subseteq \mathcal{S}$ of size n, the number of cells of depth at most k in $(X, \mathcal{S}')$ is at most $f(n,k)$. We focus on set systems whose shallow cell complexity is linear in n and polynomial in k. We say that a set system is *c-linear*, for some constant c, if its shallow-cell complexity is $O(nk^c)$.

The set systems we study in this paper are defined by a set of points and a set of regions in the plane. A *Jordan region* is a compact, simply connected set in the plane whose boundary is a simple jordan curve. We say that a set $\mathcal{R}$ of Jordan regions is a non-piercing family if for any $\gamma, \gamma' \in \mathcal{R}$, $\gamma \setminus \gamma'$ and $\gamma' \setminus \gamma$ are both path connected sets. A set of Jordan regions $\mathcal{R}$ is said to be a family of *pseudodisks* if the boundaries of every pair of regions either do not intersect or cross (i.e. intersect non-tangentially) at exactly two points. Note that a family of pseudodisks is also a family of non-piercing regions but not vice-versa.

In this paper, we study two set multicover problems defined by a set of points and a set of regions in the plane. The first is the set multicover problem in which the ground set is a finite set P of points in the plane and the ranges are obtained by intersecting P with the regions in a family $\mathcal{R}$ of non-piercing regions. Abusing notation, we denote such set systems by $(P, \mathcal{R})$. In the second set multicover problem we study, the ground set is a family of pseudodisks $\mathcal{D}$ and each range is the subset of $\mathcal{D}$ containing a particular point p in a set of points P. Again, for simplicity, we denote such a set system by $(\mathcal{D}, P)$. This variant of the set cover problem is usually called the *hitting set* problem.

3 Our Results

The results of Chekuri et al. [11] imply an $O(1)$-approximation algorithm for the set multicover problem for set systems with linear union complexity. Such set systems are c-linear for some constant c. Bansal and Pruhs [3] guarantee an $O(1)$-approximation factor for the weighted set multicover problem defined by a c-linear set system.

Since both the methods above are based on LP-rounding, the approximation factor is at least as large as the integrality gap. Even for set cover problems (i.e., all demands are 1) defined by very simple geometric regions in the plane, the integrality gap is not known to be small. For halfspaces in the plane, the integrality gap is 2 [24] which implies that it is at least 2 for disks as well. Even though no larger lower bound is known, the best upper bound currently known on the integrality gap for disks is significantly higher: 13.4 [6]. The integrality gap is probably higher when the demands are allowed to be more than 1. However, we are not aware of any results regarding this. Apart from the integrality gap, there are additional constant factors that are gained in the process of rounding. While the exact constants are not analyzed in [11] or [3], they seem to be large. For instance, since the main tool is used in [3] is the quasi-sampling technique [7, 31], the constant seems to be at least $e^{4.34362} > 76$ (see Claims 2 and 4 of [7]). We do not have accurate estimates for the constants involved in shallow cuttings used in [11] but we believe that they are not significantly smaller (and likely to be much larger since they use ϵ-nets and approximations for which the known constants are quite large). Our main result is a $(2+\epsilon)$-approximation algorithm for the set multicover problem for points and non-piercing regions in the plane, in the unweighted setting.

▶ **Theorem 1.** *The set multicover problem defined by a set system $(P, \mathcal{R})$, where P is a finite set of points and $\mathcal{R}$ is a set of non-piercing regions in the plane with an arbitrary demand function $d : P \to \mathbb{R}$ admits a polynomial time $(2+\epsilon)$-approximation algorithm for any $\epsilon > 0$.*

The result follows from the following results that we prove in Sections 4 and 5. First, we show that the set system $(P, \mathcal{R})$ is 2-linear (Lemma 25) and for any set system that is c-linear for some constant c, we obtain the following result via a simple modification of the technique of Bansal and Pruhs [3].

▶ **Theorem 2.** *Let $(X, \mathcal{S})$ be a c-linear set system for some constant c and let $m = |\mathcal{S}|$. Consider the set multicover problem defined by $(X, \mathcal{S})$ in which each element $x \in X$ has a demand $d(x)$. Let y be any feasible solution to the linear programming relaxation of this problem i.e., y satisfies the constraints: $\forall x \in X$, $\sum_{S \ni x} y_S \geq d(x)$, and let $\delta \in (0, 1)$ be a given parameter. Then, we can obtain a subset of ranges $\mathcal{S}' \subseteq \mathcal{S}$ s.t.*

(i) $\forall x \in X,\ |\mathcal{S}'(x)| \geq d(x) - 3\tau$, *where $\tau = C\delta^{-4} \log \delta^{-1}$ with a large enough C*

(ii) $|\mathcal{S}'| \leq (1 + O(\delta)) \sum_{S \in \mathcal{S}} y_S$

This shows that the LP solution can be "rounded" without increasing the objective value much and causing only a constant *deficit* in the demands. Since the *residual* demands are $O(1)$ for any constant δ, we obtain a set multicover problem with bounded demands. We then show that the set multicover problem with non-piercing regions and bounded demands has a PTAS via local search.

▶ **Theorem 3.** *Local Search yields a PTAS for the set multicover problem defined by a set system $(P, \mathcal{R})$ where P is a set of points and $\mathcal{R}$ is a family of non-piercing regions in the plane and where each point $p \in P$ has a demand bounded above by some constant Θ.*

We also obtain the same approximation factor in the dual setting, though here we are currently only able to prove the result when the regions are pseudodisks.

▶ **Theorem 4.** *Let $\mathcal{P}$ be a Set Multicover problem for the set system $(\mathcal{D}, P)$ defined by a set of pseudodisks $\mathcal{D}$ and a set of points P in the plane with demand function $d : \mathcal{D} \to \mathbb{R}$. For any $\epsilon > 0$, there is a polynomial time $(2 + \epsilon)$-approximation algorithm for $\mathcal{P}$.*

The result is obtained by showing that the set system $(\mathcal{D}, P)$ is 2-linear, which implies that Theorem 2 can be used to obtain an instance of the set multicover problem where the demands of the pseudodisks are bounded above by a constant Θ. For these instances, we show that local search yields a PTAS.

▶ **Theorem 5.** *Local Search yields a PTAS for the set multicover problem defined by a set system $(\mathcal{D}, P)$ where P is a set of points and $\mathcal{D}$ is a family of pseudodisks in the plane and where each pseudodisk $D \in \mathcal{D}$ has a demand bounded above by some constant Θ.*

Even though the PTASes obtained in Theorems 3 and 5 are not surprising, the proofs are not trivial. In fact, it would not be surprising if local search yields a PTAS for the set multicover problem with arbitrary demands. However, we are currently unable to prove such a result.

The paper is organized as follows. In Section 4, we prove Theorem 2. In Subsection 5.1, we prove Theorem 3, and we prove Theorem 5 in Subsection 5.2. Theorems 1 and 4 are proved in Section 6.

4 LP Rounding with bounded deficits

In this section we prove Theorem 2. Consider the set multicover problem defined by a c-linear set system $(X, \mathcal{S})$ and a demand function $d : X \mapsto \mathbb{R}$. The natural linear programming relaxation for this problem is the following:

$$\min \sum_{S \in \mathcal{S}} y_S \quad \text{s.t.} \quad \forall S \in \mathcal{S},\ y_S \in [0,1] \quad \text{and} \quad \forall x \in X,\ \sum_{S \ni x : S \in \mathcal{S}} y_S \geq d(x) \tag{1}$$

Our goal is to show that given any feasible solution y to the above LP and any $\delta > 0$, we can find a subset $\mathcal{S}' \subseteq \mathcal{S}$ of size at most $(1 + O(\delta)) \sum_{S \in \mathcal{S}} y_S$ and $\forall x \in X, |\mathcal{S}'(x)| \geq d(x) - O(\delta^{-4} \log \delta^{-1})$. We start with a few technical results. The lemma below follows from the techniques in [7, 31] where similar statements are proved.

▶ **Lemma 6.** *Let $(X, \mathcal{S})$ be a c-linear set system and let $m = |\mathcal{S}|$. Then, there exists an ordering $S_1, \cdots, S_m$ of the ranges in $\mathcal{S}$ s.t. in the set system $(X, \mathcal{S}_i)$ where $\mathcal{S}_i = \{S_1, \cdots, S_i\}$, the range S_i contains at most $O(k^{c+3})$ cells of depth at most k, for any k.*

Proof. We assign a weight to each cell in $(X, \mathcal{S})$ depending on its depth. A cell of depth k is assigned a weight of $1/k^{c+3}$. We define the weight of a range to be the total weight of all the cells it contains. Since there are at most $O(mk^c)$ cells of depth k (since $(X, \mathcal{S})$ is c-linear), the total weight of all cells of depth k is at most $O(m/k^3)$. Since each cell of depth k contributes to the weight of k ranges in $\mathcal{S}$, the contribution of the depth k cells to the total weight of all ranges is $O(m/k^2)$. The total weight of all ranges is therefore at most $O(m) \sum_{k=1}^{m} k^{-2} = O(m)$. This implies that there is a range $S \in \mathcal{S}$ whose weight is $O(1)$ which in turn implies that for any k, the number of depth k cells in S is at most $O(k^{c+3})$. We recursively find the ordering of $(X, \mathcal{S} \setminus \{S\})$. The ordering for $(X, \mathcal{S})$ is obtained by appending S to the ordering for $(X, \mathcal{S} \setminus \{S\})$. The lemma follows. ◀

▶ **Definition 7** (Weighted Depth). *Let $(X, \mathcal{S})$ be a set system. Let $w(S) \geq 0$ be a weight associated with each range $S \in \mathcal{S}$. Then, for any element $x \in X$, we denote by $w_{\mathcal{S}}(x)$ the total weight of the ranges in $\mathcal{S}$ containing x. We call this the weighted depth of the element x with respect to the ranges in $\mathcal{S}$ and the weight function w.*

▶ **Lemma 8** (Weighted Sampling Procedure). *Let $(X, \mathcal{S})$ be a c-linear set system for some constant c and let $m = |\mathcal{S}|$. Let $w(S) \in [0.5, 1.0]$ be a weight associated with each $S \in \mathcal{S}$ and let $\delta \in (0, 1)$ be a parameter. Then, there is a polynomial time procedure to pick a subset $\mathcal{S}' \subseteq \mathcal{S}$ s.t.*

- **(i)** *$|\mathcal{S}'| \leq (1 + O(\delta))\, W$ where $W = \sum_{S \in \mathcal{S}} w(S)$, and*
- **(ii)** *for any element $x \in X$: $|\mathcal{S}'(x)| \geq w_{\mathcal{S}}(x) - \tau$ where $\tau = C\delta^{-3} \log \delta^{-1}$ for a large enough constant C.*

Proof. The set $\mathcal{S}'$ is unweighted but we can think of each range in $\mathcal{S}'$ as having weight 1. This means that any range $S \in \mathcal{S}$ with weight $\geq 1 - \delta$ can be safely included in $\mathcal{S}'$ since this way we are increasing its weight by at most a factor of $1 + O(\delta)$. We will thus assume without loss of generality that all ranges in $\mathcal{S}$ have weight at most $1 - \delta$. We will show that a procedure similar to the quasi-uniform sampling procedure [31, 7] can be used to pick each range $S \in \mathcal{S}$ into $\mathcal{S}'$ with probability at most $(1 + O(\delta))\, w(S)$ s.t. the second condition in the lemma is satisfied. Then, the expected number of ranges in $\mathcal{S}'$ is at most $(1 + O(\delta))\, W$.

Now, by Markov inequality, the probability that $|\mathcal{S}'|$ exceeds its expectation by a factor of more than $(1 + \delta)$ is at most $1/(1 + \delta)$ which means that the with probability $\Omega(\delta)$, $|\mathcal{S}'|$ is $(1 + O(\delta))W$. We can therefore repeat the process $O(1/\delta)$ times in expectation to obtain the desired collection $\mathcal{S}'$ of sets.

Our sampling procedure has two stages. In the first stage, we pick a sample $\mathcal{T} \subseteq \mathcal{S}$ by picking each range $S \in \mathcal{S}$ independently with probability $w(S)/(1-\delta) \in [0,1]$. In the second stage, we pick another sample $\mathcal{T}' \subseteq \mathcal{S}$ s.t. each range is picked with a probability $O(\delta) = O(w(S) \cdot \delta)$ but whether or not a range is picked depends on the outcome of the first stage. We set $\mathcal{S}' = \mathcal{T} \cup \mathcal{T}'$. The probability that a particular range $S \in \mathcal{S}$ is included in $\mathcal{S}'$ is at most $w(S)/(1-\delta) + O(w(S) \cdot \delta) = w(S)(1 + O(\delta))$ as required.

Let $S_1, \cdots, S_m$ be the ordering of the ranges in $\mathcal{S}$ given by Lemma 6. Let $\mathcal{S}_i = \{S_1, \cdots, S_i\}$ and let $\mathcal{T}_i = \mathcal{T} \cap \mathcal{S}_i$ denote the subset of the ranges in $\mathcal{S}_i$ picked in the first stage. The range S_i is picked in the second stage if it is *forced* by an element $x \in X$ which happens if $k = w_{\mathcal{S}}(x) \geq \tau$, $k_i = w_{\mathcal{S}_i}(x) \geq \delta k$ and $s_i = |\mathcal{T}_i(x)| < k_i$. In words, S_i is forced by x if i) x has high weighted depth (at least τ) w.r.t. the ranges in $\mathcal{S}$, ii) the ranges in $\mathcal{S}_i$ contribute at least δ fraction of the total weight of the ranges in $\mathcal{S}$ containing x and iii) fewer than $w_{\mathcal{S}_i}(x)$ ranges among the ranges in $\mathcal{S}_i$ containing x are sampled in the first stage.

Note that the second stage guarantees that the second condition in the lemma is satisfied for all elements in X. We now bound the probability that S_i is forced by x. Since each range $S \in \mathcal{S}$ is picked independently with probability $w(S)/(1-\delta)$ in the first stage, the expected value of s_i is $\mu = k_i(1-\delta)$ and by Chernoff bound, $\Pr(s_i < k_i) = \Pr(s_i < (1-\delta)\mu) \leq \exp(-\mu\delta^2/2) \leq \exp(-k_i\delta^2/2) \leq k_i^{-(c+5)}$ since $k_i \geq \delta k \geq \delta\tau = C\delta^{-2}\log\delta^{-1}$ which for large enough C implies that $k_i\delta^2/2 \geq (c+5)\log k_i$.

Thus, we have shown that the probability that the range S_i is forced by a particular element x having weighted depth k_i w.r.t. $\mathcal{S}_i$ is at most $k_i^{-(c+5)}$. However S_i may be forced by many elements in X. To bound the probability that S_i is forced (by some element), first note that all elements lying in the same cell of $(X, \mathcal{S}_i)$ behave identically i.e., they all either force S_i or don't force S_i. Thus, we only need to consider elements in distinct cells of $(X, \mathcal{S}_i)$. By Lemma 6, for any $t \geq 1$, S_i contains at most $O(t^{c+3})$ cells of depth t in $(X, \mathcal{S}_i)$. Since each range $S \in \mathcal{S}$ has a weight $w(S) \geq 0.5$, it follows that if an element of X has (unweighted) depth t, then its weighted depth is at least $t/2$. Thus, the probability that S_i is forced by elements in X of depth t w.r.t. $\mathcal{S}_i$ is at most $O(t^{c+3}) \cdot O(t^{-(c+5)}) = O(t^{-2})$. Since the second condition in the lemma is trivially satisfied for elements having weighted depth at most τ in $(X, \mathcal{S})$, we are concerned only with elements having weighted depth $k \geq \tau$ in $(X, \mathcal{S})$, and any such an element can force S_i only if its weighted depth in $(X, \mathcal{S}_i)$ is at least $\delta k \geq \delta\tau$, the probability that S_i is forced (by some element) is at most $\sum_{t=\delta\tau}^{\infty} O(t^{-2}) = O(1/(\delta\tau)) = O(\delta)$. The lemma follows. ◀

The following is an *unweighted* version of the above lemma.

▶ **Lemma 9** (Unweighted Sampling Procedure). *Let $(X, \mathcal{S})$ be a c-linear set system and let $m = |\mathcal{S}|$. Let Δ be a large enough parameter. Then, there is a procedure to pick a subset $\mathcal{S}' \subseteq \mathcal{S}$ s.t.*

(i) $|\mathcal{S}'| \leq (1 + O(\sqrt[4]{(\log\Delta)/\Delta})\,|\mathcal{S}|/2$ *and*

(ii) *any element $x \in X$ having depth $k \geq \Delta$ in $\mathcal{S}$, has depth at least $k/2$ in $\mathcal{S}'$.*

Proof. The lemma follows from a straightforward application of Lemma 8 with parameter $\delta = \alpha \sqrt[4]{(\log\Delta)/\Delta}$ for a small enough constant α s.t. $\Delta \geq \frac{2}{\delta}\, C\, \delta^{-3} \log\delta^{-1}$ where C is the constant in Lemma 8 and setting the weight of each range in $\mathcal{S}$ to $0.5(1+\delta)$. ◀

We now restate and prove Theorem 2.

▶ **Theorem 2.** *Let $(X, \mathcal{S})$ be a c-linear set system for some constant c and let $m = |\mathcal{S}|$. Consider the set multicover problem defined by $(X, \mathcal{S})$ in which each element $x \in X$ has a demand $d(x)$. Let y be any feasible solution to the linear programming relaxation of this problem i.e., y satisfies the constraints: $\forall x \in X$, $\sum_{S \ni x} y_S \geq d(x)$, and let $\delta \in (0, 1)$ be a given parameter. Then, we can obtain a subset of ranges $\mathcal{S}' \subseteq \mathcal{S}$ s.t.*

(i) $\forall x \in X$, $|\mathcal{S}'(x)| \geq d(x) - 3\tau$, *where* $\tau = C\delta^{-4} \log \delta^{-1}$ *with a large enough* C

(ii) $|\mathcal{S}'| \leq (1 + O(\delta)) \sum_{S \in \mathcal{S}} y_S$

Proof. Since condition (i) in the lemma is trivially satisfied for elements with demand at most 3τ, we can assume without loss of generality that each element has demand more than 3τ. We associate a *value* v_S with each range $S \in \mathcal{S}$. Initially $v_S = y_S$. The proof is constructive, and consists of two phases. The first phase consists of several rounds in which we modify the values of the ranges so that they are either 0 or lie in the interval $[0.5, 1]$. In a second phase we pick each range $S \in \mathcal{S}$ into $\mathcal{S}'$ with probability equal to the value v_S at the end of the first phase.

In the first phase we maintain a partition of the set of ranges $\mathcal{S}$ into two sets $\mathcal{F}$ and $\mathcal{N}$ where $\mathcal{F}$ is the set of *frozen* ranges whose values are either 0 or in the interval $[0.5, 1]$ and $\mathcal{N} = \mathcal{D} \setminus \mathcal{F}$ is the set of *non-frozen* ranges. We do not modify the value of any range in $\mathcal{F}$ which means that once a range is in $\mathcal{F}$, it remains in $\mathcal{F}$. We continue to modify the values of the ranges in $\mathcal{N}$ until all of them move to $\mathcal{F}$.

The first phase has several rounds. At the beginning of the first round, each range S has value y_S. The total value of all ranges at this time is $\sum_{S \in \mathcal{S}} y_S$. We replace each range $S \in \mathcal{N}$ by $\lfloor m \cdot y_S \rfloor$ replicas where each replica has value $\lambda_1 = 1/m$. The value of a range S is now the product of the number of replicas and the replica value. Note that the total value of any particular range decreases by at most $1/m$ due to this and therefore for each element $x \in X$, we have $\sum_{S \ni x : S \in \mathcal{S}} v_S \geq d(x) - 1$ i.e., v satisfies the demands with a *deficit* of ≤ 1.

At the beginning of round i, each replica has value $\lambda_i = 2^{i-1}/m$. Note that the replica values are uniform in any round and we double the replica value in each round. In round i, we use the unweighted sampling procedure (Lemma 9) with the parameter Δ set to $\Delta_i = \tau/\lambda_i$ to obtain a subset of the replicas that go to the round $i + 1$. Note that the value of a frozen range is not modified by this procedure. The value of a non-frozen range changes according to the number of its replicas that make it to the next round. In particular, if a range has lost all its replicas, then its value becomes 0 and is frozen. Similarly, a range is frozen if the total value of its replicas becomes at least 0.5. The number of rounds is less than $\log_2 m$ since after so many rounds each replica has value at least 0.5.

Let v_S be the value of range S after the first phase. We claim that v satisfies $\forall x \in X$: $\sum_{S \in \mathcal{S}} v_S \geq d(x) - 2\tau$. To see this, consider any element $x \in X$ and let us say that x is *satisfied* at any point in time if the total value of the ranges containing it is at least its demand minus 1 i.e., $\sum_{S \ni x} v_S = \sum_{S \ni x : S \in \mathcal{N}} v_S + \sum_{S \ni x : S \in \mathcal{F}} v_S \geq d(x) - 1$. Note that x is satisfied at the beginning of round 1. Furthermore, if x is satisfied at the beginning of round i and in addition $\sum_{x \ni S : S \in \mathcal{N}} v_S \geq \tau$, then it is also satisfied after round i. This follows since every replica has value λ_i in round i, which means that if x's depth in the arrangement of the replicas is k then $k \geq \Delta_i = \tau/\lambda_i$ and Lemma 9 guarantees that its depth with respect to the replicas after round i is at least $k/2$. Recall that replica weights are doubled in every round which compensates for the decrease in the number of replicas covering x. Thus, if x is satisfied at the beginning of round i, then the only way it can be dissatisfied at the end of the round is if at the beginning of the round, $\sum_{S \ni x : S \in \mathcal{N}} v_S < \tau$ which means that $\sum_{S \ni x : S \in \mathcal{F}} v_S \geq d(x) - \tau - 1 \geq d(x) - 2\tau$. Since we don't modify the value of any range once it enters the set $\mathcal{F}$, this inequality is satisfied at the end of the first phase too.

We now argue that at the end of the first phase: $\sum_{S\in\mathcal{S}} v_S \leq (1+O(\delta))\sum_{S\in\mathcal{S}} y_S$. To see this note that, by Lemma 9, the total value of the ranges in $\mathcal{S}$ increases, by a factor of at most $1+O(\sqrt[4]{(\log\Delta_i)/\Delta_i})$ in round i. Therefore, the total value of all ranges increases in the first phase by a factor of at most

$$\prod_{i=1}^{t}\left(1+O\left(\sqrt[4]{\frac{\log\Delta_i}{\Delta_i}}\right)\right) \leq \exp\left[O\left(\sum_{i=1}^{t}\sqrt[4]{\frac{\log\Delta_i}{\Delta_i}}\right)\right] \leq \exp\left[O\left(\sqrt[4]{\frac{\log\Delta_t}{\Delta_t}}\right)\right] \leq (1+O(\delta))$$

where $t<\log_2 m$ is the number of rounds. The second last inequality above follows from the fact that $\sqrt[4]{(\log\Delta_i)/\Delta_i}$ increases geometrically with i since $\Delta_i=\tau m/2^{i-1}$ decreases geometrically with i. The last inequality follows from the fact that $t<\log_2 m$, which means that $\Delta_t<\tau$.

Recall that at the end of the first phase, the value of each range is either 0 or lies in the range $[0.5,1]$. In the second phase, we apply Lemma 8 to the ranges having a non-zero value $v_S\in[0.5,1]$ at the end of the first phase with the weight function $w(S)=v_S$ and the parameter δ. Since every element $x\in X$ is assumed to have demand at least 3τ, its weighted depth k with respect to the weight function w is least $d(x)-2\tau\geq\tau$. Lemma 8 then guarantees that its unweighted depth with respect to the set of ranges $\mathcal{S}'$ returned by Lemma 8 is also at least k. Thus $\mathcal{S}'$ satisfies the first condition in the lemma. It also satisfies the second condition in the lemma since Lemma 8 guarantees that $|\mathcal{S}'|\leq(1+O(\delta))\sum_{S\in\mathcal{S}} v_S$ which is at most $(1+O(\delta))\sum_{S\in\mathcal{S}} y_S$ since we had established earlier that $\sum_{S\in\mathcal{S}} v_S\leq(1+O(\delta))\sum_{S\in\mathcal{S}} y_S$. ◀

5 Set Multicover with bounded demands

Consider the set multicover problem defined by a set system $(X,\mathcal{S})$ and a demand function d s.t. for each element $x\in X$, $d(x)$ is bounded above by a constant Θ. We will show that a standard local search algorithm (see e.g. [2, 9, 28, 30] for details) yields a PTAS for this problem when X is a set of points and $\mathcal{S}$ is a set of non-piercing regions in the plane, or when X is a set of pseudodisks and $\mathcal{S}$ is a set of points in the plane. The algorithm takes as input a parameter k and starting with any feasible solution it tries to improve the solution by making *swaps* of size at most k and stops when no such improvement is possible.

In order to show that such a local search algorithm yields a PTAS, we consider an optimal solution R to the problem and a solution B returned by the local search algorithm. We want to show that $|B|\leq(1+\epsilon(k))\,|R|$ where $\epsilon(k)\to 0$ as $k\to\infty$. We can assume without loss of generality that R and B are disjoint by removing the set $S=R\cap B$ from both and considering the problem with residual demands where the residual demand of any element $x\in X$ is $d(x)-|S(x)|$. Note that the residual demands are still bounded above by Θ and if $|B\setminus S|\leq(1+\epsilon(k))\,|R\setminus S|$ then it follows that $|B|\leq(1+\epsilon(k))\,|R|$.

By standard arguments [2, 9, 28, 30], it then suffices to show that there exists a graph $G=(R\cup B,E)$ satisfying the following ***local search conditions***:

1. For any $B'\subseteq B$, $(B\setminus B')\cup N(B')$ is a feasible solution, where $N(B')$ is the set of neighbors of B' in the graph G. We call this the *local exchange property.*
2. The graph has the *sublinear separator property* (see Definition 10).

▶ **Definition 10** (Sublinear Separator Property)**.** *We say that a graph H satisfies the sublinear separator property if there exist $0<\alpha,\delta<1$ s.t. for any induced subgraph H' of H with vertex set $V(H')$, there is a vertex separator $S\subset V(H')$ so that $|S|=O(|V(H')|^{\delta})$, and each connected component of $H'\setminus S$ is of size at most $\alpha|V(H')|$.*

In all applications of this technique so far, the critical part has been showing the existence of such a graph, which is what we now focus on. Instead of the local exchange property, we will use the following *local expansion* property which implies the local exchange property.

▶ **Definition 11** (Local Expansion). *Let R and B be two feasible solutions for a set multicover problem defined by a set system $(X, \mathcal{S})$ and a demand function d. We say that a graph $G = (R \cup B, E)$ satisfies the local expansion property with respect to $(X, R \cup B)$ if for every $x \in X$ at least one of the following statements hold:*

- *There are at least $d(x)$ elements in $R(x)$ that have $d(x)$ or more neighbors in $B(x)$.*
- *There are at least $d(x)$ elements in $B(x)$ that have $d(x)$ or more neighbors in $R(x)$.*

Here, by "neighbors" we mean neighbors in the graph G.

▶ **Proposition 12.** *Let R and B be two feasible solutions to the set multicover problem defined by a set system $(X, \mathcal{S})$ and a demand function d. Then, any graph $G = (R \cup B, E)$ satisfying the local expansion property with respect to $(X, R \cup B)$ also satisfies the local exchange property (i.e., local search condition 1).*

Proof. Consider any $x \in X$. The local expansion property implies that the subgraph of G induced on $R(x) \cup B(x)$ contains a matching of size $d(x)$. Let $U \subseteq R(x)$ and $V \subseteq B(x)$ be the matched elements. Suppose that we replace B by $(B \setminus B') \cup N(B')$ for some $B' \subseteq B$. Then we may lose $k \leq d(x)$ of elements of V but we gain at least an equal number of elements from U due to the matching. This implies that $(B \setminus B') \cup N(B')$ still satisfies x's demand. Since this is true for any $x \in X$, $(B \setminus B') \cup N(B')$ is a feasible solution. ◀

Observe that the intersection graph $I(R \cup B)$ of the ranges in $R \cup B$ in which two ranges are adjacent iff they share an element of X, has the local expansion property and therefore satisfies the local exchange property. However, the intersection graph may not satisfy the sublinear separator property. The next two lemmas show that for the geometric sets systems we consider, the intersection graph does satisfy the sublinear separator property if the depth of each cell in the set system is bounded above by a constant.

▶ **Lemma 13.** *Let $\mathcal{R}$ be a family of n non-piercing regions. Then, the number of pairs of regions in $\mathcal{R}$ that intersect at a point of depth 2 in the arrangement $\mathcal{A}(\mathcal{R})$ of $\mathcal{R}$ is at most $3n - 6$.*

Proof. Let $G = (\mathcal{R}, E)$ be the planar graph obtained from part 1 of Theorem 20. There must be an edge in G between any two regions in $\mathcal{R}$ that intersect at a point of depth 2 in $\mathcal{A}(\mathcal{R})$. The lemma follows from the fact that a planar graph with n vertices has at most $3n - 6$ edges. ◀

▶ **Lemma 14.** *Let $\mathcal{R}$ be a family of n non-piercing regions whose arrangement has depth at most Δ. Then, there exists a set Q of $O(\Delta n)$ points in the plane s.t. any intersecting pair of regions in $\mathcal{R}$ also intersect at one the points in Q.*

Proof. We assume that $\Delta \geq 2$ as otherwise no pair of regions in $\mathcal{R}$ intersect. Let Q be a minimal set of points so that any pair of intersecting regions in $\mathcal{R}$ also intersect at some point in Q. Since Q is minimal, for each $q \in Q$, there must be two regions A_q and B_q in $\mathcal{R}$ which intersect at q but don't intersect at any other point in Q. Suppose now that we take a sample $\mathcal{R}'$ of $\mathcal{R}$ by picking each region in $\mathcal{R}$ independently with probability $p = 1/\Delta$. Since any point $q \in Q$ is contained in at most Δ regions in $\mathcal{R}$, the probability that we pick A_q and B_q in our sample but do not pick any other regions containing q is at least $p^2(1-p)^{\Delta-2} \geq 1/(e\Delta)^2$. The expected number of points in Q for which this happens is at least $|Q|/(e\Delta)^2$. Each such

point q corresponds to a distinct pair of regions in $\mathcal{R}'$ intersecting at a point of depth 2 (in the arrangement of $\mathcal{R}'$). Since the expected number of regions in $\mathcal{R}'$ is $pn = n/\Delta$, and there can be at most $3|\mathcal{R}'|$ pairs of regions in $\mathcal{R}'$ that intersect at a point of depth 2, by Lemma 13, we conclude that $|Q|/(e\Delta)^2 \leq 3n/\Delta$ which implies that $|Q| \leq 3e^2\Delta n$. ◀

▶ **Lemma 15.** *Let $H = (V, E)$ be a planar graph and let $\mathcal{T}$ be a set of subsets of V s.t. i) for each $T \in \mathcal{T}$ the subgraph $H[T]$ of H induced by T is connected and ii) each vertex $v \in V$ is contained in at most Δ of the sets in $\mathcal{T}$, where Δ is a constant. Then, the intersection graph of the sets in any $\mathcal{S} \subseteq \mathcal{T}$ has a balanced separator of size $O(\Delta\sqrt{|W|})$, where $W = \cup_{S\in\mathcal{S}} S$. In other words, the intersection graph of the sets in $\mathcal{T}$ satisfies the sublinear separator property.*

Proof. Fix any $\mathcal{S} \subseteq \mathcal{T}$. We assign a weight $w(v)$ to each vertex $v \in W$ as follows: each set $S \in \mathcal{S}$ has a weight of 1 and it distributes it equally among all the vertices it contains. More precisely, $w(v) = \sum_{S\in\mathcal{S}:v\in S} 1/|S|$. Note that the total weight of all vertices is $|\mathcal{S}|$. Let $X \subseteq W$ be a balanced vertex separator of $G = H[W]$ of size $O(\sqrt{|W|})$ so that the total weight of the vertices in each connected component of $G[W \setminus X]$ is at most $\alpha\,|\mathcal{S}|$ for some $\alpha < 1$. The fact that such a separator exists follows from the fact that $H[W]$ is planar and the planar graph separator theorem [27].

Let $\mathcal{X} = \{S \in \mathcal{S} : S \cap X \neq \emptyset\}$. As each vertex in X is contained in at most Δ sets in $\mathcal{S}$, $|\mathcal{X}| \leq \Delta|X| = O(\Delta\sqrt{|W|})$. Since each set $S \in \mathcal{S}$ induces a connected subgraph of H, $\mathcal{X}$ is a separator for the intersection graph I of the sets in $\mathcal{S}$. Furthermore, it is balanced since each connected component of $I[\mathcal{S} \setminus \mathcal{X}]$ corresponds to a connected component of $H[W \setminus X]$ and since the total weight of all vertices in the latter is at most αn, the number of sets in the former is also at most αn. ◀

▶ **Lemma 16.** *Let $\mathcal{R}$ be a family of n non-piercing regions in the plane whose arrangement has depth at most Δ, where Δ is a constant. Then the intersection graph of the regions in $\mathcal{R}$ has the sublinear separator property.*

Proof. Let Q be a set of $O(\Delta n)$ points obtained by applying Lemma 14. By Theorem 20, there is a planar graph $H = (Q, F)$, such that for any region $R \in \mathcal{R}$, the induced subgraph $H[Q_R]$, where $Q_R = R \cap Q$, is connected. Since every pair of intersecting regions in $\mathcal{R}$ intersect at some point in Q, the intersection graph of the sets in $\mathcal{S} = \{Q_R : R \in \mathcal{R}\}$ is isomorphic to the intersection graph of the regions in $\mathcal{R}$. Further, since the arrangement of the regions has depth Δ, no vertex of H is contained in more than Δ sets in $\mathcal{S}$. Therefore, the Lemma follows from the application of Lemma 15 to H and $\mathcal{S}$. ◀

▶ **Lemma 17.** *Let $(\mathcal{D}, P)$ be a set system defined by a set P of n points and a set $\mathcal{D}$ of pseudodisks in the plane. Then, the number of pairs of points (p, q) that lie in a common cell of depth 2 in $(\mathcal{D}, P)$ (i.e., there is a pseudodisk $D \in \mathcal{D}$ s.t. $D = \{p, q\}$) is at most $3n - 6$.*

Proof. The proof is the same as the proof of Lemma 13 except that we use part 2 of Theorem 20 instead of part 1. ◀

▶ **Lemma 18.** *Let P be a set of n points and let $\mathcal{D}$ be a family of pseudodisks in the plane s.t. for each $D \in \mathcal{D}, |D \cap P| \leq \Delta$. Then, there exists a subset $\mathcal{D}' \subseteq \mathcal{D}$ of size $O(\Delta n)$ s.t. any pair of points in P that belong to a common pseudodisk in $D \in \mathcal{D}$ also belong to a common pseudodisk $D' \in \mathcal{D}'$.*

Proof. The proof is identical to the proof of Lemma 14 except that we use Lemma 17 instead of Lemma 13. ◀

▶ **Lemma 19.** *Let P be a set of points and let $\mathcal{D}$ be a family of pseudodisks in the plane such that for any $D \in \mathcal{D}$, $|D \cap P| \leq \Delta$ for some constant Δ. Then, the graph $G(P, E)$ in which two points $p, q \in P$ are adjacent iff there is a pseudodisk $D \in \mathcal{D}$ containing both p and q, has the sublinear separator property.*

Proof. The proof is identical to the proof of Lemma 16, except that we use Lemma 18 instead of Lemma 14. ◀

In order to use the above lemmas, we need to modify a given set system $(X, R \cup B)$ so that each cell in it has bounded depth. We also require the following result which follows from Theorem 1 in [30].

