Foreword

On behalf of the Program Committee Co-Chairs, who are listed below, and the Program Committee of the 2008 International Conference on Software Engineering and Knowledge Engineering (SEKE-2008), it is an honor to welcome you to SEKE-2008 in San Francisco, California. It has been my pleasure as Program Committee Chair to help organize this year's impressive scientific and technical program and the technical proceedings. The proceedings contain the papers selected for presentation at SEKE-2008. I hope these proceedings will serve as a valuable reference for the research community.

The International Conference on Software Engineering and Knowledge Engineering has entered its 20th year. For the past nineteen years, the Conference on Software Engineering and Knowledge Engineering has provided a unique, centralized, forum for academic and industrial researchers and practitioners to discuss the application of either software engineering methods in knowledge engineering or knowledge-based techniques in software engineering. Preference is given to papers that emphasize the transference of methods between both engineering disciplines; however, outstanding papers on software engineering or knowledge engineering alone have also been presented.

This year's program committee consists of the following great team of Vice Program chairs:

Program Co-Chairs:

Guido Wirtz, Bamberg University, Germany
Jerry Gao, San Jose State University, USA
Du Zhang, California State University, USA

The SEKE-2008 Program Committee selected papers for publication in the proceedings and presentation at the Conference based upon a rigorous review process of the full papers. We received an overwhelming 252 submissions from many countries. The acceptance rate for full papers is 48% and for short papers is 16%. This year, authors from 37 countries (Australia, Austria, Brazil, Canada, China, Colombia, Czech Republic, Denmark, Egypt, Finland, France, Germany, India, Iran, Ireland, Italy, Japan, Jordan, Malta, Mexico, Netherlands, Pakistan, Portugal, Singapore, South Korea, Spain, Sri Lanka, Sweden, Switzerland, Taiwan, Thailand, Tunisia, Turkey, United Kingdom, United States, Uruguay, Venezuela) will present papers at the conference.

I appreciate having had the opportunity to serve as the Program Chair for this Conference, and am very grateful for the outstanding efforts provided by the Program Committee Co-Chairs. The Program Committee members and reviewers provided excellent support in promptly reviewing the manuscripts. I want to extend my sincere and deepest thanks to Dr. Shihong Huang and Dr. Masoud Sadjadi as the Publicity Co-Chairs, Dr. Jose' Carlos Maldonado as the South America Liaison. My appreciation also goes to the keynote speakers for sharing their insights and experiences with the conference attendees, and to the SECIML 2008 workshop and special tracks organizers. I am grateful to the authors and sessions chairs for their time and efforts to make SEKE-2008 a success. As always, Dr. S. K. Chang of the Knowledge Systems Institute, USA, provided excellent guidance throughout the effort. Last but not the least, we all owe a special debt of gratitude the heroic efforts of Mr. Daniel Li, of the Knowledge Systems Institute.

Finally, I truly hope that you will enjoy the technical programs of SEKE-2008 and encourage you to explore and enjoy the various attractions San Francisco has to offer.

Taghi M. Khoshgoftaar
SEKE-2008 Program Chair

Keynote I:
Why Doesn't the Software Do What I Need It to Do?
or Aligning IT Objectives with the Business

Cecilia Claudio

Abstract

Software Development has a long and varied history that is littered with many failures and fewer successes. While Software Developers have the best intentions the "results" when viewed from a management perspective often fall short. Schedule and budget overruns are common and often the original business objectives (and certainly the expectations) are not or only partially met. This presentation will examine the historical reasons that have resulted in unmet expectations and various strategies will be discussed for ensuring that expectations are aligned with results.

About Dr. Cecilia Claudio

Cecilia Claudio has spent the last 15 years as CIO at leading organizations and has established a proven track record of transforming IT to become a valued partner to business users. She is currently CIO at SanDisk Corporation, which she joined in February 2007. Previously Ms. Claudio was CIO of Mercury Interactive; Zurich Financial Services; Anthem Blue Cross/Blue Shield and Harvard Pilgrim Health Care.

Ms. Claudio also serves on several boards including Sybase, newScale and DiVitas and has previously served on the board of Farmers Group Inc. She has also served on CIO Advisory boards for Cisco, IBM, Siebel, Syndera and Tablus. She was recognized by Computerworld as one of the Premier 100 IT Executives worldwide in 2001, and has been recognized as one of the Top 100 Women in Computing in the US by McGraw Hill.

Ms. Claudio earned an MA in Philosophy in 1974 in Lisbon - Portugal.

Keynote II:
Impact! The Challenge of Industrial Research in Computer Science in a Web 2.0 World

Laura Haas

Abstract

The IBM Almaden Research Center, located in San Jose, California, is one of eight IBM Research Division facilities worldwide and a premier industrial research laboratory. Currently, over 200 permanent members, postdoctoral scholars, and academic visitors pursue research in computer science and closely related fields. But pressures on industrial research in computer science are increasing. Labs need to be nimble to adapt and to continue to bring value to their company and its customers. In this talk, these pressures and the resulting demands on industrial labs are illustrated through an exploration of several research projects from Almaden's computer science department. We discuss how they are changing IBM's business, their disciplines, and maybe even the world, and the diverse mechanisms they employ to have impact. Projects will be drawn from five different areas in which Almaden specializes, including computer science theory, information management, health informatics, human-computer interaction and services science, and will illustrate a number of different approaches from traditional, academic-style research to "standard" industrial research directly influencing IBM's products to research in the marketplace (featuring work directly with customers, partners and standards bodies) to spin-outs to engagement with educators to influence curriculum formation.

About Dr. Laura Haas

Laura Haas is an IBM Distinguished Engineer and Director of Computer Science at Almaden Research Center. She also leads information management research worldwide across IBM’s eight research labs. Most recently, she was responsible for Information Integration Solutions (IIS) architecture in IBM's Software Group, after leading the IIS development team through its first two years. Dr. Haas joined the development team in 2001 as manager of DB2 UDB Query Compiler development. Previously, Dr. Haas was a research staff member and manager at IBM's Almaden Research Center for nearly twenty years. In Research, she worked on and managed a number of exploratory projects in distributed database systems. She is best known for her work on the Starburst query processor (from which DB2 UDB was developed), on Garlic, a system which allowed federation of heterogeneous data sources, and on Clio, the first semi-automatic tool for heterogeneous schema mapping. Garlic technology married with DB2 UDB query processing is the basis for WebSphere Information Server's federation capabilities, while Clio capabilities are a core differentiator for the new Rational Data Architect. Dr. Haas is an active member of the database community, serving as vice chair of ACM SIGMOD from 1989-1997, and, currently, as Vice President of the VLDB Board of Trustees, as well as on many program committees for technical conferences. She has received several IBM awards for Outstanding Technical Achievement, and an IBM Corporate Award for her work on federated database technology. She is a member of the IBM Academy of Technology, an ACM Fellow, and a member of the board of the Computing Research Association.

Keynote III:
Building Global Ecosystem for Collaborative Computing Research and Education

Yi Deng

Abstract

I will present our experiences in developing international partnerships for collaborative, interdisciplinary computing research and education, from the Latin American Grid Consortium (LA Grid) to the NSF sponsored International Partnership for Research and Education (PIRE) initiative, involving leading universities, industry and governmental organizations in eight countries on four continents. I will discuss our partnership model, our problem-driven research framework, as well as our approach of using research collaboration to drive streamlined education and workforce development.

About Dr. Yi Deng

Yi Deng received his Ph.D. in Computer Science from the University of Pittsburgh in 1992. He currently serves as the Dean of School of Computing and Information Sciences at the Florida International University (FIU) – the state university of Florida in Miami, a position he has held since 2002. He is an accomplished leader in computing research and innovation, and has led many large scale multidisciplinary research and education initiatives. He founded and directed three research centers, including the Center for Advanced Distributed System Engineering, the NSF Center of Emerging Technologies for Advanced Information Processing and High Confidence Systems, and the IBM Center for Autonomic and Grid Computing at FIU. He co-founded the Latin American Grid (LA Grid) Consortium with IBM, an innovative international partnership for computing research and workforce development, with 11 member institutions in the US, Puerto Rico, Mexico, Spain and Argentina.

Transformations for Rapid Prototyping of Time-Critical Applications

Abstract: *Application software nowadays tends to be more intelligent to perform actions autonomously, and the development of such software tends to have shorter turn around time. In our approach for designing distributed intelligence systems, each object called a Tele-Action Object (TAO) is enhanced by an index cell (IC). Objects enhanced by index cells can perform actions by themselves. Therefore intelligence is distributed to these tele-action objects. An IC system is an active index consisting of a network of index cells that embodies a lot of distributed knowledge to enhance the overall intelligence of the application software. In the rapid prototyping of time-critical applications, intelligent application software can be generated by combining the technologies of IC cards, IC system (active index), relational mining and time management to transform IC card specifications into executable codes, thus accelerating and simplifying the development of time-critical applications. The Methodology for this transformation approach is described in detail in this paper.*

1. Introduction

Recent advances in communications technology, web-based applications and service oriented architecture have stimulated the need for application software development with shorter and shorter turn-around time. Nowadays customers require application software to possess the following characteristics: (a) it can integrate web services, components and legacy software into a functioning system; (b) it must be operational before deadline and remain operational until expiration time; and (c) it must satisfy user-specified timing constraints. These characteristics indicate that application software should be intelligent and capable of performing autonomous actions.

In our approach for the rapid prototyping of distributed intelligence systems, each object is called a Tele-Action Object (TAO), which is a multimedia object with associated hyper-graph structure and knowledge structure [4]. A Tele-Action Object can be as simple as a single piece of information without connection or relation to any other objects. Or we can combine several TAOs in certain connections into a new complex TAO and/or add certain knowledge to a TAO. Basically the TAO is further refined as two parts (G, K): hyper-graph G and knowledge K. For a TAO the hyper-graph G is used to describe the connections and relations between the sub-TAOs within it. The knowledge K is used to describe the actions.

The private knowledge specific to that object is enhanced by an index cell (IC). Index cells [2] behave like agents; however there can be numerous index cells. Objects enhanced by index cells can perform actions by themselves. Therefore intelligence is distributed to these tele-

action objects. Objects may also contain multimedia data. An IC system is an active index [2, 3] consisting of a network of index cells that embodies a lot of distributed knowledge to enhance the overall intelligence of the application software.

Based upon index cells and tele-action objects, in the rapid prototyping of time-critical applications we propose an approach by combining the following technologies:

– IC cards,
– IC system (active index),
– Relational Mining for appropriate web services,
– Time Management Techniques.

The IC cards enable the visual specification of an application. It captures the *interaction patterns* and *timing constraints*. The interaction patterns depict how the objects interact with each other, and the timing constraints indicate how much time the objects have for action before deadline. The interaction patterns lead to relational graphs specification and protocols, finally the transformation into IC system (active index). The timing constraints lead to time analysis based upon Petri net. The intelligence of ICs in IC system enables the ICs to automatically locate the agents they want to communicate with, and this relational mining mechanism can be used to discover appropriate web services. In component-based software engineering, "gap fulfillment" of the right components uses a similar approach.

The rapid prototyping environment and tools are illustrated by Figure 1.1. The user/developer first creates and edits the IC cards using the IC Card Management System, which generates an XML specification XMLicc. Next the user/ developer can design an IC system based upon the user requirements specified by XMLicc using the Multimedia Knowledge Eclipse Environment, which in turn produces another XML specification XMLicx. The IC Software Engineering Environment accepts the specification of the IC system XMLicx, compiles it into executable code, runs the code and produces runtime snapshots for tracing the execution. Since traceability is maintained by the rapid prototyping environment, the user/developer can go back to change the requirements by modifying the IC cards, redesign the IC system, and test it again. Using the above tools the rapid prototyping and development of time-critical applications becomes easier and more effective.

The paper is organized as follows. In Section 2 we present the IC card structure and its XMLicc schema. In Section 3 the visual editor for the IC system, MKEE, is described. In Section 4 we show where the XMLicc schema and XMLicx schema differ and how to transform one schema into the other. The compilation of the XMLicx of an IC system into codes is explained in Section 5. Section 6 describes the IC software engineering environment. In Section 7 we discuss further research topics.

2. IC Card and its XML schema

An IC card is the user's or developer's specification of an active object or an agent [5]. An active object usually interacts with other active objects according to certain interaction patterns. There are six basic interaction patterns – *quiet* (meaning this active object has no tasks and has no interactions with other active objects), *by-myself-no-interaction*, *by-myself-with-interaction*, *by-others-no-interaction*, *by-others-with-interaction*, and *mixed* (meaning both active objects have to do tasks and they have interactions). Figure 2.1 shows an example of defining an active object using IC card [5], in which interaction pattern and timing constraint are included.

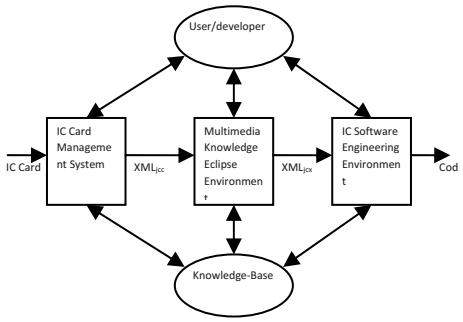

Figure 1.1. Tools for the rapid prototyping environment of time-critical applications.

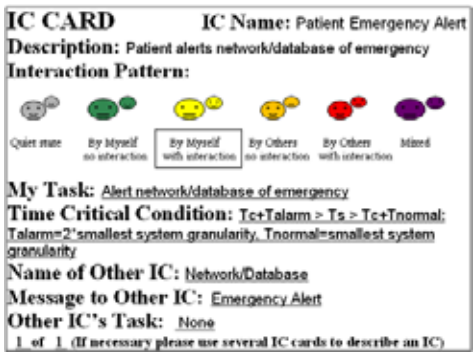

Figure 2.1.An IC card with interaction patterns.

The IC Card Management System enables efficient editing, organization, and management of IC cards. It maintains a list of *icCardEntry*, which is a collection of *icCard*. Each *icCardEntry* has icEntryName, along with EntryId indicating which group an *icCard* belongs to.

For each *icCard*, it includes the following attributes:

– icName: name of the IC
– icId: id of the IC
– icDescription: description for the IC
– icIntPattern: how current IC interacts with another IC, can be one of the six patterns
– icMyTask: task of the current IC
– icTimeCriticalCondition: the timing constraints imposed on the IC
– icNumberTotal: N, the total number of IC cards to describe current IC
– icNumberCurrent: i, the ith IC card (if N IC cards are used to describe the IC)

icCard also has a sub-element *icOther,* which keeps the needed information to interact with another IC. It includes such attributes:

- otherId: the id of the other IC which the current IC will communicate with
- icOtherName: the name of the other IC
- icOtherMessage: the message sent to the other IC
- icOtherTask: the other IC's task

3. The Visual Editor for IC System

The MKEE (Multimedia Knowledge Eclipse Environment, can be found at http://eclipse.dis.unina.it/MkeeSite/) is an Eclipse Development Environment that provides the modeling of multimedia applications and the sharing of knowledge owned by multimedia objects. A multimedia application can be modelled in terms of intelligent objects, i.e., the TAOs [4], which are tele-action objects related by hyper-graph G and enhanced by knowledge K. Every object reacts differently depending on the input that it receives from the outside. The mechanism of answering to the stimuli can be realized by associating a private knowledge to the TAO through the Index Cells [2]. Therefore the application software constructed using this approach supports both the static description of the multimedia application in terms of TAO objects, and the definition of Index Cells net representing the dynamics structure.

A typical IC system is made up of a series of interacting Index Cells, which communicate with each other through message passing. A typical Index Cell has such structure as shown in Figure 3.1:

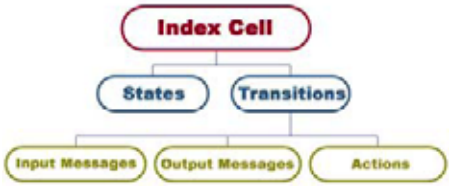

Figure 3.1. The Index Cell Structure.

The Index Cell is a particular Finite State Machine which accepts Input messages, executes operations and sends one or more output messages to one or more IC or to external environment. The amount and type (or types) of IC depends on the state and Input Messages. It is a Mealy model machine and, according to the problem domain, could be deterministic or non-deterministic, but as theory states, any ND-FSM could be transformed in a deterministic FSM.

An example of the visual specification of an IC system based on the healthcare application is illustrated in Figure 3.2. In this IC system, *Camera* captures patient's images and *Sensor* captures patient's health conditions such as blood pressure and temperature. A disabled

patient cannot make alert request by himself/herself, so an alert is initiated by *Sensor* and/or *Camera*. *Emergency Alert* forwards the alert information to *Hospital Response* when any parameter's threshold is reached. Then both the *Doctor* and *Nurse* will be informed. *Nurse* will be dispatched to assist the disabled patient if necessary, and *Nurse* can communicate with *Doctor*.

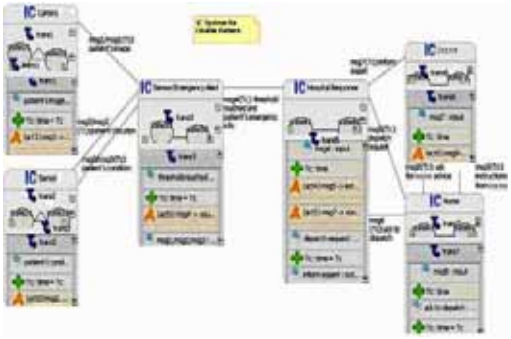

Figure 3.2. A Disabled Patient IC System.

MKEE has the advantage to be a hardware/software platform independent and enable designer to speedily generate application. These advantages are very important in the healthcare environment where a lot of hardware devices and interface to manage there exists. The MKEE tool generates XMLicx specifications of the IC system. Therefore it can be used to serve as the front end for the IC system compiler.

4. Mapping between IC Cards and MKEE IC System

In MKEE the Index Cell is a little different from the IC depicted by IC card. While mapping the same name and id from IC card to Index Cell, Index Cell provides more details such as states and transitions than IC card does. Although the visual representations of IC card Management System and the MKEE IC System are different, they both can be represented by XML, which facilitates the sharing of data across different information systems. Figure 4.1 shows the tree-structured XML schemas used in IC card and IC system.

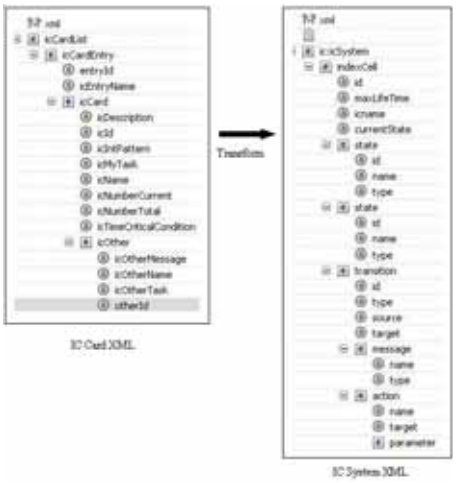

Figure4.1. IC Card XML and IC System XML

The mapping between IC card in IC Card Management System and Index Cell in MKEE IC system is shown in Table 4.1. The matching shows that the two specifications are indeed compatible.

Table 4.1. Map IC Card to MKEE IC System

IC Card Management System	MKEE IC System
icCardType.icId	IndexCell.id
icCardType.icName	IndexCell.name
icOtherType.icOtherMessage	Message.name (The message sent to target IC)
icOtherType.icOtherName	IndexCell.name of other IC (The target IC name of output message)
icCardType.icMyTask/ icOtherType.icOtherTask/ icCardType.IntPattern	Relate to the action target in transition (external/source)
icCardType. icTimeCriticalCondition	Parameter.dataValue (Time parameter in messages)

Specifically for the timing constraints, users can indicate the time during which a task should be done in an IC card's TimeCriticalCondition field. In an IC system, similar timing constraints can be imposed through the parameter of message in transition.

Since both IC Card Management System and MKEE are built on Ecore models, we can use IBM Model Transformation Framework (MTF) to implement partial transformations between the two models. MTF provides an extensible rules language that can be used to define what the

transformation should accomplish, and a transformation engine which can interpret the rules in order to perform the transformation. MTF works on models described by a compatible meta-model in order to express the correspondences in a consistent way. The output of MTF transformation is a set of mappings that relate the objects of two models. The user can specify the mapping as a *relation* that defines the type of mapping that will apply to model class instances.

5. Compiling IC Specifications

Modern compilers are typically made up of five conceptual phases. The first three phases, lexical analysis, syntax analysis, and semantic analysis, are grouped together to form the compiler's front end. The fourth conceptual phase is code optimization and is referred to as the middle end. The final phase, dubbed the back end, is the code generator.

The front end is responsible for recognizing validity, or lack thereof, of source language. It also shapes the source language into an intermediate representation (IR), typically an abstract syntax tree (AST) for the middle and back ends. In the case of the IC system, the MKEE visual editor creates the AST. The AST is then analyzed for proper semantics by the compiler. Upon completion of semantic analysis, the task of the front end is complete.

The middle end of the compiler analyzes and transforms the IR through optimizations, so as to improve code quality such as reduced execution time. The IC system compiler does not currently perform any optimizations.

The back end generates the final output in the target language. Contrary to the front end, the back end is source language independent and target language dependent. The IC system compiler generates Java classes, which can be used in cross-platform web applications.

5.1. Input to the IC System Compiler

The MKEE tool is an Eclipse visual editor for specifying IC system. It outputs an XMLicx file describing an IC system. XML documents, due to their inherit tree structure, provide an obvious mapping to an AST in a typical compiler. Once the XML file is created, it can be processed by the IC system compiler. The compiler reads in the XML file, and creates an internal IR. The MKEE tool outputs valid XML files. However, the XML may not be semantically correct for code generation. Semantic analysis is performed on the IR, and, pending valid semantics, output as a set of Java classes. The Java classes can in turn be used in web based *Java Server Pages* (JSP) applications. When a JSP page is accessed, a web page is dynamically created by compiling the Java classes used by the page. The use of server side computation and the Java programming language allows for platform independence and rapid development of web applications.

5.2. Semantic Analysis

The top level of the IC system is a collection of Index Cells. Index Cells are composed of States and Transitions. For type checking purposes, all immediate children of an Index Cell must be of type State or Transition. States themselves must have a type of internal, entering, or ending. A value of entering indicates that this is a start state. All Index Cells must have exactly one State of type entering. There can be multiple ending and internal states. Each Index Cell must also have a maximum lifetime value. Index Cell's which do not persist forever will have a numeric value specifying the lifetime in milliseconds. Once the length of the lifetime has expired, the Index Cell will die.

Transitions are hierarchal objects composed of Actions, Input Messages, and Output Messages. Transitions have a source state and a target state. Both the source state and the target state must be resolvable to valid State structures. Transitions also must have a type of boundary or internal. Internal transitions occur between states in the same Index Cell. Boundary transitions occur between states in different Index Cells and are used to pass messages. Internal transitions

areused to drive the progression between States in an Index Cell.

Messages and Actions are composed of Parameters. Parameters must have a data type and data value, as well as a name property. Output Messages have a Target Index Cell that must be resolvable to a valid Index Cell. Actions have simple semantics, requiring only a name.

5.3. Code Generation

The code generator of the IC system compiler creates a set of Java classes that can be used in JSP applications. The code generator is based on a set of transformation rules. The following example illustrates the transformation from MKEE formatted XML to Java code. It is worth mentioning that names in MKEE are entered by the user. The user-provided names are transformed to ensure that they are valid identifiers in the Java language. A simple Index Cell taken from the previously described disabled patient IC system is shown in Figure 5.1. The visualization of the Index Cell will result in the MKEE XML in Listing 5.1. The MKEE XML is passed to the compiler. The compiler will apply a set of transformation rules to the XML resulting in Java source code. Table 5.1 contains a non-exhaustive listing of transformation rules used in the compiler. Transforming most of the XML is a relatively straightforward process. Transitions provide the most challenging transformation process. The Transitions along with the States are transformed into the Index Cell's transition function. The Java implementation of the transition function for the example Index Cell is shown in Listing 5.2.

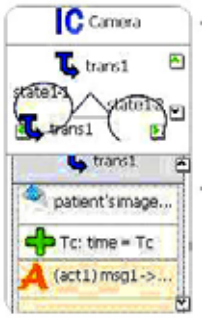

Figure 5.1. Visualization of an Index Cell.

```
<indexCell
currentState="//@icSystem/@indexCell.0/@state.0" id="ic1"
maxLifeTime="infinity" name="Camera">
   <state name="state1-1"/>
   <state name="state1-2"/>
   <transition id="trans1"
source="//@icSystem/@indexCell.0/@state.0"
target="//@icSystem/@indexCell.0/@state.1">
     <message xsi:type="ic:OutputMessage" id="msg1"
name="patient's image">
       <targetIC>ic3</targetIC>
       <parameter dataType="time" dataValue="Tc"
name="Tc"/>
     </message>
     <action body="collect image info periodically" id="act1"
name="msg1" target="source"/>
   </transition>
</indexCell>
```

Listing 5.1. Specification of an Index Cell.

Table 5.1. Example Transformation Rules.

MKEE XML		Java Transformation
<indexCell id="α">	→	public class α extends IndexCell
<indexCell currentState="β">	→	This.currentState = β;
<parameter dataType="τ"/>	→	new τ()
<action id="ρ">	→	private void ρ()
<targetIC>ψ</targetIC>	→	Ψ
<message id="ω">	→	new ω ("α", "ψ", τ)

```
public void transition() {
  switch( this.currentState )
  {
    case icSystemindexCell0state0:
      changeState( icSystemindexCell0state1 );
    break;
    case icSystemindexCell0state1:
      if ( this.previousState ==
           icSystemindexCell0state0 ) {
      act1(); postMessage( new msg1( "ic1", "ic3",
      new Object() ) );
      }
      else stateError();
    break;
    default:
      stateError();
  }
}
```

Listing 5.2. Example Transition Function.

In the target code, each Index Cell is implemented as a separate Java class. Each Index Cell class is a thread, in order to allow multiple Index Cells to run concurrently. The States of an Index Cell are implemented as a finite state machine based on the Transitions between them. Messages are implemented as objects which are passed between Index Cells.

The Messages' Parameters are implemented as the objects' data fields with corresponding inspector functions. Actions are implemented as function calls. An Action's Parameters correspond to the arguments to the function. Each Index Cell transitions through its state machine until its lifetime expires. On state transitions, any corresponding output messages and actions are executed. If the next state expects an Input Message, the thread will sleep until it receives any messages it is expecting. Finally, the next transition will be taken.

The code generator can be enhanced by relational mining as follows. If through the relational mining technique an appropriate web service is found to perform certain functions, then the code generator will only produce the Java class to invoke the available web service.

6. The IC Software Engineering Environment

The IC Software Engineering Environment (ICSEE) is an environment for compiling and generating Java codes from MKEE XML output. Figure 6.1 illustrates the interface of ICSEE. The ICSEE main screen shows the various stages including *UploadXML*, *Parsing*, *Generate*, *Compile*, *Load* and *Instantiate*, as well as the options of *Save*, *Delete*, *Logout*, and *ReadMe*. We will also use the disabled patient example here. Figure 6.1 illustrates the results after *UploadXML*, showing the various Index Cells.

After uploading the disabled patient XML which is generated by MKEE, click the "*Parsing*" button. Then all the Index Cells including Camera, Sensor, Sensor Emergency Alert, Hospital Response, Expert, and Nurse will be parsed and displayed in "Index Card Information" section. The Java source code will be generated at the server side when user clicks "*Generate*". The server will start compiling the generated Java source code, and the compiled classes will be saved. When clicking "*Load*", the generated classes will be loaded into JVM; when clicking "*Instantiate*", the created instances will be displayed in the "Index Cell Instances" section.

Using ICSEE the user/developer can easily test and trace the rapid prototyping process. The generated Java code also lays the foundation for further developing application software.

7. Discussion

The transformation approach for rapid prototyping of intelligent software applications is described in this paper. The transformation from IC systems into codes enables the user/developer to explore the design space based upon different IC systems. However the transformation from IC cards to IC systems is still at best a manual process. Our next objective should be to (partially) automate this transformation.

There are different ways to realize the transformation from IC cards to IC system: developing syntactic transformation on the XML documents, or developing graph transformation algorithms to produce a target graph from the initial graph, or using some AI techniques such as rule-based approach. Following the first approach, now we can find the matching between IC cards and IC system and define the mapping rules between the two models. However the IC cards represent an initial specification without details about interaction protocols, timing considerations and protocols. The mapping rules are incompletely defined. Therefore the other approaches are still necessary and require further investigation.

Acknowledgements:

Giuseppe Marco Scarfogliero and Lorenzo Sorrentino implemented the initial version of MKEE, the IC System Visual Editor. Dan Li implemented the software engineering environment (ICSEE) for the IC System Complier. Robert Zaremba provided the details on the implementation of remote IC subsystems. Their contributions are acknowledged.

Case Study: Applying Business Process Management Systems

Gregor Scheithauer* and Guido Wirtz

Feldkirchenstraße 21, 96052 Bamberg, Germany
gregor.scheithauer@gmail.com, guido.wirtz@uni-bamberg.de

Abstract

Business Process Management Systems aim to support the Business Process Management paradigm and to ease legacy application integration. However, do such systems really meet real-world requirements? This paper introduces and discusses a set of criteria which are important for business process management systems and applies these criteria in comparing tools from three important vendors, namely IDS Scheer*,* Oracle *and* Intalio *based on a real-world case study.*

Keywords: BPMS, usability criteria, Webservices

1. Introduction

Business Process Management Systems (BPMS) [7] are sets of tools to support the Business Process Management (BPM) life-cycle [5] that are either offered by one vendor, or multiple vendors offer parts of a BPMS. Smith [6] sees a list of key advantages in using a modern BPMS: it bridges heterogenous application environments, includes human activity by incorporating workflow, allows web service orchestration, provides the opportunity to customize the whole process for specific customers and partners, offers an integrated user interface through a single portal and back-end integration, and monitors process instances. Rather than introducing new technology or replacing existing business applications, BPMS integrate existing technologies and existing applications in a process-oriented fashion. Based on this notion of BPMS, Smith and Fingar [7] describe requirements for a BPMS as follows: a BPMS should be able to support modeling, deploying, and monitoring business processes, as well as to support integration of heterogeneous processes, automatization, and collaboration.

Table 1 depicts which BPMS tools support what step in the BPM life cycle. Business process design includes process documentation with a process notation, such as Event-driven Process Chain (EPC) [3] notation and Business Process Modeling Notation (BPMN) [9]. Configuration includes the transformation [2] from process models into formal languages such as the Business Process Execution Language (BPEL) [1]. Integration facilitates better reuse of existing applications. BPMS allows easy deployment of configured process models, and to execute them.

*The first author is funded by means of the German Federal Ministry of Economy and Technology under the promotional reference 01MQ07012.

This paper summarizes the results of a case study to find out if prominent existing BPMS meet real-world expectations. Based on a detailed list of evaluation criteria covering all steps relevant for BPMS (section 2), a real-life scenario is used to evaluate two different BPMS - a multi-vendor system based on tools from *IDS Scheer* and *Oracle* as well as a single vendor system provided by *Intalio* (section 3). The results are summarized in table 2. A more detailed description of the scenario and the case study implementation as well as a more in-depth discussion of the results is documented in [4].

2. Evaluation Criteria

The criteria used to evaluate BPMS tools take a holistic view on the entire process. The 23 criteria are clustered into three layers which are introduced in [5]: questions 1–9 cover the business layer, questions 10–19 address the integration layer, and questions 20–23 address the execution layer. The questions represent real-world requirements originating from an industry project.

1. *What kind of people are involved during design and improvement in the BPM life cycle*. These steps need to be business driven, and flexible, thus, people who manage business processes, need to be in the position to express their understanding of business, without technically founded limitations.
2. *Standard or proprietary design notation* points out if the process design notation in question was standardized by a group such as OMG or OASIS, or if it is a vendor specific format. Moreover, does the standard cover the graphical elements and the persistence of the notation? By using a standard notation, it is easy to switch process design tools or exchange process diagrams between different process design tools.
3. *Industry acceptance* shows if a process design notation is widely used in industry. Established notations are more likely to provide supporting technologies and middle-ware. In addition, if a design notation is widespread, it might undergo further and constant improvements.
4. *Completeness* of process design notations denotes the expressive power of a notation (cf [8]). Business

Table 1. BPM tools used in the process life cycle

		Design	Configuration	Integration	Deployment	Execution
IDS Scheer (ARIS)	SOA Architect		X	X		
	Business Architect	X				
Oracle	Process Manager					X
	BPEL Designer		X	X	X	
Intalio	Process Server					X
	Process Designer	X	X	X	X	

analysts need elements to express business tasks, business objects, and business partners. Missing elements result in complex process diagrams emulating missing constructs, which are difficult to maintain.