▶ **Theorem 20** ([30])**.** *Let $\mathcal{R}$ be any family of non-piercing regions in the plane, and let P be any finite set of points in the plane. Then,*

1. *There exists a planar graph $G = (\mathcal{R}, E)$ s.t. for each point $p \in \mathbb{R}^2$, the subgraph of G induced by the regions containing p is connected.*
2. *There exists a planar graph $H = (P, E')$ s.t. for each $\gamma \in \mathcal{R}$, the subgraph of H induced by $\gamma \cap P$ is connected.*

5.1 Points and Non-Piercing regions

In this subsection, we prove Theorem 3. Consider the set multicover problem defined by a set system $(P, \mathcal{R})$ where P is a set of points and $\mathcal{R}$ is a family of non-piercing regions in the plane, and in which the demand $d(p)$ of each point is at most Θ. As before, $R, B \subseteq \mathcal{R}$ represent an optimal solution and a solution returned by the local search algorithm respectively. Furthermore, as argue before, we can assume without loss of generality that $R \cap B = \emptyset$. We will show the existence of a graph $G = (R \cup B, E)$ satisfying the local search conditions, implying a PTAS for this problem.

We first need a technical tool from [30] for modifying the regions so that the arrangement of the modified regions has bounded depth. A *maximal cell* in an arrangement of regions in the plane is a cell whose depth is higher than all neighboring cells.

▶ **Definition 21** (Cell Bypassing [30])**.** *Let $\mathcal{R}$ be a non-piercing family of regions. Let $\gamma \in \mathcal{R}$ be one of the regions and let C be a maximal cell contained in γ so that that the boundary of γ contributes exactly one arc to the boundary of C. Then, if we modified γ to $\gamma' = \gamma \setminus (C \oplus K_\epsilon)$, the resulting set of regions remains a non-piercing family. Here $\oplus$ denotes Minkowski sum and K_ϵ is a disk of arbitrarily small radius ϵ.*

We refer to the modification of γ to γ' in the above theorem as the "bypassing of C by γ". Note that the modified region $\gamma' \approx \gamma \setminus C$ since ϵ is arbitrarily small.

▶ **Lemma 22.** *There exists a graph $G = (R \cup B, E)$ that satisfies the local search conditions with respect to the set system $(P, \mathcal{R})$.*

Proof. We will construct a graph that satisfies the local expansion property at every point $p \in P$ and has the sublinear separator property. In fact, we will make the first condition stronger: we require the local expansion property to be satisfied at every point in the plane. In other words, we replace P by $\mathbb{R}^2$ and for each point $q \in \mathbb{R}^2$, we define the demand $d(q)$ as $\min(|R(q)|, |B(q)|, \Theta)$. Note that R and B are still feasible solutions to this modified problem and a graph $G = (R \cup B, E)$ satisfying the local expansion property with respect to $(\mathbb{R}^2, R \cup B)$ also satisfies the property with respect to $(P, R \cup B)$.

If the depth of the arrangement of $R \cup B$ is at most 2Θ, then we can simply use Lemma 16 to obtain the required graph G. Otherwise, consider a cell C of maximum depth. By the results in [30], there exists a region $\gamma \in R \cup B$ that contributes exactly one arc to the boundary of C. Our plan is to modify γ so that it bypasses C in order to reduce the depth of the cell C.

For convenience, we will refer to the regions in R and B as *red* and *blue* respectively. We will use the following slightly modified version of the cell bypassing procedure: The process remains the same as before except when the cell C to be bypassed consists of just one side i.e., it is identical to one of the regions. In such a case, the usual cell bypassing procedure removes the region. Instead, we do the following: if the points in the region are contained in more than Θ regions of its color, then we remove the region as before. Otherwise, if the point is contained in exactly Θ regions of its color (including itself), we keep the region but make it *inactive* so that this region does not participate in any further cell bypassing. Initially, all regions are defined to be active. Note that since an inactive region lies in the interior of a cell in the arrangement of the remaining active regions, it does not affect further cell bypassing. Only a cell defined by active regions is bypassed. All inactive regions lie in the interior of some cell in the arrangement of the active regions.

Let C be a cell of maximum depth in the arrangement of the active regions in $R \cup B$ and suppose that this cell is contained in at least $\Theta + 1$ active regions of some color (either red or blue). Let us assume that it is contained in at least $\Theta + 1$ active blue regions. The other case is analogous. We will argue that a graph satisfying the local expansion property for the modified red and blue regions obtained after bypassing C by one of the active regions also satisfies the condition for the original regions. To see this, consider any point p in the cell C that we are about to bypass in the arrangement of the active regions. The point p may be contained in some of the inactive regions contained in C apart from the active regions containing C. However, p cannot be contained in any inactive blue region β since that would mean that p was contained in at most Θ blue regions when β became inactive and is now contained in more than Θ blue regions (by assumption). Since cell bypassing only contracts regions, this is impossible.

Let γ be the region bypassing C. If γ is blue, note that p is still contained in at least $\Theta \geq d(p)$ blue regions after bypassing. Therefore, a graph satisfying the local expansion property for p in the arrangement of the modified regions also satisfies the condition in the arrangement of the original regions.

Consider now the case when γ is red. Let C' be a cell contained in γ and adjacent to C in the original arrangement of the active regions. Let q be a point in C' that is not contained in any of the inactive regions. Note that the set of red regions that contain at least one of the points in $\{p, q\}$ after bypassing is the same as the set of regions containing p before bypassing. Furthermore, both p and q are contained in the same set of blue regions before and after bypassing. Thus, a graph satisfying the locality preserving condition for the points p and q in the modified arrangement also satisfies the condition for p in the original arrangement.

Each cell-bypassing operation either decreases the maximum depth of the arrangement of the active regions, or decreases the number of cells of maximum depth in that arrangement. Therefore, we eventually obtain an arrangement where the maximum number of blue or red regions containing any cell in the arrangement of active regions is at most Θ. At this point, the number of active or inactive regions of the same color containing any point in the plane is at most Θ. Thus the depth of the arrangement of all active and inactive regions is at most 2Θ. We can now obtain the required graph using Lemma 16. ◀

Theorem 3 now follows from the discussions above.

5.2 Pseudodisks and Points

In this subsection, we prove Theorem 5. Consider a set multicover problem defined by the set system $(\mathcal{D}, P)$ where P is set of points and $\mathcal{D}$ is a family of non-piercing regions in the plane, and in which each pseudodisk $D \in \mathcal{D}$ has a demand bounded above by Θ. As earlier, let $R, B \subseteq P$ represent an optimal solution and a solution yielded by the local search algorithm respectively. Also, without loss of generality, $R \cap B = \emptyset$.

▶ **Lemma 23.** *There exists a graph $G = (R \cup B, E)$ that satisfies the local search conditions with respect to the set system $(\mathcal{D}, P)$.*

In order to prove Lemma 23, we will use the following result of Pinchasi [29].

▶ **Lemma 24** ([29])**.** *Let $\mathcal{D}$ be a set of pseudodisks in the plane. For any specified $D \in \mathcal{D}$ and any point $q \in D$, we can continuously shrink D to q so that the arrangement at any time remains an arrangement of pseudodisks.*

Proof of Lemma 23. If every pseudodisk in $\mathcal{D}$ contains at most 2Θ points of P, then we can use Lemma 19 to obtain the required graph. Now, consider any pseudodisk $D \in \mathcal{D}$ containing more than 2Θ points of P. Then, $\mathcal{D}$ must contain either $> d(D)$ points of B or $> d(D)$ points of R. Using Lemma 24, we first shrink D to D' as follows: we pick any point $p \in D \cap (R \cup B)$ and imagine continuously shrinking D to the point p. During the shrinking, we stop as soon as $|D \cap R| = d(D)$ or $|D \cap B| = d(D)$. We call this modified region D'. Lemma 24 guarantees that the arrangement obtained by replacing D by D' is still a family of pseudodisks.

Note that both $|D' \cap B|$ and $|D' \cap R|$ are at least $d(D)$ and one of them is equal to $d(D)$. Assume that $|D' \cap B| = d(D)$, the other case being analogous. Then, one by one, for every $b \in D' \cap B$, we imagine shrinking a copy of D' continuously to the point b and stop when the region contains exactly $d(D)$ points of R. We call this region D_b and add it to the collection $\mathcal{D}$. Again by Lemma 24 we can do this so that the arrangement remains an arrangement of pseudodisks. Finally, we remove the pseudodisk D from the collection $\mathcal{D}$. Observe that each of the regions added to the collection contain at most $d(D)$ points of R and at most $d(D)$ points of B.

This entire procedure is repeated for each pseudodisk $D \in \mathcal{D}$ containing more than 2Θ points. Let $\mathcal{D}'$ be the collection of regions obtained in the end. We now claim that a graph $G = (R \cup B, E)$ satisfying the local expansion property with respect to $(\mathcal{D}', R \cup B)$ also satisfies the local expansion property with respect to $(\mathcal{D}, R \cup B)$.

To see this, observe that if a pseudodisk $D \in \mathcal{D}$ is still in $\mathcal{D}'$, then a graph that satisfies the local expansion property with respect to $(\mathcal{D}, R \cup B)$ also satisfies the condition for D. On the other hand, if D was removed i.e., $D \notin \mathcal{D}'$, then one of the following holds:

- There are at least $d(D)$ points $b \in B \cap D$ for each of which we have added a pseudodisk D_b contained in D s.t. D_b contains $|d(D)|$ points of $R \cap D$
- There are at least $d(D)$ points $r \in R \cap D$ for each of which we have added a pseudodisk D_r contained in D s.t. D_r contains $|d(D)|$ points of $B \cap D$.

Assume the first case holds for a pseudodisk D removed from $\mathcal{D}$. The second case is analogous. Then, since each region D_b added has exactly $d(D)$ points of R, in any graph G that satisfies the local expansion property with respect to $(\mathcal{D}', R \cup B)$, the point b must be adjacent to all of the points in $R \cap D_b \subseteq D$. Since we have added such a pseudodisk D_b for at least $d(D)$ points in $B \cap D$, we have at least $d(D)$ points $B \cap D$ each of which has at least

$d(D)$ neighbors in $R \cap D$. Thus, G satisfies the local expansion property with respect to $(\mathcal{D}, R \cup B)$. Now, since each $D \in \mathcal{D}'$ has at most 2Θ points of $R \cup B$, Lemma 19 yields the required graph G that satisfies the local search conditions with respect to $(\mathcal{D}, R \cup B)$. ◀

Theorem 5 follows from the discussions above.

6 $(2+\epsilon)$-Approximation Algorithms

In this section, we prove Theorems 1 and 4, which require the following lemmas,

▶ **Lemma 25.** *The set system $(P, \mathcal{R})$ where P is a set of points and $\mathcal{R}$ is a non-piercing family is 2-linear.*

Proof. By Theorem 20 of [30], there is a planar support for the dual set system $(\mathcal{R}, P)$ i.e., there is a planar graph $H = (\mathcal{R}, E)$ s.t. for any $p \in P$, the set of regions $\mathcal{R}(p)$ induce a connected subgraph of H. Since H has $O(m)$ edges where $m = |\mathcal{R}|$, the number of cells of depth 2 in $(P, \mathcal{R})$ is $O(m)$. By a standard Clarkson-Shor type argument, this shows that the number of cells of depth at most k is $O(mk^2)$. ◀

Note that a family of non-piercing regions may not have linear union complexity but the set system $(P, \mathcal{R})$ still has a low shallow cell complexity.

▶ **Lemma 26.** *The set system $(\mathcal{D}, P)$ where $\mathcal{D}$ is a set of pseudodisks and P is a set of points in the plane is 2-linear.*

Proof. By Theorem 20 of [30], there is a planar support for the dual set system $(P, \mathcal{D})$ i.e., there is a planar graph $H = (P, E)$ s.t. for any $D \in \mathcal{D}$, the induced subgraph on the points in D is connected. Since H has $O(m)$ edges where $m = |P|$, the number of cells of depth 2 in $(P, \mathcal{D})$ is $O(m)$. By a standard Clarkson-Shor type argument, this shows that the number of cells of depth at most k is $O(mk^2)$. ◀

Proof of Theorem 1. We solve the LP-relaxation (1) for the multicover problem, and obtain a solution y, with objective value $\sum_{D \in \mathcal{R}} y_D \leq |\textsc{Opt}|$ where Opt is an optimal solution to the given set multicover problem. By Lemma 25, the set system $(P, \mathcal{R})$ is 2-linear, and therefore we can use Theorem 2 to obtain a subset $\mathcal{R}' \subseteq \mathcal{R}$ of size at most $(1 + O(\delta)) \sum_{D \in \mathcal{R}} y_D \leq (1 + O(\delta)) |\textsc{Opt}|$, which satisfies the demands of the points in p with a deficit of at most $\Theta = O(\delta^{-4} \log \delta^{-1})$. We then consider the problem with the residual demands in which all the demands are at most Θ. For this problem, we obtain a solution $\mathcal{R}'' \subseteq \mathcal{R}$ of size at most $(1 + O(\delta)) |\textsc{Opt}|$ using Theorem 3. Then, $\mathcal{R}' \cup \mathcal{R}''$ is a solution to the set multicover and has size at most $(2 + O(\delta)) |\textsc{Opt}|$. By taking $\delta = \alpha\epsilon$ for some suitably small constant $\alpha > 0$, we get a $(2+\epsilon)$-approximation to the optimal solution. ◀

Proof of Theorem 4. The proof is exactly the same as the proof of Theorem 1 except that we use Lemma 26 instead of Lemma 25 and Theorem 5 instead of Theorem 3. ◀

7 Conclusion

In this paper, we made progress on the Set Multicover in the geometric setting. We obtained a $(2+\epsilon)$ approximation by combining LP-rounding and local search. We believe that local search itself yields a PTAS for the problem with arbitrary demands. Unfortunately we are currently able to prove that local search yields a PTAS only when the demands bounded above by a constant. Our approach does not work for the weighted setting since local search

thus far works only for the unweighted setting. It is likely that a dynamic programming approach similar to [26, 16] can give a PTAS for the weighted set multicover problem for unit size disks and squares in the plane. Obtaining a PTAS for the problem with arbitrary size squares or disks seems challenging even for the set cover problem. Even with the improved approximation factor, our algorithm remains infeasible in practice due to the prohibitive running time ($n^{\text{poly}(1/\epsilon)}$) of the local search algorithm.

Improved Distance Sensitivity Oracles with Subcubic Preprocessing Time

Hanlin Ren
Institute for Interdisciplinary Information Sciences, Tsinghua University, Beijing, China
rhl16@mails.tsinghua.edu.cn

Abstract

We consider the problem of building *Distance Sensitivity Oracles* (DSOs). Given a directed graph $G = (V, E)$ with edge weights in $\{1, 2, \ldots, M\}$, we need to preprocess it into a data structure, and answer the following queries: given vertices $u, v, x \in V$, output the length of the shortest path from u to v that does not go through x. Our main result is a simple DSO with $\tilde{O}(n^{2.7233}M^2)$ preprocessing time and $O(1)$ query time. Moreover, if the input graph is undirected, the preprocessing time can be improved to $\tilde{O}(n^{2.6865}M^2)$. Our algorithms are randomized with correct probability $\geq 1 - 1/n^c$, for a constant c that can be made arbitrarily large. Previously, there is a DSO with $\tilde{O}(n^{2.8729}M)$ preprocessing time and polylog(n) query time [Chechik and Cohen, STOC'20].

At the core of our DSO is the following observation from [Bernstein and Karger, STOC'09]: if there is a DSO with preprocessing time P and query time Q, then we can construct a DSO with preprocessing time $P + \tilde{O}(Mn^2) \cdot Q$ and query time $O(1)$. (Here $\tilde{O}(\cdot)$ hides polylog(n) factors.)

I am also grateful to the anonymous referees of ESA for their helpful comments that improves the presentation of this work.

1 Introduction

Suppose we are given a directed graph $G = (V, E)$, and we want to build a data structure that, given any three vertices $u, v, x \in V$, outputs the length of the shortest path from u to v that does not go through x. Such a data structure is called a *Distance Sensitivity Oracle* (or DSO for short).

The problem of constructing DSOs is motivated by the fact that real-life networks often suffer from failures. Suppose we have a network with n nodes and m (directed) links, and we want to route a package from a node u to another node v. Normally, it suffices to compute the shortest path from u to v. However, if some node x in this network fails, then our route cannot use x, and our task becomes to find the shortest path from u to v that does not go through x. Usually, there is only a very small number of failures. In this paper, we consider the simplest case, in which there is only one failed node.

The problem of constructing a DSO is well-studied: Demetrescu et al. [6] showed that given a directed graph $G = (V, E)$, there is a DSO which occupies $O(n^2 \log n)$ space, and can answer a query in $O(1)$ time. Duan and Zhang [8] improved the space complexity to $O(n^2)$, which is optimal for dense graphs (i.e. $m = \Theta(n^2)$).

Unfortunately, the oracle in [6] requires a large preprocessing time ($O(mn^2 + n^3 \log n)$). In real-life applications, the preprocessing time of the DSO is also very important. Bernstein and Karger [2, 3] improved this time bound to $\tilde{O}(mn)$. Note that the All-Pairs Shortest Paths (APSP) problem, which only asks the distances between each pair of vertices u, v, is conjectured to require $mn^{1-o(1)}$ time to solve [13]. Since we can solve the APSP problem by using a DSO, the preprocessing time $\tilde{O}(mn)$ is optimal in this sense.

However, if the edge weights are small positive integers (that do not exceed M), then the APSP problem can be solved in $\tilde{O}(n^{2.58}M^{0.7})$ time [20], which is significantly faster than $O(mn)$ for dense graphs with small weights (e.g. $M = O(1)$). Thus it might be possible to obtain better results than [3] in the regime of small integer edge weights. Weimann and Yuster [19] showed that for any constant $\alpha \in (0, 1)$, we can construct a DSO in $\tilde{O}(n^{1-\alpha+\omega}M)$ time. Here $\omega < 2.3728639$ is the exponent of matrix multiplication [10]. However, the query time for this oracle is $\tilde{O}(n^{1+\alpha})$, which is *superlinear*. Later, Grandoni and Williams [12] showed that for every constant $\alpha \in [0, 1]$, we can construct a DSO in $\tilde{O}(n^{\omega+1/2}M + n^{\omega+\alpha(4-\omega)}M)$ time, which answers each query in $\tilde{O}(n^{1-\alpha})$ time.

Recently, in an independent work, Chechik and Cohen [4] showed that a DSO with polylog(n) query time can be constructed in $\tilde{O}(Mn^{2.873})$ time, achieving *both* subcubic preprocessing time and polylogarithmic query time. The space complexity for their DSO is $\tilde{O}(n^{2.5})$.

1.1 Our Results

In this work, we show improved and simplified constructions of DSOs. We start with an observation.

▶ **Observation 1** (informal version). *If we have a DSO with preprocessing time P and query time Q, then we can build a DSO with preprocessing time $P + \tilde{O}(M \cdot n^2) \cdot Q$ and query time $O(1)$.*

For $\alpha = 0.2$, the oracle in [12] already achieves $\tilde{O}(n^{2.8729}M)$ preprocessing time and $O(n^{0.8})$ query time. Observation 1 implies that this query time can be brought down to $O(1)$.

Observation 1 can be proven by a close inspection of [3]: The algorithm in [3] for constructing a DSO picks $\tilde{O}(n^2)$ carefully chosen queries (u, v, x), such that the answers of all these queries can be computed in $\tilde{O}(mn)$ time. Then from these answers, we can easily compute a DSO with $O(1)$ query time. If, instead of computing these answers in $\tilde{O}(mn)$ time, we use the given DSO to answer these queries, the preprocessing time becomes $P + \tilde{O}(n^2) \cdot Q$. As the proof essentially repeats the arguments in [3], we leave it in Appendix A.

Our main result is a simple construction of DSOs with preprocessing time $\tilde{O}(n^{2.7233}M^2)$ and query time $O(1)$. If the input graph is undirected, we can achieve a better preprocessing time of $\tilde{O}(n^{2.6865}M^2)$.

▶ **Theorem 2.** *We can construct a DSO with $\tilde{O}(n^{2.7233}M^2)$ preprocessing time and $O(1)$ query time. Moreover, if the input graph is* undirected*, then we can construct a DSO with $\tilde{O}(n^{(3+\omega)/2}M^2) = \tilde{O}(n^{2.6865}M^2)$ preprocessing time and $O(1)$ query time. The construction algorithms are randomized and yield valid DSOs w.h.p.*[1]

[1] We say that an event happens *with high probability* (w.h.p.), if it happens with probability $1 - 1/n^C$, for some constant C that can be made arbitrarily large.

We remark that two drawbacks of our results compared to [4, 12, 19] are that it does not handle negative edge weights, and it has a worse (quadratic) dependence on M. However, our results have the currently best dependence on n, and is conceptually simple. Also, the space complexity of our DSO is $\tilde{O}(n^2)$, which is better than [4].

Non-unique shortest paths. A subtle technical issue is that the shortest paths in G may not be unique. Normally, if we perturb every edge weight by a small random value, then we can ensure that shortest paths are unique w.h.p. by the isolation lemma [15, 18]. However, the subcubic-time algorithms for shortest paths [16, 17, 20] depend crucially on the assumption that edge weights are small integers, so we cannot perform the random perturbation.

Therefore, we have to work without assuming the uniqueness of shortest paths. It turns out that Observation 1 is affected. Actually, if we assume the shortest paths are unique, we can build a DSO with preprocessing time $P + \tilde{O}(n^2) \cdot Q$ in the conclusion of Observation 1, regardless of the edge weights. However, without this assumption, Observation 1 somehow needs $\tilde{O}(Mn^2)$ queries to the slower DSO, instead of $\tilde{O}(n^2)$. See Remark 5 and Remark 6 for more details.

1.2 Notation

We mainly stick to the notation used in [7], namely:

- If p is a path, then $|p|$ denotes the number of edges in it, and $\|p\|$ denotes its length (i.e. the total weight of its edges).
- We use uv to denote the shortest path from u to v in the original graph, and $uv \diamond x$ the shortest path from u to v that does not go through x. In the case that there are multiple shortest paths, we will use e.g. "a path of the form $uv \diamond x$" to denote an arbitrary shortest path from uv in $G - x$ (i.e. the graph G with vertex x deleted). Note that if x is not in the original path uv, then $\|uv \diamond x\| = \|uv\|$.
- Let p be a path from u to v. For two vertices $a, b \in p$ such that a appears earlier than b, we say the interval $p[a, b]$ is the subpath from a to b, and $p(a, b)$ is the path $p[a, b]$ without its endpoints (a and b). If the path p is known in the context, then we may omit p and simply write $[a, b]$ or (a, b).

We define $\mathsf{MM}(n_1, n_2, n_3)$ as the complexity of multiplying an $n_1 \times n_2$ matrix and an $n_2 \times n_3$ matrix. Let a, b, c be real numbers, we define $\omega(a, b, c)$ be the infimum over all real numbers α such that $\mathsf{MM}(n^a, n^b, n^c) = O(n^\alpha)$. For any real number r, we have $\omega(1, 1, r) = \omega(1, r, 1) = \omega(r, 1, 1)$ [14], and we denote $\omega(r) = \omega(1, 1, r)$.

We also need the following adaptation of Zwick's APSP algorithm [20] (see also [12, Corollary 1]):

▶ **Theorem 3.** *Given a directed graph $G = (V, E)$ with edge weights in $\{1, 2, \ldots, M\}$, and an integer r, we can compute the distances between every pair of nodes whose shortest path uses at most r edges, in $\tilde{O}(rM \cdot \mathsf{MM}(n, n/r, n))$ time.*

Proof Sketch. We simply run the first $\lceil \log_{3/2} r \rceil$ iterations of the algorithm **rand-short-path** in [20]. The correctness of this algorithm is guaranteed by [20, Lemma 4.2]. ◀

2 Constructing a DSO in $\tilde{O}(n^{2.7233}M^2)$ Time

In this section, we prove Theorem 2.

▶ **Theorem 2.** *We can construct a DSO with $\tilde{O}(n^{2.7233}M^2)$ preprocessing time and $O(1)$ query time. Moreover, if the input graph is* undirected*, then we can construct a DSO with $\tilde{O}(n^{(3+\omega)/2}M^2) = \tilde{O}(n^{2.6865}M^2)$ preprocessing time and $O(1)$ query time. The construction algorithms are randomized and yield valid DSOs w.h.p.*

Given an integer r and a graph $G = (V, E)$, we define an *r-truncated DSO* to be a data structure that, when given a query (u, v, x), outputs the value $\min\{\|uv \diamond x\|, r\}$. In other words, an r-truncated DSO is a DSO which only needs to be correct when the path $uv \diamond x$ has length at most r. If this length is greater than r, it outputs r instead.

Inspired by Zwick's APSP algorithm [20], our main idea is to compute an r-truncated DSO for every $r = (3/2)^i$. Our strategies for small r and large r are completely different.

When r is small, the sampling approach in [12, 19] already suffices. Fix a particular query (u, v, x), we assume that $\|uv \diamond x\| \le r$. In particular, if we fix any path of the form $uv \diamond x$, then this path contains at most $r + 1$ vertices. Suppose we sample a graph by discarding each vertex w.p. $1/r$. With probability $\Omega(1/r)$, the resulting graph would "capture" this query in the sense that x is not in it but $uv \diamond x$ is completely included in it. Therefore, if we take $\tilde{O}(r)$ independent samples, and compute APSP for each sampled subgraph, we can deal with all queries w.h.p.

For large r, our idea is to compute a $(3/2)r$-truncated DSO from an r-truncated DSO. More precisely, given an r-truncated DSO with $O(1)$ query time, we can compute a $(3/2)r$-truncated DSO with $\tilde{O}(Mn/r)$ query time. First we sample a bridging set (cf. [20]) H of size $\tilde{O}(Mn/r)$. Let (u, v, x) be a query such that $r \le \|uv \diamond x\| \le (3/2)r$, then w.h.p. there is a "bridging vertex" $h \in H$ such that h is on some path of the form $uv \diamond x$, and both of the queries (u, h, x) and (h, v, x) are captured by the r-truncated DSO. If we iterate through H, we can answer the query (u, v, x) in $\tilde{O}(Mn/r)$ time. Then we use an "r-truncated" version of Observation 1 to transform this $(3/2)r$-truncated DSO into a new one with $O(1)$ query time.

2.1 Case I: r is Small

We make $\tilde{r} = \lceil 4Cr \ln n \rceil$ independent samples of graphs $G_1, G_2, \ldots, G_{\tilde{r}}$, where C is a large enough constant. The vertex set $V(G_i)$ of each graph is sampled by including each vertex independently w.p. $1 - 1/r$. The graph G_i is simply the induced subgraph of G on vertices $V(G_i)$. Then, for each $1 \le i \le \tilde{r}$, we compute all-pairs shortest paths of the graph G_i, but we only compute the shortest paths that use at most r edges. By Theorem 3, this step can be done in $\tilde{O}(rM \cdot \mathsf{MM}(n, n/r, n))$ time for each graph G_i. Alternatively, if the input graph is undirected, then this step can be done in $\tilde{O}(Mn^\omega)$ time [16, 17] for each G_i.

Consider a query (u, v, x), assume that $\|uv \diamond x\| \le r$, and fix any path of the form $uv \diamond x$. Let $1 \le i \le \tilde{r}$, we say i is *good* for the query (u, v, x), if both of the following hold.

- The graph G_i does not contain the failed vertex x.
- The graph G_i contains the path $uv \diamond x$ entirely.

For every i $(1 \le i \le \tilde{r})$, the probability that i is good for the particular query (u, v, x) is at least

$$(1/r) \cdot (1 - 1/r)^r \ge 1/4r \text{ (if } r \ge 2).$$

Given a query (u, v, x), we iterate through every i's such that $x \notin V(G_i)$, and take the smallest value among the distances from u to v in these graphs G_i. With high probability, there are only $\tilde{O}(1)$ valid i's such that $x \notin V(G_i)$, and we can preprocess this set of i's for every $x \in V$. Therefore the query time is $\tilde{O}(1)$.

The algorithm succeeds at a query (u, v, x) if there is an i that is good for (u, v, x). Since the G_i's are independent, the probability that there is an i good for (u, v, x) is at least

$$1 - (1 - 1/4r)^{\tilde{r}} \geq 1 - 1/n^C.$$

By a union bound over all n^3 triples of possible queries (u, v, x), it follows that our data structure is correct w.p. at least $1 - 1/n^{C-3}$, which is high probability.

In conclusion, there is an r-truncated DSO with $\tilde{O}(1)$ query time, whose preprocessing time is $\tilde{O}(\tilde{r} \cdot rM \cdot \mathsf{MM}(n, n/r, n))$ for directed graphs, and $\tilde{O}(\tilde{r} \cdot Mn^\omega)$ for undirected graphs.

2.2 An Observation

We need the following observation ("r-truncated" version of Observation 1), which roughly states that given an r-truncated DSO with preprocessing time P and query time Q, we can build an r-truncated DSO with preprocessing time $P + \tilde{O}(Mn^2) \cdot Q$ and query time $O(1)$. More formally, we have:

▶ **Observation 4.** *Let r be an integer, $G = (V, E)$ be an input graph whose edge weights are in $\{1, 2, \ldots, M\}$, and $\mathcal{D}$ be an arbitrary r-truncated DSO. We can construct* Fast($\mathcal{D}$)*, which is an r-truncated DSO with $O(1)$ query time and a preprocessing algorithm as follows.*

- *It first computes the distance matrix of G, and the outgoing shortest path trees rooted at each vertex.*
- *Then it invokes the preprocessing algorithm of $\mathcal{D}$ on the input graph G.*
- *At last, it makes $\tilde{O}(Mn^2)$ queries to $\mathcal{D}$, and spends $\tilde{O}(Mn^2)$ additional time to finish the preprocessing algorithm.*

We emphasize the following technical details that are not reflected in the informal statement of Observation 1. First, we need to compute the distance matrix and outgoing shortest path trees of G (henceforth the "APSP data" of G) before using $\mathcal{D}$. The APSP data can be computed in $\tilde{O}(Mn^{2.58})$ time [20], and in particular, the **wit-to-suc** algorithm in [20] describes how to compute the shortest path trees efficiently. Second, the preprocessing algorithm of $\mathcal{D}$ is called *only once*, and on the same graph G (on which we have already computed the APSP data). The reason that the second detail is important is: Suppose we have another routine that given an r-truncated DSO $\mathcal{D}$, constructs Extend($\mathcal{D}$) which is a $(3/2)r$-truncated DSO with a possibly large query time. Then given an 1-truncated DSO $\mathcal{D}^{\mathsf{start}}$, we can construct a (normal) DSO as follows:

$$\mathcal{D}^{\mathsf{final}} = \underbrace{\text{Fast}(\text{Extend}(\text{Fast}(\text{Extend}(\ldots \text{Extend}(\mathcal{D}^{\mathsf{start}})))))}_{O(\log n) \text{ times}}.$$

However, even if the preprocessing algorithm of Fast($\mathcal{D}$) invokes the preprocessing algorithm of $\mathcal{D}$ *twice*, the preprocessing algorithm of $\mathcal{D}^{\mathsf{final}}$ would invoke *a polynomial times* the preprocessing algorithm of $\mathcal{D}^{\mathsf{start}}$, which is too many. In contrast, if the preprocessing algorithm of both Fast($\mathcal{D}$) and Extend($\mathcal{D}$) only invokes the preprocessing algorithm of $\mathcal{D}$ once, then the preprocessing algorithm of $\mathcal{D}^{\mathsf{final}}$ would also invoke the preprocessing algorithm of $\mathcal{D}^{\mathsf{start}}$ only once, which is okay.

2.3 Case II: r is Large

Suppose we have an r-truncated DSO $\mathcal{D}$, which has preprocessing time P and query time $O(1)$. We show how to construct a $(3/2)r$-truncated DSO, which we name as Extend($\mathcal{D}$), with preprocessing time $P + O(n^2)$ and query time $\tilde{O}(nM/r)$. This is done by the following bridging set argument.

Let $\mathcal{P}$ be a set of paths that contains exactly one path of the form $uv \diamond x$, for every u, v, x such that $r \le \|uv \diamond x\| < (3/2)r$. This corresponds to the paths that $\mathcal{D}$ cannot deal with, but Extend($\mathcal{D}$) has to output the correct answer. Let $p = uv \diamond x \in \mathcal{P}$, $\mathsf{mid}(p)$ be the set of vertices $y \in p$ such that $\|p[u, y]\| < r$ and $\|p[y, v]\| < r$. (See Figure 1.) For every $y \in \mathsf{mid}(p)$, as $p[u, y]$, $p[y, v]$ are of the form $uy \diamond x$ and $yv \diamond x$ respectively, it follows that $\mathcal{D}$ can find $\|uy \diamond x\|$ and $\|yv \diamond x\|$ correctly. Moreover, $|\mathsf{mid}(p)| \ge r/3M$.

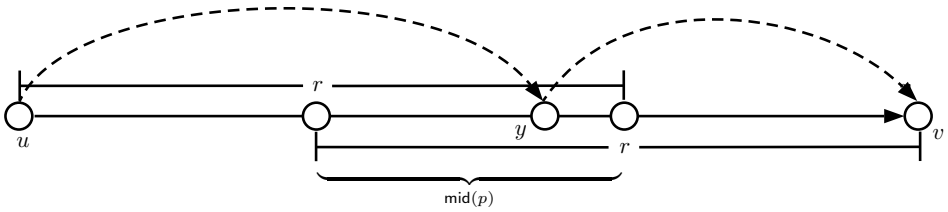

Figure 1 Example of a path $p = uv \diamond x$. If we can find a vertex $y \in \mathsf{mid}(p)$, then we can use $\mathcal{D}$ to compute $\|uy \diamond x\|$ and $\|yv \diamond x\|$, thus to compute the length of p.

Fix a large enough constant C, the preprocessing algorithm of Extend($\mathcal{D}$) is as follows: We preprocess $\mathcal{D}$, and then randomly sample a set H of vertices, where every vertex $v \in V$ is in H with probability $\min\{1, 3CM \ln n/r\}$ independently. We have $|H| = \tilde{O}(nM/r)$ w.h.p.

Fix $u, v, x \in V$, suppose $p = uv \diamond x$ and $r \le \|p\| < (3/2)r$. Then the probability that H hits $\mathsf{mid}(p)$ (i.e. $H \cap \mathsf{mid}(p) \ne \varnothing$) is at least

$$1 - (1 - 3CM \ln n/r)^{r/3M} \ge 1 - 1/n^C.$$

By a union bound over $O(n^3)$ paths in $\mathcal{P}$, it follows that w.h.p. H hits $\mathsf{mid}(p)$ for every path $p \in \mathcal{P}$.

The query algorithm for Extend($\mathcal{D}$) is as follows: Given a query (u, v, x), if $\mathcal{D}(u, v, x) < r$, then we output $\mathcal{D}(u, v, x)$; otherwise we output

$$\min\left\{(3/2)r, \min_{h \in H}\{\mathcal{D}(u, h, x) + \mathcal{D}(h, v, x)\}\right\}.$$

It is easy to see that Extend($\mathcal{D}$) is a correct $(3/2)r$-truncated DSO, has preprocessing time $P + O(n^2)$ and query time $\tilde{O}(nM/r)$.

2.4 Putting it Together

Let $a \in [0, 1]$ be a constant that we pick later, and $r = n^a$. To start, we invoke Section 2.1 to build an r-truncated DSO for $r = n^a$, which costs $\tilde{O}(r^2 M \cdot \mathsf{MM}(n, n/r, n))$ time for directed graphs or $\tilde{O}(r \cdot Mn^\omega)$ for undirected graphs. Then for every $1 \le i \le \lceil \log_{3/2}(Mn/r) \rceil$, suppose we have an $r(3/2)^{i-1}$-truncated DSO $\mathcal{D}^{i-1}$, we can construct $\mathcal{D}^i = \text{Fast}(\text{Extend}(\mathcal{D}^{i-1}))$ which is an $r(3/2)^i$-truncated DSO. This step costs $\tilde{O}(n^3 M^2/(r(3/2)^i))$ time. The preprocessing algorithm terminates when $i = i_\star = \lceil \log_{3/2}(Mn/r) \rceil = O(\log n)$, and we obtain an $r(3/2)^{i_\star}$-truncated DSO which is a (normal) DSO.

Case 1: the input graph is undirected. The total preprocessing time is

$$\tilde{O}\big(r \cdot Mn^{\omega} + n^3M^2/r\big) = \tilde{O}\Big(n^{\max\{\omega+a,3-a\}}M^2\Big).$$

When $a = (3-\omega)/2$, this time complexity is $\tilde{O}(n^{(3+\omega)/2}M^2) = \tilde{O}(n^{2.6865}M^2)$.

Therefore, given an undirected graph $G = (V, E)$, there is a DSO with $\tilde{O}(n^{2.6865}M^2)$ preprocessing time and $O(1)$ query time.

Case 2: the input graph is directed. The total preprocessing time is

$$\tilde{O}\big(r^2M \cdot \mathsf{MM}(n, n/r, n) + n^3M^2/r\big) = \tilde{O}\Big(n^{2a+\omega(1-a)}M + n^{3-a}M^2\Big).$$

(Recall that $\omega(1-a)$ is the exponent of multiplying an $n \times n^{1-a}$ matrix and an $n^{1-a} \times n$ matrix.)

Let $a = 0.276724$, then $1 - a = 0.723276$. By convexity of the function $\omega(\cdot)$ [14], we have

$$\omega(1-a) \leq \frac{(a-0.25)\omega(0.7) + (0.3-a)\omega(0.75)}{0.75-0.7}.$$

We substitute $\omega(0.7) \leq 2.154399$ and $\omega(0.75) \leq 2.187543$ [11], and obtain:

$$\omega(1-a) \leq 20 \cdot ((a-0.25) \cdot 2.154399 + (0.3-a) \cdot 2.187543) \leq 2.169829.$$

Therefore, given a directed graph $G = (V, E)$, there is a DSO with

$$\tilde{O}\Big(n^{\max\{2a+\omega(1-a),3-a\}}M^2\Big) = \tilde{O}(n^{2.723277}M^2).$$

preprocessing time and $O(1)$ query time.

3 Open Questions

The main open problem after this work is to improve the preprocessing time for DSOs. We believe it should be possible to overcome the issue that shortest paths are not unique, and improve the preprocessing time of the oracle specified in Observation 1 and Observation 4 to $P + \tilde{O}(n^2) \cdot Q$ (dropping the M factor). Then, we can build DSOs with $O(1)$ query time, and $\tilde{O}(n^{2.7233}M)$ preprocessing time (for directed graphs), or $\tilde{O}(n^{(3+\omega)/2}M)$ preprocessing time (for undirected graphs).

Can we improve the preprocessing time for directed graphs to $\tilde{O}(n^{2.58}M)$, matching the current best algorithm for APSP in directed graphs [20]? Can we improve the preprocessing time for undirected graphs to $\tilde{O}(n^{\omega}M)$, matching the nearly-optimal algorithm for APSP in undirected graphs [16, 17]?

A Proof of Observation 4 and Observation 1

In this section, we prove Observation 4. Note that Observation 1 follows from Observation 4 by setting $r = +\infty$.

▶ **Observation 4.** *Let r be an integer, $G = (V, E)$ be an input graph whose edge weights are in $\{1, 2, \ldots, M\}$, and $\mathcal{D}$ be an arbitrary r-truncated DSO. We can construct* Fast($\mathcal{D}$)*, which is an r-truncated DSO with $O(1)$ query time and a preprocessing algorithm as follows.*

- *It first computes the distance matrix of G, and the outgoing shortest path trees rooted at each vertex.*
- *Then it invokes the preprocessing algorithm of $\mathcal{D}$ on the input graph G.*
- *At last, it makes $\tilde{O}(Mn^2)$ queries to $\mathcal{D}$, and spends $\tilde{O}(Mn^2)$ additional time to finish the preprocessing algorithm.*

Let $T_{\mathsf{out}}(u)$ be the outgoing shortest path tree rooted at u. In this section, the notation uv denotes the shortest path from u to v *in the tree* $T_{out}(u)$. In particular, for any $x \in uv$, the path ux is guaranteed to be a subpath of uv.

A.1 The Preprocessing Algorithm

We review and slightly modify the preprocessing algorithm of [3]. For convenience, we denote $\|p\|_r = \min\{\|p\|, r\}$ for any path p and number r.

We define a path to be *good* if it is a subpath of some shortest path in the shortest path trees. In other words, for any vertices $u, v, x \in V$ such that $x \in uv$, we say the subpath $(uv)[x, v]$ is *good*. Note that if the shortest paths in G are unique, then the set of good paths coincides with the set of shortest paths in G. Also note that there are only $O(n^3)$ good paths even if the shortest paths are not unique.

Assigning priorities. We assign each vertex a *priority*, which is independently sampled from the following distribution: for any positive integer c, each vertex has priority c w.p. $1/2^c$. Denote $c(v)$ the priority of the vertex v. With high probability, all of the following are true:

- The maximum priority is $O(\log n)$.
- For every $c \le O(\log n)$, there are $\tilde{O}(n/2^c)$ vertices with priority c.
- Let C be a large enough constant. For every good path p with at least $C \cdot 2^c \log n$ edges, there is a vertex on p whose priority is greater than c.

In the following discussions, we will assume that all of the above assumptions hold.

Fix a pair $u, v \in V$, let s_i be the first vertex in uv with priority $\geq i$, and t_i be the last such vertex. Then we can write the path uv as

$$u \rightsquigarrow s_1 \rightsquigarrow s_2 \rightsquigarrow \ldots \rightsquigarrow s_{O(\log n)} \rightsquigarrow t_{O(\log n)} \rightsquigarrow \ldots \rightsquigarrow t_1 \rightsquigarrow v.$$

We say that the vertices u, v, s_i, t_i are *key vertices*, and the i-th key vertex is denoted as k_i. Then the path uv can also be written as

$$u = k_0 \rightsquigarrow k_1 \rightsquigarrow \ldots \rightsquigarrow k_{O(\log n)} = v.$$

It is important to see that

$$|(uv)[k_i, k_{i+1}]| \leq C \cdot 2^{\min\{c(k_i), c(k_{i+1})\}} \log n \tag{1}$$

for every valid i, as otherwise there will be another key vertex between k_i and k_{i+1}.

Data structure for quick location. Suppose we are given a query (u, v, x), the first thing we should do is to "locate" x, i.e. find the key vertices $k_i, k_{i+1} \in uv$ such that $x \in (uv)[k_i, k_{i+1}]$. We will utilize the following data (cf. [2]).

For every $u, v \in V$, we compute

- $\mathsf{CL}[u, v, c]$ (for "center left"): the first vertex in uv with priority at least c; and
- $\mathsf{CR}[u, v, c]$ (for "center right"): the last vertex in uv with priority at least c.

It is easy to compute these numbers in $\tilde{O}(n^2)$ time: for each priority c and each vertex $u \in V$, we simply perform a depth-first search on the outgoing shortest path tree $T_{\mathsf{out}}(u)$ rooted at u to compute all $\mathsf{CL}[u, \cdot, c]$ and $\mathsf{CR}[u, \cdot, c]$.

We also compute a structure called BCP (for "biggest center priority"). In this structure, for each vertex $u \in V$, we preprocess the outgoing shortest path tree $T_{\mathsf{out}}(u)$ rooted at u in $\tilde{O}(n)$ time such that given any vertices $x, y \in V$, we can find the biggest priority of any vertex on the path from x to y in $T_{\mathsf{out}}(u)$ in $O(1)$ time [5]. Then, given any good path p (p is specified by vertices u, v, x and $p = (uv)[x, v]$), we can find the biggest priority of any vertex on p in $O(1)$ time.

In addition, for every $u, v \in V$, we store the key vertices on uv into a hash table of size $O(\log n)$. Given a vertex x, we can output whether x is among these key vertices on uv in $O(1)$ worst-case time [9].

Data structure for avoiding a failure. We use $\mathcal{D}$ to preprocess the input graph. Then we compute the following data:

(Data a) For every $u, v \in V$, and every $1 \leq i \leq \min\{M \cdot C \cdot 2^{c(u)} \log n, |uv|\}$, let x_i be the i-th vertex in the path uv. (Here u is the 0-th vertex.) We compute and store the value $\|uv \diamond x_i\|_r$. Symmetrically, let x_{-i} be the *last* i-th vertex in the path vu (not uv!), for every $1 \leq i \leq \min\{M \cdot C \cdot 2^{c(u)} \log n, |vu|\}$, we compute and store $\|vu \diamond x_{-i}\|_r$.

(Data b) For every $u, v \in V$ and consecutive key vertices $k_i, k_{i+1} \in uv$, let y be the vertex in the portion $k_i \rightsquigarrow k_{i+1}$ that maximizes $\|uv \diamond y\|_r$. We compute and store $\|uv \diamond y\|_r$.

(Data c) For every $u, v \in V$ and key vertex $k_i \in uv$, we compute and store $\|uv \diamond k_i\|_r$.

For each priority $c \leq \tilde{O}(1)$, there are $\tilde{O}(n/2^c)$ vertices u whose priority is exactly c. In (Data a), we make $\tilde{O}(nM2^c)$ queries for each such u ($\tilde{O}(M2^c)$ queries for each $v \in V$). Therefore in total, we make $\tilde{O}(Mn^2)$ queries in (Data a). We will show in Appendix A.3 that we can compute (Data b) using $\tilde{O}(n^2)$ queries to $\mathcal{D}$ and $\tilde{O}(n^2)$ additional time. (Data c) can be computed in $\tilde{O}(n^2)$ queries easily.

▶ Remark 5. If shortest paths in G are unique, then in (Data a) we only need to store $\|uv \diamond x_i\|_r$ and $\|vu \diamond x_{-i}\|_r$ for $i \le C \cdot 2^{c(u)} \log n$ (shaving off a factor of M). The reason will be evident when we see the query algorithm.

A.2 The Query Algorithm

Let (u, v, x) be a query. We check whether $x \in uv$ in $O(1)$ time on the shortest path tree $T_{\mathsf{out}}(u)$. If $x \notin uv$, then it is easy to see that $\|uv \diamond x\|_r = \|uv\|_r$.

We check whether x is a key vertex on uv (that is, $x = k_i$ for some i), using the hash tables. If this is the case, we return $\|uv \diamond x\|_r$ stored in (Data c) immediately.

Otherwise, we start by finding two consecutive key vertices $k_i, k_{i+1} \in uv$ such that $x \in [k_i, k_{i+1}]$. Recall that, if ℓ is the biggest priority of any vertex on uv, then the key vertices on uv are

$$(u =)\mathsf{CL}[u,v,1] \rightsquigarrow \mathsf{CL}[u,v,2] \rightsquigarrow \ldots \rightsquigarrow \mathsf{CL}[u,v,\ell] \rightsquigarrow \mathsf{CR}[u,v,\ell] \rightsquigarrow \ldots \rightsquigarrow \mathsf{CR}[u,v,2] \rightsquigarrow \mathsf{CR}[u,v,1](= v).$$

Therefore, we can find k_i in $O(1)$ time using the following procedure. Let c_1 be the biggest priority of any vertex in ux (which coincides the $[u, x]$ portion of uv), and c_2 be the biggest priority of any vertex in the $[x, v]$ portion of uv. We can compute c_1, c_2 from the structure BCP in $O(1)$ time. If $c_2 = \ell$, then x is in the range $(u, \mathsf{CR}[u, v, \ell])$, so $k_i = \mathsf{CL}[u, v, c_1]$. Otherwise, x is in the range $(\mathsf{CR}[u, v, \ell], v)$, so $k_i = \mathsf{CR}[u, v, c_2 + 1]$. We can find k_{i+1} similarly.

By (1), if $k_i = u$, then $|(uv)[u, x]| \le C \cdot 2^{c(u)} \log n$, and we can look up the value $\|uv \diamond x\|_r$ from (Data a) directly. Similarly, if $k_{i+1} = v$ then we can also look up $\|uv \diamond x\|_r$ from (Data a).

Now we assume that $k_i \ne u$ and $k_{i+1} \ne v$. A crucial observation is that

$$\|uv \diamond x\| = \min\{\|uk_{i+1} \diamond x\| + \|k_{i+1}v\|, \|uk_i\| + \|k_iv \diamond x\|, \|uv \diamond y\|\}, \tag{2}$$

where y is the vertex in $[k_i, k_{i+1}]$ that maximizes $\|uv \diamond y\|$. The proof of (2) is as follows:

- **(i)** If there is a path of the form $uv \diamond x$ that goes through k_i, then $\|uv \diamond x\| = \|uk_i\| + \|k_iv \diamond x\|$.
- **(ii)** If there is a path of the form $uv \diamond x$ that goes through k_{i+1}, then $\|uv \diamond x\| = \|uk_{i+1} \diamond x\| + \|k_{i+1}v\|$.
- **(iii)** If every path of the form $uv \diamond x$ does not through either k_i or k_{i+1}, then every path of the form $uv \diamond x$ avoids the entire portion of $k_i \rightsquigarrow k_{i+1}$, thus also avoids y. We have $\|uv \diamond x\| \ge \|uv \diamond y\|$. But $\|uv \diamond y\| \ge \|uv \diamond x\|$ by definition of y, thus $\|uv \diamond x\| = \|uv \diamond y\|$.

It is easy to see that a similar equation holds for r-truncated DSOs:

$$\|uv \diamond x\|_r = \min\{\|uk_{i+1} \diamond x\|_r + \|k_{i+1}v\|, \|uk_i\| + \|k_iv \diamond x\|_r, \|uv \diamond y\|_r, r\}, \tag{3}$$

where y is any vertex in $[k_i, k_{i+1}]$ that maximizes $\|uv \diamond y\|_r$.

Recall that we already know the values $\|uk_i\|$ and $\|k_{i+1}v\|$. To compute $\|uk_{i+1} \diamond x\|_r$, we note that if x is the last j-th vertex in uk_{i+1}, then $j \le C \cdot 2^{c(k_{i+1})} \log n$. Therefore we can look up the value of $\|uk_{i+1} \diamond x\|_r$ from (Data a). Similarly, to compute $\|k_iv \diamond x\|_r$, we note that if x is the j-th vertex in the $k_i \rightsquigarrow v$ portion of the path uv, then $j \le C \cdot 2^{c(k_i)} \log n$. However, k_iv may be different from the $k_i \rightsquigarrow v$ portion of the path uv. Nevertheless, since $\|k_ix\| = \|(uv)[k_i, x]\| \le M \cdot C \cdot 2^{c(k_i)} \log n$, we also have $|k_ix| \le M \cdot C \cdot 2^{c(k_i)} \log n$, so we can still look up the value $\|k_iv \diamond x\|_r$ in (Data a). Finally, we can look up $\|uv \diamond y\|_r$ from (Data b).

We can see that the query time is $O(1)$.

▶ Remark 6. If shortest paths in G are unique, then the path $k_i v$ actually coincides with the $k_i \rightsquigarrow v$ portion of the path uv. Therefore, $|k_i x| = |(uv)[k_i, x]| \le C \cdot 2^{c(k_i)} \log n$. In this case we do not need to "sacrifice" a factor of M in (Data a): We can look up $\|k_i v \diamond x\|_r$ even if we only stored the values $\|k_i v \diamond x_{i'}\|_r$ for $i' \le C \cdot 2^{c(k_i)} \log n$, as in Remark 5.

A.3 Computing (Data b)

We will use the following notation. Let p be a path from u to v which is fixed in context, and a, b be two vertices in p. We will say that $a < b$ if $|p[u, a]| < |p[u, b]|$, i.e. a appears strictly before b on the path p. Similarly, $a > b$, $a \le b$, $a \ge b$ mean $|p[u, a]| > |p[u, b]|$, $|p[u, a]| \le |p[u, b]|$, $|p[u, a]| \ge |p[u, b]|$ respectively.

Let $u, v \in V$ and $s < t$ be two vertices on the path uv. Let $y \in (uv)[s, t]$ be the vertex in $(uv)[s, t]$ which maximizes $\|uv \diamond y\|_r$. We first show that *assuming we have built some oracles*, we can find this vertex y in $O(\log n)$ oracle calls and $O(\log n)$ additional time. The idea is to use a binary search described in [3, Section 6].

▶ **Lemma 7.** *Let r be an integer, $u, v \in V$, p be the path uv, and s, t be two vertices on p such that $u < s < t < v$. Suppose we have the following oracles, each with $O(1)$ query time:*

- *an oracle that given a vertex $x \in p[s, t]$, outputs $\|ut \diamond x\|_r$;*
- *an oracle that given a vertex $x \in p[s, t]$, outputs $\|sv \diamond x\|_r$;*
- *an oracle that given an interval $p[s', t']$ such that $s \le s' \le t' \le t$, outputs a vertex $x \in p[s', t']$ that maximizes the value $\|ut \diamond x\|_r$.*

Then we can find a vertex $y \in p[s, t]$ which maximizes $\|uv \diamond y\|_r$ in $O(\log n)$ time.

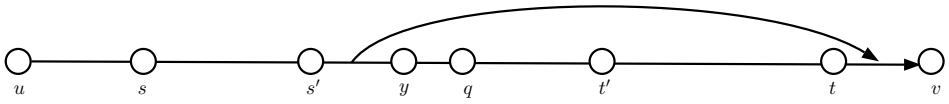

Figure 2 If every path of the form $sv \diamond y$ does not go through t, then every path of the form $sv \diamond y$ does not go through the whole interval $p[q, t']$.

Proof. For any $y \in p[s, t]$, we denote

$$h(y) = \min\{\|ut \diamond y\|_r + \|tv\|, \|us\| + \|sv \diamond y\|_r, r\}.$$

By (3), we have $\|uv \diamond y\|_r = \min\{h(y), \|uv \diamond y^\star\|_r\}$ where $y^\star$ is some vertex independent of y. Thus it suffices to find some $y \in p[s, t]$ that maximizes $h(y)$.

We use a binary search. Assume that we know the optimal y is in some interval $p[s', t']$, where $s \le s' < t' \le t$. (Initially we set $s' = s$ and $t' = t$.) If $|p[s', t']| = O(1)$ then we can use brute force to find a vertex $y \in p[s', t']$ that maximizes $h(y)$. Otherwise let q be the middle point of $p[s', t']$, and we use the third oracle to find a vertex $y \in p[s', q]$ that maximizes $\|ut \diamond y\|_r$. There are two cases:

- If $\min\{\|ut \diamond y\|_r + \|tv\|, r\} = h(y)$, then we can restrict our attention to the interval $p[q, t']$. This is because for every vertex $x \in p[s', q]$,

$$h(x) \le \min\{\|ut \diamond x\|_r + \|tv\|, r\} \le \min\{\|ut \diamond y\|_r + \|tv\|, r\} \le h(y).$$

- Otherwise, $h(y) = \|us\| + \|sv \diamond y\|_r$, and every path of the form $sv \diamond y$ does not go through t. Therefore every path of the form $sv \diamond y$ avoids every vertex in $p[q, t']$. (See Figure 2.) For every vertex $x \in p[q, t']$,

$$h(x) \le \|us\| + \|sv \diamond y\| \le h(y).$$

It follows that we can restrict our attention to the interval $[s', q]$ now.
Therefore, we can always shrink the length of our candidate interval $p[s', t']$ by a half. It follows that we can find the desired vertex y in $O(\log n)$ time. ◀

Now we show how to compute (Data b) in $\tilde{O}(n^2)$ time (assuming that (Data a) is ready). The most crucial ingredient is the following Range Maximum Query (RMQ) structures (used in the third item of Lemma 7).

For every $u, v \in V$, consider the following sequence (of length $\ell = \min\{|uv| - 1, C \cdot 2^{c(v)} \log n\}$):

$$(\|uv \diamond x_{-1}\|_r, \|uv \diamond x_{-2}\|_r, \ldots, \|uv \diamond x_{-\ell}\|_r),$$

where x_{-i} denotes the last i-th vertex in the path uv (v is the last 0-th). We build an RMQ structure of this sequence, which given a query (s, t) $(1 \le s \le t \le \ell)$, outputs a number $i \in [s, t]$ that maximizes $\|uv \diamond x_{-i}\|_r$. After we compute the above sequence, this data structure can be preprocessed in $O(\ell)$ time, and each query costs $O(1)$ time [1].

For every priority $c \le O(\log n)$, there are $\tilde{O}(n/2^c)$ vertices v of this priority, and for each vertex v we construct n RMQ structures (one for each $u \in V$) on length-$\tilde{O}(2^c)$ sequences. The total size of these RMQ structures is

$$\sum_{c=1}^{O(\log n)} \tilde{O}(n/2^c) \cdot n \cdot \tilde{O}(2^c) = \tilde{O}(n^2).$$

Therefore, these RMQ structures can be preprocessed in $\tilde{O}(n^2)$ time. (Note that every element $\|uv \diamond x_{-i}\|_r$ is already computed in (Data a).)

To compute (Data b), we enumerate u, v, k_i, k_{i+1} where k_i, k_{i+1} are consecutive key vertices in uv. There are $\tilde{O}(n^2)$ possible combinations of (u, v, k_i, k_{i+1}). As argued in Appendix A.2, we know that the following data are already computed in (Data a):

- $\|uk_{i+1} \diamond x\|_r$, for any $x \in (uv)[k_i, k_{i+1}]$;
- $\|k_i v \diamond x\|_r$, for any $x \in (uv)[k_i, k_{i+1}]$.

Since uk_{i+1} is a prefix of uv (as defined in the outgoing shortest path trees), we also have the following RMQ oracles constructed above:

- An oracle that given any interval $[s', t']$ on the path uv such that $k_i \le s' \le t' \le k_{i+1}$, finds the vertex $y \in [s', t']$ that maximizes $\|uk_{i+1} \diamond y\|_r$ in $O(1)$ time.

It follows from Lemma 7 that we can find a vertex $y \in (uv)[k_i, k_{i+1}]$ that maximizes $\|uv \diamond y\|_r$ in $O(\log n)$ time. The total time for computing (Data b) is thus $\tilde{O}(n^2)$.

Fine-Grained Complexity of Regular Expression Pattern Matching and Membership

Abstract

The currently fastest algorithm for regular expression pattern matching and membership improves the classical $\mathcal{O}(nm)$ time algorithm by a factor of about $\log^{3/2} n$. Instead of focussing on general patterns we analyse homogeneous patterns of bounded depth in this work. For them a classification splitting the types in easy (strongly sub-quadratic) and hard (essentially quadratic time under SETH) is known. We take a very fine-grained look at the hard pattern types from this classification and show a dichotomy: few types allow super-poly-logarithmic improvements while the algorithms for the other pattern types can only be improved by a constant number of log-factors, assuming the Formula-SAT Hypothesis.

1 Introduction

Regular expressions with the operations alternative $|$, concatenation $\circ$, Kleene Plus $+$, and Kleene Star $\star$ are used in many fields of computer science. For example to search in texts and files or to replace strings by other strings as the unix tool `sed` does. But they are also used to analyse XML files [17, 18], for network analysis [12, 24], human computer interaction [13], and in biology to search for proteins in DNA sequences [16, 20].

The most intuitive problem for regular expressions is the *membership* problem. There we ask whether a given text t can be generated by a given regular expression p, i.e. is $t \in \mathcal{L}(p)$? We also call p a pattern in the following. A similar problem is the *pattern matching* problem, where we are interested whether some substring of the given text t can be matched by p. To simplify notation we define the matching language of p as $\mathcal{M}(p) \coloneqq \Sigma^* \mathcal{L}(p) \Sigma^*$. Then we want to check whether $t \in \mathcal{M}(p)$. The standard algorithm for both problems runs in time $\mathcal{O}(nm)$ where n is the text length and m the pattern size [22].

Based on the "Four Russians" trick Myers showed an algorithm with running time $\mathcal{O}(nm/\log n)$ [19]. This result was improved to an $\mathcal{O}(nm \log\log n/\log^{3/2} n)$ time algorithm by Bille and Thorup [5]. Although for several special cases of pattern matching and

Table 1 Hard pattern types that have to be considered.

Pattern matching / Membership	$\circ\star$	$\circ\vert\circ$	$\circ\vert+$	$\circ+\circ$	$\circ+\vert$	$\vert\circ\vert$ / $+\vert\circ\vert$	$\vert\circ+$ / $+\vert\circ+$	$\vert+\vert\circ$

membership improved sub-quadratic time algorithms have been given [3, 11, 14], it remained an open question whether there are truly sub-quadratic time algorithms for the general case. The first conditional lower bounds were shown by Backurs and Indyk [4]. They introduced so-called homogenous patterns and classified their hardness into easy, i.e. strongly sub-quadratic time solvable, and hard, requiring essentially quadratic time assuming the Strong Exponential Time Hypothesis (SETH). This classification of Backurs and Indyk was completed by a dichotomy for all homogeneous pattern types by Bringmann, Grønlund, and Larsen [8]. They reduced the hardness of all hard pattern types to the hardness of few pattern types of bounded depth. By this it was sufficient to check few cases instead of infinitely many.

To understand what a homogeneous pattern is, we observe that one can see patterns as rooted and node labeled trees where the inner nodes correspond to the operations of the pattern. Then a pattern is homogenous if the operations on each level of the tree are equal. The type of the pattern is the sequence of operations from the root to the leaves. See Section 2 for a formal introduction.

But as SETH rules out only polynomial improvements, super-poly-logarithmic runtime improvements are still feasible. Such improvements are know for Orthogonal Vectors (OV) [2, 9], for example, although there is a known conditional lower bound based on SETH. But for pattern matching and membership no faster algorithms are known. By a reduction from Formula-SAT Abboud and Bringmann showed that in general pattern matching and membership cannot be solved in time $\mathcal{O}(nm/\log^{7+\epsilon} n)$ under the Formula-SAT Hypothesis [1].

For Formula-SAT one is given a De Morgan formula F over n inputs and size s, i.e. the formula is a tree where each inner gate computes the AND or OR of two other gates and each of the s leaves is labeled with one of the n variables or their negation. The task is to find a satisfying assignment for F. While the naive approach takes time $\mathcal{O}(2^n s)$ to evaluate F on all possible assignments, there are polynomial improvements for formulas of size $s = o(n^3)$ [10, 15, 21]. But despite intense research there is currently no faster algorithm known for $s = n^{3+\Omega(1)}$. Thus it seem reasonable to assume the following hypothesis:

▶ **Hypothesis 1.1** (Formula-SAT Hypothesis (FSH) [1]). *There is no algorithm that can solve Formula-SAT on De Morgan formulas of size $s = n^{3+\Omega(1)}$ in $\mathcal{O}(2^n/n^\epsilon)$ time, for some $\epsilon > 0$, in the Word-RAM model.*

Although the new lower bound of $\mathcal{O}(nm/\log^{7+\epsilon} n)$ is quite astonishing since before only polynomial improvements have been ruled out, the bound is for the general case. It remained an open question whether it also holds for homogeneous patterns of bounded depth. Using the results by Bringmann, Grønlund, and Larsen [8] relating the hardness of different pattern types to each other, it suffices to check the pattern types in Table 1 for the corresponding problem.

We answer this last question and give a dichotomy for these hard pattern types: For few pattern types we give the currently fastest algorithm for pattern matching and membership. For the remaining patterns we show improved lower bounds of the form $\Omega(nm/\log^c n)$.

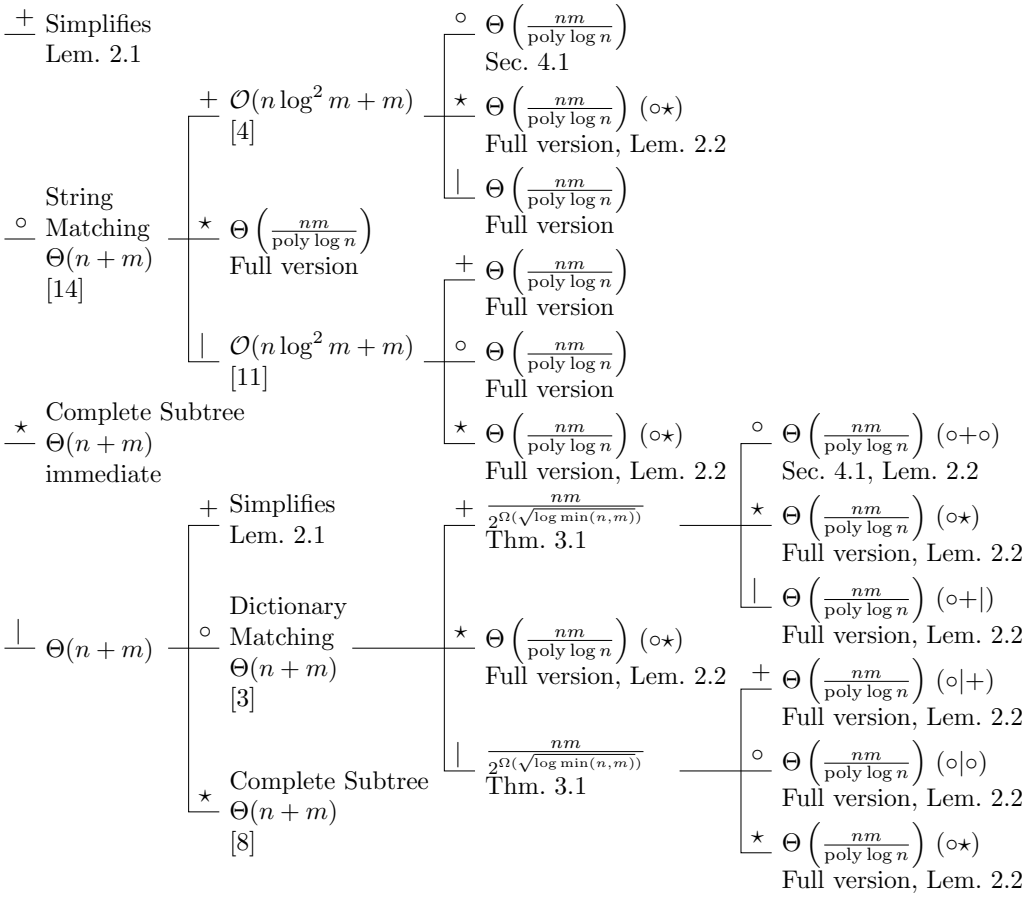

Figure 1 The classification of the patterns for pattern matching.

▶ **Theorem 1.2.** *For texts of length n and patterns of size m we have the following time bounds for the stated problems:*

- $nm/2^{\Omega(\sqrt{\log \min(n,m)})}$ *for* $|\circ|$*- and* $|\circ+$*-pattern matching, and* $+|\circ|$*- and* $+|\circ+$*-membership*
- $\Theta(nm/\operatorname{poly}\log n)$ *for pattern matching and membership with types* $\circ+|$*,* $\circ|+$*,* $\circ+\circ$*,* $\circ|\circ$*, and* $\circ\star$ *and for* $|+|\circ$*-membership, unless FSH is false.*

This dichotomy result gives us a simple classification for the hard pattern types. Depending on the pattern type one can decide if there is super-poly-logarithmic algorithm, or if even the classical algorithm is optimal up to a constant number of log-factors. See Figure 1 for an overview of the results for pattern matching. Further, the dichotomy shows that the type of a pattern has a larger impact on the hardness than the depth. The alternative as outer operation of the "easier" patterns allows us to split the pattern into independent sub-patterns. This is crucial for the speed-up since pattern matching for $\circ+$ and $\circ|$ is near-linear time solvable [4, 11]. Contrary almost all hard pattern types have a concatenation as outer operation which does not allow this decomposition into independent problems. Further, the length of the matched texts can vary largely. The pattern $(a \mid aba)(b \mid bca)(a \mid ab)$, for example, can match strings of length 3 to 8. We exploit both properties in our reductions, especially to encode a boolean OR.

In Section 2 we give a formal definition of homogeneous patterns and state the problems we start reducing from and the ones we reduce to. We show the algorithms for the upper bounds in Section 3. In Section 4 we give the improved lower bounds for pattern matching while the ones for membership are given in Section 5.

2 Preliminaries

Regular expressions. Recall, that patterns over a finite alphabet Σ are build recursively from other patterns using the operations $|$, $\circ$, $+$, and $\star$. We construct the patterns and the language of each pattern (i.e. the set of words matched by the pattern) as follows. Each symbol $\sigma \in \Sigma$ is a pattern representing the language $\mathcal{L}(\sigma) = \{\sigma\}$. Let in the following p_1 and p_2 be two patterns. For the alternative operation we define $\mathcal{L}(p_1 \mid p_2) = \mathcal{L}(p_1) \cup \mathcal{L}(p_2)$. For the concatenation we define $\mathcal{L}(p_1 \circ p_2) = \{w_1 w_2 \mid w_1 \in \mathcal{L}(p_1) \wedge w_2 \in \mathcal{L}(p_2)\}$. For the Kleene Plus we set $\mathcal{L}(p_1^+) = \{w \mid \exists k \geq 1 : \exists w_1, \ldots, w_k \in \mathcal{L}(p_1) : w = w_1 \ldots w_k\}$. With ε as the empty word we have $\mathcal{L}(p_1^\star) = \mathcal{L}(p_1^+) \cup \{\varepsilon\}$ for the Kleene Star.

Based on this construction it is easy to see patterns as rooted and node-labeled trees where each inner node is labeled by an operation and the leaves are labeled by symbols. We call this tree the *parse tree* of a pattern in the following. Then each node is connected to the node representing the sub-pattern p_1 and also for p_2 in the case of the binary operations $\circ$ and $|$. We extend the definition of the alternative and the concatenation in the natural way to more than two sub-patterns. To simplify notation we omit the symbol $\circ$ from the patterns in the following. We define the *size* of a pattern to be the number of inner nodes plus the number of leaves in the parse tree.

We call a pattern *homogeneous* if for each level of the parse tree, all inner nodes are labeled with the same operation. We define the *type* of a homogeneous pattern p to be the sequence of operations from the root of the parse tree of p to the deepest leaf. The *depth* of a pattern is the depth of the tree, which is equal to the number of operations in the type. For example, the pattern $[(abc \mid c)(a \mid dc)c(db \mid c \mid bd)]^+$ is of type $+\circ|\circ$ and has depth 4.

Relations between pattern types. Backurs and Indyk showed in [4] the first quadratic time lower bound for several homogeneous patterns based on SETH. This classification was completed by the dichotomy result of Bringmann, Grønlund, and Larsen in [8]. As there are infinitely many homogeneous pattern types, they showed linear-time reductions between different pattern types. By these reductions lower bounds also transfer to other (more complicated) pattern types and faster algorithms also give improvements for other (equivalent) pattern types.

▶ **Lemma 2.1** (Lemma 1 and Lemma 8 in the full version of [8]). *For any type T, applying any of the following rules yields a type T' such that both are equivalent for pattern matching and membership under linear-time reductions, respectively:*

- *For pattern matching: remove prefix $+$ and replace prefix $|+$ by $|$.*
- *For membership: replace any substring $+|+$ by $+|$ and replace prefix $r\star$ by $r+$ for any $r \in \{+, |\}^*$.*
- *For both problems: replace any substring pp, for any $p \in \{\circ, |, \star, +\}$, by p.*

We say that T simplifies *if one of these rules applies. Applying these rules in any order will eventually lead to an unsimplifiable type.*

▶ **Lemma 2.2** (Lemma 6 and Lemma 9 in the full version of [8]). *For types T and T', there is a linear-time reduction from T-pattern matching/membership to T'-pattern matching/membership if one of the following sufficient conditions holds:*

- *T is a prefix of T',*
- *we may obtain T' from T by replacing a $\star$ by $+\star$,*
- *we may obtain T' from T by inserting a $|$ at any position,*
- *only for membership: T starts with $\circ$ and we may obtain T' from T by prepending a $+$ to T.*

Together with the already known sub-quadratic time algorithms for various pattern types [3, 4, 8, 11, 14], it suffices to check the remaining cases in Table 1 to get a fine-grained dichotomy for the hard pattern types (i.e. the ones requiring essentially quadratic time under SETH).