5. *Data management*. indicates the possibility to design business objects with the process design tool. Business objects make the process diagram semantically richer and better to understand for process stake-holders.
6. *Is a methodology behind process design notation*. A methodology covers the semantics of the notation and reduces the complexity of business process design via guidelines how to use and how to combine the elements of the notation.
7. *Does the design tool support the full design notation in its recent version.* The more a tool supports a design notation standard, the greater the ability to exchange process diagrams.
8. *Diagram repository* states if the process design tool accesses diagrams from a shared repository or from a local machine. A process repository has the advantage that more people are allowed to access processes, thus, processes are viewed and re-viewed by more people, which, to an extend, improve process diagrams.
9. *Process version control* shows if a process design tool contains or has access to version control. Next to a shared repository, this is a very useful tool for maintaining process diagrams. Business analysts are able to roll back to a prior version of the process, if necessary, or browse the evolution of a process for a better understanding of the meaning behind the current version.
10. *What kind of people are involved in the configuration and the integration step of the life cycle.* Process diagrams should not be altered much to be executed. No change in business logic should be needed, but a technical mapping is required. People on this level must not be faced with the complexity of business logic.
11. *Compatibility of design notation and execution language* refers to what extent the design notation is transformable into the execution language. There are two main reasons for incompatible languages: (i) languages are either block-oriented or graph oriented or, (ii) languages may support different concepts and use richer semantics.
12. *Standard or proprietary execution language* points out if the execution language in question was standardized, or if it is vendor specific. This covers the language and the persistence of the language. Using a standard language eases switching execution engines or exchanging process configurations between different engines.
13. *Industry acceptance* shows if an execution language is widely used in industry. Besides the importance to use standards, it is necessary to find supporting technologies and middle-ware to support execution languages.
14. *Message type management*. Is it possible to design or even import message types with the configuration tool? Next to configure the flow of business tasks between applications, departments and companies, it is necessary to define message types. These types may be imported from service definitions, database table definitions or class definitions from a programming language. Otherwise, they might be defined with the configuration tool.
15. *Configuration complexity* measures how many tools are needed for a successful process configuration. Besides an integrated configuration tool, it may necessary to apply configuration to other middle-ware before deployment is possible. The more tools and middle-ware need to be configured, the higher the complexity.
16. *Is process configuration part of a shared repository*. This criteria points out if the configuration tool accesses process configurations from a shared repository or from a local machine. The former has the advantage that more people access the configuration, thus process configuration might be adapted by many people.
17. *Is the process configuration attached to the process diagram*. If there is a well-defined link between a process diagram and the process configuration, changing the diagram as well as the configuration consistently becomes much easier.
18. *Is process configuration bound to one execution platform* refers to the *vendor lock* issue. This is the case, if process configurations are only be executed on the platform which the process diagram was configured with. This may happen if execution engines do not support standards or industry accepted execution languages. A vendor lock makes it difficult to switch between different execution engines.
19. *Legacy applications integration* explains what kind of applications and their services may be integrated. However, middle-ware technology makes it possible to integrate those application as services.
20. *What kind of people are involved in the deployment step*. System analysts should be qualified to accomplish this task. If other than the system analyst needs to be involved, process deployment is a too complex step.

21. *Deployment tool integration* tells whether a deployment tool is integrated into an IDE or not. Users do not need different tools, the acceptance of the user is higher and users already know how the tools behave.
22. *Deployment complexity* measures how many tools are needed for a successful process deployment. Next to an integrated deployment tool, it may be necessary to deploy to more than one execution engine. The more deployment steps are required, the higher is the complexity for process deployment.
23. *Process version control*. This refers to what will happen if instances of a process are running and a new version of that process will be deployed. There are four possibilities. Firstly, all instances are stopped and deleted. The new process will be deployed. Secondly, a deployment of a new version is refused, when instances of that process are still running. Thirdly, the tool tries to merge running instances with the new process definition. If a merge is possible, the new version will be deployed, otherwise the deployment will be refused. Running instances may run until they terminate. New instances are based on the new version of the process. The old version of that process will be archived when every instance has been terminated.

These criteria are used to evaluate the different tools when realizing the example process that is introduced next.

3. Case Study and Results

Two companies are involved in the case study: *Shade Tree Garage* (STG), a garage shop in New Jersey, repairs cars for nearly all makes of cars wehereas the *SPC* company manufactures car spare parts and distributes them to garage shops. Prices for spare parts are not fixed and change on a daily basis. Shade Tree Garage wants to minimize its stocking costs and to maximize planning reliability. SPC identifies this demand as a selling proposition, and intends to offer a *Garage Shop Information System* (GSIS) to garage shops.

The business process, which is shown in figure 1, offers price information and quantity information for spare parts to garage shops. On the business level, the following business tasks are identified: (1) *Request spare part information* on the garage shop side, (2) *Receive spare part information request*, (3) *Get price information for spare part*, (4) *Get quantity information for spare part*, and (5) *Send spare part information* on the SPC side. The business objects include (1) *unique ID for spare parts*, (2) *Price*, and (3) *Quantity*. On the service level, two services are needed: (1) *PriceService*, and (2) *QuantityService*. Both services are available as web services and provide a WDSL file. The appropriate message exchange pattern between SPC and garage shops is a Request-Response pattern. To access the GSIS, the *GSISRequestMessage* is used which contains a placeholder for a spare part ID. Spare part information is received by the *GSISResponseMessage* which contains a placeholder for price and quantity information.

The case study comprises an end-to-end business process that contains reasonable business logic and has relevance in today's business. Moreover, it spans more than one company's department and more than a single application. Hence, it is suitable to check technical capabilities and business to business integration issues. The results of applying our criteria when implementation GSIS using two different BPMS are summarized in table 2; for a detailed discussion refer to [4].

4. Outlook

Future work has to include better integration of different tools into a BPMS. Further adoption and improvement of standards, such as BPEL, and WSDL might tackle this issue. Tool providers must enhance tool functionality and better separate the roles in the life cycle. Moreover, process design notations must advance in the direction of BPMS, that is, that business processes are intended to be supported by webservices. Lastly, as business processes become executable and traceable by means of process portals, BPMS should permit the monitoring of important data and processing of this data. Business analysts might even model Key Performance Indicators (KPI) with a process design notation and get processed results for process instances on those indicators. This allows to identify bottlenecks and shortages in business processes.

Only after lots of ambitious efforts and their successful completion over the next years, BPMS will become easier to use during the entire life cycle of business processes.

Verification of optimization algorithms: a case study of a quadratic assignment problem solver

Tsong Yueh Chen[*], Huimin Lin[†], Robert Merkel & Daoming Wang

Abstract

It is often difficult to verify the solutions of computationally intensive mathematical optimization problems. Metamorphic testing is a technique to verify software test output even when a complete testing oracle is not present. We apply metamorphic testing to a classic optimization problem, the quadratic assignment problem (QAP). A number of metamorphic relations for the QAP are described in detail, and their effectiveness in "killing" mutated versions of an exact QAP solver is compared. We show that metamorphic testing can be effectively applied to the QAP in the absence of an oracle, and discuss the implications for the testing of solvers for other hard optimization problems.

1 Introduction

In software testing, an "oracle" is a means by which it is determined whether the output of a test case meets the software's specification. In some cases, a convenient oracle is readily available; however, there are many situations where the oracle's evaluation is manually conducted, a slow and error-prone process. For some applications - a notable example is scientific simulation - even this may not be possible.

Metamorphic testing is a testing technique designed to allow the checking of test output where there is no oracle, or it is too expensive to verify against the oracle [1]. In this paper, we investigate the use of metamorphic testing on a class of problems where oracles are difficult to find - mathematical optimization problems. A classic example of this class, the quadratic assignment problem, serves as the subject of our case study.

1.1 The Quadratic Assignment Problem

Mathematical optimization problems, in general, involve finding the maxima or minima of functions, usually taking into account constraints of the function parameters. Many practically important classes of optimization problems are NP-hard[1], or even harder. In practice, given that we need an actual solution rather than simply knowing the existence of one, this means that verifying that a solution is indeed optimal can be very difficult.

The Quadratic Assignment Problem (QAP) is a classic example of this kind of difficult operations research problem. Informally, the problem can be viewed as "the assignment of facilities to locations" [2]. For example, consider a company which intends to build k factories denoted as $f_1, f_2, \ldots, f_k$. The factories can be constructed in k distinct locations $l_1, l_2, \ldots, l_k$. The output of some factories is used as the input to others. The amount of goods that will move between factories is quantified as the "weight". This weight can be represented as a $k \times k$ matrix w, where $w(i, j)$ represents the weight of the items moving from factory f_i to factory f_j.

The relative expense of moving items around between locations can be represented in another $k \times k$ matrix c, where $c(i, j)$ represents the cost of moving a unit of weight from location l_i to location l_j. In many real-world applications, the cost corresponds to the distance between two locations. Therefore, it is common for $c(i, j)$ and $c(j, i)$ to be the same for all i and j, and thus for the matrix to be symmetric, but this is not compulsory according to the formal definition of the problem. The quadratic assignment problem is to assign factories to locations such that the total transport cost is minimised. More formally [3], the goal is to find a bijection $g : \{f_1 \ldots f_k\} \rightarrow \{l_1 \ldots l_k\}$ such that the following summation is minimised:

$$\sum_{i=1}^{k} \sum_{j=1}^{k} w(i, j)\, c(g(i), g(j)) \qquad (1)$$

Like many other optimization problems, the solution g may not be unique (as will be illustrated in section 2.1).

Given that the problem is NP-hard, and the obvious practical applications, there has been a great deal of research to find efficient approximation algorithms for the QAP (see [4] for a survey).

In this paper, however, our interest in the QAP was in demonstrating the detection of faults in an exact QAP solver.

[1] in their decision problem form

Lau [5] provides such a solver, implemented in Java. Primarily intended for educational purposes, this solver meets our needs as a relatively straightforward implementation that could be easily incorporated into a test harness. Lau's code base contains a large number of other methods that implement other optimization algorithms, that are not executed when using the QAP solver. To avoid irrelevant and time-consuming processing of this code in our experimental setup, methods unrelated to the QAP (and thus never executed) were removed from the source code.

1.2 Metamorphic Testing

Metamorphic testing [1] is a method for verifying test output in the absence of an oracle. It is based on the idea of taking pre-existing *source* test cases T, and systematically generating a set of *follow-up* test cases T' based on T. While it may not be known directly whether the program output on individual members of T or T' is correct, T' is constructed in such a way so that certain relations between T, T', and their corresponding outputs, must hold if the software is functioning according to its specification.

To take a simple example, consider that the software under test is designed to compute the sine of an angle θ. Elementary trigonometry tells us that $\sin(-\theta) = -sin(\theta) \forall \theta$. We can use this property as a *metamorphic relation* to derive follow-up test cases and relationships between the outputs for the original and follow-up test cases. Therefore, if we have executed a test case θ_i with output s_{θ_i}, we can derive a follow-up test $-\theta_i$. The output from the execution of the follow-up test case $-\theta_i$ must be equal to $-s_{\theta_i}$ for the metamorphic relationship to hold. If it does not, then a failure in the software under test is revealed.

This metamorphic relation is a simple one-to-one correspondence between a single source test case and a single follow-up test case, but metamorphic relations can be defined between multiple tests. For instance, consider the trigonometric tangent function. The tangent addition formula states that for angles θ and ϕ, $\tan(\theta + \phi) = \frac{\tan\theta + \tan\phi}{1 - \tan\theta\tan\phi}$. To use this metamorphic relation with two source test cases, θ and ϕ, a follow-up test case $(\theta + \phi)$ is constructed and executed, and the metamorphic relation is then checked. Furthermore, while these examples have made use of an equality relationship, this is not obligatory; other relationships can be defined, such as inequalities, greater-than or less-than relationships, or non-numeric relationships such as subsets.

Metamorphic testing has been examined in a number of contexts, including COTS component testing [6], context-sensitive middleware [7], and programs involving symmetries [8]. It has been shown to provide effective testing in the absence of an oracle.

In this paper, we seek to demonstrate the application of metamorphic testing for a solver of a well-known optimization problem.

2 Some Metamorphic Relations for the QAP

For most software under test, there are many valid metamorphic relations that might be used to check software correctness. However, not all of them will be effective in revealing software failures; as a trivial example, if we have a program P that takes some input I (assuming there is no internal state), and returns P(I), clearly P(I) = P(I) for all I. However, this will probably reveal only a very few failures.

We devised a number of metamorphic relations that we hoped would be effective for evaluating the correctness of a QAP solver. The three types of metamorphic relations (six relations in total), were identified quickly, over a few hours. None of the authors had any previous experience in the area of QAP solvers. All the metamorphic relations we constructed, were evaluated experimentally. We did not cherry-pick a few satisfactory metamorphic relations from a much larger, mostly unsatisfactory bunch!

2.1 Relabelling

The labelling of factories and locations in the QAP does not affect the nature of the solutions, only their names. For instance, assume that we have a QAP of size 3 with an optimal assignment of f_1 to l_2 f_2 to l_1 and f_3 to l_3. If we relabel factories f_1, f_2, and f_3 as $f_2\prime$, $f_3\prime$, and $f_1\prime$ respectively, without changing the weights between the relabelled factories, we know that assigning factory $f_2\prime$ to l_1, $f_3\prime$ to l_2, and $f_1\prime$ to l_3 will be optimal for the relabelled QAP.

However, for any given QAP, there may be more than one optimal solution - for a trivial example, consider a QAP where all weights are zero and hence every possible assignment is an optimal solution. However, the QAP solver does not guarantee to return any particular optimal assignment. Therefore, we cannot assume that the optimal solution found to a relabelled problem will be the corresponding relabelling of the optimal assignment found for the original problem. However, all optimal solutions by definition have the same total cost; therefore, any optimal solution to the relabelled problem will have the same total cost as the optimal solution to the original problem.

Consider the QAP denoted by Q_a with weight and distance matrices defined as follows:

$$w_a = \begin{matrix} 0 & 5 & 8 \\ 0 & 0 & 0 \\ 0 & 4 & 0 \end{matrix}, c_a = \begin{matrix} 0 & 7 & 2 \\ 7 & 0 & 10 \\ 2 & 10 & 0 \end{matrix} \quad (2)$$

If we relabel the factories such that $f_1\prime = f_3$, $f_2\prime = f_1$, and $f_3\prime = f_2$, we can obtain a weight matrix $w_a\prime$:

$$w_a\prime = \begin{matrix} 0 & 0 & 4 \\ 8 & 0 & 5 \\ 0 & 0 & 0 \end{matrix} \quad (3)$$

Similarly, if we relabel the locations $l_1\prime = l_2, l_2\prime = l_3, l_3\prime = l_1$, we get a distance matrix $c_a\prime$:

$$c_a\prime = \begin{matrix} 0 & 10 & 7 \\ 10 & 0 & 2 \\ 7 & 2 & 0 \end{matrix} \quad (4)$$

The QAP instance $Q_a\prime$, with weight matrix $w_a\prime$ and distance matrix c_a has an optimal solution with exactly the same cost as Q_a. The QAP instance $Q_a\prime\prime$, with weight matrix w_a and distance matrix $c_a\prime$ will also have an optimal solution with the same cost, as would (though we did not use this) $Q_a\prime\prime\prime$ with $w_a\prime$ and $c_a\prime$.

We implemented this metamorphic relation by developing a tool that randomly permutes the weight of any given problem instance, and then separately permutes the distance of the problem instance, resulting in two follow-up problem instances. The QAP solver is then used to solve both the source problem instance Q_a and the two follow-up problem instances $Q_a\prime$ and $Q_a\prime\prime$. The total cost of all three must be equal.

2.2 Adding a new factory

There is no straightforward way to predict the effect on the optimal solution after an arbitrary addition of a factory and location to an existing QAP. However, if it is possible to ensure that any optimal solution must have the new factory being placed in the new location, calculating the cost of the optimal solution to the expanded problem, is then quite straightforward.

One way to ensure this is to make the new location a very long distance M from all the existing locations (much greater than distances between existing factories), and assign zero weights between the new factory and all existing factories. As discussed earlier, there is the possibility that there are multiple optimal solutions to the original QAP, and therefore there are multiple optimal solutions for the expanded QAP. If this is the case, we cannot be sure that the optimal solution found by the solver for the expanded QAP will simply be the optimal solution found for the original one, with the new factory assigned to the new location. Regardless, any optimal solution must have the new factory in the new location, and hence the total cost must not change.

One potential flaw in such a scheme is that there are still certain obvious types of faults that such a relation will not detect. For instance, consider a bug in the cost calculator such that it always finds a total cost of 0, regardless of the assignment of factories to locations. Therefore, a modified version of this metamorphic relation was sought. Instead of zero weights between the new factory and all existing factories, one existing factory f_i is chosen randomly, and a weight smaller than all existing non-zero weights is assigned between the new factory f_n and f_i, with weights between the new and existing factories other than f_i set to 0. In this case, the new factory will still be assigned to the new location, but the cost of an optimal solution will be increased. If the distance between f_n and f_i is d, and the weight is ϵ, the total cost will increase by $d \cdot \epsilon$. For this relationship to hold, there must be no "isolated" factories (that is, factories for whom all weights are 0) in the existing problem.