Hypothesis. As mentioned in the introduction, we follow the ideas of Abboud and Bringmann in [1] and show reductions from Formula-SAT to pattern matching to prove lower bounds. Likewise as in their result, we also start from the intermediate problem Formula-Pair: Given a *monotone* De Morgan formula F with size s, that is a De Morgan formula where each leaf is labeled with a variable, i.e. no negation allowed, and each variable is used only once. Further, one is given two sets A, B of half-assignments to $s/2$ variables of F with $|A| = n$ and $|B| = m$. The task is to find a pair $a \in A, b \in B$ such that $F(a, b) = \mathsf{true}$.

There is an intuitive reduction from Formula-SAT to Formula-Pair as shown in [1]. Thus, FSH implies the following hypothesis, which we prove in Appendix A:

▶ **Hypothesis 2.3** (Formula-Pair Hypothesis (FPH)). *For all $k \geq 1$, there is no algorithm that can solve Formula-Pair for a monotone De Morgan formula F of size s and sets $A, B \subseteq \{0,1\}^{s/2}$ of size n and m, respectively, in time $\mathcal{O}(nms^k/\log^{3k+2} n)$ in the Word-RAM model.*

Batch-OV. For the upper bounds we transform texts and patterns into bit-vectors such that they are orthogonal if and only if the text is matched by the pattern. This gives us a reduction from pattern matching to Orthogonal Vectors (OV) ([9, 23]). But to improve the runtime we process many text simultaneously using the following lemmas.

▶ **Lemma 2.4** (Batch-OV, cf. [9]). *Let $A, B \subseteq \{0,1\}^d$ with $|A| = |B| = n$ and $d \leq 2^{c^{-1}\sqrt{\log n}}$ for some constant $c > 0$. We can decide for all vectors $a \in A$ whether there is a vector $b \in B$ such that $\langle a, b\rangle = 0$ in time $n^2/2^{\epsilon c\sqrt{\log n}}$ for sufficiently small $\epsilon > 0$.*

We generalize this balanced case to the unbalanced case which we use later:

▶ **Lemma 2.5** (Unbalanced Batch-OV). *Let $A, B \subseteq \{0,1\}^d$ with $|A| = n$ and $|B| = m$ and $d \leq 2^{c^{-1}\sqrt{\log \min(n,m)}}$ for some constant $c > 0$. We can decide for all vectors $a \in A$ whether there is a vector $b \in B$ such that $\langle a, b\rangle = 0$ in time $nm/2^{\epsilon c\sqrt{\log \min(n,m)}}$ for sufficiently small $\epsilon > 0$.*

Proof. If $n \leq m$, partition B into $\lceil m/n \rceil$ sets of size n and run the algorithm from Lemma 2.4 on every instance in time $\lceil m/n \rceil n^2/2^{\epsilon c\sqrt{\log n}} \approx nm/2^{\epsilon c\sqrt{\log n}}$. Analogously for $n > m$. ◀

3 Upper Bounds

For patterns p of type $|\circ|$ and $|\circ+$ let $p = (p_1 \mid p_2 \mid \ldots \mid p_k)$ be the pattern of size m. Likewise for the patterns with a Kleene Plus as additional outer operation. Let further $t = t_1 \cdots t_n$ be the text of length n. The main idea of the fast algorithm is to compute a set of matched substrings: $M = \{(i, j) \mid \exists \ell \in [k] : t_i \cdots t_j \in \mathcal{L}(p_\ell)\} \subseteq [n] \times [n]$. From M we construct a graph where the nodes correspond to different prefixes that can be matched. The tuples in M represent edges between these nodes. Then it remains to check whether the node corresponding to t is reachable.

▶ **Theorem 3.1** (Upper Bounds). *We can solve in time* $nm/2^{\Omega\sqrt{\log\min(n,m)}}$*:*

1. $|\circ|$*-pattern matching and* $+|\circ|$*-membership.*
2. $|\circ+$*-pattern matching and* $+|\circ+$*-membership.*

To compute M we split the patterns into large and small ones. For the large patterns we compute the corresponding values of M sequentially while for the small patterns we reduce to unbalanced Batch-OV and use the fast algorithm for this problem shown in Lemma 2.5.

3.1 Patterns of Type $+|\circ|$ and $|\circ|$

As mentioned in the beginning of this section, we compute the set M of matched substring by partitioning the sub-patterns into large and small ones.

▶ **Lemma 3.2.** *Given a text* t *of length* n *and patterns* $\{p_i\}_i$ *of type* $\circ|$ *such that* $\sum_i |p_i| = m$*. We can compute* M *in time* $nm/2^{\Omega(\sqrt{\log\min(n,m)})}$*.*

▶ **Lemma 3.3** (Large Sub-Patterns). *Given a text* t *of length* n *and patterns* $p_1, \ldots, p_\ell$ *of type* $\circ|$ *such that* $\sum_{i=1}^{\ell} |p_i| \leq m$*. We can compute* M *in time* $\mathcal{O}(\ell n \log^2 \min(n,m) + m)$*.*

Proof. From a result by Cole and Hariharan [11] we know that there is a $\mathcal{O}(n\log^2 \hat{m} + \hat{m})$ time algorithm for $\circ|$-pattern matching with patterns of size $\hat{m}$. We run this algorithm sequentially for every pattern. We can ignore all p_i with $|p_i| > |\Sigma|n$ since they match more than n symbols. We get $|p_i| \leq \min(|\Sigma|n, m) \leq \min(n^2, m) \leq \min(n^2, m^2)$. Since $\log\min(n^2, m^2) = 2\log\min(n,m)$, each iteration takes time $\mathcal{O}(n\log^2\min(n,m) + |p_i|)$ and the claim follows. ◀

▶ **Lemma 3.4** (Small Sub-Patterns). *Given a text* t *of length* n *and patterns* $p_1, \ldots, p_m$ *of type* $\circ|$*. There is a* $f \in 2^{\Omega(\sqrt{\log\min(n,m)})}$ *such that the following holds: If* $|p_i| \leq f$ *for all* $i \in [m]$*, then we can compute* M *in time* $nm/2^{\Omega(\sqrt{\log\min(n,m)})}$ *with small error probability.*

We postpone the proof of this lemma and first combine the results for small and large patterns to proof the main theorem.

Proof of Lemma 3.2. Choose $f \in 2^{\Omega(\sqrt{\log\min(n,m)})}$ as in Lemma 3.4 and split the patterns into large patterns of size $> f$ and small patterns of size $\leq f$.

For the at most m/f large patterns compute $M_>$ by Lemma 3.3 in time $\mathcal{O}(m/f \cdot n\log^2\min(n,m) + m) \in nm/2^{\Omega(\sqrt{\log\min(n,m)})}$. Duplicate the ℓ small-patterns m/ℓ times and compute $M_\leq$ for the m small patterns by Lemma 3.4 in the claimed running time. ◀

Proof of Theorem 3.1 Item 1. Construct M by Lemma 3.2. Check for $|\circ|$-pattern matching whether $M = \emptyset$ since any matched substring is sufficient.

For $+|\circ|$-membership we construct a graph G with nodes $v_0, \ldots, v_n$ where we put an edge from v_{i-1} to v_j if $(i,j) \in M$. Then v_n is reachable from v_0 iff there is a decomposition of t into substrings which can be matched by the p_is. This reachability check can be performed in time $\mathcal{O}(n + |M|)$ by a depth-first search starting from v_0. ◀

For the proof of Lemma 3.4 we proceed as follows. For the construction of M for small sub-patterns we define some threshold f and check for every substring of t of length at most f whether there is a pattern that matches this substring. This check is reduced to Batch-OV by encoding the substrings and patterns as bit-vectors.

For small alphabets with $|\Sigma| < f$ this encoding is rather simple since we can use a one-hot encoding of the alphabet. But for larger alphabets this does not work as the dimension of the vectors would increase too much and the fast algorithm for Batch-OV could not be used

anymore. Therefore, we define a randomised encoding χ to ensure that the final bit-vectors are not to large. For simplicity we can assume $|\Sigma| = \Theta(\min(n,m))$ by padding Σ with fresh symbols. The construction in the following lemma is based on the idea of Bloom-Filters [6].

▶ **Lemma 3.5** (Randomised Characteristic Vector). *For a finite universe Σ and a threshold $f \leq 2^{\mathcal{O}(\sqrt{\log|\Sigma|})}$ there is a randomised $\chi : \mathcal{P}(\Sigma) \to \{0,1\}^d$ with $d \in \mathcal{O}(f \log|\Sigma|)$ such that for all $\sigma \in \Sigma$ and $S \subseteq \Sigma$ with $|S| \leq f$ the following holds:*

- *If $\sigma \in S$, then $\chi(\sigma) \coloneqq \chi(\{\sigma\}) \subseteq \chi(S)$, i.e. $\forall i \in [d] : \chi(\{\sigma\})[i] = 1 \implies \chi(S)[i] = 1$.*
- *If $\chi(\sigma) \subseteq \chi(S)$, then $\sigma \in S$ with high probability, i.e. $\geq 1 - 1/\operatorname{poly}(|\Sigma|)$.*

Proof. We define χ element-wise and set for $S \subseteq \Sigma$: $\chi(S)[i] \coloneqq \bigvee_{s\in S} \chi(s)[i]$, i.e. the bitwise OR over $\chi(s)$ for $s \in S$. Hence, the first claim already holds by definition. For each $\sigma \in \Sigma$ we define $\chi(\sigma)$ independently by setting $\chi(\sigma)[i] = 1$ with probability $1/f$ for all $i \in [d]$. Let $S \subseteq \Sigma$ with $|S| \leq f$ and $\sigma \in \Sigma \setminus S$. For all $i \in [d]$:

$$\begin{aligned}
\Pr[\chi(\sigma)[i] \not\subseteq \chi(S)[i]] &= \Pr[\chi(\sigma)[i] = 1 \wedge \chi(S)[i] = 0] \\
&= \tfrac{1}{f}\Big(1 - \tfrac{1}{f}\Big)^{|S|} \geq \tfrac{1}{f}\Big(1 - \tfrac{1}{f}\Big)^{f} \geq \tfrac{\mathrm{e}^{-2}}{f} \\
\Pr[\chi(\sigma) \subseteq \chi(S)] &= \prod_{i=1}^{d} \Pr[\chi(\sigma)[i] \subseteq \chi(S)[i]] = \prod_{i=1}^{d} (1 - \Pr[\chi(\sigma)[i] \not\subseteq \chi(S)[i]]) \\
&\leq \prod_{i=1}^{d} \Big(1 - \tfrac{\mathrm{e}^{-2}}{f}\Big) = \Big(\Big(1 - \tfrac{\mathrm{e}^{-2}}{f}\Big)^{d}\Big).
\end{aligned}$$

Setting $d = fc\ln|\Sigma|$ for some arbitrary $c > \mathrm{e}^2$, we get:

$$= \Big(1 - \tfrac{\mathrm{e}^{-2}}{f}\Big)^{f\cdot c\ln|\Sigma|} \leq \mathrm{e}^{-1/\mathrm{e}^2 \cdot c\ln|\Sigma|} = |\Sigma|^{-c/\mathrm{e}^2} = 1/\operatorname{poly}|\Sigma|. \qquad \blacktriangleleft$$

Proof of Lemma 3.4. Define $f = 2^{\sqrt{\epsilon}/3\cdot\sqrt{\log\min(n,m)}}$ with ϵ as in Lemma 2.5 and let a be some fresh symbol we add to Σ. Let $\chi : \mathcal{P}(\Sigma) \to \{0,1\}^{f^2}$ be as in Lemma 3.5. For simplicity one can think of χ as the one-hot encoding of alphabet Σ.

We define $T_j \coloneqq \{t_i \cdots t_{i+j-1} \mid 1 \leq i \leq n-j+1\}$ and $P_j \coloneqq \{p_i \mid \mathcal{L}(p_i) \subseteq \Sigma^j\}$ for all $j \in [f]$. Then replace all symbols and sub-patterns of type $|$ by bit-vectors by applying χ. Finally, pad every vector in T_j and P_j by $f - j$ repetitions of $\chi(a)$ and flip all values of P_j bit-wise such that 1s become 0s and vice versa. Let T be the set of all $\leq nf$ modified texts and P be the set of all m transformed patterns.

We observe that a text-vector in T is orthogonal to a pattern-vector in P iff the original text was matched by the original pattern. Since $f \cdot f^2 \leq 2^{\sqrt{\epsilon}\sqrt{\log\min(n,m)}} \leq 2^{\sqrt{\epsilon}\sqrt{\log\min(nf,m)}}$, we can apply Lemma 2.5 for T and P:

$$\frac{nfm}{2^{(\epsilon/\sqrt{\epsilon})\sqrt{\log\min(nf,m)}}} \leq \frac{nm}{2^{(\sqrt{\epsilon}-\sqrt{\epsilon}/3)\cdot\sqrt{\log\min(n,m)}}} \in \frac{nm}{2^{\Omega(\sqrt{\log\min(n,m)})}}. \qquad \blacktriangleleft$$

3.2 Patterns of Type $+|\circ+$ and $|\circ+$

First observe that even for small patterns M can be too large to be computed explicitly. For $t = 0^n1^n$ and $p = 0^+1^+$ we have $M = [1,n] \times [n+1,2n]$ and thus cannot write down M explicitly in time $o(nm)$.

To get around this problem we first define the *run-length encoding* $r(u)$ of a text u as in [4]: We have $r(\varepsilon) = \varepsilon$. For a non-empty string starting with σ, let ℓ be the largest integer such that the first ℓ symbols of u are σ. Append the tuple (σ, ℓ) to the run-length encoding

and recurse on u after removing the first ℓ symbols. We use the same approach for patterns of type $\circ+$. But if there occurs a σ^+ during these ℓ positions, we add $(\sigma, \geq \ell)$ to the encoding, otherwise $(\sigma, = \ell)$. We write σ^ℓ for the tuple (σ, ℓ) and similar for $\sigma^{=\ell}$ and $\sigma^{\geq\ell}$ to shorten notation. For example, $r(aaa^+b^+bc) = a^{\geq 3}b^{\geq 2}c^{=1}$.

The idea is to compute a subset of M which only contains those (i, j) such that there is no distinct (i', j') in the subset with $i' \leq i$ and $j' \geq j$ and both substrings of t are matched by the same pattern p_ℓ. We augment each tuple with two boolean flags, indicating whether the first and last run of the pattern p_ℓ contains a Kleene Plus. From this set $M' \subseteq \{0, 1\} \times [n] \times [n] \times \{0, 1\}$ we can fully recover M. For our above example we get $M' = \{(1, n, n + 1, 1)\}$.

▶ **Lemma 3.6.** *Given a text t of length n and patterns $\{p_i\}_i$ of type $\circ+$ such that $\sum_i |p_i| = m$. We can compute M' in time $nm/2^{\Omega(\sqrt{\log \min(n,m)})}$.*

▶ **Lemma 3.7** (Large Sub-Patterns)**.** *Given a text t of length n and patterns $p_1, \ldots, p_\ell$ of type $\circ+$ such that $\sum_{i=1}^{\ell} |p_i| \leq m$. We can compute M' in time $\mathcal{O}(\ell n \log^2 \min(n, m) + m)$.*

Proof. We modify all patterns such that their first and last run is of the form $\sigma^{=\ell}$, i.e. we remove every Kleene Plus from these two runs. There is a $\mathcal{O}(n \log^2 \hat{m} + \hat{m})$ time algorithm for $\circ+$-pattern matching with patterns of size $\hat{m}$ shown in [4]. We run this algorithm sequentially for each altered pattern. For every tuple (i, j) the algorithm outputs, we add (f, i, j, e) to M' where f and e are set to 1 iff the first and last run of the pattern contain a Kleene Plus, respectively.

We can ignore all p_i with $|p_i| > |\Sigma|n$ because they match more than n symbols. Since $|p_i| \leq \min(|\Sigma|n, m) \leq \min(n^2, m) \leq \min(n^2, m^2) = 2 \log \min(n, m)$, each iteration takes time $\mathcal{O}(n \log^2 \min(n, m) + |p_i|)$ and the claim follows. ◀

▶ **Lemma 3.8** (Small Sub-Patterns)**.** *For a text t of length n and patterns $p_1, \ldots, p_m$ of type $\circ+$, there is a $f \in 2^{\Omega(\sqrt{\log \min(n,m)})}$ such that the following holds: If $|p_i| \leq f$ for all $i \in [m]$, then we can compute M' in time $nm/2^{\Omega(\sqrt{\log \min(n,m)})}$.*

We postpone the proof of this lemma and first show the final upper bound as the proof of Lemma 3.2 also works for Lemma 3.6.

Proof of Theorem 3.1 Item 2. Use Lemma 3.6 to construct M' and check for $|\circ+$-pattern matching whether $M' = \emptyset$.

For $+|\circ+$-membership we define a graph $G = (V, E)$. Instead of having nodes $v_0, \ldots, v_n$ as for $+|\circ|$-membership we have for each node v_i three versions, $V \coloneqq \{v_i^0, v_i^1, v_i^2 \mid 0 \leq i \leq n\}$. The versions correspond to the different ways a suffix or prefix of a run can be matched. For node v_i^0 we need that all symbols are explicitly matched by a pattern. For v_i^1 we need that the suffix of the run containing t_i has to be matched by a pattern starting with t_i^+. For v_i^2 we say that the prefix has to be matched by a pattern ending with t_{i-1}^+. Hence, we add edges for the runs simulating the σ^+ of a pattern: For each run σ^ℓ from position i to j in t with $\ell > 1$ we add the edges (v_{k-1}^1, v_k^1) and (v_k^2, v_{k+1}^2) to the graph for $i \leq k < j$. Further, we add edges (v_i^2, v_i^0) and (v_i^0, v_i^1) to change between the states for all $0 \leq i \leq n$. While this construction solely depends on the text, we add for each $(f, i, j, e) \in M'$ the edge (v_{i-1}^f, v_j^{2e}) to the graph. We claim that there is a path from v_0^0 to v_n^0 if and only if $t \in \mathcal{L}((p_1 \mid \cdots \mid p_k)^+)$. We prove this claim in Appendix B. See Figure 2 for an example of the construction.

The time for the construction is linear in the output size. The graph has $\Theta(n)$ nodes and $|M'| + \mathcal{O}(n)$ edges. As the DFS runs in linear time, the overall runtime follows. ◀

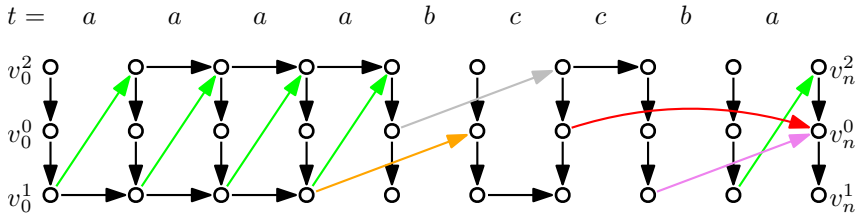

Figure 2 Graph for the pattern $(a^+ \mid a^+b \mid bc^+ \mid cba \mid b^+a)^+$ and text $aaaabccba$.

It remains to show how the set M' is constructed for small patterns.

Proof of Lemma 3.8. Set $f := 2^{\sqrt{\epsilon}/5\sqrt{\log \min(n,m)}}$ with ϵ as in Lemma 2.5 and consider all $\leq n/f^3$ many long runs of length $\geq f^3$ in t. Check for each long run by an exhaustive search whether there is a p_i such that the following holds: The run in the text is matched by one of the $\leq |p_i|$ runs in p_i and the remaining runs of p_i can match the contiguous parts of the text. This check can be performed in the following time for all large runs:

$$\frac{n}{f^3}\sum_{i=1}^{m}|p_i|^2 \leq \frac{n}{f^3}\sum_{i=1}^{m}f^2 \leq \frac{nm}{f}$$

Since a pattern can have at most f runs and each run matches now at most f^3 symbols, it remains to check substrings of t of length at most f^4. Hence, define $T = \{t_i \cdots t_{i+j-1} \mid \forall j \in [f^4], i \in [n-j+1]\}$ and ignore all substrings with more than f runs or runs longer than f^3. Convert these substrings and the patterns into bit-vectors by replacing the runs by the following bit-vectors of length $2\log|\Sigma| + 2f^3$:

$$c^r \mapsto \langle c\rangle\overline{\langle c\rangle}0^r1^{f^3-r}1^r0^{f^3-r} \qquad c^{=r} \mapsto \overline{\langle c\rangle}\langle c\rangle1^r0^{f^3-r}0^r1^{f^3-r} \qquad c^{\geq r} \mapsto \overline{\langle c\rangle}\langle c\rangle1^r0^{f^3-r}0^{f^3}$$

$\langle c\rangle$ denotes the unique binary representation of symbol c and $\overline{\langle c\rangle}$ its bit-wise negation. One can easily see that two such vectors are orthogonal if and only if the runs match each other. Thus, a text and a pattern vector resulting from this transformation are orthogonal iff the text is matched by the pattern. By padding the vectors with 1s we normalise their length but still preserve orthogonality between text and pattern vectors with the same number of runs. Let T' and P' be the resulting sets with $\leq nf^4$ and m elements, respectively.

From $\log|\Sigma| \leq \log \min(n,m) \leq f$ we get $f(2\log|\Sigma| + 2f^3) \leq f^5 \leq 2^{\sqrt{\epsilon}\sqrt{\log \min(nf^4,m)}}$ and hence can apply Lemma 2.5 for T' and P'. Actually we have to partition P' depending on whether a pattern has a Kleene Plus in its first and last run. Thus, we need four iterations but we can always duplicate patterns such that there are m patterns in each group.

$$\frac{nf^4m}{2^{\epsilon/\sqrt{\epsilon}\sqrt{\log \min(nf^4,m)}}} \leq \frac{nm}{2^{(\sqrt{\epsilon}-4/5\sqrt{\epsilon})\sqrt{\log \min(n,m)}}} \in \frac{nm}{2^{\Omega(\sqrt{\log \min(n,m)})}}.$$ ◀

4 Lower Bounds for Pattern Matching

Abboud and Bringmann showed in [1] a lower bound for pattern matching (and membership) in general of $\mathcal{O}(nm/\log^{7+\epsilon} n)$, unless FSH is false. We use this result and the corresponding reduction as a basis to show similar lower bounds for the remaining hard pattern types. But we also do not start our reductions directly from Formula-SAT but from Formula-Pair as defined in Section 2 and use the corresponding Formula-Pair Hypothesis from Hypothesis 2.3.

▶ **Theorem 4.1.** *There are constants $c_{\circ\star} = 76, c_{\circ+\circ} = c_{\circ|+} = 72, c_{\circ|\circ} = 81$, and $c_{\circ+|} = 27$ such that pattern matching with patterns of type $T \in \{\circ\star, \circ+\circ, \circ|\circ, \circ+|, \circ|+\}$ cannot be solved in time $\mathcal{O}(nm/\log^{c_T} n)$ even for constant sized alphabets, unless FPH is false.*

We show the lower bounds by a reduction from Formula-Pair to pattern matching:

▶ **Lemma 4.2.** *Given a Formula-Pair instance with a formula of size s, depth d, and sets A and B with n and $m \leq n$ assignments. (If $m > n$, swap A and B.) We can reduce this to pattern matching with a text t and a pattern p of type $T \in \{\circ\star, \circ+\circ, \circ|\circ, \circ+|, \circ|+\}$ over a constant sized alphabet in time linear in the output size.*

$|t| \in \mathcal{O}(n5^d s \log s)$ except for $\circ+|$, there we have $|t| \in \mathcal{O}(n2^d s \log s)$ Further, $|p| \in \mathcal{O}(mb_T^d s \log s)$ with $b_{\circ\star} = 6, b_{\circ+\circ} = b_{\circ|+} = 5, b_{\circ|\circ} = 8$, and $b_{\circ+|} = 1$.

Proof of Theorem 4.1. We show the result only for patterns of type $\circ+\circ$, the proof for the other types is analogous.

Let F be a formula of size s with two sets of n half-assignments each, and d be the depth of F. Applying the depth-reduction technique of Bonet and Buss [7] gives us an equivalent formula F' with size $s' \leq s^2$ and depth $d' \leq 6 \ln s$. By Lemma 4.2 we get a pattern matching instance with a text t and pattern p. Both of size $\mathcal{O}(n5^{d'} s' \log s') = \mathcal{O}(n5^{6 \ln s} s^2 \log s) = \mathcal{O}(ns^{6 \ln 5+2} \log s)$. Now assume there is an algorithm for pattern matching with the stated running time and run it on t and p:

$$\mathcal{O}\left(\frac{ns^{6 \ln 5+2} \log s \cdot ns^{6 \ln 5+2} \log s}{\log^{72}(ns^{6 \ln 2+2} \log s)}\right) \subseteq \mathcal{O}\left(\frac{n^2 s^{12 \ln 5+4} \log^2 s}{\log^{72} n}\right) \subseteq \mathcal{O}\left(\frac{n^2 s^{23.314}}{\log^{72} n}\right).$$

But this contradicts FPH which was assumed to be true. ◀

4.1 Proof of Lemma 4.2

Again we only give the proof for patterns of type $\circ+\circ$. The reduction for the other pattern types can be found in the full version of the paper. We first encode the evaluation of a formula on two half-assignments, then the encoding for finding such a pair. In the following we define the actual text t_g and pattern p_g. The universal text u_g and universal pattern q_g are needed for technical purposes and do not depend on the assignments.

4.1.1 Encoding the Formula

A formula of size s (i.e. s leaves) has $s-1$ inner gates and thus $2s-1$ gates in total. We assign every gate g a unique integer in $[2s-1]$, its ID, and write $\langle g \rangle$ for the binary encoding of the ID of gate g. We can always see $\langle g \rangle$ as a sequence of $\lfloor \log(2s-1) \rfloor + 1 \leq \lfloor \log s \rfloor + 2 = \Theta(\log s)$ bits padded with zeros if necessary. For a fixed gate g we define a separator gadget $G := 2\langle g \rangle 2$ with 2 as a new symbol.

INPUT Gate The text and the pattern depend on the variable that is read:

For $F_g(a, b) = a_i$ define $t_g := 0a_i1$ as the text and $p_g := 0^+11^+$ as the pattern.

For $F_g(a, b) = b_i$ define $t_g := 011$ as the text and $p_g := 0^+b_i1^+$ as the pattern.

Define $u_g := 0011$ as the universal text and $q_g := 0^+1^+$ as the universal pattern.

AND Gates We define: $t_g := t_1 G t_2$, $p_g := p_1 G p_2$, $u_g := u_1 G u_2$, and $q_g := q_1 G q_2$.

OR Gates The texts and the patterns for gate g are defined as follows where the parentheses are just for grouping and are not part of the text or pattern:

$$\begin{aligned} t_g &:= (u_1GGu_2)G(u_1GGu_2)G(t_1GGt_2)G(u_1GGu_2)G(u_1GGu_2) \\ u_g &:= (u_1GGu_2)G(u_1GGu_2)G(u_1GGu_2)G(u_1GGu_2)G(u_1GGu_2) \\ q_g &:= (u_1GGu_2)G(u_1GGu_2)G(q_1GGq_2)G(u_1GGu_2)G(u_1GGu_2) \\ p_g &:= (u_1GGu_2G)^+(q_1GGp_2)G(p_1GGq_2)(Gu_1GGu_2)^+ \end{aligned}$$

▶ **Lemma 4.3** (Correctness of the Construction). *For all assignments a, b and gates g:*

- $F_g(a,b) = \mathit{true} \iff t_g(a) \in \mathcal{L}(p_g(b))$
- $t_g(a) \in \mathcal{L}(q_g)$
- $u_g \in \mathcal{L}(q_g) \cap \mathcal{L}(p_g(b))$

Proof. The proofs of the second and third claim follow inductively from the encoding of the gates and especially because of the encoding of the INPUT gate. For the first claim we do a structural induction on the output gate of the formula.

INPUT Gate "⇒" Follows directly from the definition.

INPUT Gate "⇐" If the gate is not satisfied, then there are not enough 0s or 1s in the text than the pattern has to match.

AND Gate "⇒" Follows directly from the definition.

AND Gate "⇐" By the uniqueness of the binary encoding, the G in the middle of the text and the pattern have to match. Since the whole text is matched, we get $t_1 \in \mathcal{L}(p_1)$ and $t_2 \in \mathcal{L}(p_2)$ and $F_g(a,b)$ is satisfied by the induction hypothesis.

OR Gate "⇒" $F_g(a,b) = F_{g_1}(a,b) \vee F_{g_2}(a,b) = \mathsf{true}$. Assume w.l.o.g. that $F_{g_1}(a,b) = \mathsf{true}$, the other case is symmetric. Repeat $(u_1GGu_2G)^+$ only once to transform q_1GGp_2 into the second u_1GGu_2 by our third claim of the lemma. Now p_1GGq_2 matches t_1GGt_2 by the second claim and the assumption $t_1 \in \mathcal{L}(p_1)$. Finally, we match $Gu_1GGu_2Gu_1GGu_2$ by two repetitions of $(Gu_1GGu_2)^+$.

OR Gate "⇐" By the uniqueness of the binary encoding there are exactly 14 Gs in the text and the pattern can match 11 Gs when taking both repetitions once. Since each additional repetition increases the number by 3, exactly one repetition is taken twice. If the first repetition is taken once, the following q_1GGp_2 has to match the second u_1GGu_2 in the text. But then p_1 is transformed into t_1 showing that F_g is satisfied by the inductive hypothesis. The case for the second repetition is symmetric. ◀

Length of the text and the pattern. All texts and patterns for a specific gate only depend on the texts and patterns for the two sub-gates. Thus, we can compute the texts and patterns in a bottom-up manner and the encoding can be done in time linear in the size of the output. It remains to analyse the length of the texts and the size of the patterns:

▶ **Lemma 4.4.** $|u_r|, |t_r|, |p_r|, |q_r| \in \mathcal{O}(5^d s \log s)$.

Proof. p_g is obviously smaller than u_g. Since the sizes of u_g, t_g, and q_g are asymptotically equal, it suffices to analyse the length of u_g: $|u_g| \leq 5|u_1| + 5|u_2| + \mathcal{O}(\log s)$. Inductively over the $d(F_g)$ levels of F_g, i.e. the depth of F_g, this yields $|u_g| \leq \mathcal{O}(5^{d(F_g)} s \log s)$. The factor of $s \log s$ is due to the $\mathcal{O}(s)$ inner gates each introducing $\mathcal{O}(\log s)$ additional symbols. ◀

4.1.2 Final Reduction

In the first part of the reduction we have seen how to evaluate a formula on one specific pair of half-assignments. It remains to design a text and a pattern such that such a pair of half-assignments can be chosen. For this let $A = \{a^{(1)}, \dots, a^{(n)}\}$ be the first set and $B = \{b^{(1)}, \dots, b^{(m)}\}$ be the second set of half-assignments. Inspired by the reduction in Section 3.4 in the full version of [4] we define the final text and pattern as follows:

$$t \coloneqq \bigodot_{i=1}^{3n} \Big(33u_r3u_r3u_r3t(a^{(i)})3u_r3u_r3u_r3u_r\Big)$$

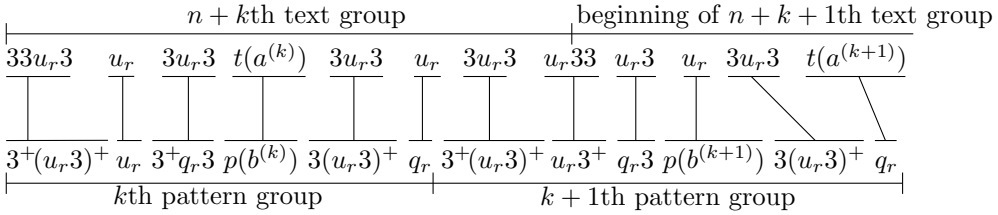
$$p \coloneqq 3u_r3u_r3u_r3u_r \bigodot_{j=1}^{m} \Big(3^+(u_r3)^+u_r3^+q_r3p(b^{(j)})3(u_r3)^+q_r\Big)3u_r3u_r3u_r3u_r.$$

Where we set $a^{(j)} = a^{(j \mod n)}$ for $j \in [n+1, 3n]$. We call the concatenations in t and p for each i and j the ith text group and the jth pattern group, respectively.

▶ **Lemma 4.5.** *If there are $a^{(k)}$ and $b^{(l)}$ such that $F(a^{(k)}, b^{(l)}) = \mathsf{true}$, then $t \in \mathcal{M}(p)$.*

Proof. Assume w.l.o.g. $a^{(k)}$ and $b^{(k)}$ satisfy F. Otherwise we have to shift the indices for the text and the pattern accordingly in the proof. We match the prefix of p to the suffix of the nth text group. Then we match the $n+i$th text group by the ith pattern group for $i = 1, \dots, k-1$: Both $(u_r3)^+$ are repeated twice. Then the remaining parts are matched in a straightforward way by transforming the q_rs into $t(a^{(i)})$ and u_r, and $p(b^{(i)})$ into u_r.

Then, we match the kth and $k+1$th pattern group to the $n+k$th text group and a part of the $n+k+1$th text group:



For the last step we shift the groups in the remaining text t' such that it becomes easier to prove which part of the text the remaining pattern matches:

$$\begin{aligned} t' =& 3u_r3u_r3u_r3u_r \bigodot_{i=n+k+2}^{3n} \Big(33u_r3u_r3u_r3t(a^{(i)})3u_r3u_r3u_r3u_r\Big) \\ =& \bigodot_{i=n+k+2}^{3n} \Big(3u_r3u_r3u_r3u_r33u_r3u_r3u_r3t(a^{(i)})\Big)3u_r3u_r3u_r3u_r. \end{aligned}$$

For each of the remaining pattern groups the first repetition is taken three times. With this the $n+i$th group of t' and the ith pattern group are matched in a straightforward way for $i = k+2, \dots, m$. The suffix of the pattern is matched to the start of the $n+m+1$th text group in the obvious way. ◀

▶ **Lemma 4.6.** *If $t \in \mathcal{M}(p)$, then there are $a^{(k)}$ and $b^{(l)}$ such that $F(a^{(k)}, b^{(l)}) = \mathsf{true}$.*

Proof. By the design of the pattern and the text, there must be a $j \leq n$ such that the prefix of the pattern is matched to the suffix of the $j-1$th text group. Likewise the suffix of the pattern has to match the same sequence in some other text group because nowhere else the

four $3u_r$ could be matched. Thus, not all text groups and pattern groups match each other precisely and there is a text group k and a pattern group l such that the pattern group does not match the whole text group or it matches more than this group. Choose the first of these groups, i.e. the pair with smallest k and l.

Since all prior groups have been matched precisely, the first repetition can be taken at most twice. Otherwise the following u_r could not be transformed into a part of the text. Now assume it is repeated exactly once. Then the following u_r matches the second u_r of the text group. Since 3 is a fresh symbol, q_r has to match the third u_r. But then $p(b^{(k)})$ has to be transformed into $t(a^{(l)})$ and Lemma 4.3 gives us a satisfying assignments.

It remains to check the case when $(u_r 3)^+$ is repeated twice. Then q_r is transformed into $t(a^{(l)})$ and $p(b^{(k)})$ is transformed into the fourth u_r. The second repetition has to be taken exactly twice in this case. Because otherwise the 33 from the beginning of the next text group could not be matched. But if the pattern $(u_r 3)^+$ is repeated twice, this pattern group is completely matched to a text group, contradicting our assumption. ◀

▶ **Lemma 4.7.** *The final text has length $\mathcal{O}(n5^d s \log s)$ and the pattern has size $\mathcal{O}(m5^d s \log s)$.*

By this we conclude the proof of Lemma 4.2 for this pattern type. ⌟

5 Lower Bounds for Membership

Instead of giving all reductions from scratch, we reduce pattern matching to membership and make use of the results in Lemma 4.2. By this we get the same bounds as for pattern matching given in Theorem 4.1. For the remaining pattern type $|{+}|\circ$ we give a new reduction from scratch which is necessary due to the missing concatenation as outer operation.

5.1 Reducing Pattern Matching to Membership

▶ **Lemma 5.1** (Reducing Pattern Matching to Membership). *Given a text t and a pattern p with type in $\{\circ\star, \circ{+}\circ, \circ|\circ, \circ{+}|, \circ|{+}\}$ over a constant sized alphabet.*

We can construct a text t' and a pattern p' of the same type as p in linear time such that $t \in \mathcal{M}(p) \iff t' \in \mathcal{L}(p')$. Further, $|t'| \in \mathcal{O}(|t|)$ and $|p'| \in \mathcal{O}(|t| + |p|)$, except for $\circ{+}|$, there we even have $|p'| \in \mathcal{O}(|p|)$.

Proof. Again we only show the proof for type $\circ{+}\circ$. The reductions for the other types can be found in the full version.

Let $\Sigma = \{1, \dots, s\}$ be the alphabet. We first encode every symbol such that we can simulate a universal pattern (i.e. matching any symbol) by some gadget U of type $\circ{+}$. Let $f : \Sigma \to \Sigma^{s+1}$ be this encoding with $f(x) = 1 \cdots (x-1)xx(x+1) \cdots s$. Since we can extend f in the natural way to texts by applying it to every symbol, we can also modify patterns of type $\circ{+}\circ$ by applying f to every symbol *without* changing the type. After applying f we still have $t \in \mathcal{M}(p) \iff f(t) \in \mathcal{M}(f(p))$.

For the step from pattern matching to membership we set $U \coloneqq 1^+2^+ \cdots s^+$ and $R \coloneqq 12 \cdots s$. Obviously $R \in \mathcal{L}(U)$ and $f(\sigma) \in \mathcal{L}(U)$ for all $\sigma \in \Sigma$. But we also get $R \notin \mathcal{L}(f(\sigma))$ since R does not contain a repetition of σ. Finally, we define $t' \coloneqq R^{|t|+1} f(t) R^{|t|+1}$ and $p' = R^+ U^{|t|} f(p) U^{|t|} R^+$. We claim $t \in \mathcal{M}(p) \iff t' \in \mathcal{L}(p')$.

"$\Rightarrow$" If $t \in \mathcal{M}(p)$, then there is a substring $\hat{t}$ of t matched by p. By the above observations, $f(p)$ matches $f(\hat{t})$ which is a substring of $f(t)$. Then we use $U^{|t|}$ to match the not matched suffix and prefix of $f(t)$ and a part of $R^{|t|+1}$. The remaining repetitions of R are matched by the R^+ in the beginning and the end. "$\Leftarrow$" If $t' \in \mathcal{L}(p')$, then $f(p)$ has to match some substring of $f(t)$ because R cannot be matched by the above observation. ◀

5.2 Patterns of Type $|+|\circ$

Even though the remaining hard pattern type $|+|\circ$ does not have a concatenation as outer operation, we can still show a similar lower bound as for the other types.

▶ **Theorem 5.2.** *$|+|\circ$-membership cannot be solved in time $\mathcal{O}(nm/\log^{17} n)$ even for constant sized alphabets, unless FPH is false.*

To proof the theorem it suffices to show that Formula-Pair can be reduced to membership with a text of length $\mathcal{O}(ns^2 \log s)$ and a pattern of size $\mathcal{O}(ms^3 \log s)$. Then the claim directly follows from the definition of FPH as for the other types.

Idea of the reduction. As for the other lower bounds, we first encode the evaluation of the formula on two fixed half-assignments. We define for each gate g a text t_g and two dictionaries D_g^M and D_g^S of words. The final dictionary for a gate g is defined as $D_g = \bigcup_{g' \in F_g} D_{g'}^S \cup D_{g'}^M$. The final pattern is D_r^+ where r is the root of F.

D_g^M corresponds to p_g and allows us to match the whole text t_g if the formula is satisfied. The texts of the sub-gates are then matched by the corresponding dictionaries. But for the OR gate we have to be able to ignore the evaluation of one sub-formula. For this we define the set D_g^S which corresponds to q_g and allows us to match the text independently from the assignments. As main idea we include the path from the root of the formula to the current gate in the encoding. This trace is appended to the text as a prefix and in reverse as suffix. The words in D_g^M for OR gates g allow us to jump to a gate in such a trace of exactly one sub-formula. Then we use corresponding words from D^S to propagate this jump to the sub-formulas. Because the included trace started at the root, we can proceed to the INPUT gates. There we add words to accept all evaluations of the gate. For the way back up we add the corresponding words in reverse to the dictionaries.

We make sure that these words are just used at one specific position by embedding the encoding of the corresponding gate in the trace. Since the gate number can be made unique these words can only be used at one specific position. This procedure allows us to write down the words as a set and not as a concatenation as for the other reductions.

Encoding the Formula. We identify each gate g with its ID, i.e. an integer in $[2s]$. Let $\langle g \rangle$ be the binary encoding of the gate ID with $\lfloor \log s \rfloor + 2 = \Theta(\log s)$ bits padded with zeros if necessary. Further, let $h_0 h_1 \dots h_d$ be the path from the root $r = h_0$ of F to the gate $g = h_d$ of depth $d \geq 0$. To simplify notation we define $h_i^g = 2\langle h_i \rangle \langle g \rangle 2$, i.e. the encoding of the gate on the path and the gate where the path ends.

INPUT Gates We set $D_g^S \coloneqq \{h_i^g \dots h_d^g 0 h_d^g \dots h_i^g, h_i^g \dots h_d^g 1 h_d^g \dots h_i^g \mid i \in [d]\}$.
For $F_g(a,b) = a_i$, we set $t_g \coloneqq h_0^g \dots h_d^g a_i h_d^g \dots h_0^g$ and $D_g^M \coloneqq \{h_0^g \dots h_d^g 1 h_d^g \dots h_0^g\}$
For $F_g(a,b) = b_i$, we set $t_g \coloneqq h_0^g \dots h_d^g 1 h_d^g \dots h_0^g$ and $D_g^M \coloneqq \{h_0^g \dots h_d^g b_i h_d^g \dots h_0^g\}$

AND Gate We define the text and the corresponding dictionaries as follows:

$$
\begin{aligned}
t_g &\coloneqq h_0^g \dots h_d^g t_1 t_2 h_d^g \dots h_0^g \\
D_g^M &\coloneqq \{h_0^g \dots h_d^g, h_d^g \dots h_0^g\} \\
D_g^S &\coloneqq \{h_i^g \dots h_d^g h_0^{g_1} \dots h_{i-1}^{g_1}, h_{i-1}^{g_1} \dots h_0^{g_1} h_0^{g_2} \dots h_{i-1}^{g_2}, h_{i-1}^{g_2} \dots h_0^{g_2} h_d^g \dots h_i^g \mid i \in [d]\}
\end{aligned}
$$

OR Gate We define the text and the additional dictionaries for g as:

$$\begin{aligned} t_g &:= h_0^g \dots h_d^g t_1 h_d^g t_2 h_d^g \dots h_0^g \\ D_g^M &:= \{h_0^g \dots h_d^g, h_d^g h_0^{g_2} \dots h_d^{g_2}, h_d^{g_2} \dots h_0^{g_2} h_d^g \dots h_0^g\} \\ &\quad \cup \{h_0^g \dots h_d^g h_0^{g_1} \dots h_d^{g_1}, h_d^{g_1} \dots h_0^{g_1} h_d^g, h_d^g \dots h_0^g\} \\ D_g^S &:= \{h_i^g \dots h_d^g h_0^{g_1} \dots h_{i-1}^{g_1}, h_{i-1}^{g_1} \dots h_0^{g_1} h_d^g h_0^{g_2} \dots h_{i-1}^{g_2}, h_{i-1}^{g_2} \dots h_0^{g_2} h_d^g \dots h_i^g \mid i \in [d]\} \end{aligned}$$

▶ **Lemma 5.3.** *For all assignments a, b and gates g:*

- $t_g(a) \in \mathcal{L}(h_0^g \dots h_{i-1}^g (D_g(b))^+ h_{i-1}^g \dots h_0^g)$ *for all* $i \in [d]$.
- $t_g(a) \notin \mathcal{L}(h_0^g \dots h_{i-1}^g (D_g(b))^+ h_{j-1}^g \dots h_0^g)$ *for all* $i \neq j \in [0, d]$, *where* $h_0^g h_{-1}^g$ *and* $h_{-1}^g h_0^g$ *denote the empty string.*

Proof. The first claim follows by a structural induction on the output gate using only words from $D_{g'}^S$ for the current gate g'. Likewise we show the second case by a structural induction on the output gate.

INPUT Gate The statement holds by the definition of the dictionary.

AND Gate Assume the claim is false for g. We can only match the "prefix" $h_i^g \dots h_d^g$ with the word $h_i^g \dots h_d^g h_0^{g_1} \dots h_{i-1}^{g_1}$. And analogously for the "suffix". The joining part of $t_1 t_2$ has to be matched by some $h_{k-1}^{g_1} \dots h_0^{g_1} h_0^{g_2} \dots h_{k-1}^{g_2}$ for $k \in [0, \dots, d]$ (possibly the empty string). Hence, $t_1 \in \mathcal{L}(h_0^{g_1} \dots h_{i-1}^{g_1} (D_{g_1}(b))^+ h_{k-1}^{g_1} \dots h_0^{g_1})$ and $t_2 \in \mathcal{L}(h_0^{g_2} \dots h_{k-1}^{g_2} (D_{g_2}(b))^+ h_{j-1}^{g_2} \dots h_0^{g_2})$. But from $i \neq j$ it follows that $k \neq i$ or $k \neq j$ and we have a contradiction to the induction hypothesis for g_1 and g_2.

OR Gate The "prefix" $h_i^g \dots h_d^g$ has to be matched by $h_i^g \dots h_d^g h_0^{g_1} \dots h_{i-1}^{g_1}$ and analogously for the "suffix". If the joining part of $t_1 h_d^g t_2$ was matched by $h_{k-1}^{g_1} \dots h_0^{g_1} h_d^g h_0^{g_2} \dots h_{k-1}^{g_2}$ for some $k \in [d]$, the same proof as for the AND gate applies. Otherwise, either $h_d^{g_1} \dots h_0^{g_1} h_d^g$ or $h_d^g h_0^{g_2} \dots h_d^{g_2}$ was used. Let it w.l.o.g. be the first one. Since $i \in [0, d]$, we have $i \neq d+1$ and hence a contradiction to the inductive hypothesis for t_1. ◀

▶ **Lemma 5.4** (Correctness of the Construction)**.** *For all assignments a, b and gates g:* $F_g(a, b) = \mathit{true} \iff t_g(a) \in \mathcal{L}((D_g(b))^+)$.

Proof. We proof the claim by an induction on the output gate.

INPUT Gate Follows directly from the construction of the text and the dictionary.

AND Gate "⇒" We can use D_1^+ and D_2^+ to match t_1 and t_2 by the induction hypothesis, respectively. The remaining parts are matched by the words in D_g^M.

AND Gate "⇐" The initial and last h_0^g of the text have to be matched. Since the gate g is part of the encoding, we can only use words from D_g^M for this. It follows directly that t_1 is matched by words from D_1 because the initial $h_0^{g_1}$ has to be matched too and the words in D_g^S are not eligible for this. The same argument shows that t_2 is matched by words from D_2. Hence, the claim follows by the induction hypothesis.

OR Gate "⇒" Assume w.l.o.g. that $F_{g_1}(a, b) = \mathsf{true}$, the other case is symmetric. We match the prefix of t_g in the obvious way by the corresponding word from D_g^M. By assumption we match t_1 with words from D_1. The prefix $h_0^{g_2} \dots h_d^{g_2}$ of t_2 is matched by the corresponding word in D_g^M. By the first claim of the previous lemma, we have $t_2 \in \mathcal{L}(h_0^{g_2} \dots h_d^{g_2} (D_{g_2})^+ h_d^{g_2} \dots h_0^{g_2})$ and the remaining suffix can be matched by the corresponding word from D_g^M.

OR Gate "⇐" By Lemma 5.3 the joining part of $t_1 h_d^g t_2$ has to be matched by either $h_d^g h_0^{g_2} \dots h_d^{g_2}$ or $h_d^{g_1} \dots h_0^{g_1} h_d^g$. Let it w.l.o.g. be the first one. Then t_1 has to be matched by words from D_1 again by the lemma. The inductive hypothesis gives us a satisfying assignment. ◀

▶ **Lemma 5.5.** *We have the following size bounds:*
- $|t_r| \in \mathcal{O}(sd \log s) \subseteq \mathcal{O}(s^2 \log s)$
- $|D_r| \in \mathcal{O}(sd) \subseteq \mathcal{O}(s^2)$
- $\forall x \in D_r : |x| \in \mathcal{O}(d \log s) \subseteq \mathcal{O}(s \log s)$

Proof. The lemma follows directly from the definitions and the observations that $|t_g| \leq |t_1| + |t_2| + \mathcal{O}(d \log s)$, $|D_g^M| \in \mathcal{O}(1)$, and $|D_g^S| \in \mathcal{O}(d)$. ◀

Outer OR. Let $A = \{a^{(1)}, \ldots, a^{(n)}\}$ be the first set and $B = \{b^{(1)}, \ldots, b^{(m)}\}$ be the second set of half-assignments. Again we encode A by the text and B by the pattern. For this we observe that the first step of the reduction produced a pattern of type $+|\circ$. Thus, we can use the outer alternative to encode the outer OR to select a specific $b^{(j)}$. To match the whole text, we blow up the text and the pattern and pad each symbol with three new symbols such that we can distinguish between the following three matching states: (1) ignore the padding and match a part of the original text to the original pattern, i.e. we evaluate the formula on two half-assignments. (2) Match an arbitrary prefix, i.e. the symbols before the actual match in state (1). (3) Match some arbitrary suffix, i.e. the symbols after the actual match from state (1). We allow a change between these states only at the end of a text group and require that we go through all three states if and only if the text can be matched by the pattern.

▶ **Definition 5.6** (Blow-Up of a Text). *Let $t = t_1 \cdots t_n$ be a text of length n and u be some arbitrary string. We define $t\Uparrow^u := ut_1ut_2 \cdots ut_n$ and extend it in the natural way to sets.*

Using this we define the final text and pattern as follows:

$$t := 563 \bigodot_{i=1}^{n} \Big(t(a^{(i)})3 \Uparrow^{456} \Big) 45$$

$$p := p_1^+ \mid p_2^+ \mid \cdots \mid p_m^+$$

$$p_j := 5604 \mid 5614 \mid 5624 \mid 5634 \mid 563 \mid D_r(b^{(j)}) \Uparrow^{456} \mid 456345 \mid 6045 \mid 6145 \mid 6245 \mid 6345$$

▶ **Lemma 5.7.** *If there are $a^{(k)}$ and $b^{(l)}$ such that $F(a^{(k)}, b^{(l)}) = \mathsf{true}$, then $t \in \mathcal{L}(p)$.*

Proof. It suffices to show that we can match t to p_l^+. The prefix of t and the first $k-1$ text groups are matched by repetitions of $56x4$ for values $x \in \{0, 1, 2, 3\}$ while the last three symbols of the $k-1$th group are matched by 563. This is possible by our blow-up with 456. By Lemma 5.4 and the definition of the blow-up we get $t(a^{(k)}) \Uparrow^{456} \in \mathcal{L}((D_r(b^{(l)}) \Uparrow^{456})^+)$. The following 456345 is matched by the corresponding pattern while the remaining symbols of the text are matched in a straight forward way by repetitions of $6x45$. ◀

▶ **Lemma 5.8.** *If $t \in \mathcal{L}(p)$, then there are $a^{(k)}$ and $b^{(l)}$ such that $F(a^{(k)}, b^{(l)}) = \mathsf{true}$.*

Proof. By the structure of the pattern we can already fix l. As there is no way to match the text just with words $56x4$ or $6x45$, the word 563 must have been used at the end of some group to switch to the first state. Hence, let the kth text group be the first group not matched by words of the form $56x4$. Observe that we cannot directly switch to an application of $6x45$ and thus get $t(a^{(k)}) \Uparrow^{456} \in \mathcal{L}((D_r(b^{(l)}) \Uparrow^{456})^+)$. Since the blow-up 456 always matches each other, we can ignore it and get $t(a^{(k)}) \in \mathcal{L}(D_r(b^{(l)})^+)$ proving the claim by Lemma 5.4. ◀

▶ **Corollary 5.9.** *The final text has length $\mathcal{O}(nsd \log s) \subseteq \mathcal{O}(ns^2 \log s)$ and the pattern has size $\mathcal{O}(msd^2 \log s) \subseteq \mathcal{O}(ms^3 \log s)$.*

This finishes the proof of Theorem 5.2. ⌟

A FSH implies FPH

We use the following relation between Formula-SAT and Formula-Pair to show that FSH implies FPH:

▶ **Lemma A.1** (Weak version of Lemma B.2 in the full version of [1]). *An instance of Formula-SAT on a De Morgan formula of size s over n variables can be reduced to an instance of Formula-Pair with a monotone De Morgan formula of size $k = \mathcal{O}(s)$ and two sets of size $\mathcal{O}(2^{n/2})$ in linear time.*

Proof Idea. Let F be the formula for Formula-SAT on n variables and size s. We define F' to be the same formula as F but each leaf is labeled with a different variable and we remove the negations from the leaves.

For all half-assignments x to the first half of variables of F we construct a new half-assignment a_x for F' as follows: Let l be a leaf in F with a variable from the first half of inputs and let l' be the corresponding variable/leaf in F'. We set $a_x[l'] = \mathsf{true}$ if and only if l evaluates to true under x. We construct the set B analogous for the second half of inputs of F. Since F has n inputs this results in $2^{n/2}$ assignments for A and B. ◀

▶ **Lemma A.2.** *FSH implies FPH.*

Proof. Assume FSH holds and FPH is false for some fixed $k \geq 1$. Let F be a formula for Formula-SAT on N inputs and size $s = N^{3+1/(4k)} \in N^{3+\Omega(1)}$. By Lemma A.1 we transform F into a monotone De Morgan formula F' of size $s' = \mathcal{O}(s)$ and two sets with $n, m \in \mathcal{O}(2^{N/2})$ assignments. We run the algorithm for Formula-Pair on this instance to contradict FSH:

$$\mathcal{O}\left(\frac{n \cdot m \cdot s'^k}{\log^{3k+2} n} \log^{1+o(1)} 2^N\right) \subseteq \mathcal{O}\left(\frac{2^{N/2} 2^{N/2} s^k N^{1.25}}{\log^{3k+2} 2^{N/2}}\right) = \mathcal{O}\left(2^N \frac{N^{3k+0.25+1.25}}{N^{3k+2}(1/2)^{3k+2}}\right)$$
$$= \mathcal{O}\left(2^N \frac{N^{3k+1.5}}{N^{3k+2}}\right) = \mathcal{O}\left(\frac{2^N}{N^{0.5}}\right).$$

See the following paragraph for the additional factor of $N^{1+o(1)}$. ◀

As Abboud and Bringmann [1] we use the *Word-RAM* model as our computational model. The word size of the machine will be fixed to $\Theta(\log N)$ many bits for input size N. Likewise we assume several operations that can be performed in time $\mathcal{O}(1)$ (e.g. AND, OR, NOT, addition, multiplication, ...).

While this is sufficient for our reductions, we also need that the operations are robust to a change of the word size to state FPH. As in [1] we require that we can simulate the operations on words of size $\Theta(\log N)$ on a machine with word size $\Theta(\log \log N)$ in time $(\log N)^{1+o(1)}$.

In the above proof the input size increased from N to $n = 2^N$. Hence, we have to simulate the algorithm for Formula-Pair with word size $\log n = N$ on a machine with word size $\log N$ to get an algorithm for Formula-SAT. Thus, the running time slows down by a factor of $(\log n)^{1+o(1)} = N^{1+o(1)}$.

B Correctness of the Graph Construction for +|∘+-Membership

We show the correctness of the graph construction given in the proof of Theorem 3.1 Item 2.

▷ Claim B.1. If $t \in \mathcal{L}(p)$, then there is a path from v_0^0 to v_n^0.

Proof. Assume $p = (p_1 \mid \ldots \mid p_k)^+$. Since $t \in \mathcal{L}(p)$, we can decompose t into $t = \tau_1 \cdots \tau_\ell$ such that for all $l \in [\ell]$ $\tau_l \in \mathcal{L}(p_{k_l})$ for some $k_l \in [k]$. Define $\lambda_l = |\tau_1 \cdots \tau_l|$ as the length of the first l parts of t for all $l \in [\ell]$. We claim that if $\tau_1 \cdots \tau_l \in \mathcal{L}(p)$, then there is a path from v_0^0 to $v_{\lambda_l}^0$.

For $l = 0$, the claim is vacuously true as $\varepsilon \notin \mathcal{L}(p)$. Now assume the claim holds for arbitrary but fixed l. We define $i = \lambda_l + 1$ and $j = \lambda_{l+1}$ to simplify notation and get $\tau_{l+1} = t_i \cdots t_j$. From $\tau_{l+1} \in \mathcal{L}(p_{k_{l+1}})$ and Lemma 3.6 we know $(f, i', j', e) \in M'$ for some $i \leq i' \leq j' \leq j$. Further, f, e are set to 1 if and only if the first and last run of $p_{k_{l+1}}$ contains a Kleene Plus, respectively. Hence, $v_{j'}^{2e}$ is reachable from $v_{i'-1}^f$. Now it suffices to show that (1) $v_{i'-1}^f$ is reachable from v_{i-1}^0 and (2) v_j^0 is reachable from $v_{j'}^{2e}$. Then the claim follows inductively as v_{i-1}^0 is reachable from v_0^0.

We first show (1). If $f = 0$, we must have $i = i'$ and the claim holds. Thus assume $f = 1$. We know $\tau_{l+1} = t_i \cdots t_j \in \mathcal{L}(p_{k'})$ and $t_{i'} \cdots t_{j'} \in \mathcal{L}(p_{k'})$ for some $k' \in [k]$. As the first run of $p_{k'}$ contains a Kleene Plus, the symbols, $t_i, t_{i+1}, \ldots, t_{i'}$ are all equal. That is, they form a run from i to i'. By the construction of the graph, there are edges $(v^1_{i-1}, v^1_i), \ldots, (v^1_{i'-2}, v^1_{i'-1})$. But there is also the additional edge (v^0_{i-1}, v^1_{i-1}) proving (1).

By a symmetric argument one can show claim (2). ◁

▷ Claim B.2. If there is a path from v^0_0 to v^0_n, then $t \in \mathcal{L}(p)$.

Proof. First observe that it is not possible to reach v^0_n from v^0_0 without using edges introduced by tuples in M'. Now fix some path P from v^0_0 to v^0_n and let $P_1, \ldots, P_\ell$ be the edges on the path that are introduced by tuples in M'. Let $P_l = (v^{f_l}_{i'_l-1}, v^{2e_l}_{j'_l})$, i.e. $(f_l, i'_l, j'_l, e_l) \in M'$.

Assume $j'_0 = 0$ and $i'_{\ell+1} = n + 1$ in the following to simplify notation. For each tuple there are two indices i_l and j_l such that $j'_{l-1} \leq i_l - 1 \leq i'_l - 1$ and $j'_l \leq j_l \leq i'_{l+1} - 1$ and the path P goes through $v^0_{i_l-1}$ and $v^0_{j_l}$. These nodes exist, as every path from $v^{2e_{l-1}}_{j'_{l-1}}$ to $v^{f_l}_{i'_l-1}$ has to go through some node v^0_r. We have $j_l + 1 = i_{l+1}$ for all $l \in [0, \ell]$ with $j_0 = 0$ and $i_{\ell+1} = n + 1$ and hence, $t = t_{i_1} \cdots t_{j_1} t_{i_2} \cdots t_{j_2} \cdots t_{i_\ell} \cdots t_{j_\ell}$. Thus, it suffices to show that for every $l \in [\ell]$ there is a $k' \in [k]$ such that $t_{i_l} \cdots t_{j_l} \in \mathcal{L}(p_{k'})$.

We fix l in the following and omit it as index to simplify notation. By the construction of the graph we have $(f, i', j', e) \in M'$ and hence by Lemma 3.6 $t_{i'} \cdots t_{j'} \in \mathcal{L}(p_{k'})$ for some $k' \in [k]$. We extend this result and claim $t_i \cdots t_{j'} \in \mathcal{L}(p_{k'})$. Recall, that there is a path from v^0_{i-1} to $v^f_{i'-1}$ in P. If $f = 0$, then $i' = i$ and the claim follows. Otherwise, we know that the first run of $p_{k'}$ contains a Kleene Plus for some symbol α. As no edge resulting from a tuple in M' can be chosen, the edge (v^0_{i-1}, v^1_{i-1}) is contained in the path P. By the construction of the graph, the sequence $t_i \cdots t_{i'}$ is contained in some run β^c. But $\alpha = \beta$ and we get $t_i \cdots t_{i'-1} t_{i'} \cdots t_{j'} \in \mathcal{L}(p_{k'})$.

We can apply the symmetric argument to show that $t_i \cdots t_{j'} t_{j'+1} \cdots t_j \in \mathcal{L}(p_{k'})$ proving the claim. ◁

Space-Efficient, Fast and Exact Routing in Time-Dependent Road Networks

Abstract

We study the problem of computing shortest paths in massive road networks with traffic predictions. Incorporating traffic predictions into routing allows, for example, to avoid commuter traffic congestions. Existing techniques follow a two-phase approach: In a preprocessing step, an index is built. The index depends on the road network and the traffic patterns but not on the path start and end. The latter are the input of the query phase, in which shortest paths are computed. All existing techniques have either large index size, slow query running times, or may compute suboptimal paths. In this work, we introduce CATCHUp (Customizable Approximated Time-dependent Contraction Hierarchies through Unpacking), the first algorithm that simultaneously achieves all three objectives. The core idea of CATCHUp is to store paths instead of travel times at shortcuts. Shortcut travel times are derived lazily from the stored paths. We perform an experimental study on a set of real world instances and compare our approach with state-of-the-art techniques. Our approach achieves the fastest preprocessing, competitive query running times and up to 30 times smaller indexes than competing approaches.

1 Introduction

Routing in road networks is a well-studied topic with a plethora of real world applications. The core problem is to compute a fastest route between a source and a target. The idealized problem can be formalized as the classic shortest path problem. Streets are modeled as arcs. Street intersections are modeled as nodes. Travel times are modeled as scalar arc weights. Unfortunately, this idealized view does not model certain important real world effects. An important example are recurring commuter congestions. In this paper, we consider an extended problem in which travel times are time-dependent. The travel time of an arc is a function of the moment where a car enters the arc. Figure 1 depicts an example.

Computing shortest-paths using Dijkstra's [12] algorithm is possible both in the classical and in the time-dependent setting. However, for many applications, its running time is too large. To achieve fast running times, a two-phase approach is used. In the first phase, the

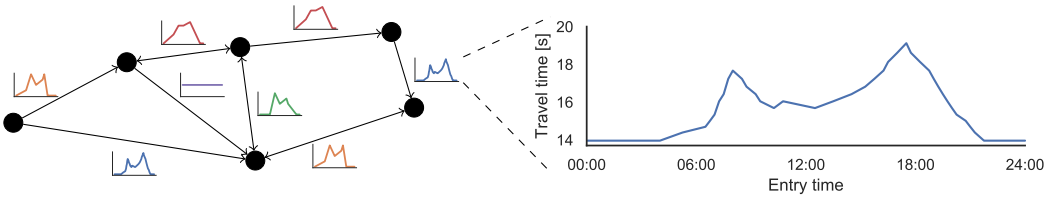

Figure 1 The graph of a small road network with predicted travel times for each road segment.

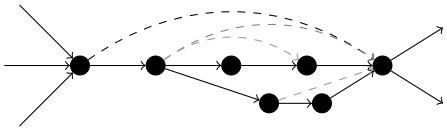
preprocessing phase, an index is constructed. The index only depends on the road networks and the time-dependent arc weights. In the second phase, the *query* phase, shortest paths are computed utilizing this index.

An important ingredient for many such two-phase techniques [1, 4, 9, 11, 15] are *shortcuts*. Shortcuts are additional arcs introduced during preprocessing, which bypass parts of the input graph like in Figure 2a. The weight of a shortcut is set to the length of the shortest path between its endpoints. When computing shortest paths, only few shortcuts are explored instead of many arcs in the input graph. The path represented by a shortcut can be obtained lazily, for example by running local Dijkstra searches [8], or by iterating over possible middle nodes when shortcuts always represent exactly two other (shortcut) arcs [11, 15].

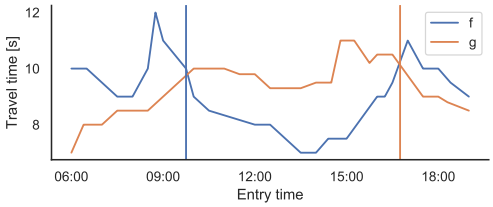
This approach has been extended to the time-dependent setting [2, 5]. Shortcuts are no longer associated with scalar weights. Instead *travel time functions* are used that map the entry time into a shortcut onto the travel time through it. Unfortunately, in practice these functions become very complex. Computing and storing them is expensive. Implementations represent these functions typically as piecewise linear functions. They are stored as a sequence of *breakpoints*. The number of breakpoints in a shortcut's function practically corresponds to the accumulated number of breakpoints of the functions of the arcs it bypasses. Contrary to the classic setting, shortcuts aggregate the complexity of paths they represent, rather than skipping over it. This leads to slow preprocessing and prohibitive memory consumption.

In this paper, we explore an alternative approach to shortcut travel time functions. Rather than explicitly storing them and obtaining paths lazily, we store paths and obtain travel times lazily. We expect that the shortest path between two nodes changes less frequently than the travel time. Intuitively, going via a highway may be slower due to congestion but is usually still the fastest option. Consider the functions f and g in Figure 2b. These functions are travel time functions of two paths between the same endpoints and have many breakpoints. If we want to store the travel time function of a shortcut between these endpoints, we need to store the function $h = \min(f, g)$. Storing h explicitly requires roughly a number of breakpoints proportional to the number of breakpoints in f and g. However, if we only store which path is the fastest, we only need to store the points in time when the faster path switches. We expect significantly fewer switches than breakpoints. In this paper, we employ this alternative approach to adapt an existing speed-up technique to the time-dependent setting, describe engineering techniques employed in our implementation, and present experimental results demonstrating that our approach significantly reduces memory consumption while achieving competitive query times.

Related Work. Routing in road networks has been extensively studied in the past decade. An overview over the field can be found in [1]. Here, we focus on speed-up techniques for time-dependent road networks. Several time-independent speed-up techniques have been generalized to the time-dependent setting. ALT [17], an approach using landmarks to obtain



(a) A shortcut arc (dashed, black) bypassing several nodes. In our implementation, shortcuts always skip over exactly one node and two arcs, which may in turn be shortcut arcs (dashed gray arcs).



(b) Travel time functions for two different paths between the same start and end node.

Figure 2 Shortcuts and their travel time functions.

good A* [19] potentials has been generalized to TD-ALT [24] and successively extended with node contraction to TD-CALT [9]. Even when combined with approximation, TD-CALT queries may take longer than 10 ms on continental sized graphs. SHARC [4], a combination of ARC-Flags [23] with shortcuts which allows unidirectional queries was also extended to the time-dependent scenario [7]. It can additionally be combined with ALT yielding L-SHARC [7]. SHARC can find short paths in less than a millisecond but does not always find a shortest path. MLD/CRP [8, 20] has been extended to TD-CRP [5] which can be used in a time-dependent setting. TD-CRP requires approximation to achieve reasonable memory consumption. It may find suboptimal paths. Another approach is FLAT [21] and its extension CFLAT [22]. CFLAT features sublinear query running time after subquadratic preprocessing and guarantees on the approximation error. Unfortunately, preprocessing takes long in practice and generates a prohibitively large index size.

There are several approaches based on CH [15]. Three were introduced in [2]: Time-dependent CH (TCH), inexact TCH, and Approximated TCH (ATCH). TCH achieve great query performance but at the cost of a huge index size on state-of-the-art continental sized instances. The index size can be reduced at the cost of exactness (inexact TCH) or query performance (ATCH). An open-source reimplementation of [2] named KaTCH[1] exists. A simple heuristic named Time-Dependent Sampling (TD-S) was introduced in [26]. It samples a fixed set of scalar values from the time-dependent functions. It has manageable index sizes and fast query times but does not always find shortest paths.

Contribution and Outline. In this work, we explore a variant of time-dependent CH, where shortcuts store paths instead of travel times. We introduce CATCHUp – Customizable Approximated Time-dependent Contraction Hierarchies trough Unpacking, a time-dependent generalization of Customizable Contraction Hierarchies [11] and a thoroughly engineered implementation. Preprocessing takes only a few minutes even on modern production-grade continental sized instances with tens of millions of nodes. We also present algorithms which allow us to employ approximation to accelerate preprocessing without sacrificing exactness for the queries. Our implementation achieves fast and exact queries with performance competitive to TCH queries while requiring up to 30 times less memory.

The rest of this paper is organized as follows. In Section 2, we introduce some notation and existing algorithms we build on. We describe our shortcut data structure, and the preprocessing and query algorithms in Section 3. In Section 4, we discuss our experimental evaluation. We conclude in Section 5.

2 Preliminaries

We model road networks as directed graphs $G = (V, A)$. A node $v \in V$ represents an intersection and an arc $a = uv \in A$ with $u, v \in V$ represents a road segment. A path is a sequence of nodes $[v_1, ..., v_k]$ such that $v_i v_{i+1} \in A$. Every arc a has a *travel time function* $f_a : \mathbb{R} \to \mathbb{R}^{>0}$ mapping departure time to travel time. We assume that travel time functions fulfill the *First-In-First-Out* (FIFO) property, that is for any $\sigma, \tau \in \mathbb{R}$ with $\sigma \leq \tau$, $\sigma + f(\sigma) \leq \tau + f(\tau)$ has to hold. Informally, this means that it is not possible to arrive earlier by starting later. If there are arcs that do not fulfill the FIFO property, the shortest path problem becomes $\mathcal{NP}$-hard [25]. In our implementation, travel time functions are periodic piecewise linear functions represented by a sequence of *breakpoints*. We denote the number of breakpoints by $|f|$.

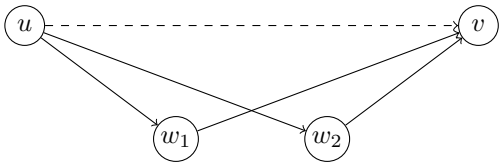
Given two travel time functions f and g for arcs uv and vw, we are often interested in the travel time function of traversing first uv and then vw, that is $(g \circ f)(\tau) = f(\tau) + g(f(\tau) + \tau)$. Computing this function is called *linking*. When combining two travel time functions f and g for different paths $[u, ..., v]$ with the same start and end, we often want to know the travel time of the best path between u und v, that is $\min(f, g)$. Computing this function is called *merging*. Both linking and merging can be implemented with coordinated linear sweeps over the breakpoints of both functions.

Given a departure time τ and nodes s and t, an earliest-arrival query asks for earliest point in time one can arrive at t when starting from s at τ. Such a query can be handled by Dijkstra's algorithm [12] with little modifications [14]. The algorithm keeps track of the earliest known arrival time ea_v at each node v. These labels are initialized with τ for s and ∞ for all other nodes. A priority queue is initialized with (s, τ). In each step, the node u with minimal earliest arrival ea_u is popped from the queue and outgoing arcs are *relaxed*. To relax an arc uv, the algorithm checks if $\text{ea}_u + f_{uv}(\text{ea}_u)$ improves ea_v and updates label and queue position of v accordingly. Once t is extracted from the queue, the earliest arrival at t is known. To retrieve the shortest path, one can use *parent pointers* which for each node store the previous node on the shortest path from s. We refer to this algorithm as *TD-Dijkstra*.

The *A* algorithm* [19] is an extension to Dijkstra's algorithm. It reduces the number of explored nodes by guiding the search towards t. Each node u has a potential $\rho_t(u)$ which is an estimate of the distance to t. The priority queue is then ordered by $\text{ea}_u + \rho_t(u)$.