For instance, consider again Q_a from the previous section. The distance matrix for the follow-up test cases, $Q_a\prime$ and $Q_a\prime\prime$, $c_a\prime$, is defined as follows:

$$c_a\prime = \begin{matrix} 0 & 7 & 2 & M \\ 7 & 0 & 10 & M \\ 2 & 10 & 0 & M \\ M & M & M & 0 \end{matrix} \quad (5)$$

We can define the corresponding weight matrices, $w_a\prime$ for the zero-weight case, and $w_a\prime\prime$ for the non-zero weight case:

$$w_a\prime = \begin{matrix} 0 & 5 & 8 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{matrix}, w_a\prime\prime = \begin{matrix} 0 & 5 & 8 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 4 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{matrix} \quad (6)$$

The QAP problem $Q_a\prime$ made up of $w_a\prime$ and $c_a\prime$ will have the same total cost as Q_a. The QAP problem $Q_a\prime\prime$ defined by $w_a\prime\prime$ and $c_a\prime$ will have a total cost $M > Q_a$.

Both versions of this metamorphic relation, linking Q_a with $Q_a\prime$, and Q_a with $Q_a\prime\prime$, were implemented as described.

2.3 Merging

The previous metamorphic relations are straightforward one-to-one correspondences. As explained in section 1.2, it is possible to define metamorphic relations for the QAP involving multiple test cases. Here, we define a metamorphic relation based on the merger of two existing problem instances.

Such a merged problem Q_m can be constructed in a fairly straightforward manner from two smaller problems Q_a and Q_b. The factories for Q_m are the union of the factories from Q_a and Q_b. If $l_{a1}, l_{a2} \ldots, l_{aj}$ designate the locations in Q_a, let $l_{ma1}, l_{ma2}, \ldots, l_{maj}$ designate all the locations in Q_m taken from Q_a. For all possible pairs of $l_{ma\alpha}$ and $l_{ma\beta}$, let the distance between them be the same as the distance between the corresponding locations in Q_a, $c_{a\alpha a\beta}$. Similarly, for $l_{mb1}, l_{mb2}, \ldots l_{mbk}$, the distances between the pairs should be the same as the corresponding locations in Q_b. The weights for the merged problem should be constructed in the same manner.

The key insight enabling the optimal solution to the merged problem to be predicted is the distances and the weights between pairs, where one member of the pair is from Q_a and one from Q_b. This can be achieved by making the distance between the pairs of locations of this type some very large value M - much larger than the distances between all pairs where both are from Q_a, or both from Q_b. The weights between pairs of factories where one is from Q_a and one from Q_b are zero. To minimise the total cost, any optimal solution will ensure that the very long distances correspond with the

zero weights, and thus ensures that the factories corresponding to Q_a are in one "cluster" of locations, with the factories corresponding to Q_b at the other cluster.

If the "clusters" of factories end up at the locations corresponding to their corresponding problems, the total cost of the merged problem will be the sum of the two original problems, thus giving us a metamorphic relation. But we must guarantee that the factories are located in this manner. The simplest way to guarantee this is to ensure that the original problems are of different sizes - any attempt by the solver to place the factories in the "wrong" cluster will result in at least one very large cost penalty, and will thus not be an optimal solution.

A second metamorphic relation can be created by a technique similar to that for adding nodes, by ensuring that there is one small weight between a pair of factories, one in each cluster. One factory originally from Q_a, f_{maj}, and a factory from Q_b, f_{mbk} are randomly selected, and rather than a zero weight between them a very small weight ϵ, smaller than all existing weights, is added between them, such that $w(aj, bk) = \epsilon$. The total cost of the optimal solution to the merged problem is then the sum of the total costs of the original problems and $\epsilon \times \Delta$.

To illustrate this, we consider Q_a from the previous examples, and Q_b defined as follows:

$$w_b = \begin{matrix} 0 & 20 & 0 & 0 \\ 0 & 0 & 10 & 0 \\ 0 & 0 & 0 & 30 \\ 5 & 0 & 0 & 0 \end{matrix}, c_b = \begin{matrix} 0 & 25 & 15 & 22 \\ 25 & 0 & 12 & 44 \\ 15 & 12 & 0 & 68 \\ 22 & 44 & 68 & 0 \end{matrix} \quad (7)$$

We can now define follow-up test cases for the two variants of the metamorphic relations, Q_m for the zero-weight case and $Q_m\prime$ for the weight case. In both cases, the distance matrix c_m is defined as follows:

$$c_m = \begin{matrix} 0 & 7 & 2 & M & M & M & M \\ 7 & 0 & 10 & M & M & M & M \\ 2 & 10 & 0 & M & M & M & M \\ M & M & M & 0 & 25 & 15 & 22 \\ M & M & M & 25 & 0 & 12 & 44 \\ M & M & M & 15 & 12 & 0 & 68 \\ M & M & M & 22 & 44 & 68 & 0 \end{matrix} \quad (8)$$

The weight matrix for the zero-weight case, w_m and for the weight case, $w_m\prime$, are as follows:

$$w_m = \begin{matrix} 0 & 5 & 8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 20 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 10 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 30 \\ 0 & 0 & 0 & 5 & 0 & 0 & 0 \end{matrix} \quad (9)$$

$$w_m\prime = \begin{matrix} 0 & 5 & 8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 4 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 20 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 10 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 30 \\ 0 & 0 & 0 & 5 & 0 & 0 & 0 \end{matrix} \quad (10)$$

Q_m has a total cost equal to the sums of the costs of Q_a and Q_b, and $Q_m\prime$ has a total cost equal to $Q_m + M$.

Both of these metamorphic relations were implemented as described, with a small program written to transform two existing problem instances into a single merged one, with zero or non-zero weight between a pair of members of different original problems.

3 Experimental evaluation

As we did not have access to a set of faulty QAP solvers, we instead used the technique of mutation testing to assess the effectiveness of our metamorphic relations.

In our experiment, we compared the proportion of mutants killed by the various metamorphic relations we have devised, to the proportion killed by checking against a pre-computed correct solution - that is, with a test oracle.

3.1 Mutations - Jumble

Mutation testing is a well-established technique in which faults are deliberately inserted into software to form "mutants" to determine whether a set of test cases can detect them. It can be used for a number of different purposes, including making an assessment of the quality of test cases in terms of mutation scores, denoting the proportion of mutants killed. Jumble [9] is a mutation testing tool designed for assessing the quality of unit tests written in the JUnit unit testing framework for Java software. Jumble supports the evaluation of a test case by the following procedure:

- identifying all locations in a Java class where its supported mutation operations can be performed, producing a set of mutants.
- For each mutant, executing the specified JUnit test, and recording whether the test detects a failure.
- Reporting the proportion of mutants detected.

Jumble allows the user to specify a number of different mutation methods, but by default two types of mutations are enabled. The first involves *conditionals*, where a condition in an `if`, `while`, `do`, and `for` statements, is replaced by its negation. The second default mutation type is for arithmetic operators, where arithmetic operator is replaced by another according to a predefined table - for instance, the "+" operator is replaced with "-". Only the default mutation types were used in our experiments.

3.2 Sample cases as source test data

For our experiment, we required some QAP instances that could serve as the basis for a suitable source test set. Rather than generating our own QAP instances, we started with some sample instances from the QAPLIB library of quadratic assignment problem instances, which is widely used in the QAP research community as a testbed to determine the performance of new exact and approximate solvers. [10].

The nature of our experiment meant that even the smallest problems in QAPLIB were too slow to be practical. More tractable QAP instances were created by selecting a contiguous, randomly selected subset of the factories and locations in a problem instance in QAPLIB. The use of contiguous subsets, rather than just selecting random factories and locations, was on the basis that many of the problem instances in QAPLIB seemed to have the shortest distances to numerically contiguous factories, and many had quite sparse weight matrices, with the vast majority of non-zero weights to near neighbours. By this measure, we hoped to retain the "flavour" of the original problems.

Even so, the limited computing resources available made it impractical to apply Jumble mutations to many different test cases. Only a few test cases were therefore tried with each metamorphic relation, but using a large number of mutants.

In this study, for most problems only three problem instances were used as the source test cases (referred to as t_1, t_2 and t_3 in Table 1). 768 mutants were tried with each test case. For the "merge" relations, two source test cases are required, and that the two source test cases must be of different sizes. For these relations, three additional QAP instances, slightly smaller than t_1, t_2, and t_3, were created by the same shrinking procedure. These new QAP instances were paired with the corresponding t_i to provide the necessary second source test for the merge relation.

3.3 Testing procedure

For each selected QAP instance and each metamorphic relation (or pairs of problem instances in the case of the "merge" metamorphic relation), a JUnit test case was created. The JUnit test executes the source test case, the follow-up test case, and checks whether the specified metamorphic relation holds, and succeeds or fails accordingly. Jumble was then used to repeatedly apply the JUnit test to all the different mutated versions of the QAP solver. The proportion of mutants that were detected was recorded.

4 Results

Table 1 shows the proportion of mutants killed by running the three test cases and the various metamorphic relations. For the merge relations, as noted previously, two source test cases of different sizes were created to apply this relation. For these relations, therefore, the column t_i should be read as "t_i and another, smaller, source test case".

Metamorphic Relation	Mutants killed (%)		
	t_1	t_2	t_3
Oracle	71	73	75
Relabelling	13	13	14
Add (zero weight)	25	25	25
Add (weight)	75	74	74
Merge (zero weight)	21	22	24
Merge (weight)	77	74	76

Table 1. Proportion of mutants killed by metamorphic relations

It is not surprising that the oracle case did not kill all mutants, simply because a single test case is not necessarily a failure-revealing input for any specific mutant. What may be slightly more surprising to the reader is that the performance of two of the metamorphic relations, "Add (weight)" and "Merge (weight)" is higher than that of the oracle. This can also be explained in terms of the number of test cases executed. Effectively, "Add (weight)" executes two test cases for each source test case, and "Merge (weight)" executes three test cases for each pair of source test cases, while testing using the oracle only involves the execution of one test case. An error revealed by any of the source or follow-up test cases may violate the metamorphic relation and hence reveal the failure.

The results show dramatic differences in the effectiveness of different metamorphic relations - the "Relabelling" relation detected around 13% of mutants, whereas the "Merge (weight)" relation detected around 75% of mutants. This shows that selection of metamorphic relations is vital for the effective application of metamorphic testing

Furthermore, we observe that a seemingly minor difference in a metamorphic relation - the difference between "weight" and "zero weight" for both the "Add" and "Merge" metamorphic relations - results in dramatic differences in failure-revealing effectiveness. It is interesting to consider why this small difference contributed to such contrasting failure-revealing effectiveness. There are a number of possible explanations. One explanation, discussed in [11], is that the "weight" versions of the metamorphic relations led the program execution patterns in the follow-up test cases and the source test cases to be more divergent, giving more chance for a bug to be exposed. If so, this indicates that testers should choose relations that encourage divergent execution patterns.

There are, of course, a wide variety of other metamorphic relations that could be tried for this problem. One property of the QAP, (and many other optimization problems), is that a problem instance may have multiple optimal solutions. This makes it difficult to devise metamorphic relations based on the mapping of factories to locations, rather than the total cost. However, making metamorphic relations

conditional may make this easier. For instance, if problem instance Q has assignments a and total cost t, we create a follow-up problem instance $Q\prime$ identical to Q except that one randomly selected weight value $w_m\prime(i,j) = w_m(i,j) + \epsilon$, where ϵ is a positive constant. We can unconditionally say that $t \leq t\prime \leq t + \epsilon * c_m(i,j)$. However, two other conditional metamorphic relations exist. If the assignment for the optimal solution for $Q\prime$ is still a, the total cost c must increase by precisely $\epsilon \cdot c_m(i,j)$. Furthermore, if the cost increase is strictly smaller than $\epsilon \cdot c_m(i,j)$, $a\prime$ the assignment for the optimal solution to $Q\prime$, must be different to a.

In this experiment, we have used an exact solver that guarantees to find a globally optimal solution to the QAP. In practice, heuristic approximation algorithms are typically used; under such conditions, the metamorphic relations above would not be suitable. Some work has already been conducted in applying metamorphic testing to heuristic algorithms [12].

The dramatic difference in effectiveness of different metamorphic relations suggests it would be desirable to have some method to screen a set of metamorphic relations to find an effective subset. This study suggests that mutation analysis may prove useful for this purpose.

5 Conclusion

In this study, we have shown that metamorphic testing can be effectively used to find faults in an exact QAP solver.

To our pleasant surprise, we found that it was relatively easy, even for non-experts in the problem domain, to come up with effective metamorphic relations. Even given the relatively small scope of this study, we feel that this is a strong indication of the likely practical utility of this approach.

Our results suggest that the metamorphic testing approach is very likely to be useful for ensuring the quality of other solvers of hard optimization problems, given the difficulty of verifying the correctness of their solutions.

The simplicity of metamorphic testing suggests that relatively inexperienced practitioners, or even end users, can perform useful verification using this technique. The tester can specifically target the properties that are important for their own use of the software. Furthermore, the technique is very straightforward to describe, and requires only a small amount of domain knowledge to apply.

Towards a Theoretical Model for Evaluating the Acceptance of Model-Driven Measurement Procedures

Abstract

Software development based on transformation models has resulted in increasing interest in full automatic software measurement from conceptual models. In this paper, we propose a theoretical model for evaluation of the extent to which a model-driven measurement procedure would be accepted in practice. We identified a number of factors that could affect perceived usefulness and ease of use, and which would in turn affect the intention to use.

Keywords: *acceptance model, software measurement, model driven process, functional size*

1. Introduction

Software measurement, considered in the literature as essential for software product and process improvement, has not yet been accepted in practice. A study reported that 21.1% of software professionals contacting the Software Engineering Institute from 2004-2005 did not use a measurement method [1]. Another study showed that less than 10 percent of practitioners classified metrics programs as positive [2].

In our experience, one important reason for this gulf between researchers and practitioners is a lack of confidence among practitioners, who view manual or semi-automatic software measurement as a complex and difficult undertaking.

However, with the appearance of the model-driven development process, several proposals have arisen for automatic measurement of specific artifacts developed at early stages and in particular contexts [3][4][5][6][7].

This paper aims to explore the various factors that affect practitioners' perceptions, and how such perceptions can affect the acceptance of a model-driven measurement procedure in practice.

A number of models exist for evaluating the acceptance of new techniques and technology, in particular the Technology Acceptance Model (TAM) [8], which is considered the most applicable model in many usage scenarios. The Method Evaluation Model (MEM) [9], which uses the same TAM constructs, was the first to be applied in the context of Functional Size Measurement (FSM) procedures ([4], [10]).

From preliminary results obtained with MEM, we define an acceptance model for model driven measurement procedures, identifying particular factors that affect perceptions of usefulness and ease of use.

The structure of the paper is as follows. In section 2 we present a brief overview of the literature. Section 3 presents our proposal to evaluate the acceptance of FSM procedures. Finally, we present our conclusions and suggest further work

2. Literature Review

According to Cooper and Zmud [11], acceptance is one of the stages in the diffusion of technological innovations, and is defined from an employee perspective. This means that an organization's personnel are induced to commit to Information Technology application usage. Acceptance must not be confused with adoption; for Cooper and Zmud, adoption is defined as stage where negotiations are started in relation to the decision to adopt the innovation and mobilizing of organizational and financial resources for doing so.

The acceptance of technology has been investigated in a number of different fields (Internet-based health applications [11], multimedia information systems for learning [12], CASE tools [13], etc.). However, in the software measurement field few papers on this subject were found in the literature.

* This work has been Supported by the SESAMO project, ref. TIN2007-62894 and co-financed by FEDER.

Among the relevant literature is the proposal of Umarji and Emurian [14] focused on evaluation of the likelihood of acceptance of a metrics program. Their model takes as input organizational culture, and the nature of the metrics program.

Gopal et al. [15] researched the influence of institutional factors on the assimilation of metrics in software organizations. They also identified a set of determinants for metrics program success [16]. These determinants are divided into organizational and technical variables.

In our research we do not deal with in-depth organizational variables, since our proposal focuses on measurement procedure acceptance from a software practitioner's perspective and on the intrinsic nature of software measures.

To define our acceptance model, we first present our experience using MEM [9] in the functional size measurement context.

3. A Theoretical Model for Evaluating the Acceptance of FSM Procedures

In this section, we define a model for evaluating the acceptance of FSM procedures in practice by means of the extension of a theoretical model.

3.1. Previous research: MEM and FSM

In the last seven years we have been working on functional size measurement at early stages of the model-driven development process, defining and empirically evaluating three FSM procedures: 1) OOmFP [4], a measurement procedure designed for sizing conceptual schemas in function points; 2) OOmFPweb [4], extended procedure to size Web applications; and 3) RmFFP [6], a procedure designed to measure size from object-oriented functional requirements specifications.

The empirical evaluation of these FSM procedures was carried out by applying MEM [9], with the results of this evaluation reported in [4] and [10]. MEM combines Rescher's theory of pragmatic justification [17], and Davis's Technology Acceptance Model (TAM) [8]. The core of the MEM consists of the same perception-based constructs as the TAM, but which were adapted to evaluate Information System design methods. These constructs are called the Method Adoption Model (MAM).

- *Perceived Ease of Use*: the extent to which a person believes that using a particular method would be free of effort.
- *Perceived Usefulness:* the extent to which a person believes that a particular method will be effective in achieving intended objectives.
- *Intention to Use:* the extent to which a person intends to use a particular method.

We used MEM in its original form, and analyzed its applicability to functional size measurement, based on an integrative review of these three empirical evaluations reported in [18].

Only one of the MEM relationships was corroborated. This means that the intention to use an FSM procedure is influenced more significantly by perceived usefulness than by perceived ease of use. In addition, the relationship between perceived usefulness and ease of use was not significant for the FSM procedures context.

We therefore came to the conclusion that perceived usefulness should not only be evaluated with respect to the effectiveness of the FSM procedure in achieving objectives intended by the users, but that other factors should be included.

3.2. Extending the MAM to evaluate FSM procedures

We have extended the MEM core (MAM) by the inclusion of the factors that influence perceptions of usefulness and ease of use when users are using a model driven FSM procedure (see Figure 1). Two types of factors were identified:

- *Intrinsic Factors* corresponding to quality and tangibility of results, and the minimum number of actions required for calculating the functional size using an automated measurement procedure.
- *Extrinsic Factors* corresponding to the experience and job relevance of the software practitioner.

Next, we describe each of the factors included in our proposed model.

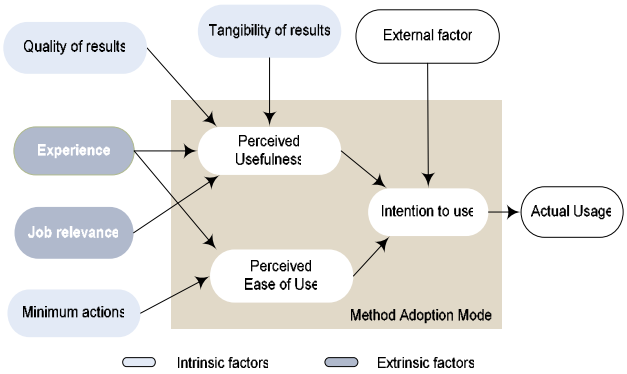

Figure 1. Model for evaluating acceptance of an FSM Procedure

3.2.1. Quality of results. According to the ISO/IEC 14143-3 report [19], certain performance properties of an FSM method have to be taken into account when analyzing the quality of results. These properties are

expressed in terms of accuracy, repeatability, reproducibility and convertibility:

Accuracy: closeness of agreement between a quantity value obtained by measurement and the true value of the measurand.

Precision: closeness of agreement between quantity values obtained by repeated measurements of a quantity, under specified conditions, i.e. repeatability and reproducibility.

Convertibility: this is defined as the ability to convert the results obtained by applying two or more FSM Methods in the measurement of the same set of Functional User Requirements.

Automated measurement achieves precision. Therefore, we consider accuracy and convertibility as quality properties that may influence the usefulness perceived by the users when they use a Model-Driven FSM procedure. We therefore propose that:

P1: There will be a positive relationship between Quality of results and Perceived Usefulness

3.2.2 Tangibility of results. This factor is also called result demonstrability, which has been refined by Moore and Benbasat for information systems and is derived from Innovation Diffusion Theory used in the sociology field [20].

In our case, even if a measurement procedure produces effective (accurate, precise and convertible) results, if these results are not interpreted by an indicator (they are "indistinct"), users will have difficulty understanding the usefulness of the measurement procedures.

For this reason, we have redefined this factor as the extent to which an individual believes that the results of using a FSM procedure can be observable and understandable. Thus we propose:

P2: There will be a positive relationship between Tangibility of Results and Perceived Usefulness

3.2.3. Minimum actions. Previous empirical studies, [4], [23] corroborated that for manual measurement, *measurement productivity*[1] has a positive effect on perceived ease of use. However, this variable is irrelevant for fully automated FSM procedures. We believe that perceived ease of use could be influenced by the minimum number of actions necessary for the obtaining of the functional size. Therefore, we propose:

P3: There will be a positive direct relationship between Minimum Number of Actions required to obtain the functional size and perceived ease of use.

3.2.4 Job relevance. It is possible for a model-driven measurement procedure not to be perceived as useful even though the procedure provides accurate and convertible results, possibly because the use of the FSM procedure is not relevant for the job type (e.g. executive, project manager, designer, etc.) of the software practitioner concerned.

We have redefined job relevance as the extent to which an individual believes that an FSM procedure is applicable and relevant to his or her job. Thus we intend to examine whether:

P4: There will be a positive relationship between Job Relevance and Perceived Usefulness

3.2.5 Experience. Various studies assert that subjects with direct hands-on experience would be more likely to hold stronger perceptions as to ease of use and perceived usefulness of a technology, based on the subjects' ability to generate more beliefs and to extrapolate from past behaviors related to their experience [21],[22]. We hypothesize that measurement and modeling experience should have a strong effect on user's perceptions. For instance, less experienced modelers may be unable to adequately understand the software artifact to be measured, which could cause erroneous perceptions regarding usefulness and ease of use of an FSM procedure.

We define the experience factor as knowledge or skill gained in use measurement and development methods over a period of time.

Thus we propose the following:

P5: There will be a positive relationship between measurement and modeling Experience and Perceived Ease of use.

P6: There will be a positive relationship between measurement and modeling Experience and Perceived Usefulness.

3.2.6 External factors. These are factors that do not depend on the measurement procedure in itself, but on the organization as a whole. These include where the business follows trends in the market based on advertising and marketing or peer company use, or has business priorities giving rise to time or cost constraints, or the maturity level of an organization [16]. We intend to determine whether these external factors influence the intention to use a Model Driven FSM procedure. Thus, we propose the following premise:

P7: There will be a relationship between External Factors and the intention to use.

4. Conclusions and further work

We have defined a theoretical model to evaluate the acceptance of model-driven measurement procedures from an individual perspective. This model was

[1] Number of size units that can be measured per unit of time.

defined by means of the extension of the MEM core (MAM), by including two types of factors that influence perceptions of usefulness and ease of use (intrinsic and extrinsic factors).

We have considered result quality to be a primary and intrinsic factor that will affect the intention to use model driven measurement procedure. As these results cannot in themselves be interpreted, another intrinsic factor was used to evaluate whether obtained results are understandable by practitioners when using an estimation model (are tangible). Finally, as this measurement is automated, manual measurement productivity has not been considered. The minimum actions required to obtain functional size in a model driven context have been taken into account.

With respect to extrinsic factors that will influence perceptions of usefulness and ease of use, we have considered the factors that affect the practitioner's viewpoint when using a measurement procedure (e.g. level of experience, job relevance and organizational factors).

Finally, we plan to carry out an empirical study to verify causality relationships between both extrinsic and intrinsic factors and .the MAM constructs.

Abstract

A large body of research in software requirement engineering domain has been dedicated to enhancing the structure of task scenarios using scenario schemas and predefined structures. However, less attention has been paid to the application of schemas in extracting design knowledge from scenarios. In this paper, we propose a schema-based technique to extract the design knowledge embodied in the text of scenarios and represent them using multi-view design diagrams. In this context, we define a framework and a scenario syntax that allow for generating a set of structured scenarios that cover the requirements of a software system. We define a novel scenario schema to parse the informal text of scenarios and populate an objectbase to maintain the design knowledge building blocks. Consequently, a set of guidelines are defined to incrementally build design diagrams for software views such as data and function. As a case study, the design diagram generation for a restaurant system is presented.

KEYWORDS: Knowledge; Transformation; Scenario; Schema; Design; Multiple Views; Object base.

1 Introduction

Scenario-based knowledge extraction from requirements has attracted significant attention within the requirement engineering field [13]. Scenarios are represented in a variety of formal and informal methods ranging from simple text and graphical media to relational algebra [6]. In this paper, we define a scenario as "*a structured narrative text describing a system's requirements in terms of system-environment interactions at business rule level*". Scenarios are considered as easy-to-use and effective means in different phases of software engineering process, such as: requirement elicitation and analysis, design representation, code development, testing, and maintenance [11, 8, 10, 14]. A wide range of research in knowledge extraction from software requirements attempt to investigate: the enhancement of scenario generation by using scenario schemas or pre-defined structures [3, 17]; scenario analysis and knowledge extraction [2]; and design-related document generation [15, 16].

In this paper, we introduce a novel technique to transform the knowledge from scenarios into well-formed design diagrams in two views of data and function. In this technique scenarios are generated using domain knowledge and in conformance with a regular expression syntax that imposes a structure to the scenario representation. The proposed approach allows us to reuse the domain knowledge and business rules within the scenarios through a scenario template knowledge base. Further, the generated structured scenarios are parsed using a novel *scenario schema* to populate an objectbase of design related entities and dependencies. The populated objectbase serves both as a data source during the design diagram construction and as a valuable electronic asset of design knowledge to be analyzed, augmented, and used during the maintenance phase of the software system. Finally, the information in the objectbase is used to create standard diagrams, such as Entity-Relationship diagram (ER) for data view, and function diagram for function view.

The contributions of this paper include: i) a framework to transform the structured knowledge of the scenarios into view-based design diagrams; and ii) a novel schema that allows for decomposing the scenarios into an objectbase of design-related entities and dependencies. As a case study, the design diagram generation for a fast-food restaurant system is presented.

2 Related work

The proposed approach in this paper relates to the literature for capturing and representing knowledge from task scenarios for various purposes. We present several approaches and discuss their similarities and contrasts with our work.

Anton and Potts [1] discuss different representations of scenarios in object oriented software engineering and requirements engineering. Jarke et al. [9] present a review on approaches to scenario-based requirement engineering and research issues.

Lamsweerde et al. [5] introduces KAOS methodology that supports requirements extraction from high-level goals, and assigns objects and operations to the various agents in a system. Their meta-model has similarities with our schema, however our approach aimed at extracting design diagrams after capturing the requirements.

In [6] a formal representation of scenarios using tabular expression is introduced in order to simplify the tasks of scenario validation, verification, and integration. In [3] a schema for semantic model of scenarios is defined to help requirement refinements. Leite et al. [7] aid the process of scenario construction and management by structuring scenarios using a conceptual model along with a form-oriented language. However, in addition to requirement elicitation and validation, our framework transforms the generated structured scenarios into design diagrams. Damas et al. [4] propose tool-supported techniques to generate behavior models from end-user scenarios, whereas we extract design diagrams from scenarios. Hufnagel et al. [16] present a scenario-driven object oriented requirements analysis to support design of a system. This approach does not define a scenario schema and also it is methodology dependent. In [12] a method for modular representation of the scenarios is proposed that supports the reusability of the scenarios in different design contexts. This approach is similar to ours in the sense that it attempts to define a structure for the scenarios.

Overall, the significance of our approach is that we generate scenarios using semi-structured templates and transform the knowledge within the text of scenarios into design relevant knowledge using guidelines that provide a repeatable and view-based design reconstruction process.

3 Proposed framework

In this section, we discuss the steps for transformation of the knowledge embodied in the text of scenarios into design knowledge represented by two views data and function of a software system. These steps are presented using the framework of Figure 1. In a nutshell, the proposed framework generates a set of structured scenarios and uses a schema to parse these scenarios into ingredients of the view-based design representations. The proposed framework consists of three stages, as follows.

3.1 Stage 1: scenario generation

This stage consists of generating a set of structured text-based scenarios that conform with a regular expression syntax. To facilitate scenario generation and controlling the format and vocabulary of the generated scenarios, a predefined set of domain-specific templates can be utilized.

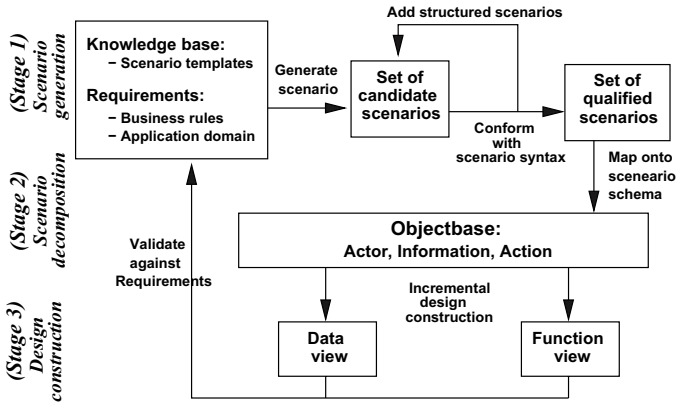

Figure 1. The proposed design construction framework from scenarios.

Consequently, at the end of this stage a set of qualified scenarios are produced that cover a part or the whole of the system requirements.

Scenario structure. We define a structure for scenarios that is imposed by the regular expression syntax in Figure 2 and the semantics that are defined by the application domain's business rules. In this scenario syntax, *Actor, Action*, and *WorkingInformation* are the entity-types and action-types that will be defined in Section 3.2. Each scenario consists of a sequence of one or more *Actors*, *Actions*, and *Working Information*, each of which can have between zero or more *Constraints*. In this form we can generate syntactically correct scenarios which will be further decomposed to populate the objectbase in Section 3.2 and generate design diagrams in Section 3.3.

Scenario templates. In order to facilitate generation of structured scenarios and reuse of the captured domain knowledge and vocabulary, the proposed framework leverages a tool to populate a knowledge-base of scenario templates which are organized to store the structured scenarios in a specific application domain. This allows a software engineer to assemble scenarios using a repository of domain-specific vocabulary that is maintained for a software domain. Figure 3 illustrates a sample scenario template form for a fast-food restaurant system. This form consists of fields such as: Actor, Information, and Action, where each field possesses a vocabulary of corresponding business terms. The generated scenario at the bottom of the form is a proper assembly of the terms selected from these fields.

$$Scenario : \{Actor + \{Constraint\}^{0..N}\}^{1..N} + \{Action + \{Constraint\}^{0..N}\}^{1..N} + \{Working\ information + \{Constraint\}^{0..N}\}^{1..N}$$

Figure 2. Regular expression syntax for scenario generation, where "+" and "0..N" represent composition and range, respectively.

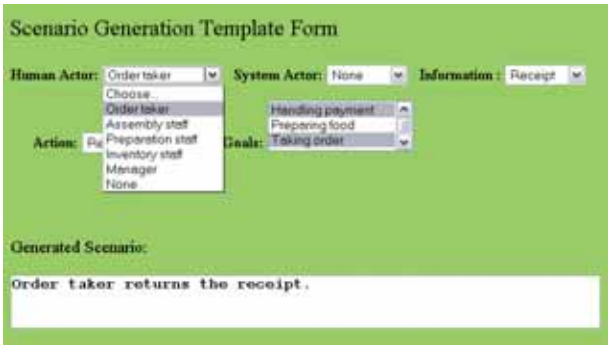

Figure 3. Scenario generation template form for a fast-food restaurant system.

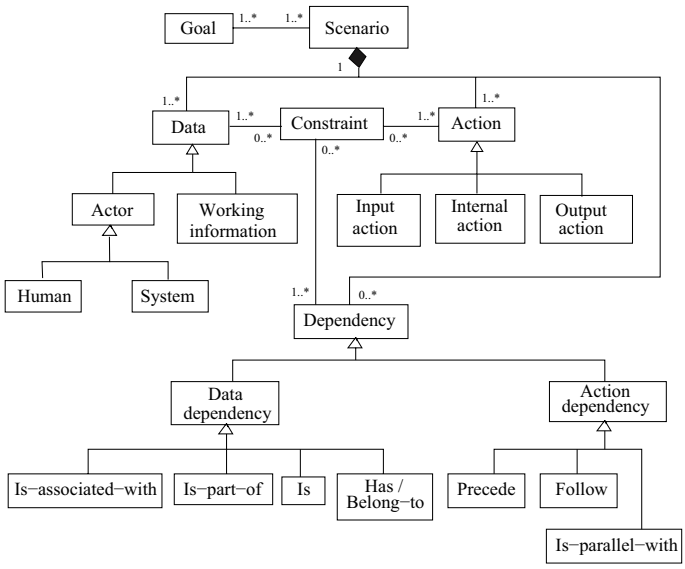

Figure 4. Scenario Schema to parse a scenario and populate an objectbase.

3.2 Stage 2: scenario decomposition

In this stage, the qualified scenarios are mapped onto the proposed scenario schema in Figure 4 which allows us to parse the structured scenarios and generate instances of classes Goal, Actor, Working information, Action, and their corresponding dependencies that are defined in the scenario schema. The generated instances incrementally populate an objectbase of design knowledge that is used to generate design-related diagrammatic representations.

Using the class diagram representation of the scenario schema in Figure 4 the texts of the structured scenarios are parsed and the resulting instances of the classes are stored in the objectbase. The objectbase is represented as a group of columns, where each column stores the instances of a class in the scenario schema that belong to different scenarios. In other words, a scenario (as a row) in the populated objectbase consists of the instances of the relevant classes of the scenario schema that are stored in different columns, and a unique *index* that identifies the scenario.