Contraction Hierarchies (CH) [15] is a speed-up technique exploiting the inherent hierarchy in road networks. Nodes are heuristically ranked by their importance. Nodes with higher rank should cover more shortest paths. During preprocessing, all nodes are *contracted* in order of ascending importance. Contracting a node v means removing it from the network but preserving all shortest distances among the remaining higher ranked nodes. This is achieved by inserting *shortcut arcs* between the neighbors of v if a shortest path goes through v. A shortcut is only necessary if it represents the only shortest path between its endpoints. This can be checked with a local Dijkstra search (called *witness search*) between the endpoints. The result of the preprocessing is called an *augmented graph*. Queries can be answered by performing a bidirectional Dijkstra search on the augmented graph where only arcs to higher ranked nodes are relaxed. The construction guarantees that this algorithm will find a shortest up-down-path which has the same length as shortest paths in the original graph.

Customizable Contraction Hierarchies (CCH) [11] is a CH extension, splitting CH preprocessing into two steps where only the second one uses arc weights. In the first step, a separator decomposition and an associated nested dissection order [3, 16] are computed. This order determines the node ranks. Nodes in the top-level separators have the highest ranks,



00:00	uw_1	w_1v
07:32	uw_2	w_2v
15:42	uw_1	w_1v

Figure 3 A shortcut with associated time-dependent unpacking information.

followed by the nodes of each cell, recursively ordered by the same method. Then, nodes are contracted without running witness searches, so all potential shortcuts are added. In the second step (called *customization*), shortcut arc weights are computed. All arcs are processed in ascending order of their lower ranked endpoint. To process an arc uv, all *lower triangles* $[u, w, v]$, where w has lower rank than u and v are enumerated, checking if the path $[u, w, v]$ can improve the weight of uv. The CH query algorithm can be reused without modifications. Another query algorithm is described in [11] based on the *elimination tree* which does not need priority queues. The parent of each node in the elimination tree is its lowest-ranked upward neighbor in the augmented undirected graph. A nodes ancestors in the elimination tree are exactly the set of nodes that are reachable in a CH search from this node [3]. Thus, instead of exploring the search space through Dijkstra searches, the elimination tree query traverses the same nodes by traversing the path to the root in the elimination tree.

3 Algorithms

In this section, we describe our algorithms, data structures and implementation. Our approach builds upon CCH. However, instead of storing travel time functions at shortcuts, we store unpacking information to efficiently reconstruct the represented paths in the original graph. We start by describing our representation of this unpacking information. Then, we continue by presenting our adapted CCH algorithms for the time-dependent setting.

3.1 Shortcut Data Structure

The key element of our approach is the information we store with each shortcut. We store time-dependent unpacking information, which allows us to efficiently reconstruct the original path represented by a shortcut for a point in time. In (C)CH, shortcuts uv are inserted when a node w is contracted and the arcs uw and wv exist. Thus, a shortcut uv always skips over a triangle $[u, w, v]$. However, there may be several triangles and which one is the fastest may change over time. This is the information our shortcut data structure has to capture.

For each shortcut arc uv, we store a set of time-dependent *expansions* X_{uv} for unpacking. See Figure 3 for an example. For an expansion $x \in X_{uv}$, we denote the time during which x represents the shortest path as the *validity interval* Π_x of x and the lower node of the triangle $[u, w_x, v]$ as w_x. In our implementation, the expansion information is represented as an array of triples (π, uw_x, w_xv). π is the beginning of the validity interval and uw and wv are arc ids. This information can be stored in 16 bytes for each entry – 8 bytes for the timestamp and 4 bytes for each arc id. Beside the unpacking information, we also store a scalar lower bound $\underline{b}_{uv}$ and an upper bound $\overline{b}_{uv}$ to prune unnecessary operations.

To obtain the shortest path represented by a shortcut uv for a time τ, we first need to determine the relevant expansion x such that $\tau \in \Pi_x$. This can be done performing a binary search in X_{uv}. The shortcut can then be expanded to $[u, w_x, v]$. However, uw_x or w_xv may also be shortcuts. Thus, we recursively apply the operation to (u, w_x) at τ and to (w_x, v) at

$\tau + f_{(u,w_x)}(\tau)$. Evaluating the travel time of the first arc is always necessary to determine the time for unpacking for the second arc. The travel time of a shortcut can be obtained by unpacking the path and then evaluating the travel times of the original arcs successively.

3.2 Preprocessing

The first step of CCH preprocessing is performed only on the topology of the graph. Since no travel time functions are involved, we can adapt the algorithms of [11] without modification. We use InertialFlowCutter [18] to obtain the nested dissection order. To generate the shortcut augmented graph, we implement an improved contraction algorithm first presented in [27]. When contracting a node, we insert all upward neighbors of the current node only into the neighborhood of its lowest ranked upward neighbor. This algorithm can be implemented to run in linear time in the size of the output graph.

The goal of the second step of preprocessing for classical CCH is to compute the shortcut weights. So for our approach, we have to compute travel time bounds and unpacking information for all shortcuts[2]. Recall that a shortcut uv always bypasses one or many lower triangles $[u, w_i, v]$ for different nodes w_i, where w_i has lower rank than u and v. For the bounds, we want to find the minimum and maximum travel time of the fastest travel time function between u and v over any w_i. For the unpacking information, we need to determine for each point in time which triangle is the fastest. Assuming we know the final travel time functions of all uw_i and w_iv, we can obtain the travel time function for each triangle by linking f_{uw_i} and f_{w_iv}. By merging these linked functions, we can compute both the final bounds and the times during which each triangle is the fastest. This leads to the following algorithmic schema: Iterate over all arcs in a bottom-up fashion. For each arc enumerate lower triangles. Link and merge their functions to compute the function, bounds, and unpacking information of the current arc. Keep the current arc's travel time function in memory until it is no longer needed.

We implement this schema as follows: We process all arcs uv ordered ascending by their lower ranked endpoint. Since the middle node w of a lower triangle $[u, w, v]$ has always lower rank than u and v, the arcs uw and wv will have been processed already. To process an arc uv we enumerate lower triangles $[u, w, v]$. For each triangle, we obtain the function of $[u, w, v]$ by linking the functions of the arcs uw and wv, and merge it with the current function of the shortcut uv. Once all arcs uv have been processed where u is the lower ranked endpoint, we drop the travel time functions of all arcs wu where u is the higher ranked endpoint.

When enumerating triangles, we order them ascending by $\underline{b}_{uw} + \underline{b}_{wv}$. This way, we process triangles, which are likely faster first. This gives us preliminary bounds on the travel time of uv. Before linking the functions of another triangle f_{uw} and f_{wv}, we check if $\overline{b}_{uv} \leq \underline{b}_{uw} + \underline{b}_{wv}$. If so, the linked path would be dominated by the shortcut, and we can skip linking and merging completely. If not, we link f_{uw} and f_{wv} and obtain $f_{[u,w,v]}$. We still can skip merging if one function is strictly smaller than the other, that is either $\overline{b}_{uv} \leq \min(f_{[u,w,v]})$ or $\max(f_{[u,w,v]}) \leq \underline{b}_{uv}$. Even if the bounds overlap, one function might still dominate the other. To check for this case, we simultaneously sweep over the breakpoints of both functions, determining the value of the respectively other function by linear interpolation. Only when this check fails, we perform the merge operation.

[2] Note that actually all arcs in the augmented graph have to be treated as shortcuts. We represent arcs from the original graph as a special expansion element pointing to the original arc.

Before the time-dependent customization, we first use the basic and perfect customization algorithms from [11] to compute preliminary scalar upper and lower bounds for all shortcuts. With these bounds, we can skip additional linking and merging operations. Also, we can remove some shortcuts completely, when a shorter path through higher ranked nodes exists.

Parallelization. We employ both loop based and task based parallelism. The original CCH publication [11] suggests processing shortcuts with their lower ranked endpoint on the same *level* in parallel. The level of a node is the level of its highest ranked downward neighbor increased by one, or zero if the node does not have downward neighbors. We use this approach to process arcs in the top-level separators.

In [6], a task based parallelism approach utilizing the separator decomposition of the graph is described. Each task is responsible for a subgraph G'. Removing the top-level separator in G' decomposes the subgraph into two or more disconnected components. For each component, a new task is spawned to process the shortcuts the component. After all child tasks are completed, the shortcuts in the separator are processed utilizing the loop based parallelization schema. If the size of subgraph G' is below a certain threshold, the task processes the shortcuts in G' sequentially without spawning subtasks.

Approximation. As we process increasingly higher ranked shortcuts, the associated travel time functions become more and more complex. This leads to two problems. First, linking and merging becomes very time-consuming as running times scale with the complexity of the input functions. Second, storing these functions for later reuse – even though it is only temporary – requires a lot of memory. We employ approximation to mitigate these issues. However, for exact queries, we need exact shortcut unpacking information. We achieve this by lazily reconstructing parts of exact travel time functions during merging.

When approximating, we do not store one approximated function but two – a lower bound function and an upper bound function with maximum error ϵ where ϵ is a configurable parameter. These approximations replace the exact function stored for later merge operations and will also be dropped when no longer needed. To obtain the bound functions, we first compute an approximation using the algorithm of Douglas and Peucker [13]. Then, we add or subtract ϵ to the value of each breakpoint to obtain an upper or lower bound, respectively. This yields valid upper or lower bounds, but they may not be as tight as possible. Therefore, we iterate over all approximated points and move each point back towards the original function. Both adjacent segments in the approximated functions have a minimum absolute error to the original function. We move the breakpoint by the smaller of the two errors. This yields sufficiently good bounds.

When linking approximated functions, we can link both lower and both upper bound functions. Linking two lower bounds yields a valid lower bound function of the linked exact functions because of the FIFO property. The same argument holds for upper bounds.

Merging approximated shortcuts is slightly more involved. Our goal is to determine the exact unpacking information for each shortcut. We use the approximated bounds to narrow down the time ranges where intersections are possible. To identify these parts, we merge the first function's lower bound with the second function's upper bound and vice versa. Where the bounds overlap, an intersection might occur. We then obtain the exact functions in the overlapping parts through unpacking and perform the exact merging. To obtain approximated upper and lower bounds of the merged function, we merge both lower bounds and both upper bounds.

We approximate whenever a function has more than β breakpoints. This includes already approximated functions. Both β and the maximum error ϵ are tuning parameters which influence the performance (but not the correctness).

3.3 Queries

Our query algorithm is based on the CCH elimination tree query algorithm [11]. There are two challenges. First, we can not perform a backwards search, as we do not know the arrival time at the target node. Second, to evaluate the travel time of a shortcut, we need to obtain the path in the original graph. Since unpacking shortcuts is expensive, we try to keep the number of these operations as small as possible.

Our query algorithm works in two phases. In the first phase, we perform an elimination tree interval query using the lower and upper travel time bounds of the arcs. The backward search is possible since these bounds are not time-dependent. This yields a shortest path corridor. This corridor is made up of both original and shortcut arcs and always contains the actual shortest path. In the second phase, we perform a unidirectional Dijkstra search on this corridor, which lazily unpacks shortcuts.

Elimination Tree Interval Query. The elimination tree interval query is a bidirectional search starting from both the source node s and the target node t. Node labels contain an upper $\overline{t}_v$ and a lower bound $\underline{t}_v$ on the travel time to/from the search origin and a parent pointer to the previous node. The bounds $\overline{t}_s$, $\overline{t}_t$, $\underline{t}_s$, $\underline{t}_t$ are all initialized to zero in their respective direction, all other bounds to infinity. We also track tentative travel time bounds for the total travel time from s to t. For both directions, the path from the start node to the root of the elimination tree is traversed. For each node u, all arcs uv to higher ranked neighbors are relaxed, that is checking if $\overline{t}_u + \overline{b}_{uv} < \overline{t}_v$ or $\underline{t}_u + \underline{b}_{uv} < \underline{t}_v$ and improving the bounds of v if possible. When the new travel time bounds from an arc relaxation overlap with the current bounds, more than one label has to be stored. After both directions are finished, we have several meeting nodes in the intersection of the search spaces. Where the sum of the forward and backward distance bounds of a node overlaps with the total travel time bounds, the parent pointers are traversed to the search origin and all arcs on the paths are marked as part of the shortest path corridor.

Lazy Corridor Dijkstra. In the second query phase, we perform Dijkstra's algorithm on the corridor obtained in the first phase. At the beginning, the corridor contains many shortcuts, which need to be unpacked, to determine their travel time. We perform unpacking lazily. The algorithm starts with the same initialization as a regular TD-Dijkstra. All earliest arrivals are set to infinity, except for the start node which is set to the departure time. The start node is inserted into the queue. Then, nodes are popped from the queue until it is empty or the target node is reached. For each node, all outgoing arcs within the shortest path corridor are relaxed. When an arc is from the original graph, the travel time can be evaluated directly. Shortcut arcs, however, need to be unpacked. The unpacking algorithm defers the work as much as possible: Only the first arc of the triangle of each shortcut will be recursively unpacked until an original arc is reached, the second arc will be added to the corridor. See Figure 4 for an example. This way, we unpack only the necessary parts and avoid relaxing arcs multiple times when shortcuts share the same paths.

Corridor A*. The query can be accelerated further, by using the lower bounds obtained during the elimination tree interval query as potentials for an A*-search. For nodes in the CH search space of t, the lower bounds from the backward search can be used. For nodes in the

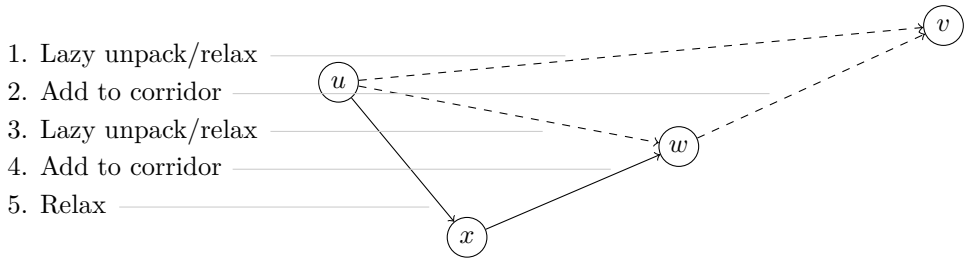


Figure 4 Lazy relaxation of shortcut uv. Since uv is a shortcut, it needs to be unpacked. This causes wv to be added to the corridor and uw to be relaxed. Relaxing uw causes xw to be added to the corridor and ux to be relaxed. In this example, ux is an original arc and the recursion stops. xw will be relaxed (or unpacked) only once x is popped from the queue.

Table 1 Characteristics of test instances used. The third column contains the percentage of arcs with a non-constant travel time. The fourth column the average number of breakpoints among those.

	Nodes [$\cdot 10^3$]	Arcs [$\cdot 10^3$]	TD arcs [%]	Avg. $\lvert f \rvert$ per TD arc	Size [GB]
Ger06	4 688	10 796	7	17.6	0.2
Ger17	7 248	15 752	29	29.6	0.7
Eur17	25 758	55 504	27	27.5	2.3

CH search space of s, we start at the meeting nodes from the corridor search and propagate the bounds backwards down along the parent pointers. This yields potentials for all nodes in the initial corridor. However, we also need potentials for nodes added to the corridor through unpacking. These potentials are computed during the shortcut unpacking. When unpacking a shortcut uv into the arcs uw and wv, then $\rho(w)$ will be set to $\min(\rho(w), \rho(v) + \underline{b}_{wv})$.

4 Experiments

We implement our algorithms in Rust[3] and compile them with rustc 1.36.0-nightly (372be4f36 2019-05-14) in the release profile with the target-cpu=native option[4]. To compile competing implementations written in C++, we use GCC 7.4. All experiments were conducted on a dual 8-core Intel Xeon Gold 6144 CPU with a base frequency of 3.5 GHz with 192 GiB of DDR4 RAM (clocked at 2.6 GHz). Preprocessing utilized all 16 cores (without hyperthreading). The running times are averages over five runs. We generate 100 000 source, target, departure time triples chosen uniformly at random for each graph and report average query times. Queries were performed sequentially.

We use two production-grade instances for Germany and Europe and with traffic predictions from 2017. To compare our algorithms to related work, we also include an old instance of Germany from 2006. The instances were provided by PTV[5] and include traffic predictions as piecewise linear functions. We use traffic predictions for a car on a typical midweek day. Table 1 lists key characteristics of each graph.

Table 2 reports numbers on our preprocessing. On Ger06, the first preprocessing step takes longer than the second. However, for the newer instances with more time-dependent arcs and more breakpoints per function this changes and the second step becomes more

[3] The code is available at `https://github.com/kit-algo/catchup`.
[4] We disabled AVX512 instructions, as they caused misoptimizations.

Table 2 Preprocessing statistics. Running times are for parallel execution on 16 cores.

	CCH arcs	Expansions per shortcut			Index	Step 1	Step 2
	$[\cdot 10^3]$	Avg.	Max.	$= 1$ [%]	[GB]	[s]	[s]
Ger06	22 521	1.075	44	98.4	1.06	31	18
Ger17	31 517	1.090	107	98.5	1.50	35	92
Eur17	115 023	1.100	115	98.4	5.48	196	479

Table 3 Mean query performance and search space sizes with and without our A* query extension.

	Elimination tree interval query		Lazy corridor Dijkstra					
	Nodes in search space	Relaxed shortcuts	Queue pops		Relaxed arcs		Time [ms]	
			no A*	A*	no A*	A*	no A*	A*
Ger06	735	48 574	3 328	831	3 845	995	1.62	0.54
Ger17	770	58 903	18 499	3 099	19 986	3 502	8.70	1.59
Eur17	1 302	162 295	39 717	6 876	43 654	7 928	19.55	3.76

expensive. Despite that, the size of the final index corresponds to the number of shortcut arcs and does not grow as much for the newer instances. The augmented graphs have about twice as many arcs as the original graphs. On average, only 1.1 expansions per shortcut need to be stored for all graphs. About 98% of all shortcuts have only one expansion. The maximum number of expansions per shortcuts is only 115 even for our largest graph. This is two orders of magnitude less than the number of breakpoints in the travel time function of that shortcut. This clearly shows the superiority of shortcuts with expansion information over explicitly storing travel time functions.

Table 3 depicts the performance of our query algorithms in terms of running time and search space sizes. Without the A* optimization, queries take up to 5.5 times longer and the search space of the corridor Dijkstra grows roughly by the same factor. Both query variants relax only little more arcs than they settle nodes. This is caused by the shortcut unpacking. Large parts of the unpacked search space are just long paths of nodes with degree two.

Table 4 provides an overview over different techniques, their preprocessing and query times, space overhead of the index data structures and average query errors where approximation is used. Where possible, we obtained the code of competing algorithms[6] and evaluated them with same methodology, instances and queries as our algorithms. For other competitors, we report available numbers from the respective publications.

In our comparison, KaTCH, heu SHARC, CFLAT and CATCHUp all achieve query times around 0.6 ms on Ger06. The original research implementation TCH reports slightly slower times than KaTCH. This may be because experiments were run on an older machine, but also because according to the KaTCH documentation, the newer query is somewhat more efficient. TCH pays for this speed with 4.7 GB index data. Reducing the KaTCH memory consumption while keeping exactness (ATCH) brings query times up to 1.24 ms. ATCH also feature a configuration where they only keep upper and lower bounds for each profile (ATCH ∞). This configuration uses even less memory than CATCHUp because the optimized order results in fewer shortcuts. Giving up on exactness allows keeping the query times at 0.7 ms (inex. TCH) but introduces some noticeable errors.

[6] KaTCH: `https://github.com/GVeitBatz/KaTCH`
TD-S: `https://github.com/ben-strasser/td_p`

Table 4 Comparison with related work. We list unscaled numbers as reported in the respective publications for algorithms we could not run ourselves. Values not reported are indicated as n/r. OOM means that the program crashed while trying to allocate more memory than available. A similar overview with scaled numbers can be found in [10].

		Preprocessing		Index	Query		
		Time	Cores	size	Time	Rel. error

	CATCHUp	**675**	16	**5.48**	4.50	exact	

While achieving competitive query times for acceptable memory consumption, heu SHARC suffers from huge preprocessing times of several hours. The original publication does not report average query errors, only a maximum error of 0.61%. TDCALT has the smallest memory consumption of all approaches but does not achieve competitive query times, even when approximating. FLAT and CFLAT both suffer from extreme preprocessing times and memory consumption despite having no exact queries. CATCHUp offers competitive query times for exact results while keeping memory consumption reasonable. TD-CRP offers even lower memory consumption. But this is only possible through the use of approximation. TD-CRP queries depict a noticeable error and perform somewhat worse than KaTCH or CATCHUp queries. TD-S+9 depicts the smallest average error of all non-exact approaches[7].

[7] [22] report another CFLAT configuration with even smaller errors but significantly slower queries.

On Ger17, KaTCH query times increase by a factor of about two. Memory usage on the other hand, grows by almost an order of magnitude. For TD-S, both the growth in space consumption and query times corresponds roughly to the growth of the graph size, but not the increased number of breakpoints. For the index data of CATCHUp, this growth factor also roughly applies. Query times get about 2.7 times slower.

On Eur17, the memory consumption of KaTCH becomes prohibitive. While KaTCH is still able to finish preprocessing and output 150 GB of data, queries crash since the 192 GB RAM of our machine are not enough. Using ATCH or inexact TCH, the memory consumption could likely be reduced sufficiently to perform queries. But this would either introduce errors or slow down queries significantly. On the other hand, with only 5.5 GB of index data, CATCHUp is still able to perform exact queries in less than 5 ms on average. This is fast enough to enable interactive applications. Total preprocessing for CATCHUp takes less than a quarter of the time KaTCH needs. TD-S+9 is also able to handle this instance with similar query times but only with a small average error.

5 Conclusion and future work

We introduce CATCHUp, a speed-up technique for routing in time-dependent road networks. It features a small index size and fast, exact queries. To the best of our knowledge, our approach is the first to simultaneously achieve all three objectives. We perform an experimental study to evaluate the performance of CATCHUp and compare it to competing approaches. Our approach achieves the fastest preprocessing, competitive query running times and up to 30 times smaller indexes than other approaches.

Revisiting ATCH, TCH, and TD-CRP with the insights gained in this work could be fruitful. Combining ATCH with our A* query extension could reduce ATCH query running times. CATCHUp makes use of travel time independent node orders. Combining CATCHUp with TCH-like node orders could result in even smaller index sizes and query running times. We further expect that some of our optimizations to the preprocessing can also be applied in a TD-CRP context. Another possible direction for future research would be to support partial updates to further accelerate the second step of preprocessing. This could enable the integration of live traffic information.

Improved Prophet Inequalities for Combinatorial Welfare Maximization with (Approximately) Subadditive Agents

Hanrui Zhang
Duke University, Durham, NC, USA
hrzhang@cs.duke.edu

Abstract

We give a framework for designing prophet inequalities for combinatorial welfare maximization. Instantiated with different parameters, our framework implies (1) an $O(\log m/\log\log m)$-competitive prophet inequality for subadditive agents, improving over the $O(\log m)$ upper bound via item pricing, (2) an $O(D\log m/\log\log m)$-competitive prophet inequality for D-approximately subadditive agents, where $D\in\{1,\dots,m-1\}$ measures the maximum number of items that complement each other, and (3) as a byproduct, an $O(1)$-competitive prophet inequality for submodular or fractionally subadditive (a.k.a. XOS) agents, matching the optimal ratio asymptotically. Our framework is computationally efficient given sample access to the prior and demand queries.

1 Introduction

Prophet inequalities are a classical topic in stopping theory. The problem is neat and natural: an agent plays a game, where there are n boxes, each containing a reward (e.g., some amount of cash). The agent cannot see through the boxes to know precisely the amounts of cash inside each box. However, she has the prior knowledge that the amounts are drawn independently for each box, and fortunately, knows the distributions according to which the amounts are drawn. Now nature opens the boxes one by one. Upon seeing the inside of each box, the agent gets to make a choice: she can either (1) take the cash in the box and leave, or (2) let the current box expire (which means she gains nothing from the current box and it disappears), in which case the game proceeds with the remaining boxes. What is the maximum expected amount of cash the agent can get, and how to achieve that?

Quite surprisingly, the agent can guarantee half the amount of reward that a *prophet* is able to get, who sees through the boxes and therefore always picks the box with the largest reward [21, 22]. Moreover, the agent can achieve this by executing a simple threshold-based protocol: accept the first box containing a reward exceeding a pre-calculated amount. The existence of such 2-approximate protocols lead to the name "prophet inequalities."

Prophet inequalities were recently rediscovered in computer science and economics. Since then, they have been drawing increasing interest in both fields. Hajiaghayi et al. [18] observe the connection between prophet inequalities and a pricing problem in auctions. They formulate the problem in the following equivalent way: a seller has an indivisible item to

sell. n buyers arrive one by one, each of which has a value for the item, drawn independently from a distribution known to the seller. When a buyer arrives, the seller learns the value of the buyer (or otherwise negotiates with the buyer), and decides whether to sell the item to the buyer. The buyer then leaves forever (with the item if sold to the buyer). The goal of the seller is to maximize the utility of the buyer who receives the item, or just the total utility (i.e., the *welfare*) of all buyers, since all other buyers have utility 0. Here, each buyer corresponds to a box in the classical formulation, and the value of the buyer represents the reward in the box. A threshold-based protocol can then be translated directly into a take-it-or-leave-it offer – a buyer receives the item (i.e., she *buys*) iff her value exceeds the pre-calculated price, and so buying is preferred to not buying.

Given this connection, various forms of auctions have been considered in the prophet inequality context (see, e.g., the recent survey by Lucier [23]). Examples include (1) the case where the seller has k identical items to sell and each buyer wants only one of them (or equivalently, up to k boxes can be accepted) [18], (2) the setting with a knapsack style constraint, requiring that the total "weight" of sellers who get an item cannot exceed 1 [17], and (3) the setting where m possibly distinct items are available for sale, and each agent has a *combinatorial* (as opposed to additive) valuation function assigning every subset of items a value [16]. The third setting, known as *combinatorial welfare maximization*, appears particularly interesting and general, as it nicely captures the potentially complex interaction between items. For instance, a Coke and a Pepsi substitute each other, in the sense that having a Coke or a Pepsi probably gives one roughly the same utility (say 1), whereas having both likely gives *strictly less* utility than the sum, 2, of the former values, since one can only drink so much at a time.

In this paper, we consider combinatorial welfare maximization in the prophet inequality context. We begin our investigation with *subadditive* (also known as *complement-free*) agents, who regard items only as substitutes but not complements to each other. From there, we generalize our results to accommodate valuations that are *approximately subadditive*, which have remained largely unexplored even in offline environments.

1.1 Our Contributions

1.1.1 Current Landscape of the Problem

Feldman et al. [16] were the first to explicitly study combinatorial welfare maximization with rich valuations in the prophet inequality context. They give an existential 2-approximate protocol and a computationally efficient $(2e)/(e-1)$-approximate protocol when agents are submodular or fractionally subadditive (which are strict subclasses of subadditive valuations). Dütting et al. [10] propose a powerful framework, unifying a number of prophet inequalities, and yielding a computationally efficient 2-approximate protocol for the same class of valuations, which is optimal given a lower bound inherited from the single-item setting. These bounds, through a standard approximation result, extend directly to subadditive agents with a loss of factor $O(\log m)$, where m is the number of items. The best known lower bound for subadditive agents, however, is again 2, leaving a huge gap in between. This gap, as acknowledged by Feldman et al. [16] and Dütting et al. [10], raises a curious question:

Can we do better than $O(\log m)$ for subadditive agents?

1.1.2 The Logarithmic Barrier for Subadditive Agents

The above question did not have an immediate answer. For subadditive agents, all existing results essentially build on the same argument: one first computes prices that $O(\log m)$-approximately "support" the optimal allocation. Such prices have the property, that if one posts the prices on the items, and let agents, one by one in some arbitrary order, purchase their utility-maximizing bundles of items, then the resulting allocation $O(\log m)$-approximately maximizes the expected welfare. With these prices, one can implement an $O(\log m)$-approximate threshold-based protocol, by running a posted-price auction with the supporting prices for each arriving agent, and allocating the set of items purchased to the agent. The bottleneck of this approach is that the $O(\log m)$ factor of approximate supporting prices is tight: there are subadditive valuations for which no $o(\log m)$-approximate supporting prices exist [2]. Therefore, any protocol relying on supporting prices (including all currently existing results) cannot possibly give better ratios than $O(\log m)$. In fact, given the tightness of this $O(\log m)$ factor, one may even suspect that the right ratio for subadditive agents is precisely $\Theta(\log m)$. We show that this is *not* the case.

1.1.3 A Sublogarithmic Prophet Inequality for Subadditive Agents

We give a framework for designing prophet inequalities for combinatorial welfare maximization, which implies an $O(\log m/\log\log m)$-approximate prophet inequality for subadditive agents, breaking the foregoing logarithmic barrier. Our framework is computationally efficient given: (1) sample access to the prior distributions, and (2) demand queries to the sample valuations. Unlike previous results, our protocol is not based on pricing items via approximately supporting prices and running sequential auctions – which enables the protocol to bypass the obstacle discussed above, at the cost of losing incentive compatibility.[1] As a byproduct, we show that our framework, instantiated with different parameters, also gives an $O(1)$-approximately optimal prophet inequality for submodular or fractionally subadditive agents. Our approach provides an alternative view of combinatorial welfare maximization in the prophet inequality context, which may be of independent interest.

Very recently, in independent work, Dütting et al. [11] give an $O(\log\log m)$-approximate prophet inequality for combinatorial welfare maximization with subadditive agents using radically different techniques from ours. Their result is a major breakthrough in the research of prophet inequalities for combinatorial welfare maximization. In particular, the work of Dütting et al. significantly improves over our main result in that (1) they "truely" improve the approximation ratio from $O(\log m)$ all the way to $O(\log\log m)$, and (2) their approach is based on pricing individual items, which shows that it is possible to beat $O(\log m)$ using item-pricing schemes, which are incentive-compatible.

1.1.4 Generalizing to Approximate Subadditivity

Utilizing the same framework, we give a family of parameters, which imply an $O(D\log m/\log\log m)$-approximate prophet inequality when agents have valuations with *superadditive width* at most $D > 0$ (see Definition 1). As a corollary, we obtain an $O(D\log m/\log\log m)$-approximation algorithm for the offline combinatorial welfare maximization problem with the same class of valuations. Here, D roughly measures the maximum

[1] In some scenarios, incentive incompatibility is not an issue – one such example is a government agency allocating resources among projects arriving online.

number of items that may complement each other, and generalizes the notion of subadditivity. In particular, valuations with superadditive width 0 are precisely valuations that are subadditive. The implication of the above bound is twofold: concretely, to our knowledge, this is the first nontrivial prophet inequality for valuations that are *approximately* subadditive; conceptually, the existence of parameters leading to this bound demonstrates the capacity of the parametrized framework we propose. We remark that while Feldman et al. [16] and Dütting et al. [10] present results of a similar flavor, their bounds are based on the *Maximum-over-Positive-Hypergraph (MPH)* hierarchy [15], which does not directly model approximate subadditivity, and thus is incompatible with the goal of this paper.

1.2 Technical Overview

We present a parametrized protocol, which works by rounding online a standard LP relaxation of the welfare maximization problem. The protocol is inspired by the two-stage offline rounding procedure by Dobzinski et al. [9], which works roughly as follows:

1. Compute a distribution over sets of items for each agent. These distributions together satisfy: (1) each item in expectation goes to at most 1 agent, and (2) the total expected value enjoyed by all agents is maximized.
2. For each agent i, draw i's tentative set of items according to i's distribution. Note that after this step, an item can appear in multiple agents' tentative sets.
3. Break ties for items, by independently allocating each item j to one of the agents whose tentative sets contain j, uniformly at random.

Dobzinski et al. [9] show that the above procedure outputs an $O(\log m)$-approximation for the combinatorial welfare maximization problem when agents are subadditive, and Feige [14] further proves a tighter bound of $O(\log m/\log\log m)$.

Intuitively, we wish to carry out Dobzinski's rounding procedure online. One main difficulty, however, is to deal with incomplete information, since when handling one agent, the protocol does not know the actual valuation of any agent yet to arrive. As a result, it is impossible to round online the solution to the LP with respect to all agents' actual valuations. To this end, we create a partially fictitious LP for each agent, by chaining this agent's actual valuation (which becomes available to the protocol upon the agent's arrival) with independently drawn dummy valuations for all other agents. By doing this, each agent is intuitively playing against the average case configuration of all other agents. Moreover, in each agent's fictitious LP, her share of the fractional allocation gives her precisely the expected value she would get in the actual optimal fractional allocation. So if we can round the fictitious LP solutions with mild loss, the resulting welfare will in fact be approximately optimal.

To achieve this, we need to deal with another difficulty, i.e., instead of breaking ties for each item simultaneously with all the tentative sets available, we now have to irrevocably decide which items are being allocated to each agent immediately upon his arrival, before seeing the valuations of all agents yet to arrive. And still, we need to make sure no item is allocated twice. This rules out the possibility of the independent uniform tie-breaking performed in Step 3 of Dobzinski et al.'s rounding procedure, which is crucial in the proofs for the approximation ratios in both papers.[2] To overcome this issue, we break ties in a correlated way, which pairs gracefully with (approximate) subadditivity. Roughly speaking,

[2] With some additional tricks one can simulate online the uniformity and independence conditions required in those papers, but even then the online version of Feige's argument works only for exactly subadditive valuations, and fails for approximately subadditive ones.

we first draw a (not necessarily uniformly) random integer r from $\{1, \ldots, n\}$, where n is the number of agents. We then partition each agent's tentative set into n subsets according to the number of times each item has appeared in some agent's tentative set so far, and give the agent all items that have appeared exactly r times. The intuition is that, if the valuations are subadditive, we then know that the sum of the values of these subsets is at least the value of the tentative set itself, which gives us a way to relate the expected value of the allocated subset to the value of the tentative set. Also, no item is possibly allocated twice, since each item can appear the r-th time only once throughout the procedure. Given the above, by choosing the distribution of r and other parameters in different ways, the parametrized protocol yields the desired bounds for subadditive, approximately subadditive, and fractionally subadditive valuations respectively.

1.3 Additional Related Work

Kleinberg and Weinberg [20] study the setting where possible combinations of boxes that can be accepted satisfy a matroid constraint. Dütting and Kleinberg [12] consider polymatroids, generalizing the above setting. Rubinstein and Singla [25] further consider subadditive reward functions. Their setting, while also being combinatorial, is different from combinatorial welfare maximization considered in this paper.

Another line of research consider revenue maximization in the prophet inequality context. We list a few results here. Blumrosen and Holenstein [3] give a constant factor protocol in the single-item setting. When agents are unit-demand – that is, they only want a single item – Chawla et al. [5] give constant factor posted-price policies. Cai and Zhao [4] study truthful policies for combinatorial auctions with subadditive agents. Their goal, however, is to maximize the revenue of the protocol, instead of the welfare as we consider.

Prior to Feldman et al., Chawla et al. [6] and Alaei [1] consider welfare maximization with unit-demand agents. Cohen-Addad et al. [8] further show that dynamic pricing achieves optimal welfare for unit-demand agents. Ehsani et al. [13] show that the ratio improves to $e/(e-1)$ for combinatorial welfare maximization with submodular or fractionally subadditive agents, if agents arrive in a random order.

2 Preliminaries

Throughout the paper, we use n to denote the number of agents, and m the number of items. In general, we use i as the index of an agent, and j as the index of an item.