As shown is Figure 4, in our model every instance of the *Scenario* class is composed of one or more instances of *Actor*, *Working information*, and *Action* classes, and zero or more instances of *Dependency* class. Every Action, Actor, and Working information is associated with zero ore more *Constraint*s. Moreover, every *Scenario* instance is associated with one or more instances of *Goal* class. In the rest of this section the classes of the proposed scenario schema are introduced along with examples from a fast-food restaurant system domain.

Goal: represents the reasons and the desired effects for which the subject system has been produced and used. A goal can be *functional* which corresponds to performing a task, or *objective* which refers to achievement of a quality for the system. Examples of goals in a fast-food restaurant system are as follows: handling payment (functional), preparing food (functional), and shortening order preparation time (objective).

Actor: an actor is a "human" or a "system" or a "component of a system" that interacts with other actors during the execution of the scenarios. Examples of actors in a restaurant system include: order taker (human), raw material supplier (system), or food assembly station (component of a system).

Action: an action is an activity that is performed by an actor during the execution of the scenarios. Generally, an

action manipulates an instance of *Working information*. Actions can be categorized into three different types of *Input, Internal*, and *Output*, based on the scope of the system. Examples include: taking order (input), computing the price of an order (internal), and delivering food (output).

Working information: refers to the information that is manipulated (exchanged, transported, communicated, operated on, stored, etc.) by the scenario's actor during the execution of the scenario's actions. Examples are: customer's order, raw material, menu item, and item price.

Dependency: refers to a binary relationship between two instances of the classes *Actor, Action*, or *Working information*. When needed, the multiplicity of the participants in a dependency should be mentioned in the dependency instance. In such a case, the dependency can be represented by a quadruple with the multiplicity of each participant proceeding it.

In our schema, a dependency can be of type *Data dependency* or *Action dependency*. Data dependency can be one of the following subtypes: *Is*, e.g., "order taker *Is* an employee"; *Is-associated-with*, e.g., "every menu item *Is-associated-with* a recipe" (or (1,menu item,1, recipe)); *Has*, e.g., "every menu item *Has* a name"; *Belong-to*, that is the inverse[1] of *Has*, e.g., "an ID *Belongs-to* an employee"; *Is-part-of*, e.g., "a kitchen *Is-part-of* a restaurant".

Action dependency can be one of the following subtypes: *Precede*, e.g., "order payment *Precedes* order delivery"; *Follow*, that is the inverse of *Precede*, e.g., "order preparation *Follows* order taking". *Is-parallel-with*, e.g., "sending order to assembly station *Is-parallel-with* sending order to preparation station".

The proposed scenario schema in Figure 4 includes a *Constraint* class that associates any quantifiable constraint to *Data*, *Action*, and *Dependency* classes. Examples of different types of constraints include: *capacity*, *value range*, *ordinal*, *timing*, *privilege*, etc. As an example, a restaurant system may have "*younger than 10*" as a *constraint* associated with *actor* of some scenario, in order to perform a specific *action* such as "offering kids deal".

3.3 Stage 3: design construction

In this section, we discuss the guidelines that transform the contents of the objectbase obtained in Stage 2 into design diagrams. Entity-Relationship (ER) and function diagrams are the most intuitive and relevant diagrams that can be directly extracted from the objects within the objectbase and represent data view and function view of the system, respectively.

Data view. The following guidelines specify the generation of ER diagrams from the objectbase:

Data view step I. Extract all instances of *Actor*, *Working information*, and *Data dependency* classes from the object base and apply the following rules on them:

1. Instances of *Actor* and *Working information* are candidate entities/attributes.
2. Instances of *Is* dependency imply generalization and inheritance relationships, i.e., A *Is* B, means A is sub-entity of B, or B is super-entity of A.
3. Instances of *Is-associated-with* dependency imply candidate association relationships.
4. Instances of *Has* and *Belong-to* dependencies are used to identify the attributes of the entities, i.e., A *Has* B (or B *Belongs-to* A) means B is an attribute of entity A.
5. Instances of *Is-part-of* dependency imply candidate decomposition relationships.
6. Candidate entities/attributes that never appear on the right-hand side of a *Has* dependency (or left-hand side of a *Belong to*) dependency are entities and not attributes.
7. Candidate entities/attributes that appear on either side of a *Is*, *Is-associated-with*, or *Is-part-of* relationship are considered as entities.
8. Candidate entities/attributes that appear on the left-hand side of a *Has* dependency (right-hand side of a *Belong to* dependency) are considered as entities.
9. Candidate entities/attributes that appear on the right-hand side of a *Has* dependency (or left-hand side of a *Belong to* dependency) and do not apply in any of the rules vi-viii, are considered as the attributes of the entity on the other side of that dependency.

Data view step II. Depict every entity by a rectangle, every attribute of an entity as a bubble connected to it and label them by their names. Every relationship between two entities can be represented by a line connecting them. Label every relationship according to the type of dependency it came from, e.g., "is", "is-part-of", etc.

Function view. Function view of a system is well represented by function diagrams. The following guideline specifies the generation of function diagrams from the objectbase.

Function view step I. Extract all instances of *Action*, *Action dependency*, and *Constraint* classes from the object base and apply the following rules on them:

1. Instances of *Action* class are the functions.
2. Instances of the *Follow* and *Precede* dependencies determine the time-order of execution of the functions. To simplify the diagram generation, transform all the *Precede* dependencies to *Follow*, i.e., for all functions f_1 and f_2, change $f_1 Precede f_2$ to $f_2 Follow f_1$.

[1] For some dependencies, their inverse dependencies are also included in the schema to facilitate back tracing of dependencies in the objectbase.

3. The participants of a *Is-parallel-with* dependency must be executed concurrently.
4. The condition(s) for a function to follow another is determined by the *Constraint*s related to the function, actor, and working information in the corresponding scenario that the "following" appears.

Function view step II. Generate $Follow^+$ relationship (the transitive-closure of the *Follow*), i.e., $f_1 Follow^+ f_2$ means there exists a set of functions g_i where, f_1 *Follow* g_1, g_1 *Follow* g_2, ..., g_n *Follow* f_2.

Function view step III. Sort the functions in ascending order based on the number of the functions they follow, i.e., based on the number of times they appear on the left hand side of a *Follow* relationship.

Function view step IV. Start from the beginning of the sorted list, depict the first function (name A) with a square and label it by its name. List all the functions that *Follow* A. If the list contains only one function (name B), depict B and connect A to B with an arrow. If the followers list contains more than one function (name B, C, ...), then a choice condition has occurred. If there are any pair of functions (name B and C) in the list that have an *Is-parallel-with* dependency, connect A to B and C with arrows and an *AND* bubble. Otherwise the functions are connected using an *OR* bubble. Next, all arrows are labeled with the triggering condition(s) obtained in rule "4" above. Finally, remove A from the list and repeat *Function view step IV*, until the list is empty.

The functions in the function view correspond to the actions performed by the actors in the system, and can be considered as candidate methods of classes in the detailed design of the system. Also, the sequence and the AND and OR relationships between the functions reflect the design decisions that should be considered during the implementation phase of the system.

The above guideline can be semi-automated. User involvement is required in cases of conflicts or inconsistencies, such as duplicate usage of actor or action names in different roles, etc. In such cases user can be prompted to perform manual resolution.

The realization of the scenario to design transformation will be presented as a case study in the next section.

4 Case study: Fast-food Restaurant System

In this section, the results of applying the proposed framework to the case of a fast-food restaurant system is presented.

4.1 Stage 1: scenario generation

The following scenarios that conform with the proposed scenario syntax in Figure 2 were generated using our proprietary scenario generation tool. Note that for simplicity in demonstration, the following scenarios demonstrate little interactions and few conditions.

• Scenario #1: *"Order taking station computes and reports the price of the orders."*
• Scenario #2: *"Order taking station sends the paid orders to assembly station."*
• Scenario #3: *"Order taker logs into the OT station using ID and password."*
• Scenario #4: *"Order taker initiates orders."*
• Scenario #5: *"Order taker adds and removes (edit) menu items of an unpaid order."*
• Scenario #6: *"Order taker enters the amount of money received from the customer (cash-in) to OT station."*
• Scenario #7: *"Order taker defers the payment of orders."*
• Scenario #8: *"Order taker reviews the orders."*
• Scenario #9: *"Order taker calls-back unpaid orders."*
• Scenario #10: *"Order taker returns the change (and receipt) for the order."*
• Scenario #11: *"Order taker sends the cash exceeding cash limit to the cash safe."*
• Scenario #12: *"Order taker logs out from his/her ID."*

4.2 Stage 2: scenario decomposition

At this stage, the scenarios were mapped onto the proposed scenario schema to instantiate different class instances and the resulting instances are stored in the objectbase. Table 1 presents a part of the objectbase that is populated with instances of *Data* and *Action* and five *Dependency* classes from Scenarios #1 to #10 above.

4.3 Stage 3: design construction

In this stage we followed the guideline presented in Section 3.3 to construct the diagrams for data and function views.

Data view. Candidate entities/attributes are stored in different *Data* columns (i.e., $Actor|_{System}$, $Actor|_{Human}$, and $Working\ information$) of the objectbase. Similarly, the dependencies among these candidates are stored in the objectbase (under *Is*, *Belong-to*, ... columns). A part of the the ER diagram for the restaurant system (i.e., order taker component), constructed using the guideline for **Data view** is shown in Figure 5.

Function view. The list of extracted functions sorted by $Follows^+$ relationship is shown in Table 2. Also, the extracted dependencies between these actions are stored in different *Action dependency* columns of the objectbase. The function diagram for the order-taker component of the restaurant system (constructed using the guideline for **Function view**) is shown in Figure 6.

Table 1. A part of the objectbase created from the scenarios #1 to #10.

$Index$	$Actor\|_{System}$	$Actor\|_{Human}$	$Working\ information$	$Action\|_{Input}$	$Action\|_{Internal}$	$Action\|_{Output}$
1	OT Station	-	order,price	-	compute price	report price
2	OT Station, ASM station	-	paid order	-	-	send paid order to ASM station
3	-	order taker,OT station	ID&password	-	login to system	-
4	-	order taker	order	-	initiate order	-
5	-	order taker	menu item,unpaid order	-	add/remove menu item	-

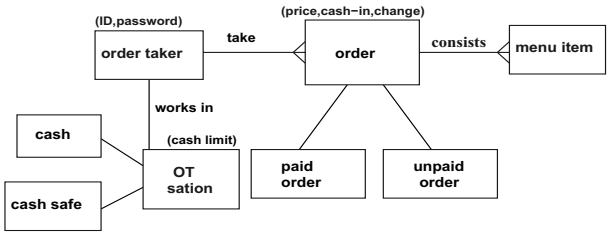

Figure 5. Generated Entity-Relationship diagram for the order taking component.

The generated design diagrams and the existing knowledge in objectbase will enable us to extract other design diagrams such as class diagram of the system. Figure 7 illustrates the complete class diagram of the restaurant system. This diagram is obtained from the ER diagram of the system that was generated in the proposed framework. The space limitation of the paper does not allow us to provide the required guidelines.

5 Discussion and conclusion

In this paper, we presented a systematic and semi-automatic approach for transforming the design knowledge within task scenarios onto a set of design diagrams. We proposed a framework with three major stages of scenario generation, scenario decomposition, and design construction.

Table 2. List of actions in order taking component and corresponding to *Follow* relation.

Index	Action	$Follows^+$
1	Login using ID & password	-
2	Logout the system	1
3	Review orders	1
4	Initiate order	1
5	Call-back unpaid orders	1
6	Edit orders	1,5
7	Compute price	1,5,6
8	Report price	1,5,6,7
9	Defer order payment	1,5,6,7,8
10	Enter cash-in	1,4,5,6,7,8
11	Return change & receipt	1,4,5,6,7,8,10
12	Send order to assembly station	1,5,6,7,8,10,11
13	Send excess cash to cash safe	1,4,5,6,7,8,10,11,12

The task scenarios are structured by the means of a regular expression syntax and can be reused through a knowledge-base of scenario templates. A scenario schema has been proposed as the core of the approach that allows us to decompose scenarios into design entities and dependencies as the means to populate an objectbase. The generated objectbase would maintain the building blocks that allow the

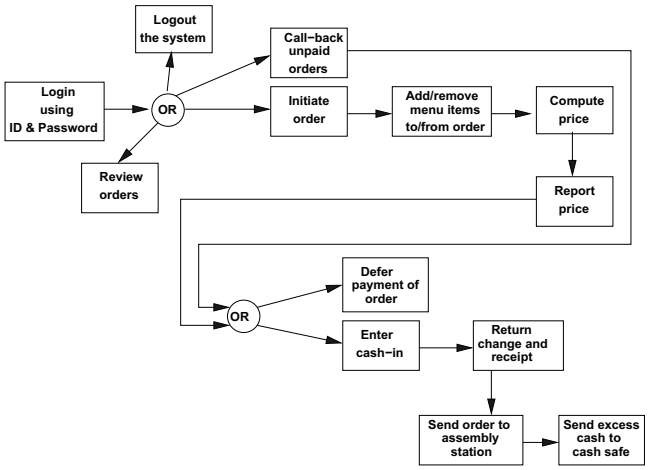

Figure 6. Generated function diagram for order taking component.

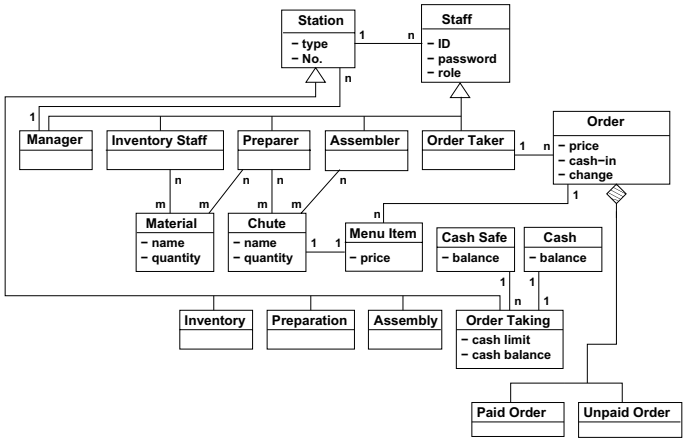

Figure 7. Generated class diagram of the whole restaurant system.

engineer to generate the design diagrams for two views of the software system using common-practice modeling.

We compared the constructed Entity Relationship diagram in Figure 5 with the similar diagram generated for the same restaurant system by a software engineer. In this comparison 6 out of 8 entities for the order taking component were the same in both diagrams which indicates a promising result. The proposed technique provides a disciplined and structured approach to requirement-to-design transformation process within the knowledge engineering field. The proposed scenario schema provides a clear understanding of the major building blocks of the software system's functional entities and their relationships. The populated objectbase serves both as a data source during the design diagram construction and as a valuable electronic asset of design knowledge to be analyzed, augmented, and used during the maintenance phase of the software system. Specifically, the objectbase can be mined to extract more general design decisions that is not feasible by a human-based analysis.

***Abstract*— The discipline of Personal Software Process (PSP) can help developers to understand their ability, improve their software process, and increase their productivity and software quality. However, to improve the software process, developers need to gather their own process data. This does impose substantial overhead to developers. This paper presents an Eclipse plug-in tool that can help developers to measure and analyze their software process based on the principles of PSP. Specifically, the program size, process time, and defect data can be collected automatically or semi-automatically using the tool. In addition, the tool can provide valuable process information, such as the size and time statistics, defect distribution, and productivity, to help developers to assess their performance and to improve their software process.**

I. Introduction

The Personal Software Process (PSP) [1], [2] was proposed by Watt S. Humphrey to help developers to improve their personal software process. The main idea of the PSP is to understand and improve software process through planning, tracking, measuring, and analyzing the defined process. It has been shown that, by adopting the PSP practices, developers can significantly reduce the number of defects, increase the software quality and productivity, and improve the predictability of software process [3], [4]. This facilitates developers to deliver high quality software with less development time and cost.

Although the PSP practices can help developers to improve their performance, developers must collect their own process data, such as the size of programs, the time spent on each process phase, the number of injected and removed defects, the types of defects, and the defect fix time, to evaluate their process. However, gathering these process data can be time-consuming and error-prone even though the PSP framework has provided many well-designed forms to help developers recording their process data. The data gathering still involves lots of work and requires to be done consistently and carefully, which imposes a large amount of overhead to developers. Thus, a supporting tool that can help to reduce the overhead, avoid the human errors introduced in the data collection, and facilitate the process analysis has become critical for developers to use PSP.

Although there have been several PSP tools [5], [6], [7], [8], [9] that can support PSP data collection, most of the tools are not integrated with an Integrated Development Environment (IDE) tool. This makes developers have to use a PSP tool, such as a spreadsheet, to manually record their process data while using an IDE tool to develop their programs. The separation of data gathering and program development tools causes inconvenience and additional tool-switching overhead to developers. It also increases the possibility of making mistakes in recording the process data.

This paper proposes a PSP supporting tool for Eclipse platform [10], called the PSP data Collection and Analysis Tool (PSPCAT), to assist developers to collect their PSP data automatically or semi-automatically in the development phase. Eclipse is an open source programming platform and has been widely used in software community. In particular, Eclipse provides a Plug-in Development Environment (PDE) [11] that can enable plug-in tools to be integrated with Eclipse and to access the resources of Eclipse workbench. With the PSPCAT, developers can write programs and gather their process data using Eclipse without switching tools so that the data collection overhead can be reduced and the data accuracy can be improved.

The PSP can help developers to improve their software process. However, not all the developers are familiar with the PSP framework and follow the PSP defined process. In order to support most developers to gather their process data, the PSPCAT is designed to provide three data collection modes: automatic, semi-automatic, and manual modes with different levels of data accuracy. Developers can choose one of them according to their preferences or familiarity with the PSP. Moreover, to gather the defect data automatically, the PSPCAT can extract the compiling and testing error messages from the Eclipse JDT compiler and JUnit [12] and compute defect fix time automatically based on how the defects are selected to remove by the developers. In addition, through analyzing the accumulated historical data, the PSPCAT can provide various process analysis reports, such as the project summary, the trends of quality and productivity, and the statistics of defects, time, and program size. These reports can help developers to understand their current process performance and analyze the causes to improve their software process.

The rest of the paper is organized as follows. In the next section, existing PSP supporting tools are briefly reviewed. Sections 3 and 4 describe the approaches used by PSPCAT to gather the PSP time and defect data, respectively. Section 5

presents the architecture design and the uses of the PSPCAT. The last section summarizes the conclusions and describes our future work.

II. Related Work

In this section, we briefly review several PSP data collection and analysis tools and make a comparison between these tools and PSPCAT.

Personal Software Process Studio (PSPS) [5] is proposed to facilitate the PSP discipline. It supports the tables and forms required for the entire PSP framework from PSP0 to PSP3. Basically, the PSPS allows developers to manually record the program size, time, and defect data. In addition, it provides PSP size estimation and project planning forms, design templates, project summary report, and Process Improvement Proposal (PIP) tables. The major deficiency of the PSPS is that developers need to keep track of the process data by themselves and have to manually record the data into the PSPS.

PSP Process Dashboard [6] is an open source PSP tool that provides all the scripts, tables, forms, standards, and analysis reports defined in the PSP. The PSP Process Dashboard completely advocates the PSP framework. It supports all the process definitions from PSP0 to PSP3 and, for each process definition, it includes all the process phases from the planning to the postmortem phase. However, similar to the PSPS, the PSP Process Dashboard is a standalone tool which is not integrated with any IDE tool. Thus, it requires developers to manually record their process data.

Hackystat [7] is an open source framework for automatic collection and analysis of process and product data. The Hackystat employs a client-server architecture. In particular, the Hackystat has provided various clients (or sensors) integrating with other tools, such as Eclipse, Emacs, JUnit, and Ant. These sensors can gather process and product data and send to a repository at server for further analysis. Developers can check their process and product data and corresponding analysis from the Hackystat server. Hackystat is able to collect the PSP data automatically. However, many defect data, such as defect type, defect injection and removal phases, and fix time, are not gathered. This could pose some limitations on defect analysis.

PSP Assistant (PSPA) [8] is a client-sever PSP supporting tool. The client of PSPA is an Eclipse plug-in that can automatically gather the program size and some defect data. Specifically, the PSPA can classify and rank the defects to assist developers to analyze their performance. It also can consolidate the schedules and defect data of individual developers into a schedule and defect library for the development team.

DuoTracker [9] is a tool for supporting software defect data collection and analysis. The DuoTracker can be integrated into a defect tracking tool, such as Bugzilla [13]. It allows developers to view the defect records reported in the defect tracking tool. The developers then can enter the PSP required information for selected defects. In addition, by integrating with the defect tracking tool, the DuoTracker can gather the defects occurred beyond the compile and test phases.

Table I shows the comparisons of the PSPCAT and other PSP supporting tools. In particular, the PSPCAT mainly focuses on the development phases of the process. It can avoid the cumbersome introduced by tool-switching and gather PSP data automatically or manually with different levels of data accuracy. Moreover, the PSPCAT can automatically compute the defect fix time and suggest the defect type. It also provides several PSP analysis reports and can export the process data in terms of XML format for the consolidation of team process data.

III. The Collection of the PSP Time Data

In order to better understand and improve software process, the PSP framework explicitly defines the process structure. Basically, a defined process consists of several phases, such as plan, design, code, compile, test, and postmortem. Developers have to gather the time and defect data for each phase. Since most developers employ the IDE tool only for developing programs not for planning or designing the projects, the PSPCAT is designed to gather the process data for the code, compile, and test phases instead of the entire PSP process.

Because not all the programmers are familiar with the PSP framework, the PSPCAT provides three data gathering modes: automatic, semi-automatic, and manual modes with different levels of data accuracy and user intervention to support most programmers to gather their process data. Developers can choose the data collection mode according to their familiarity with PSP or their needs for data accuracy. For example, the automatic mode can automatically track the process phases and gather the time and defect data of each phase without user intervention. However, this mode is unable to count the interrupt time of the process since there is no way to determine if the developers are thinking of the design or taking a break when they are not interacting with the computer. As a result, the time data gathered may not be fully accurate. To count the actual time spent on each phase correctly, developers can manually pause and resume the PSPCAT timer for each break (manual mode) or they can manually modify the automatically recorded time data to reflect the interrupt time (semi-automatic mode).

Moreover, the Eclipse supports continuous compilation in order to save the compilation time. This means that, when developers are writing code, the Eclipse will continuously compile the programs and show the syntax errors found so far. In such a case, there is no specific compile phase as defined in the PSP process structure. However, if the developers would like to analyze their process in detail, they may want to disable the continuous compilation in the Eclipse and to get their time spent on the compile phase. To support this, the PSPCAT gathers the time data of compile phase in the semi-automatic and manual modes. Table II lists the differences among the three data collection modes supported by PSPCAT. Basically, the automatic mode can change the process phase automatically, but it does not consider the compile phase and interrupt time. The manual mode requires developers to switch the process phases and record the interrupt time manually. The

TABLE I

THE COMPARISONS OF PSPCAT AND OTHER PSP TOOLS

Name	Time Logging	Defect Logging	LOC Counting	Project Summary/Analysis Reports	Data Export
PSP Process Dashboard	manual	manual	manual	project plan summary (PPS), analysis (full support)	no
PSPS	manual	manual	manual	PPS, analysis (full support)	no
Hackystat	auto	auto (no defect type & fix time)	auto	process summaries, analysis	yes
PSPA	auto	auto (no defect type & fix time)	auto	PPS, analysis (schedule, defects)	yes
DuoTracker	N/A	semi-auto	N/A	N/A	no
PSPCAT	manual/auto	manual/auto	manual/auto	PPS, analysis (quality, time, defect, size)	yes

TABLE II

THE DIFFERENCES AMONG THE PSPCAT DATA COLLECTION MODES

Differences	Auto Mode	Manual Mode	Semi-Auto Mode
Supported Process Phases	code, test	code, compile, test	code, compile, test
Change of Phase	automatic	manual	automatic (allow manual change)
Time Calculation	automatic (no interrupt time)	automatic (allow to pause/resume timer & change data)	automatic (allow to pause/resume timer & change data)
Interrupt or Break	not support	support	support
Defect Collection	automatic (no compile phase)	automatic	automatic

Process Analysis Reports	productivity, quality, defect, time, size (no compile phase)	productivity, quality, defect, time, size	productivity, quality, defect, time, size

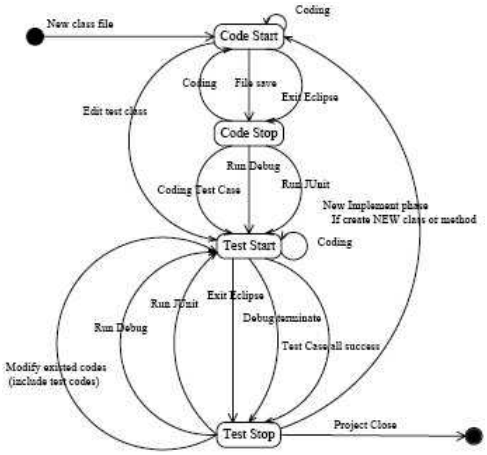

Fig. 1. The state diagram used to track the process phases (automatic mode)

semi-automatic mode is similar to the automatic mode, except it allows the recorded data to be updated manually.

It should be noted that the developers may not exactly follow the order of process steps defined in the PSP framework which requires the process phases to be changed sequentially. For example, developers can finish all the coding first and then compile and test the program; or they can code a little and test a little. To count the time spent on each phase without user involvement (i.e., automatic mode), the PSPCAT has to automatically track the current process phase of the project under development. To achieve this goal, the PSPCAT considers the start and stop of coding, compile, and test tasks as different states. The various events invoked by the developers or JUnit, such as creating a new class, exiting Eclipse, and invoking JUnit, are considered as transitions between the states. By listening to these events and computing the time period between the start and stop of the tasks, the PSPCAT can obtain the time that developers spend on each task (i.e., phase).

Figure 1 shows the task state diagram used to track the process phases in the automatic mode of the PSPCAT. The PSPCAT will detect the events occurred and change the states accordingly. For example, the occurrence of new class event indicates that the coding task is started. Likewise, the occurrence of "file save" event suggests that the coding task is stopped. Thus, the time spent on the code phase can be obtained by computing the time period between the start and stop of the coding task. Similarly, the process will change from the code phase to the test phase when developers create a new test class, lunch the Eclipse debug function, or invoke JUnit. The process will remain at test phase until the Eclipse debug function is terminated or all the JUnit test cases are passed.

IV. THE COLLECTION OF THE PSP DEFECT DATA

As compared with the time data collection, the gathering of the defect data is more time-consuming and error prone. Thus, the major focus of PSPCAT is to reduce the defect data collection overhead while increasing the data quality. To reduce human involvement, the PSPCAT employs two techniques to obtain the defect data automatically through (1) inserting a listener at Eclipse workbench to observe the compiling error messages; and (2) using the extension points provided by JUnit to obtain the execution results of test cases. The former allows the PSPCAT to gather the compiling defect data in the compile and test phases and the later allows the PSPCAT to collect the functional defect data in the test phase.

Note that the PSP defect data include the time when the defect was found, the defect number, the defect type, the defect injection phase, the defect removal phase, the defect fix time, and a brief defect description. Based on whether the defect data can be automatically obtained, the PSPCAT either collects the data directly or simply gives a default value. For example, to gather the defect descriptions, the PSPCAT obtains

the error messages directly from the Java compiler and JUnit. For gathering the defect types, the PSPCAT will initially assign the type of syntax error to those defects found by the compiler and the type of function error to those defects revealed by the JUnit. After reviewing the defect, developers can change the initial value and provide an appropriate defect type for the defect if necessary.

Moreover, to compute the defect fix time automatically, the PSPCAT exploits the "Goto" function provided by Eclipse. The "Goto" function basically allows developers to double click on an error message appeared in the Eclipse problems view so that the cursor of the Java editor will automatically move to the location of the corresponding error. It can help to locate the defect that developers would like to fix. Thus, by listening to the "Goto" event, the PSPCAT can obtain the defect that the developers may possibly aim to fix and record the start time (denoted as T_{start}) for removing the defect. After changing and recompiling the code, if the error does not appear in the problems view, the PSPCAT will consider this error being removed and record the stop time (denoted as T_{stop}) for fixing the defect. Thus, the defect fix time (denoted as T_{fix}) for this error can be computed using the following equation:

$$T_{fix} = (T_{stop} - T_{start})/N, \tag{1}$$

where N is the number of defects disappeared in the problems view due to this code modification. Since developers may not use the "Goto" function to fix a defect, the PSPCAT considers three possible debugging practices: (1) All defects are removed using the "Goto" function; (2) No defects are removed using the "Goto" function; and (3) Only part of the defects is removed using the "Goto" function. For the first case, the defect fix time can be computed by simply using equation (1). For the second case, the PSPCAT does not know which defect is going to be fixed by developers. Under such circumstance, the PSPCAT considers the defect fix time of each individual error as the average time spent on fixing a defect. Assume that the process is in the compile phase, the total number of compiling errors found is N_{total}, and the time spent on the compile phase is $T_{compile}$. The average fix time for each compiling error can be obtained using the equation below:

$$T_{fix} = T_{compile}/N_{total}. \tag{2}$$

For the last case, the PSPCAT uses equation (1) to compute the fix time for those defects removed through using the "Goto" function. The fix time for the remaining defects is derived from equation (2). Suppose that the process is in the compile phase, the total number of defects removed by the "Goto" function is N_{goto}, and the total time to fix these defects is T_{goto}. The average fix time for the remaining defects then can be derived from the following equation:

$$T_{fix} = (T_{compile} - T_{goto})/(N_{total} - N_{goto}). \tag{3}$$

In addition to compute the fix time of compiling defects, the PSPCAT also derives the fix time for the functional defects appeared in the JUnit failures window. The computation of fix time for the functional defects is similar to that of fix time for the compiling defects since the JUnit also supports the "Goto" function allowing developers to double click on a failure test method in order to open the test method in the Java editor.

V. The Architecture Design and the Uses of the PSPCAT

In this section, the system architecture of PSPCAT is briefly described and some screen shots are provided to illustrate the uses of the PSPCAT. Figure 2 shows the architecture design of the PSPCAT. Basically, the PSPCAT consists of four subsystems. Each of the subsystems is described briefly as follows:

- The Data Collection Subsystem (DCS) mainly focuses on the gathering of process data, including the project plan summary, size, time, and various defect data.
- The Controller and Plug-in Subsystem (CPS) manages the interactions among the subsystems and the Eclipse platform. In particular, the CPS controls the changes of the PSP phases, observes various Eclipse events through the workbench, and accesses the project information through the Eclipse workspace.
- The Data Analysis Subsystem (DAS) provides the PSP project plan summary and various statistic analysis reports based on the collected process data, such as the size and time trends, productivity, defect distribution, and quality analysis.
- The Data Management Subsystem (DMS) mainly supports the management of the gathered process data. It provides the repository for the historical project data and the functionality to export and upload the data to external server.

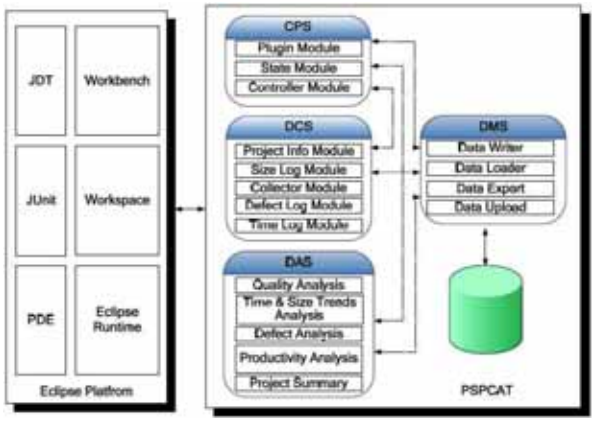

Fig. 2. The architecture of the PSPCAT

To use the PSPCAT, developers first need to enable the data collection and specify the data collection mode and data repository. Once the data collection is enabled, the process

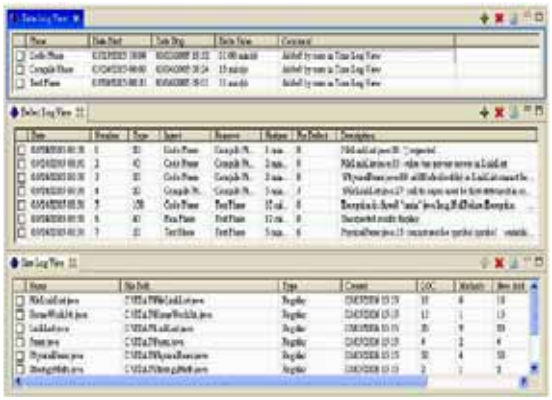

Fig. 3. Examples of the size, time, and defect logs in PSPCAT

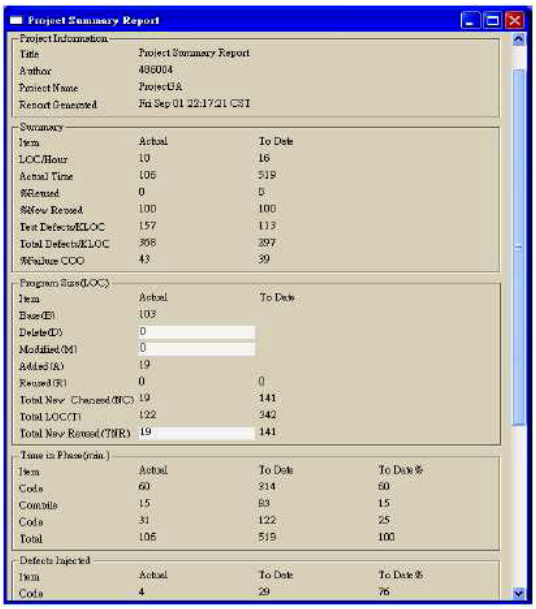

Fig. 4. An example of the PSPCAT project plan summary

data of the project under development can be gathered automatically or manually. The gathered data are then shown in the corresponding log views. Figure 3 presents the log views for the size, time, and defect data. Developers can insert, delete, update, or sort out the data records in each log view.