2.1 Combinatorial Valuations

A combinatorial valuation function $f : 2^{[m]} \to \mathbb{R}^+$ maps any subset S of the ground set $[m] = \{1, 2, \ldots m\}$ to a nonnegative real number $f(S)$. In this paper, we consider valuation functions that are *monotone*: f is monotone iff for any $S \subseteq T \subseteq [m]$, $f(S) \leq f(T)$. The following subclasses of valuation functions are considered or helpful for our purposes:

- *subadditive*: f is subadditive iff for any $S, T \subseteq [m]$, $f(S) + f(T) \geq f(S \cup T)$.
- *additive* valuations: f is additive iff for any disjoint $S, T \subseteq [m]$, $f(S) + f(T) = f(S \cup T)$.
- *submodular* valuations: f is submodular iff for any $S, T \subseteq [m]$, $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$.
- *fractionally subadditive* (or *XOS*) valuations: f is fractionally subadditive iff there exist additive valuations $c^1, \ldots, c^\ell$, such that for any $S \subseteq [m]$, $f(S) = \max_{k \in [\ell]} c^k(S)$. Each such additive valuation c^k is called a *clause*.

It is known that every additive valuation is submodular, every submodular valuation is fractionally subadditive, and every fractionally subadditive function is subadditive. Beyond subadditive valuations, we also consider valuations of limited superadditivity, parametrized by the superadditive width, defined below.

▶ **Definition 1** (Superadditive Width [7]). *Fix a ground set $M = [m]$. A set $T \subseteq M$ is* superadditive *w.r.t. a valuation function f, if there exists $S \subseteq M$, such that*

$$f(S \mid T) > \max_{T' \subsetneq T} f(S \mid T'),$$

where $f(A \mid B) := f(A \cup B) - f(B)$ is the marginal value of A given B for any two sets $A, B \subseteq M$. The superadditive width of f is defined to be the size of the largest superadditive set, i.e.,

$$\mathrm{SAW}(f) := \max\{|T| \mid T \text{ is superadditive w.r.t. } f\}.$$

In words, the definition says that the superadditive width of a valuation is the size of the largest set, which provides strictly more marginal value for another set, than any of its strict subsets. Intuitively, the smaller this quantity is, the closer a valuation is to being subadditive. In particular, any subadditive valuation has superadditive width 0.

2.2 Problem Formulation

We formulate the problem in the following way: There are n agents and m items, and a prior $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_n$ for the valuations of the agents over the items. All agents are monotone and subadditive (resp., fractionally subadditive), i.e., for any agent i, any valuation function f_i in the support of $\mathcal{F}_i$ is monotone and subadditive (resp., fractionally subadditive). Agents arrive one by one in an adversarial order. When agent i arrives, we see the realization $f_i \sim \mathcal{F}_i$ of her valuation (through query oracles discussed below), and must allocate irrevocably some items to the agent. The agent then takes the items and departs, and all items allocated to the agent become unavailable to subsequently arriving agents.

The goal is to maximize the expected (over the realization of the valuations and the randomness of the protocol) welfare of all agents. In particular, we wish to compete against the offline optimal allocation (i.e., the prophet), which has unlimited computational power, and knows beforehand the realization of all agents' valuations $\{f_i\}_i$. The competitive ratio is defined to be the ratio between the expected welfare (denoted OPT) of the offline optimal allocation[3] and the expected welfare produced by the online protocol.

2.3 Oracle Access to Valuation Functions

The representation of a combinatorial valuation function may be exponentially large in the number of items m. Given this complexity, it is standard to assume that the protocol may access valuation functions only through query oracles. In particular, the following two types of queries are commonly allowed (see, e.g., [14, 16, 10]):

- *value* queries: given a valuation function f and a set S, return the value of S, $f(S)$.
- *demand* queries: given a valuation function f and prices $\{p_j\}_{j\in[m]}$, return a utility-maximizing set (i.e., a demand set) with respect to f under the given prices. That is, the query returns a set S that maximizes $f(S) - \sum_{j\in S} p_j$.

In this paper, we assume the protocol has access to both kinds of queries.

[3] Note that the offline optimal allocation may be hard to find, computationally and / or information theoretically.

2.4 The Welfare Maximizing LP

The following LP relaxation of the welfare maximization problem has been considered in [9, 24, 14]:

$$\begin{array}{rll} \text{maximize} & \sum_{i\in[n]}\sum_{S\subseteq[m]} x_{i,S} f_i(S) & \\ \text{s.t.} & \sum_{S\subseteq[m]} x_{i,S} \le 1 & \forall i \in [n] \\ & \sum_{i\in[n],S\subseteq[m]:j\in S} x_{i,S} \le 1 & \forall j \in [m] \\ & x_{i,S} \ge 0 & \forall i \in [n], S \subseteq [m]. \end{array}$$

One may interpret the LP in the following way: $x_{i,S}$ stands for the probability that agent i receives bundle S. The objective is therefore the total expected value of all agents, which is the expected welfare. The first constraint requires that each agent i receives at most 1 bundle, and the second requires that each item goes to at most 1 agent, in expectation.

It is known (see, e.g., [9, 24]) that the above LP can be solved with polynomially many value and demand queries to $f_1, \ldots, f_n$. Let $x_{i,S}(\{f_{i'}\}_{i'})$ (parameters omitted when clear from the context) denote the value of variable $x_{i,S}$ in the optimal solution to the LP with respect to valuation functions $\{f_{i'}\}_{i'}$.[4] Given $\mathcal{F}$, denote the expected value enjoyed by agent i in this optimal solution by

$$\mathsf{LP}_i := \mathbb{E}_{\{f_{i'}\}_{i'}\sim\mathcal{F}}\left[\sum_{S\subseteq[m]} x_{i,S}(\{f_{i'}\}_{i'}) \cdot f_i(S)\right],$$

and the optimal objective value by

$$\mathsf{LP} := \sum_{i\in[n]} \mathsf{LP}_i = \mathbb{E}_{\{f_{i'}\}_{i'}\sim\mathcal{F}}\left[\sum_{i\in[n],S\subseteq[m]} x_{i,S}(\{f_{i'}\}_{i'}) \cdot f_i(S)\right].$$

Note that for any prior $\mathcal{F}$, we always have $\mathsf{LP} \ge \mathsf{OPT}$. We will use the welfare maximizing LP and its solution as a building block of our framework in a blackbox manner.

3 The Framework

In this section, we present our general framework, in the form of a parametrized protocol, for designing prophet inequalities for combinatorial welfare maximization. The framework works for any arrival order of agents, but for ease of presentation, we assume agents arrive according to their indices. That is, agent 1 arrives first, followed by agent 2, etc. We also let $f_{-i} := (f_1, \ldots, f_{i-1}, f_{i+1}, \ldots, f_n)$ (i.e., f_{-i} denotes the valuations of all agents but i) and use g_{-i} and $\mathcal{F}_{-i}$ similarly. Below is our parametrized protocol:

1. For each item j, initialize counter $c_j \leftarrow 0$.
2. Draw positive integer $r \in [n]$, where $\Pr[r = k] = p_k$ for any $k \in [n]$, and $\{p_k\}_{k\in[n]}$ are parameters of the protocol.
3. Upon agent i's arrival:
   a. Let f_i be agent i's realized valuation; draw dummy valuations $g_{-i} \sim \mathcal{F}_{-i}$ for all other agents.[5]

[4] If there are multiple such solutions, let $\{x_{i,S}(\{f_{i'}\}_{i'})\}_{i,S}$ be the one produced by the efficient LP solving algorithm which we use as a subroutine of the protocol.

[5] Note that we abuse notation here, so for any $i_1 \neq i_2$, g_{-i_1} and g_{-i_2} are independent – they are not different parts of a same group of valuations.

b. Solve the welfare maximizing LP with valuations (f_i, g_{-i}), and let $\{x_{i',S}(f_i, g_{-i})\}_{i',S}$ be the solution.

c. Now view $\{x_{i,S}\}_S$ as a distribution over sets of items.[6] Draw set $S_i \sim \{x_{i,S}\}_S$ from this distribution, where for any S, $\Pr[S_i = S] = x_{i,S}$. We say agent i *demands* set S_i.

d. For each item $j \in S_i$, let $c_j \leftarrow c_j + 1$ (i.e., increase the counter for item j). For any $k \in [n]$, let S_i^k be the set of items in S_i whose counters are exactly k right after demanded by agent i.

e. With probability q, where q is a parameter of the protocol, *serve* agent i by giving i all items in S_i^r (i.e., item j goes to agent i iff agent i is chronologically the r-th agent demanding item j and being served); otherwise, for each item $j \in S_i$, let $c_j \leftarrow c_j - 1$ (i.e., undo the increase for all items demanded by i).

For any agent i, let $\text{ser}_i = \mathbb{I}[i \text{ is served}]$ be the indicator variable that i is served in Step 3(e). Note that the above protocol never allocates an item to more than one agent, since once r is fixed, at most one agent can be the r-th demanding an item. As a result, the protocol always produces a valid allocation.

We now present a meta-analysis for the above protocol, which yields a parameter-dependent welfare guarantee. In later sections, we will show how one can instantiate the protocol by setting different parameters, so that the general guarantee realizes into specific bounds for the respective classes of valuations of interest.

▶ **Theorem 2.** *Let u_i be the value enjoyed by agent i. For each agent i, fixing f_i and S_i, the above protocol guarantees agent i expected value*

$$\mathbb{E}_{R_i}[u_i \mid f_i, S_i] = q \cdot \sum_{k \in [n]} p_k \cdot \mathbb{E}_{R_i}[f_i(S_i^k)],$$

where R_i summarizes all the randomness other than f_i, g_{-i} and S_i, both from the protocol and from the realization of the valuations.

Proof. The theorem is essentially a claim regarding independence of random variables. Recall that for any agent i', $\text{ser}_{i'} = \mathbb{I}[i' \text{ is served}]$. Fixing f_i and S_i, i's expected value can be written as

$$\mathbb{E}_{R_i}[u_i \mid f_i, S_i] = \mathbb{E}_{R_i}\left[\text{ser}_i \cdot \sum_{k \in [n]} \mathbb{I}[r = k] \cdot f_i(S_i^k) \,\middle|\, f_i, S_i\right].$$

R_i here summarizes $\{(f_{i'}, g_{-i'}, S_{i'})\}_{i' \neq i}$, the choice of r, and whether i' is served for all i' (including $i' = i$). To simplify this, first observe that the conditioning can be removed, because the randomness involved in the expectation, R_i, is independent of f_i and S_i. In particular, $\{f_{i'}\}_{i' \neq i}$ are independent of f_i because $\mathcal{F}$ is a product distribution. Moreover, the three factors within the expectation are independent, because whether i is served depends only on the coin flipping in Step 3(e) when agent i arrives, the choice of r depends only on the random draw in Step 2, and fixing S_i, $f_i(S_i^k)$ depends only on the realization of $\{f_{i'}\}_{i' < i}$ and the random bits of the protocol dealing with the agents arriving before i. Given the above, we have

[6] It is possible that $\sum_S x_{i,S} < 1$, in which case with probability $1 - \sum_S x_{i,S}$, $S_i = \emptyset$.

$$\begin{aligned}\mathbb{E}_{R_i}[u_i \mid f_i, S_i] &= \mathbb{E}_{R_i}\left[\mathrm{ser}_i \cdot \sum_{k\in[n]} \mathbb{I}[r=k]\cdot f_i(S_i^k)\right] \\ &= \Pr[\mathrm{ser}_i = 1]\cdot \sum_{k\in[n]} \Pr[r=k]\cdot \mathbb{E}_{\{(f_{i'},g_{-i'},S_{i'},\mathrm{ser}_{i'})\}_{i'<i}}[f_i(S_i^k)] \\ &= q\cdot \sum_{k\in[n]} p_k \cdot \mathbb{E}_{R_i}[f_i(S_i^k)]. \end{aligned}$$

◀

Before proceeding to the specific instantiations of the protocol, we note the following high-level interpretation of the above parameter-dependent bound, which provides important intuition and leads to our choices of parameters for different classes of valuations. For concreteness, suppose agents are subadditive. First observe that the share of agent i in the optimal solution of the welfare maximizing LP is

$$\begin{aligned}\mathsf{LP}_i &= \mathbb{E}_{\{f_{i'}\}_{i'}\sim\mathcal{F}}\left[\sum_S x_{i,S}(\{f_{i'}\}_{i'})\cdot f_i(S)\right] \\ &= \mathbb{E}_{(f_i,g_{-i})\sim\mathcal{F},S_i\sim\{x_{i,S}(f_i,g_{-i})\}_S}[f_i(S_i)] = \mathbb{E}_{f_i,S_i}[f_i(S_i)].\end{aligned}$$

On the other hand, since $\{S_i^k\}_{k\in[n]}$ is a partition of S_i, by the subadditivity of f_i, we always have

$$\sum_{k\in[n]} \mathbb{E}_{R_i}[f_i(S_i^k)] \geq \mathbb{E}_{R_i}[f_i(S_i)] = f_i(S_i).$$

So hypothetically, if somehow we were able to set $q = 1$ and $p_k = 1$ for every $k \in [n]$ simultaneously (which is of course impossible), then fixing any choice of f_i and S_i, the above protocol would yield at least $f_i(S_i)$ as the expected value for agent i. Further taking expectation over f_i and S_i, this would imply a 1-approximate prophet inequality against the welfare maximizing LP.

In reality, however, one cannot set p_k to be large for all k simultaneously. In fact, these probabilities must sum to 1. Still, our goal is to guarantee a decent fraction of $f_i(S_i)$ for any choice of f_i and S_i. This is possible when, for example, the total value of S_i, $f_i(S_i)$, concentrates in relatively few entries among its n parts, $\{\mathbb{E}_{R_i}[f_i(S_i^k)]\}_{k\in[n]}$. In such cases, we can let r be uniformly distributed over the indices of these entries, leading to a competitive ratio proportional to the number of such heavy entries. The key step here is analyzing the distribution of $f_i(S_i)$ into $\{f_i(S_i^k)\}_{k\in[n]}$, over the randomness in R_i. We will further develop the above intuition in later sections.

4 Warmup: the Case of Fractionally Subadditive Agents

We start with the relatively simple case of fractionally subadditive agents, the analysis for which provides tools for the more involved cases to be handled in later sections. Throughout this section, we consider the following choice of parameters: $p_1 = 1$, $p_k = 0$ for any $1 < k \leq n$, and $q = 1/2$. That is, each agent is served with probability $1/2$, and whenever an agent is served, he receives all the items demanded which are not yet taken. We now analyze our protocol with the above parameters for fractionally subadditive agents.

▶ **Theorem 3.** *The protocol in Section 3 with $p_1 = 1$, $p_k = 0$ for any $1 < k \leq n$, and $q = 1/2$ is 4-competitive when agents are fractionally subadditive.*

Proof. In light of Theorem 2, we only need to show that for any agent i, fixing f_i and S_i,

$$\mathbb{E}_{R_i}[f_i(S_i^1)] \geq \frac{1}{2} f_i(S_i). \tag{1}$$

The theorem then follows by plugging the above into Theorem 2 and taking expectation over f_i and S_i, which yields

$$\mathbb{E}_{f_i,S_i}[\mathbb{E}_{R_i}[u_i \mid f_i, S_i]] = \mathbb{E}_{f_i,S_i}\left[\frac{1}{2}\mathbb{E}_{R_i}[f_i(S_i^1)]\right] \geq \frac{1}{4}\mathbb{E}_{f_i,S_i}[f_i(S_i)] = \frac{1}{4}\mathsf{LP}_i.$$

Summing over the agents, we get the following lower bound on the expected welfare:

$$\mathbb{E}\left[\sum_{i\in[n]} u_i\right] \geq \frac{1}{4}\sum_{i\in[n]} \mathsf{LP}_i = \frac{1}{4}\mathsf{LP} \geq \frac{1}{4}\mathsf{OPT},$$

where the expectation is over all the randomness, both from the protocol and from the realization of agents' valuations. This gives precisely the desired competitive ratio of 4. The rest of the proof is dedicated to establishing (1) when i, f_i and S_i are fixed.

Recall the following property of fractionally subadditive functions.

▶ **Lemma 4.** *For fractionally subadditive f and any set of items S, let T be such that for any $j \in S$, $j \in T$ with probability at least p. Then*

$$\mathbb{E}[f(T)] \geq p \cdot f(S).$$

While this is sometimes considered standard, we give below a quick proof for completeness.

Proof. Let c^k be the clause of f such that

$$f(S) = c^k(S) = \sum_{j\in S} c^k(\{j\}).$$

By the fractional subadditivity of f, for any $S' \subseteq S$,

$$f(S') \geq c^k(S').$$

This is in particular true for T, which implies

$$\begin{aligned}
\mathbb{E}[f(T)] &\geq \mathbb{E}[c^k(T)] \\
&= \sum_{j\in S} \mathbb{E}[\mathbb{I}[j \in T] \cdot c^k(\{j\})] \\
&= \sum_{j\in S} \Pr[j \in T] \cdot c^k(\{j\}) \\
&\geq p \cdot \sum_{j\in S} c^k(\{j\}) \\
&= p \cdot f(S).
\end{aligned}$$

◀

Given Lemma 4, the plan is to show that each item j in S_i appears in S_i^1 with probability at least $1/2$. That is, with probability at least $1/2$, no agent $i' < i$ demands item j and gets served simultaneously. To see why this is true, consider the unconditional distribution of the set $S_{i'}$ demanded by any agent i'. Let $y_{i',S} = \Pr[S_{i'} = S]$ be the probability that agent i' demands set S, over $f_{i'}$, $g_{-i'}$, and the random bits of the protocol. Note that $y_{i',S}$ is not random, and depends only on the prior $\mathcal{F}$. We first show that $\{y_{i',S}\}_{i',S}$ form a feasible solution to the welfare maximizing LP, regardless of the actual valuations of the agents. This is well-defined, since fixing n and m, the precise values of sets do not appear in any constraint of the welfare maximizing LP.

▶ **Lemma 5.** *$\{y_{i',S}\}_{i',S}$ satisfy:*

- *for any agent $i' \in [n]$, $\sum_{S\subseteq[m]} y_{i',S} \le 1$,*
- *for any item $j \in [m]$, $\sum_{i'\in[n],S\subseteq[m]:j\in S} y_{i',S} \le 1$, and*
- *for any $i' \in [n]$, $S \subseteq [m]$, $y_{i',S} \ge 0$.*

Proof. Observe that according to the protocol, for any i', S,

$$y_{i',S} = \mathbb{E}_{f_{i'}\sim\mathcal{F}_{i'},g_{-i'}\sim\mathcal{F}_{-i'}}[x_{i',S}(f_{i'},g_{-i'})] = \mathbb{E}_{\{f_{i''}\}_{i''}\sim\mathcal{F}}[x_{i,S}(\{f_{i''}\}_{i''})].$$

In other words, $y_{i',S}$ is the expected value of the variable $x_{i',S}$ in the optimal solution to the welfare maximizing LP, when valuations are distributed according to prior $\mathcal{F}$. Now since for any realization of $\{f_{i''}\}_{i''}$, $\{x_{i',S}(\{f_{i''}\}_{i''})\}_{i',S}$ satisfy the LP constraints, it follows from linearity of expectation that the expected values $\{y_{i',S}\}_{i',S}$ also satisfy the constraints. The lemma follows. ◀

For any agent i' and item j, let $d^j_{i'}$ be the probability that item j is demanded by agent i'. That is,

$$d^j_{i'} := \Pr_{f_{i'},g_{-i'}}[j \in S_{i'}] = \sum_{S:j\in S} y_{i',S}.$$

The feasibility of $y_{i',S}$ (Lemma 5) implies: for any $j \in [m]$,

$$\sum_{i'\in[n]} d^j_{i'} = \sum_{i'\in[n],S:j\in S} y_{i',S} \le 1.$$

Also, whether agent i' demands j is independent of whether i' is served, so for any $j \in [m]$,

$$\begin{aligned}
\Pr[\exists i' < i : (j \in S_{i'} \wedge i' \text{ is served})] &\le \sum_{i'<i} \Pr[j \in S_{i'} \wedge i' \text{ is served}] && \text{(union bound)}\\
&\le \sum_{i'\in[n]} \Pr[j \in S_{i'} \wedge i' \text{ is served}]\\
&= \sum_{i'\in[n]} d^j_{i'} \cdot \Pr[\mathrm{ser}_{i'} = 1]\\
& && \text{(independence of } S_{i'} \text{ and } \mathrm{ser}_{i'})\\
&\le 1 \cdot q = \frac{1}{2}, && \text{(Lemma 5)}
\end{aligned}$$

which concludes the proof of the theorem. ◀

5 The Case of Subadditive Agents

Equipped with tools developed in previous sections, now we proceed to the case of subadditive agents. Here we choose $q = 1$ and

$$p_k = \begin{cases} 1/C, & 1 \le k \le C \\ 0, & C < k \le n, \end{cases}$$

where $C = \min(100 \log m/\log\log m, n) = O(\log m/\log\log m)$. We prove the following bound for subadditive agents.

▶ **Theorem 6.** *The protocol in Section 3 with the above parameters is $O(\log m/\log\log m)$-competitive when agents are subadditive.*

Proof. When $n \le 100 \log m / \log\log m$, the theorem is easy to prove. Below we focus on the case where $C = 100 \log m / \log\log m < n$. Consider any agent i. Fix f_i and S_i. In light of Theorem 2, our goal here is to show

$$\sum_{1 \le k \le C} \mathbb{E}_{R_i}[f_i(S_i^k)] = \Omega(f_i(S_i)). \tag{2}$$

That is, the first C terms in $\{f_i(S_i^k)\}_{k \in [n]}$ contribute a constant fraction of $f_i(S_i)$ in expectation. The theorem then again follows by plugging the above into Theorem 2, yielding

$$\mathbb{E}_{R_i}[u_i \mid f_i, S_i] \ge q \cdot \sum_{1 \le k \le C} p_k \cdot \mathbb{E}_{R_i}[f_i(S_i^k)] = \Omega(f_i(S_i)/C).$$

Taking expectation over f_i and S_i, and summing over the agents, we have

$$\sum_i \mathbb{E}[u_i] \ge \Omega(1/C) \cdot \sum_i \mathbb{E}[f_i(S_i)] = \Omega(1/C) \cdot \mathsf{LP} \ge \Omega(1/C) \cdot \mathsf{OPT}.$$

A competitive ratio of $O(C) = O(\log m / \log\log m)$ follows. The rest of the proof is dedicated to establishing (2) when i, f_i and S_i are fixed.

The plan is to show, with constant probability over R_i, $S_i^k = \emptyset$ for all $k > C$. Denote this event by $\mathcal{E}_i$. Whenever this happens, $\bigcup_{1 \le k \le C} S_i^k = S_i$, and by the subadditivity of f_i,

$$\sum_{1 \le k \le C} f_i(S_i^k) \ge f_i(S_i).$$

As a result,

$$\sum_{1 \le k \le C} \mathbb{E}_{R_i}[f_i(S_i^k)] \ge \sum_{1 \le k \le C} \mathbb{E}_{R_i}[f_i(S_i^k) \mid \mathcal{E}_i] \cdot \Pr[\mathcal{E}_i] \ge \Pr[\mathcal{E}_i] \cdot f_i(S_i).$$

We show below $\Pr[\mathcal{E}_i] = \Omega(1)$.

Fix an item j, and consider the probability that $j \in S_i^k$ for some $k > C$, or equivalently,

$$\Pr\left[\sum_{i' < i} \mathbb{I}[j \in S_{i'}] \ge C\right].$$

To bound the above probability, recall the following fact about independent Bernoulli variables (see, e.g., [14, 19]).

▶ **Lemma 7.** *For any $n \in \mathbb{Z}^+$, independent Bernoulli random variables $X_1, \ldots, X_n$ where $\mathbb{E}\left[\sum_{i \in [n]} X_i\right] \le 1$, and any $k \in \mathbb{Z}^+$,*

$$\Pr\left[\sum_i X_i \ge k\right] = O\left(\frac{1}{k!}\right) = k^{-\Omega(k)}.$$

The lemma says, that if the sum of independent Bernoulli variables in expectation does not exceed 1, then the tail of this sum decays factorially fast. Now observe that $S_1, \ldots, S_{i-1}$, and therefore $\mathbb{I}[j \in S_1], \ldots, \mathbb{I}[j \in S_{i-1}]$ are independent. This is because for any i', $S_{i'}$ depends only on $f_{i'}$ and $g_{-i'}$. Also, since

$$\mathbb{E}\left[\sum_{i' < i} \mathbb{I}[j \in S_{i'}]\right] = \sum_{i' < i} \Pr[j \in S_{i'}] = \sum_{i' < i} d_j^{i'} \le \sum_{i' \in [n]} d_j^{i'} \le 1,$$

random variables $\{\mathbb{I}[j \in S_{i'}]\}_{i'<i}$ satisfy the conditions of Lemma 7. So for large enough m, we can bound the probability that $j \in S_i^k$ for some $k > C$ using Lemma 7. Recall that $C = 100 \log m / \log\log m$. Plugging this in, Lemma 7 then gives

$$\Pr\left[\sum_{i'<i} \mathbb{I}[j \in S_{i'}] \geq C\right] \leq C^{-\Omega(C)} = O\left(\frac{1}{m^2}\right).$$

Now taking a union bound over all items, we get

$$\Pr[\mathcal{E}_i] \geq 1 - \sum_{j\in[m]} \Pr\left[\sum_{i'<i} \mathbb{I}[j \in S_{i'}] \geq C\right] = 1 - \sum_{j\in[m]} O\left(\frac{1}{m^2}\right) = 1 - O\left(\frac{1}{m}\right) = \Omega(1).$$

This concludes the proof of the theorem. ◀

6 Generalizing to Approximately Subadditive Agents

In this section, we consider valuations with superadditive width at most $D > 0$. In order to utilize the boundedness of the superadditive width, we set $q = \frac{1}{4D}$, and

$$p_k = \begin{cases} \frac{1}{2} + \frac{1}{2C}, & k = 1 \\ \frac{1}{2C}, & 1 < k \leq C \\ 0, & C < k \leq n, \end{cases}$$

where again $C = \min(100 \log m / \log\log m, n) = O(\log m / \log\log m)$. One may check that $\{p_k\}_{k\in[n]}$ in fact sum to 1. We prove the following competitive ratio.

▶ **Theorem 8.** *The protocol in Section 3 with the above parameters is $O(D \log m / \log\log m)$-competitive when all valuations have superadditive width at most D.*

Proof. Again, fix an agent i, f_i and S_i. Our goal is to show that one of the following two claims is always true:

- Claim (i):

$$\mathbb{E}_{R_i}[f_i(S_i^1)] = \Omega\left(f_i(S_i)/C\right).$$

- Claim (ii):

$$\sum_{1\leq k\leq C} \mathbb{E}_{R_i}[f_i(S_i^k)] = \Omega(f_i(S_i)).$$

We first show how the above condition implies the theorem. Again, by applying Theorem 2,

$$\begin{aligned} \mathbb{E}_{R_i}[u_i \mid f_i, S_i] &\geq q \cdot \sum_{1\leq k\leq C} p_k \cdot \mathbb{E}_{R_i}[f_i(S_i^k)] \\ &= \Omega(1/D) \cdot \left(\mathbb{E}_{R_i}[f_i(S_i^k)] + \frac{1}{C} \sum_{1\leq k\leq C} \mathbb{E}_{R_i}[f_i(S_i^k)]\right) \\ &= \Omega(1/D) \cdot \Omega(f_i(S_i)/C) \\ &= \Omega\left(\frac{D \log m}{\log\log m} \cdot f_i(S_i)\right). \end{aligned}$$

The theorem then follows by taking expectation over f_i and S_i, and summing over the agents.

The rest of the proof is dedicated to establishing the above condition. We consider the most valuable $2D$ items for agent i in S_i, i.e.,

$$S_i^* := \text{argmax}_{S:S\subseteq S_i,|S|\leq 2D} f_i(S).$$

We show below that when the value of S_i^*, $f_i(S_i^*)$, is small, then Claim (i) holds. Otherwise, Claim (ii) holds. Since f_i and S_i are fixed, one of the two claims is always true.

First suppose

$$f_i(S_i^*) \geq f_i(S_i)/(2C).$$

In such cases, we show that with constant probability, $S_i^* \subseteq S_i^1$. Whenever this happens, monotonicity implies

$$f_i(S_i^1) \geq f_i(S_i^*) \geq f_i(S_i)/(2C).$$

Taking expectation over R_i, this implies Claim (i).

We now bound the probability that $S_i^* \subseteq S_i^1$. Fix $j \in S_i^*$. Consider the probability that $j \notin S_i^1$, or equivalently,

$$\Pr\left[\sum_{i'<i} \mathbb{I}[j \in S_{i'} \wedge i' \text{ is served}] \geq 1\right].$$

We upper bound this probability in the following way.

$$\begin{aligned}
\Pr\left[\sum_{i'<i} \mathbb{I}[j \in S_{i'} \wedge i' \text{ is served}] \geq 1\right] &\leq \sum_{i'<i} \Pr[j \in S_{i'} \wedge i' \text{ is served}] && \text{(union bound)}\\
&= \sum_{i'<i} d_{i'}^j \cdot q \leq \sum_{i'\in[n]} d_{i'}^j \cdot q\\
&\leq q = \frac{1}{4D}. && \text{(Lemma 5)}
\end{aligned}$$

So for any $j \in S_i^*$,

$$\Pr[j \notin S_i^1] \leq \frac{1}{4D}.$$

Since $|S_i^*| = 2d$, taking a union bound over all items in S_i^*, we get

$$\Pr[S_i^* \subseteq S_i^1] \geq 1 - \sum_{j\in S_i^*} \Pr[j \notin S_i^1] \geq 1 - 2D \cdot \frac{1}{4D} = \frac{1}{2}.$$

This implies Claim (i) as argued above.

Now suppose

$$f_i(S_i^*) < f_i(S_i)/(2C).$$

Given this, we show Claim (ii) holds. First we need the following property of valuations with bounded superadditive width.

▶ **Lemma 9** ([7]). *Let $f : 2^{[m]} \to \mathbb{R}_+$ be a valuation function such that $\text{SAW}(f) \leq D$. For any $S, T \subseteq [m]$,*

$$f(S \mid T) \leq \min_{T':T'\subseteq T,|T'|\leq D} f(S \mid T').$$

Consider the prefix unions of $\{S_i^k\}_{k\in[C]}$. To be precise, let $U_i^0 = \emptyset$, and for any $k \in [C]$,

$$U_i^k = U_i^{k-1} \cup S_i^k.$$

Recall that for any $S, T \subseteq [m]$, $f_i(S \mid T) = f_i(S \cup T) - f_i(T)$ is the marginal value of S given T. For any $k \in [C]$, we have

$$\begin{aligned}
f_i(U_i^k) &= f_i(S_i^k \mid U_i^{k-1}) + f_i(U_i^{k-1}) \\
&\le f_i(S_i^k \mid X) + f_i(U_i^{k-1}), \text{ where } X = \operatorname{argmin}_{S:S\subseteq U_i^{k-1}, |S|\le D} f_i(S_i^k \mid S) \\
&\qquad\qquad \text{(Lemma 9)} \\
&\le f_i(S_i^k \cup X) + f_i(U_i^{k-1}) \qquad \text{(monotonicity of } f_i\text{)} \\
&= f_i(X \mid S_i^k) + f_i(S_i^k) + f_i(U_i^{k-1}) \\
&\le f_i(X \mid Y) + f_i(S_i^k) + f_i(U_i^{k-1}), \text{ where } Y = \operatorname{argmin}_{S:S\subseteq S_i^k, |S|\le D} f_i(X \mid S) \\
&\qquad\qquad \text{(Lemma 9)} \\
&\le f_i(X \cup Y) + f_i(S_i^k) + f_i(U_i^{k-1}) \qquad \text{(monotonicity)} \\
&\le f_i(S_i^*) + f_i(S_i^k) + f_i(U_i^{k-1}). \quad \text{(definition of } S_i^* \text{ and } |X \cup Y| \le |X| + |Y| \le 2D\text{)}
\end{aligned}$$

Now recall that $\mathcal{E}_i$ is the event that for all $k > C$, $S_i^k = \emptyset$. In the proof of Theorem 6, we have shown that $\Pr[\mathcal{E}_i] = \Omega(1)$. Also, whenever $\mathcal{E}_i$ happens, we have $U_i^C = S_i$. As a result, when $\mathcal{E}_i$ happens, we can bound $f_i(S_i)$ in the following way.

$$\begin{aligned}
f_i(S_i) = f_i(U_i^C) &\le f_i(S_i^*) + f_i(S_i^C) + f_i(U_i^{C-1}) \\
&\le 2f_i(S_i^*) + f_i(S_i^C) + f_i(S_i^{C-1}) + f_i(U_i^{C-2}) \\
&\le \dots \\
&\le C \cdot f_i(S_i^*) + \sum_{1\le k\le C} f_i(S_i^k).
\end{aligned}$$

Compared to the subadditive case, here we have the additional term $C \cdot f_i(S_i^*)$. However, as we are in the world where $f_i(S_i^*)$ is small, this term does not affect the bound too much. Concretely, whenever $\mathcal{E}_i$ happens, we have

$$\sum_{1\le k\le C} f_i(S_i^k) \ge f_i(S_i) - C \cdot f_i(S_i^*) > f_i(S_i) - C \cdot \frac{f_i(S_i)}{2C} = \frac{f_i(S_i)}{2}.$$

Again, since $\Pr[\mathcal{E}_i] = \Omega(1)$, we have

$$\sum_{1\le k\le C} \mathbb{E}_{R_i}[f_i(S_i^k)] = \Omega(f_i(S_i)),$$

which is precisely Claim (ii), and therefore concludes the proof of the theorem. ◀

On the Approximation Ratio of the k-Opt and Lin-Kernighan Algorithm for Metric and Graph TSP

Xianghui Zhong
University of Bonn, Germany
zhong@cs.uni-bonn.de

Abstract

The k-Opt and Lin-Kernighan algorithm are two of the most important local search approaches for the Metric TSP. Both start with an arbitrary tour and make local improvements in each step to get a shorter tour. We show that for any fixed $k \geq 3$ the approximation ratio of the k-Opt algorithm for Metric TSP is $O(\sqrt[k]{n})$. Assuming the Erdős girth conjecture, we prove a matching lower bound of $\Omega(\sqrt[k]{n})$. Unconditionally, we obtain matching bounds for $k = 3, 4, 6$ and a lower bound of $\Omega(n^{\frac{2}{3k-3}})$. Our most general bounds depend on the values of a function from extremal graph theory and are tight up to a factor logarithmic in the number of vertices unconditionally. Moreover, all the upper bounds also apply to a parameterized version of the Lin-Kernighan algorithm with appropriate parameter. We also show that the approximation ratio of k-Opt for Graph TSP is $\Omega\left(\frac{\log(n)}{\log\log(n)}\right)$ and $O\left(\left(\frac{\log(n)}{\log\log(n)}\right)^{\log_2(9)+\epsilon}\right)$ for all $\epsilon > 0$.

1 Introduction

The traveling salesman problem (TSP) is probably the best-known problem in discrete optimization. An instance consists of the pairwise distances of n vertices and the task is to find a shortest Hamiltonian cycle, i.e. a tour visiting every vertex exactly once. The problem is known to be NP-hard [12]. A special case of the TSP is the Metric TSP. Here the distances satisfy the triangle inequality. This TSP variant is still NP-hard [15].

Since the problem is NP-hard, a polynomial-time algorithm is not expected to exist. In order to speed up the calculation of a good tour in practice, several approximation algorithms are considered. The approximation ratio is one way to compare approximation algorithms. It is the maximal ratio, taken over all instances, of the output of the algorithm divided by the optimum solution. The best currently known approximation algorithm in terms of approximation ratio for Metric TSP was independently developed by Christofides and Serdjukov [6, 24] with an approximation ratio of $\frac{3}{2}$. However, in practice other algorithms are usually easier to implement and have better performance and runtime [3, 14, 22]. One natural approach is the k-Opt algorithm which is based on local search. It starts with an arbitrary tour and replaces at most k edges by new edges such that the resulting tour is

shorter. It stops if the procedure cannot be applied anymore. For the 2-Opt algorithm Plesník showed that there are infinitely many instances with approximation ratio $\sqrt{\frac{n}{8}}$, where n is the number of vertices [21]. Chandra, Karloff and Tovey showed that the approximation ratio of 2-Opt is at most $4\sqrt{n}$ [5]. Levin and Yovel observed that the same proof yields an upper bound of $\sqrt{8n}$ [19]. Recently, Hougardy, Zaiser and Zhong closed the gap and proved that the approximation ratio of the 2-Opt algorithm is at most $\sqrt{\frac{n}{2}}$ and that this bound is tight [13]. For general $k > 2$ Chandra, Karloff and Tovey gave a lower bound of $\frac{1}{4}\sqrt[2k]{n}$ [5], no non-trivial upper bound is known so far. In the case where the instances can be embedded into the normed space $\mathbb{R}^d$ the approximation ratio of 2-Opt is between $\Omega(\frac{\log(n)}{\log\log(n)})$ and $O(\log(n))$ [5].

Beyond the worst-case analysis there are also results about the average case behavior of the algorithm. For example the smoothed analysis of the 2-Opt algorithm by Englert, Röglin and Vöcking [7]. In their model each vertex of the TSP instance is a random variable distributed in the d dimensional unit cube by a given probability density function $f_i : [0,1]^d \to [0,\phi]$ bounded from above by a constant $1 \leq \phi < \infty$ and the distances are given by the L_p norm. They show that in this case the expected approximation ratio is bounded by $O(\sqrt[d]{\phi})$ for all p. In the model where any instance is given in $[0,1]^d$ and perturbed by a Gaussian noise with standard deviation σ the approximation ratio was improved to $O(\log(\frac{1}{\sigma}))$ by Künnemann and Manthey [17].

One of the best practical heuristics by Lin and Kernighan is based on k-Opt [20]. The Lin-Kernighan algorithm, like the k-Opt algorithm, modifies the tour locally to obtain a new tour. Instead of replacing arbitrary k edges with new edges, which results in a high runtime for large k, it searches for specific changes: Changes where the edges to be added and deleted are alternating in a closed walk, a so called closed alternating walk. Since the Lin-Kernighan algorithm uses a super set of the modification rules of the 2-Opt algorithm, the same upper bound as for 2-Opt also applies. Apart from this, no other upper bound was known.

A special case of the Metric TSP is the Graph TSP. In this case an undirected unweighted graph is given and the distance between two vertices is the distance between them in the graph. Apart from the upper bounds of the Metric TSP, which also apply to the special case, only a lower bound of $2(1-\frac{1}{n})$ on the approximation ratio of the k-Opt algorithm is known so far: Rosenkrantz, Stearns and Lewis describe a Metric TSP instance with this ratio that is also a Graph TSP instance [23].

New results. For fixed $k \geq 3$, we show that the approximation ratio of the k-Opt algorithm is related to the extremal graph theoretic problem of maximizing the number of edges in a graph with fixed number of vertices and no short cycles. Let $\mathrm{ex}(n, 2k)$ be the largest number of edges in a graph with n vertices and girth at least $2k$, i.e. it contains no cycles with less than $2k$ edges. For instances with n vertices we show for Metric TSP that:

▶ **Theorem 1.** *If* $\mathrm{ex}(n, 2k) \in O(n^c)$ *for some* $c > 1$*, the approximation ratio of* k*-Opt is* $O(n^{1-\frac{1}{c}})$ *for all fixed* k*.*

▶ **Theorem 2.** *If* $\mathrm{ex}(n, 2k) \in \Omega(n^c)$ *for some* $c > 1$*, the approximation ratio of* k*-Opt is* $\Omega(n^{1-\frac{1}{c}})$ *for all fixed* k*.*

Using known upper bounds on $\mathrm{ex}(n, 2k)$ in [1] we can conclude:

▶ **Corollary 3.** *The approximation ratio of* k*-Opt is in* $O(\sqrt[k]{n})$ *for all fixed* k*.*

If we further assume the Erdős girth conjecture [10], i.e. $\mathrm{ex}(n, 2k) \in \Theta(n^{1+\frac{1}{k-1}})$, we have:

▶ **Corollary 4.** *Assuming the Erdős girth conjecture, the approximation ratio of k-Opt is in $\Omega(\sqrt[k]{n})$ for all fixed k.*

Using known lower bounds on $\mathrm{ex}(n, 2k)$ from [8, 9, 4, 2, 25, 26, 18] we obtain:

▶ **Corollary 5.** *The approximation ratio of k-Opt is in $\Omega(\sqrt[k]{n})$ for $k = 3, 4, 6$ and in $\Omega(n^{\frac{2}{3k-4+\epsilon}})$ for all fixed k where $\epsilon = 0$ if k is even and $\epsilon = 1$ if k is odd.*

Comparing our upper and lower bounds we obtain:

▶ **Theorem 6.** *Our most general upper bound depending on $\mathrm{ex}(n, 2k)$ is tight up to a factor of $O(\log(n))$.*

The upper bounds can be carried over to a parameterized version of the Lin-Kernighan algorithm:

▶ **Theorem 7.** *The same upper bounds from Theorem 1 and 3 hold for a parameterized version of the Lin-Kernighan algorithm with appropriate parameter.*

Although the Lin-Kernighan algorithm only considers special changes, namely changes by augmenting a closed alternating walk, we are able to show the same upper bound as for the general k-Opt algorithm. For the original version of Lin-Kernighan we get an improved upper bound of $O(\sqrt[3]{n})$. Our results solve two of the four open questions in [5], namely:

- Can the upper bounds given in [5] be generalized to the k-Opt algorithm, i.e. for increasing k the performance guarantee improves?
- Can we show better upper bounds for the Lin-Kernighan algorithm than the upper bound obtained from the 2-Opt algorithm?

We also bound the approximation ratio of the k-Opt algorithm for Graph TSP.

▶ **Theorem 8.** *The approximation ratio of k-Opt with $k \geq 2$ for Graph TSP is $\Omega\left(\frac{\log(n)}{\log\log(n)}\right)$.*

▶ **Theorem 9.** *The approximation ratio of 2-Opt for Graph TSP is $O\left(\left(\frac{\log(n)}{\log\log(n)}\right)^{\log_2(9)+\epsilon}\right)$ for all $\epsilon > 0$.*

Note that the same upper bound also applies to the k-Opt algorithm and the Lin-Kernighan algorithm since they produce 2-optimal tours. Hence, up to a constant factor of at most $\log_2(9)$ in the exponent the k-Opt algorithm does not achieve asymptotically better performance than the 2-Opt algorithm in contrast to the metric case.

Outline of the paper. We start with the basic definitions we need for the analysis in the preliminaries. Then, an outline of the analysis roughly describes the main ideas for the lower and upper bounds on the approximation ratio for Metric and Graph TSP. In the main part of the paper we will only focus on the upper bound on the approximation ratio of the k-Opt algorithm for Metric TSP. Note that the same analysis can be carried over to the Lin-Kernighan algorithm by showing that the k-moves we consider can be performed by augmenting appropriate alternating cycles. For more details on this and the analysis of the other bounds we refer to the full version of the paper.

1.1 Preliminaries

1.1.1 TSP

An instance of Metric TSP is given by a complete weighted graph (K_n, c) where the costs are non-negative and satisfy the triangle inequality: $c(\{x, z\}) + c(\{z, y\}) \geq c(\{x, y\})$ for all $x, y, z \in V(K_n)$. A *cycle* is a closed walk that visits every vertex at most once. A *tour* is a cycle that visits every vertex exactly once. For a tour T, let the *length* of the tour be defined as $c(T) := \sum_{e \in T} c(e)$. The task is to find a tour of minimal length. We fix an *orientation* of the tour, i.e. we consider the edges of the tour as directed edges such that the tour is a directed cycle. From now on, let n denote the number of vertices of the instance.

Graph TSP is a special case of the Metric TSP. Each instance arises from an unweighted, undirected connected graph G. To construct a TSP instance (K_n, c), we set $V(K_n) = V(G)$. The cost $c(\{u, v\})$ of the edge connecting any two vertices $u, v \in V(G)$ is given by the length of the shortest u-v-path in G.

An algorithm A for the traveling salesman problem has *approximation ratio* $\alpha(n) \geq 1$ if for every TSP instance with n vertices it finds a tour that is at most $\alpha(n)$ times as long as a shortest tour and this ratio is achieved by an instance for every n. Note that we require here the sharpness of the approximation ratio deviating from the standard definition in the literature to express the approximation ratio in terms of the Landau symbols. Nevertheless, the results also hold for the standard definition with more complicated notation.

1.1.2 k-Opt and Lin-Kernighan Algorithm

A *k-move* replaces at most k edges of a given tour by other edges to obtain a new tour. It is called *improving* if the resulting tour is shorter than the original one. A tour is called *k-optimal* if there is no improving k-move.

For the 2-Opt algorithm recall the following well known fact: Given a tour T with a fixed orientation, it stays connected if we replace two edges of T by the edge connecting their heads and the edge connecting their tails, i.e. if we replace edges $(a, b), (c, d) \in T$ by (a, c) and (b, d).

An *alternating walk* of a tour T is a walk starting with an edge in T where exactly one of two consecutive edges is in T. An edge of the alternating walk is called *tour edge* if it is contained in T, otherwise it is called *non-tour edge*. A *closed alternating walk* and *alternating cycle* are alternating walks whose edges form a closed walk and cycle, respectively.

We consider a parameterized version of the Lin-Kernighan algorithm described in Section 21.3 of [16] for the analysis. In this version two parameters p_1 and p_2 specify the depth the algorithm is searching for an improvement. Since this extended abstract will focus on the k-Opt algorithm, we do not describe the Lin-Kernighan algorithm here and refer to the Section 21.3 of [16] or the full version of the paper.

1.2 Girth and Ex

The *girth* of a graph is the length of the shortest cycle contained in the graph if it contains a cycle and infinity otherwise. Let $\mathrm{ex}(n, 2k)$ be the maximum number of edges in a graph with n vertices and girth at least $2k$. Moreover, define $\mathrm{ex}^{-1}(m, 2k)$ as the minimal number of vertices of a graph with m edges and girth at least $2k$.

2 Outline of the Analysis

In this section we give an outline of the analysis for the lower and upper bounds of k-Opt for the Metric TSP and Graph TSP.

2.1 Outline of Lower Bound for Metric TSP

In this subsection we sketch the lower bound of k-Opt for the Metric TSP given by Theorem 2. We use the following lemma from [5]:

▶ **Theorem 10** (Lemma 3.6 in [5]). *Suppose there exists a Eulerian unweighted graph $G_{k,n,m}$ with n vertices and m edges, having girth at least $2k$. Then, there is a Metric TSP instance with m vertices and a k-optimal tour T such that $\frac{c(T)}{c(T^*)} \geq \frac{m}{2n}$, where T^* is the optimal tour of the instance.*

For the previous lower bound the theorem was applied to regular Eulerian graphs with high girth. Instead, we show that for every graph that there is a Eulerian subgraph with similar edge vertex ratio and apply the theorem to the Eulerian subgraphs of dense graphs with high girth to get the new bound.

2.2 Outline of Upper Bound for Metric TSP

In this subsection we briefly summarize the ideas for the analysis of the upper bound for the Metric TSP given by Theorem 1. For a fixed k assume that an instance is given with a k-optimal tour T. We fix an orientation of T and assume w.l.o.g. that the length of the optimal tour is 1. To bound the approximation ratio it is enough to bound the length of T. Our general strategy is to construct an auxiliary graph depending on T and bound its girth. More precisely, we show that if this graph has a short cycle this would imply the existence of an improving k-move contradicting the k-optimality of T. Moreover, the auxiliary graph contains many long edges of T so the bound on its girth also bounds the number of long edges in the tour and hence the approximation ratio.

Let the graph G consist of the vertices of the instance and the edges of T, i.e. $G := (V(K_n), T)$. We first divide the edges of T in length classes such that the lth length class consists of the edges with length between c^{l+1} and c^l for some constant $c < 1$, we call these edges *l-long*. For each $l \in \mathbb{N}_0$ we want get an upper bound on the number of l-long edges that depends on the number of vertices.

If we performed the complete analysis on G, we would get a bad bound on the number of l-long edges since G contains too many vertices. To strengthen the result we first construct an auxiliary graph containing all l-long edges for some fixed l but fewer vertices and bound the number of l-long edges in that graph: We partition $V(G)$ into classes with help of the optimal tour such that in each class any two vertices have small distance to each other. We contract the vertices in each class to one vertex and delete self loops to get the multigraph G_1^l. We can partition $V(G)$ in such a way that G_1^l contains all the l-long edges. Note we did not delete parallel edges in G_1^l and hence every edge in G_1^l has a unique preimage in G.

Unfortunately, we cannot directly bound the girth of G_1^l since the existence of a short cycle would not necessarily imply an improving k-move for T. For that we need a property of the cycles in the graph: The common vertex of consecutive edges in any cycle has to be head of both or tail of both edges according to the orientation of T. Therefore, we construct the auxiliary graph G_2^l from G_1^l as follows: We start with G_2^l as a copy of G_1^l and color the vertices of G_2^l red and blue. We only consider l-long edges in G_2^l from a red vertex to a blue vertex according to the orientation of T and delete all other edges. We can show that the coloring can be done in such a way that at least $\frac{1}{4}$ of the l-long edges remain in G_2^l.

We claim that the underlying undirected graph of G_2^l has girth at least $2k$. Note that by construction the graph is bipartite and hence all cycles have even length. Assume that there is a cycle C with $2h < 2k$ edges. We call the preimage of the edges of C in G the *C-edges*. Our aim is to construct a tour T' with the assistance of C that arises from T by an improving k-move.

For every common vertex w of two consecutive edges e_1, e_2 of C in G_2^l we consider the preimage e_1^{-1}, e_2^{-1} of e_1, e_2 in G. Then there have to be endpoints $u \in e_1^{-1}$ and $v \in e_2^{-1}$ such that the images of u and v after the contraction in G_2^l are both w. We will call the edge $\{u, v\}$ a *short edge*. In fact since both endpoints of a short edge are mapped to the same vertex in G_1^l after the contraction and we contracted vertices which have small distance to each other, they are indeed short. Furthermore, we can show that the total length of all the short edges is shorter than that of any single C-edge. The number of the short edges is equal to the number of C-edges which is $2h$. Now, observe that the cycle C defines an alternating cycle in G in a natural way: Let the preimages of C in G be the tour edges and the short edges be the non-tour edges.

To construct a new tour T' from T we start by augmenting the alternating cycle. Afterwards, the tour may split into at most $2h$ connected components. A key property is that the coloring of the vertices in G_2^l ensures that every connected component contains at least two short edges. Since there are $2h$ short edges, we know that after the augmentation we actually get at most h connected components. To reconnect and retain the degree condition we add twice a set L of at most $h-1$ different C-edges, i.e. in total at most $2h-2$ edges. In the end we shortcut to the new tour T' in a particular way without decreasing $|T \cap T'|$.

Note that the original tour T contains $2h$ C-edges, thus T' contains at least 2 fewer C-edges than T. The additional short edges T' contains are cheap, therefore T' is cheaper than T. Moreover, T' arises from T by replacing at most $2h - |L|$ C-edges since we deleted the C-edges and added twice the set L consisting of C-edges. Therefore, we know that T' arises from T by a $2h - |L| \leq 2h$-move. By the k-optimality of T, we have $2h > k$ or $2h \geq k + 1$. This already gives us a lower bound of $k + 1$ for the girth of the graph G_2^l as C contains $2h$ edges.

In the next step we use the previous result to show that there is actually a cheaper tour T' that arises by an $h + 1$-move. This implies that $h + 1 > k$ or $2h \geq 2k$, i.e. the girth of G_2^l is at least $2k$. As we have seen above the number of edges we have to replace to obtain T' from T depends on $|L|$, the number of C-edges T' contains. Therefore, we modify T' iteratively such that the number of C-edges in T' increases by 1 after every iteration while still maintaining the property that T' is cheaper than T. We stop when the number of C-edges in T' is $h - 1$ as then T' would arise from T by a $2h - (h - 1) = h + 1$-move.

To achieve this we start with the constructed tour T' and iteratively perform 2-moves that are not necessarily improving but add one more C-edge to T'. In every iteration we consider C-edges e not in the current tour T'. We can show that there is an edge in $T' \backslash T$ incident to each of the endpoints of e. Let the two edges be f_1 and f_2. We want to replace f_1 and f_2 in T' by e_1 and the edge connecting the endpoints of f_1 and f_2 not incident to e. To ensure the connectivity after the 2-move we need to find edges e such that the corresponding edges f_1, f_2 fulfill the following condition: Either both heads or both tails of f_1 and f_2 have to be endpoints of e. It turns out that we can find such edges e in enough iterations to construct T' with the desired properties.

In the end we notice that a lower bound on the girth of G_2^l gives us an upper bound on the number of edges in G_2^l by previous results on extremal graph theory. This implies an upper bound on the number of l-long edges as G_2^l contains at least $\frac{1}{4}$ of the l-long edges in T. That gives us an upper bound on the length of T and thus also an upper bound on the approximation ratio as we assumed that the optimal tour has length 1.

2.3 Outline of Lower Bound for Graph TSP

For the lower bound of Graph TSP given by Theorem 8 let an integer f be given. We construct an instance with approximation ratio $\Theta(f)$ and $(c_1 f)^{c_2 f}$ vertices for some constants $c_1, c_2 > 0$. Thus, the approximation ratio is $\Omega\left(\frac{\log n}{\log\log n}\right)$.

The construction starts with a dense $2f$-regular Eulerian graph G with high girth. Let $W = (v_0, v_1, \ldots, v_{|E(G)|-1})$ be a Eulerian walk of G. Traverse through G according to W starting at v_0 and mark every fth vertex both in G and in W. Whenever we would mark an already marked vertex v in G, we add a new copy v' of v adjacent exactly to the neighbors of v and mark v' instead. Moreover, we replace this occurrence of v in W by v' and mark v'. Let G' be the graph containing G and all the copies of the vertices we made. After the traversal of W, we mark for every unmarked vertex in G' one occurrence of it in W. Since we only need the property that every vertex of G' is marked in W it does not matter which occurrence we mark. The tour T consists of the edges connecting consecutive marked vertices in W.

The proof that T is k-optimal uses the same basic idea as the lower bound of the approximation ratio in the metric case in [5]: If there was an improving k-move, it has to contain an alternating cycle with negative cost. By construction, the length of every edge in T is bounded by f. Thus, such an alternating cycle would imply the existence of a short cycle in G' that can be transformed to a short cycle in G contradicting its high girth.

The constructed instance has approximation ratio $\Theta(f)$ since on the one hand, almost every edge in T has length $\Theta(f)$ leading to a total length of approximately $f|V(G')|$. On the other hand, the length of the optimal tour can be bounded by twice the length of the minimum spanning tree which is at most $2|V(G')|$ in the case of Graph TSP.

2.4 Outline of Upper Bound for Graph TSP

This subsection comprises a sketch of the proof of Theorem 9. Assume that an instance of Graph TSP (K_n, c) is given where c arises from the unweighted graph G. Let a 2-optimal tour T be given for the instance and fix an orientation.

First, note that every edge with length l corresponds to shortest paths with l edges in G between the endpoints of the edges. Now, if the corresponding shortest paths of two edges share a common directed edge, we see that there is an improving 2-move contradicting the assumed 2-optimality of T (Figure 1). Hence, the directed edges of the corresponding shortest paths are disjoint. Note that the optimal tour contains n edges and hence has length at least n. Thus, if the approximation ratio is high, we must have many edges in the union of the shortest paths corresponding to the edges in T and hence also in G. The main challenge now is to exploit this fact in a good way since a simple bound of $n(n-1)$ on the number of directed edges in G would only give an upper bound of $O(n)$ on the approximation ratio, which is worse than the upper bound of $O(\sqrt{n})$ for Metric TSP.

To get a better result we use the same idea from the analysis of the upper bound for Metric TSP: We contract vertices and get a graph with fewer vertices and many edges. Instead of contracting once, we iteratively partition the vertices into sets and contract each set to a single vertex to get a new graph. (We note that we actually just contract the vertices and construct the edges of the new graph in a slightly different way. But let us assume for simplicity that the edges of the new graph are images of the contraction of edges in the old graph.) Starting with G in every iteration we ideally want to partition the vertices of the current graph into sets, contract each set to a vertex and delete self loops such that:

1. The number of vertices decreases much faster than the number of edges.
2. The subgraphs induced by the sets we contract have small diameter.

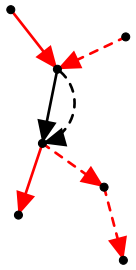

Figure 1 The solid and dashed edges are shortest paths that correspond to two edges in T. If they share a directed edge, there exists an improving 2-move replacing these two edges. The cost of the new edges is bounded by the number of the red edges which is less than the total cost of the two original edges.

The first condition ensures that we get a better bound after every iteration. The second condition builds the connection between the approximation ratio and the number of edges in the contracted graph: It ensures that if the shortest paths corresponding to two edges of T share a directed edge in the contracted graph, then they are also not far away in G, so there is an improving 2-move replacing these two edges. This means that a high approximation ratio would imply a high number of edges in the contracted graph.

Unfortunately, it is not easy to ensure both conditions at the same time even if we know that the graph has many edges as the edges are not equally distributed in the graph. It might happen that there are many vertices with very low degree. If we contract them while still ensuring that the subgraphs have small diameter, the number of vertices cannot decrease fast enough. Therefore, we consider a subset of vertices we call *active* vertices and only require that the number of active vertices decreases fast. If an active vertex has low degree, we will not contract it and consider it as inactive in future iterations. Initially, all vertices are active and we use the following theorem from [11] to find a good partition of the active vertices:

▶ **Theorem 11** (Theorem 6 in [11]). *Given $\epsilon > 0$ every graph G on n vertices can be edge partitioned $E = E_0 \cup E_1 \cup \cdots \cup E_l$ such that $|E_0| \leq \epsilon n^2, l \leq 16\epsilon^{-1}$, and for $1 \leq i \leq l$ the diameter of E_i is at most 4.*

In every iteration we apply the theorem to the subgraph induced by the currently active vertices. The vertices only incident to edges in E_0 become inactive after this iteration. For each of the sets $E_1, \ldots, E_l$ we contract the vertices incident to an edge in the set to a single vertex. These are the active vertices in the next iteration. By choosing ϵ appropriately, we can ensure that the number of vertices decreases significantly and the number of vertices that become inactive in every iteration is small.

After a fixed number of iterations, we have at least one edge and one active vertex remaining. Since the number of active vertices decreased much faster than the edges, we can conclude that G only contains few edges compared to the number of vertices. This implies a bound on the approximation ratio.

3 Upper Bound for Metric TSP

In this section we give an upper bound on the approximation ratio of the k-Opt algorithm.

Fix a $k > 2$ and assume that a worst-case instance with n vertices is given. Let T be a k-optimal tour of this instance. We fix an orientation of the optimal tour and T. Moreover, let w.l.o.g. the length of the optimal tour be 1. We divide the edges of T into length classes.

▶ **Definition 12.** *An edge e is* l-long *if* $(\frac{4k-5}{4k-4})^{l+1} < c(e) \leq (\frac{4k-5}{4k-4})^{l}$.

Note that the shortest path between every pair of vertices has length at most $\frac{1}{2}$ since the optimal tour has length 1. Thus, by the triangle inequality every edge with positive length in T has length at most $\frac{1}{2}$ and is l-long for exactly one l. For every l we want to bound the number of l-long edges. Let us consider from now on a fixed l. In the following we define auxiliary graphs we need for the analysis and show some useful properties of them.

▶ **Definition 13.** *We view the optimal tour as a circle with circumference 1. Let the vertices of the instance lie on that circle in the order of the oriented tour where the arc distance of two consecutive vertices is the length of the edge between them. Divide the optimal tour circle into* $4(k-1)\lceil(\frac{4k-4}{4k-5})^{l}\rceil$ *consecutive arcs of length* $\frac{1}{4(k-1)\lceil(\frac{4k-4}{4k-5})^{l}\rceil}$. *Two vertices are called* near *to each other if they lie on the same arc.*

▶ **Definition 14.** *Let the directed graph* $G := (V(K_n), T)$ *consist of the vertices of the instance and the oriented edges of* T *(an example is shown in Figure 2, the colors of the edges will be explained later). The directed multigraph* G_1^l *arises from* G *by contracting all vertices near to each other to a vertex and deleting self-loops (Figure 3).*

Note that G_1^l may contain parallel edges. Moreover, edges between vertices which are near to each other are not l-long and hence G_1^l contains all l-long edges.

▶ **Lemma 15.** *There exists a coloring of the vertices of* G_1^l *with two colors such that at least* $\frac{1}{4}$ *of the* l*-long edges in* G_1^l *go from a red vertex to a blue vertex according to the fixed orientation of* T.

Proof Sketch. The proof is similar to the standard proof that a maximal cut of a graph contains at least $\frac{1}{2}$ of the edges (see for example Theorem 5.3 in [27]). ◀

▶ **Definition 16.** *We obtain the directed multigraph* G_2^l *by coloring the vertices of* G_1^l *red and blue according to Lemma 15 and deleting all edges that are not* l*-long edges from a red vertex to a blue vertex according to the fixed orientation of* T *(Figure 4, the colors of the edges will be explained later).*

Now, we claim that the underlying undirected graph of G_2^l has girth at least $2k$. In particular, it is a simple graph. Assume the contrary, then there has to be a cycle C with $2h < 2k$ edges since G_2^l is bipartite by construction. We call the preimage of the edges of C in G the C*-edges*. Note that the preimages are unique since we do not delete parallel edges after the contraction.

▶ **Definition 17.** *Let the* connecting paths *be the connected components of* $(V(K_n), T \backslash C)$, *i.e. the paths in* T *between consecutive heads and tails of* C*-edges (the red edges in Figure 2 and 4). Define* head *and* tail *of a path* p *as the head of the last edge and the tail of the first edge of* p *according to the orientation of* T, *respectively. The head and tail of a connecting path are also called the* endpoints *of the connecting path.*

▶ **Definition 18.** *For any two endpoints* v_1, v_2 *of* C*-edges in* G *which are near to each other we call the edge* $\{v_1, v_2\}$ *a* short edge.

The definition of near ensures that the short edges are indeed short. In fact the total length of all short edges is smaller than that of any C-edge. The number of short edges is $2h$ which is equal to the number of C-edges.

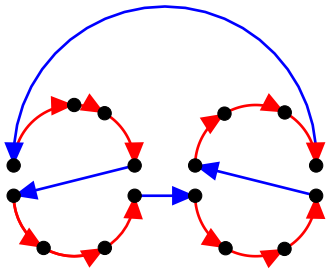

Figure 2 An example instance with a k-optimal tour, i.e. the directed graph G. The blue and red edges are the C-edges and connecting path edges that arise from the chosen cycle in G_2^l in Figure 4, respectively.

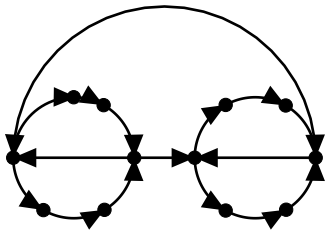

Figure 3 The directed multigraph G_1^l: We contracted vertices that lie near to each other in the optimal tour. Note that the optimal tour is not drawn here, so it is not clear from the figure which vertices to contract.

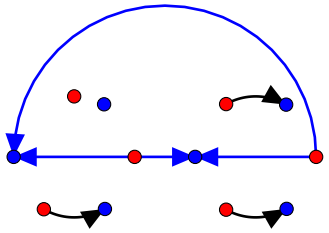

Figure 4 The directed multigraph G_2^l: Coloring the vertices and only considering the l-long edges from red to blue. In this example the upper left edge is not l-long and hence not drawn. The blue edges form the undirected cycle C, the black edges are the remaining edges of the connecting paths corresponding to this cycle.

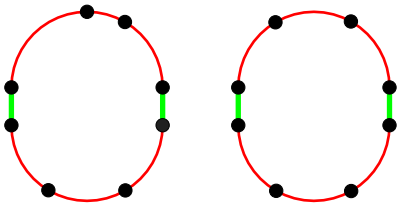

Figure 5 The graph $G_3^{l,C}$: The green edges are the short edges, the red edges are the connecting paths.

▶ **Definition 19.** *We construct the graph $G_3^{l,C}$ as follows: The vertex set of $G_3^{l,C}$ is that of G and the edge set consists of the connecting paths and the short edges (Figure 5).*

▶ **Lemma 20.** *$E(G_3^{l,C})$ is the union of at most h disjoint cycles.*

Proof Sketch. We can show that the degree of every vertex in $G_3^{l,C}$ is two. Moreover, we can see by considering the incident C-edges that the two endpoints of a connecting path are not near to each other since otherwise the common endpoint of the connecting path in G_2^l has to be colored red and blue. Hence, every connected component consists of at least two out of $2h$ connecting paths and we have at most h disjoint cycles. ◀

Now, we show that the existence of C implies that there is an improving k-move contradicting the k-optimality of T.

▶ **Lemma 21.** *There is a tour T' containing the connecting paths and $u-1$ C-edges, where u is the number of connected components of $G_3^{l,C}$.*

Proof Sketch. We construct such a tour T'. Start with a graph G' with the same vertex set and edge set as $G_3^{l,C}$. First, add a set of C-edges to $E(G')$ that makes the graph connected. This is possible since T consists of the C-edges and connecting paths and is connected. We call these C-edges the *fixed C-edges*. Next, add another copy of the fixed C-edges (Figure 6). After shortcutting in a particular way without decreasing $|T \cap T'|$, we get a tour with the desired properties. ◀

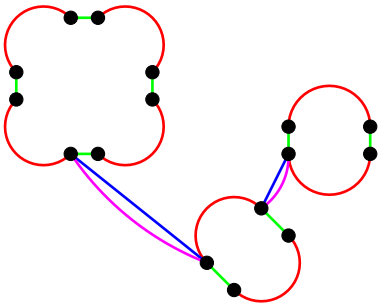

Figure 6 Sketch for Lemma 21. The red curves represent the connecting paths. The green edges are the short edges, the blue edges are the fixed C-edges and the pink edges are the copies of the fixed C-edges. The tour T' results from shortcutting the green and pink edges while leaving the other edges fixed.

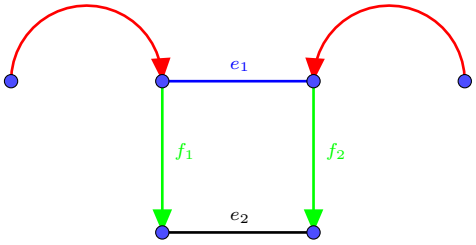

Figure 7 Sketch for Lemma 25. The drawn orientation is that of T'. The red curves represent oppositely oriented connecting paths connected by a C-edge e_1. The green edges f_1 and f_2 are the non-connecting path edges of T' incident to e_1. The edge e_2 connects the other two endpoints of f_1 and f_2 not incident to e_1.

▶ Remark 22. The last lemma already gives us a bound on the girth of G_2^l: By Lemma 20, $G_3^{l,C}$ has at most h connected components. Therefore, we added in the construction above at most $2h-2$ C-edges and some cheap short edges. As T contains $2h$ C-edges, we can show that T' is shorter than T. Moreover, T' arises from T by replacing at most $2h$ C-edges, i.e. by a $2h$-move. If $2h \leq k$, this would contradict the k-optimality of T, hence G_2^l has girth at least $k+1$.

Next, we improve this result and show that G_2^l has girth at least $2k$. We achieve this by starting at T' and iteratively performing 2-moves that are not necessarily improving but include one more C-edge in T'. We stop when the number of C-edges in T' is $h-1$. Then, T' arises from T by a $2h-(h-1) = h+1$ move.

▶ **Definition 23.** *Given a tour T' containing the connecting paths. An* ambivalent 2-move *replaces two non-connecting path edges of T' to obtain a new tour containing at least one more C-edge.*

▶ **Definition 24.** *Fix an orientation of T', we call a connecting path p* wrongly oriented *if the orientation of p in T' is opposite to the orientation in T. Otherwise, it is called* correctly oriented.

▶ **Lemma 25.** *If a tour T' contains a short edge and all connecting paths, then there is an ambivalent 2-move that increases the length of the tour by at most two C-edges.*

Proof Sketch. The coloring of the vertices in G_2^l ensures that every short edge e connects either two heads or two tails of connecting paths. If in addition $e \in T'$, one of them is correctly oriented and the other one is wrongly oriented. Thus, as long as there is a short edge in T', there has to be at least one correctly oriented and one wrongly oriented connecting path. In this case there has to be a C-edge e_1 connecting two oppositely oriented connecting paths since the C-edges connect the connecting paths to the tour T. By definition, every C-edge connects a head and a tail of two connecting paths. If $e_1 \in T'$, the incident connecting paths would be both correctly or both wrongly oriented. Thus, e_1 is not contained in T'. Let e_2, f_1 and f_2 be defined as in Figure 7. Now, we can make a 2-move replacing f_1, f_2 by e_1 and e_2 to obtain a new tour with the additional C-edge e_1. The property that e_1 connects

two oppositely oriented connecting paths ensures that the tour stays connected after the 2-move. By the triangle inequality, we have $c(e_2) \leq c(f_1) + c(e_1) + c(f_2)$ and thus each of the 2-moves increases the length of the tour by at most two C-edges. ◀

▶ **Lemma 26.** *T is not $h+1$-optimal.*

Proof Sketch. By Lemma 21, we can construct a tour T' using the connecting paths and $u-1$ C-edges where u is the number of connected components of $G_3^{l,C}$. We iteratively perform ambivalent 2-moves to increase the number of C-edges in T'. Since after every such 2-move the number of short edges decreases by at most two, we can perform by Lemma 25 a sufficient number of iterations such that we get a tour with $h-1$ C-edges. There are in total $2h$ C-edges, hence the resulting tour arises by an $2h-(h-1) = h+1$-move from T. As every ambivalent 2-move increases the length of the tour by at most two C-edges, we can show that in the end the resulting T' is still shorter than T. ◀

Since $h < k$, this is a contradiction to the assumption that T is k-optimal. Hence, such a cycle C with less than $2k$ edges cannot exist and this gives us a lower bound of $2k$ on the girth of G_2^l. Next, we conclude an upper bound on the length of T:

▶ **Corollary 27.** *For $l^* := \min_j\{j | \sum_{l=0}^{j} 4\,\mathrm{ex}(4(k-1)\lceil(\frac{4k-4}{4k-5})^l\rceil, 2k) \geq n\}$ we have*

$$c(T) \leq \sum_{l=0}^{l^*} \frac{4\,\mathrm{ex}(4(k-1)\lceil(\frac{4k-4}{4k-5})^l\rceil, 2k)}{(\frac{4k-4}{4k-5})^l}.$$

Proof Sketch. Let q_l be the number of l-long edges in T. The definition of near ensures that two vertices which are near to each other have shorter distance than the length of any l-long edge. Hence, G_1^l also has q_l l-long edges. Since we have chosen a coloring according to Lemma 15, G_2^l has at least $\frac{1}{4}q_l$ edges. By the k-optimality and Lemma 26, G_2^l has girth at least $2k$ and thus at most $\mathrm{ex}(|V(G_2^l)|, 2k) \leq \mathrm{ex}(4(k-1)\lceil(\frac{4k-4}{4k-5})^l\rceil, 2k)$ edges. Therefore, $q_l \leq 4\,\mathrm{ex}(4(k-1)\lceil(\frac{4k-4}{4k-5})^l\rceil, 2k)$. This leads to a bound on the length of T. ◀

This is also a bound on the approximation ratio since the length of the optimal tour is 1. With certain assumptions about the growth of $\mathrm{ex}(n, 2k)$, we obtain the main result:

▶ **Theorem 28.** *If $\mathrm{ex}(x, 2k) \in O(x^c)$ for some $c > 1$, the approximation ratio of the k-Opt algorithm is $O(n^{1-\frac{1}{c}})$.*

By a rather technical calculation comparing the upper and lower bound, we get:

▶ **Theorem 29.** *The upper bound from Corollary 27 for the approximation ratio of k-Opt is tight up to a factor of $O(\log(n))$.*