After a project is completed, the PSPCAT can analyze the process data logs and provide the PSP plan summary for the project. As shown in Figure 4, the project plan summary includes the overall summary of the project and the statistics of the collected size, time, and defect data. Based on the gathered data, the PSPCAT also provides process analysis reports that can help developers to examine and improve their software process. Figure 5 shows some examples of the process analysis reports provided by PSPCAT.

VI. Conclusions and Future Work

This paper has presented an Eclipse plug-in tool called PSPCAT to support automatic PSP data collection and analysis. By integrating with the Eclipse platform, the proposed tool

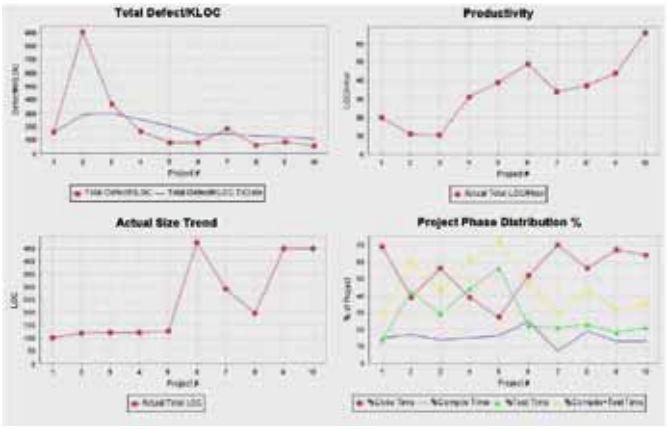

Fig. 5. Examples of process analysis reports provided by PSPCAT

can reduce the tool-switching overhead and the possibility of making mistakes in gathering process data. In particular, the tool provides three data collection modes with different levels of data accuracy to support different needs of developers and programming practices. The proposed tool also provides various analysis reports to help developers to understand their development performance and to improve their software process.

Currently, the PSPCAT gathers only the PSP data in the code, compile, and test phases. In the future, we plan to enhance the PSPCAT to support the entire PSP framework. Moreover, we plan to extend the PSPCAT to support the Team Software Process (TSP) [14] based on the client-server architecture. The process data of each team member collected by the PSPCAT client can be consolidated at the PSPCAT server so as to obtain the TSP data to analyze the team performance and to improve the team software process.

A Systematic Method for Process Tailoring Based on Knowledge Reuse

Xiao-yang He, Ya-sha Wang*, Yu-xin Teng and Jin-gang Guo
Institute of Software, School of Electronics Engineering and Computer Science, Peking University, Beijing 100871, China;
Key laboratory of High Confidence Software Technologies (Peking University), Ministry of Education, Beijing 100871, China

Abstract Process tailoring largely depends on experts' knowledge and might be time-consuming, costly and error-prone. Actually, process tailoring knowledge should be captured, documented and reused for future projects. To address this problem, a systematic method for process tailoring is proposed. The factors that strongly influence process tailoring are recognized as process drivers. The reusable process tailoring knowledge is organized by packages. Each package contains a certain process driver and its impact on the process framework which is the general process for tailoring. Aided by a conflict resolving model which checks and resolves possible conflicts between different packages, the packages can be reused for generating a project-specific process. A case study of RUP tailoring is presented to validate the method proposed.

1. Introduction

A well-defined software process is critical to improving software productivity and quality. Many a software process framework has been published, such as Rational Unified Process(RUP)[1], V-Modell XT[2] etc., which provides a good starting point in software process construction. However, they have to be tailored, downscaled and specialized to the context of use[3, 4].

Certain factors that strongly influence process tailoring have been recognized, for example, system scale, system complexity and time pressure of the project. Generally, experts make tailoring decisions based on the perceiving of the factors in a given context and the knowledge of the factors' influence on the process. These factors are named as process drivers in this paper.

According to [3], the practice of adjusting a standard software development process to accommodate differences among projects is called tailoring. So far, process tailoring largely depends on experts' knowledge, and might be time-consuming, costly, and error-prone[4, 5]. To address this problem, a systematic way for process tailoring based on knowledge reuse is proposed.

Our method consists of two steps. (1) Capturing and documenting the reusable knowledge of process tailoring. The reusable knowledge is packaged in the light of process drivers. Each package contains the information of a certain process driver and its influence on the process. (2) Tailoring the process by reusing the packaged knowledge. A conflict resolving model, which is abbreviated to conflict model, give support to resolve possible conflicts when more than one package is applied to process framework.

2. The Method for Process Tailoring

The purpose of this paper is to improve the effectiveness and efficiency of process tailoring by capturing and sharing the tailoring knowledge within the organization. The knowledge is explicitly documented and organized as reusable process tailoring packages.

There are two principal roles. The first one is Process Engineer who is in charge of capturing the process tailoring knowledge and developing the tailoring packages for reuse in different projects, while the other one is Project Manager who is responsible for creating project-specific process with reuse of the tailoring packages. The process of the method is presented with UML activity diagram in Figure 1.

Generally, Process Engineer has abundant knowledge of the process framework, as well as the insight into the development situation of the organization. He is responsible for identifying process drivers from different aspects (e.g. project, organization, person and product). These drivers characterize the profile of development situation, and each driver defines some project-specific requirement of the process which can be transformed into process tailoring operations on the process framework. For example, the *new system development* project requires more user-developer interaction than the *existing system modification* project. The Process Engineer may identify a process driver, which is called *new system development*. This process driver requires supplementing some user interaction activities and

The work is funded by Grant 2006AA01Z189 from Hi-Tech Research and Development Program of China and Grant2005CB321805 from the National Key Basic Research of China.

adding additional prototype-development iteration into the process framework; furthermore, the activity of *analyze the difference between the existing system and new system*

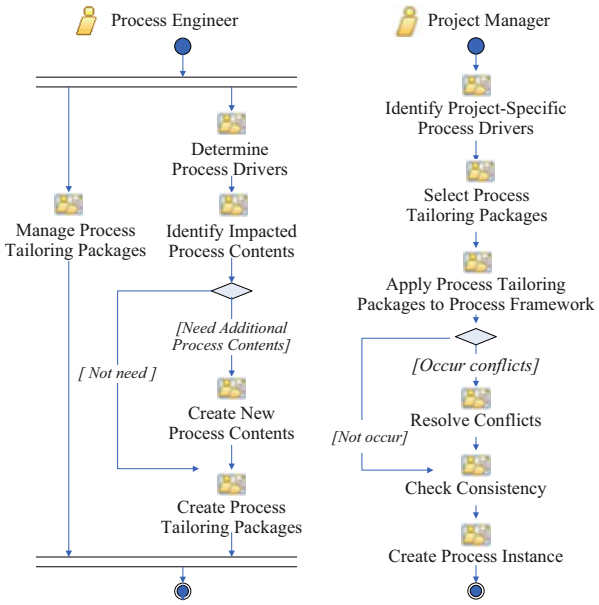

Figure 1 Process of the Tailoring Method

requirement in the process framework can be deleted. For every process driver, Process Engineer should analyze which process contents are impacted. If the existing process could not fully meet with the requirements of process drivers, new process contents are created. Process Engineer, then, creates Process Tailoring Packages, which present how process drivers impact the process contents. Process Tailoring Package itself is not a complete software process but externally defines the modifications to process framework.

Project Manager analyzes the characteristics of the project at hand and determines the project-specific process drivers. For every process driver, a Process Tailoring Package is selected. When more than one package is applied to the process framework, conflicts may occur. In this case, the project manager should resolve the conflicts with the help of a predefined conflict model explained in section 4. Finally, the project-specific process instance is created.

3. Meta-model of Reusable Knowledge Packages

To effectively represent and organize the process tailoring knowledge, a meta-model is proposed to demonstrate the core concepts and their relationships. It is shown in Figure 2 with UML class diagram.

For the sake of concision and clarity, we only focus on those fundamental concepts of process meta-model. A Work Definition describes a unit of work with the clear purpose, usually expressed in terms of creating or updating some Work Products. Within a Work Definition, each performing Role achieves a well-defined goal. Work Definition is the abstract class of Activity and Task. Activity supports the nesting and logical grouping of Tasks which can be broken down into Steps.

A Process Driver focuses on a certain concern which the process tailoring aims to handle. Every Process Driver is associated with a Process Tailoring Package. A Process Tailoring Package consists of one to more Impact Pieces which describes the information of exactly one tailoring operation. There are three classes named Contribute, Suppress, and Replace implementing the abstract class Impact Operation. They define the concrete types of tailoring operation, which denote adding, deleting and modifying Work Definition respectively.

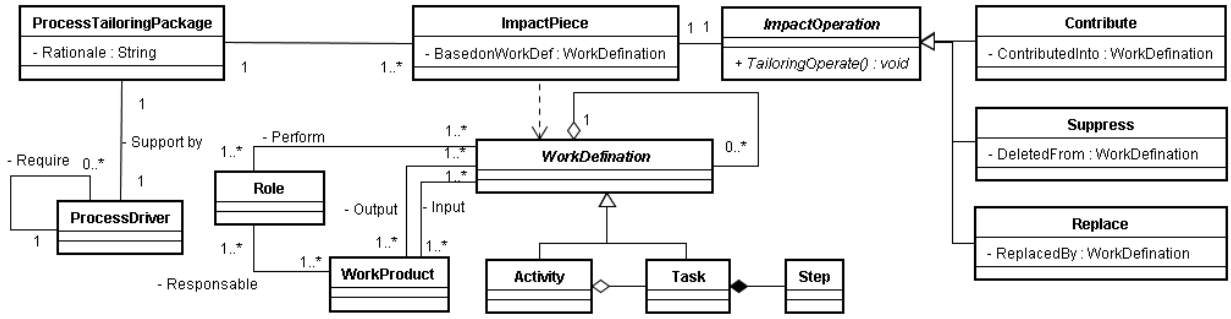

Figure 2 Meta-model of the Reusable Tailoring Knowledge

4. Conflict Resolution

Conflicts may occur when more than one Process Tailoring Package is applied to process framework. The conflicts result from different Process Tailoring Packages attempting to modify the same Work Definition in different way. For example, one Process Tailoring Package may attempt to replace an activity while another one may want to remove it.

In order to resolve the conflicts, two issues should be concerned: (1) How to identify the place where the conflict occurs? (2) What action should be taken if conflict occurs?

According to the place where the conflicts occur, two types of conflict are identified. Assuming Work Definition W_a and W_b are impacted by two Process Tailoring Packages, say package P_a and P_b respectively. If W_a and W_b are exactly the same Work Definition, a homo-place conflict

occurs. If W_a is a part of W_b (e.g., W_a is a sub-activity of W_b), a hetero-place conflict occurs, vice versa. Considering an example, a certain package demands delete an activity, while another package requires replace a task in the same activity, a hetero-place conflict appears.

+C	*+C*

+R	*+R*	*+R*	*+R*
	- C	**- S**	**- R**

(b) Hetero-place Model

Figure 3 Confliction Model

The conflict models of these two types are shown in Figure 3. C, S and R respectively represent the tailoring operation Contribute, Suppress and Replace. Additionally, a special mark ('+' / '-') is added as the prefix of the Impact Operation. Symbol '+' means the Impact Operation directly acting on the Work Definition; Symbol '-' means the Impact Operation acting on the sub-element of the Work Definition. The cross units represents the action of conflict resolution actually taken. Besides the typical Impact Operation types, there are additional action types:

- *N*: Two operation types would not occur simultaneously.
- *H*: Operation actually adopted is up to Project Engineer.

Moreover, the reasons behind the operation 'S' are further analyzed:

- *Not needed*: the Work Definition is not needed at all. An example is that the development of operation system does not need the activity of "Design the Database".
- *Valueless*: There is not enough time and effort to implement a certain Work Definition, or the Work Definition would not bring any value.

Symbol '/' separates the action types by the reasons behind the operation 'S'. The former action is taken if the reason is "Not needed", or else the latter is taken.

```
Create a tree T by composition relationship between the Work Definitions;
For every ImpactPiece instance I:
   mark node I.BasedonWorkDef with '+' and I. OperationType;
Post-order Traversal (T):
   While node X.Number of marks >=2 and X.Number of marks ('+')>=1:
      Select any Impact Operations Ia, Ib on condition that (Ia.mark = '+'
         or Ib.mark = '+)';
      If Ia.mark='+' and Ib.mark='+':
         Then take action A according to Figure 3(a);
      Else take action A according to Figure 3(b);
      If A ='H':
         Then { Insert node X into Conflict list C; set X.OperationType='R';}
      Delete unneeded Operation Ia or Ib from Node X;
   End while;
   If X.OperationType ='S': Then delete node X and all X Offspring;
   Else if X.OperationType ='R': Then delete all node X.Offspring;
   If X. Number of OperationType >0:
      Then Append mark '-' and X. OperationType to X.Parent
End Traversal;
If C.IsEmpty: output (T);                    //Output the tailored process
Else output C;          //Output all conflicts needed manual intervention
```

Figure4 Conflict Checking and Resolving Algorithm

A conflict checking and resolving algorithm described with pseudo code is shown in Figure 4. Firstly, a tree is generated in terms of composition relationship between the Work Definitions in process framework. Special marks are added to corresponding node for every Impact Piece. Each node is checked by post-order traversal then. If there is a homo-place or hetero-place conflict, an action is taken according to conflict model. If there is no conflict which needs manual intervention, a tailored process is generated, or else the places conflicts occur are pointed out.

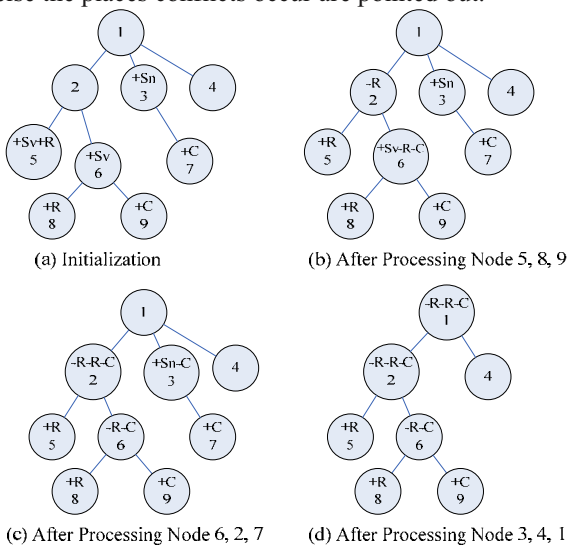

Figure 5 Example of the Algorithm Applied

An example is shown to illustrate the algorithm mentioned above. The initial status of the tree is shown in Figure 5(a). The nodes are checked in turns by post-order transversal. In Figure 5(b), the Impact Operation 'R' of node 8 and the Impact Operation 'C' of node 9 are transferred to node 6 and marked with '-', so the mark of node 6 is changed to "+S-R-C". There is a hetero-place conflict between "+S" and "-C", thus the conflict is resolved according to Figure 3(b). In particular, the operation 'S' here is "Valueless" suppression, so the actual tailoring operation adopted is 'R' and the mark of node 6 is changed to "-R-C". Now node 6 doesn't have any other conflict and its operation 'R' and 'C' is transferred to node 2. Other nodes are processed in the same way, shown in Figure 5(c) and 5(d).

5. Case Study

For empirical validation of the method proposed, we applied it in a company which specialized in software development of web-based solutions to general business. The company had adopted RUP as its process framework but process tailoring was carried out in an ad-hoc way, so it showed great readiness to improve process tailoring.

First, we worked with the company's experts to identify those distinct characteristics of the organization and its common project types. After that we captured and documented the knowledge of how these drivers impact the RUP based on the experts' previous experience. For

example, the driver of "High Usability" specially focuses on analyzing user and usability requirements, and asks for adding two new tasks into the activity of "Understand Stakeholder Needs". A process asset library is established to store the reusable process tailoring knowledge.

A project of online bookstore made a request for tailoring process. The size of project was small that only five developers were engaged within the duration of three to four months. The customers of online bookstore are members of the general public, not technical experts. Hence, application usability must be high. The customers also pay extremely attention to privacy protection and security of transaction security. As a result, the drivers of "Small Size Project", "High Usability" and "High Security" are the first-class concerns. Then the corresponding process tailoring packages selected are applied to RUP to generate project-specific process. For lack of space, the resulting process is omitted in this paper.

With the accumulation of the process tailoring knowledge within the organization, the method proposed can drastically improve the efficiency of tailoring.

6. Related Work

Although process tailoring is a mandatory activity for organization adopting process framework, it strongly depends on experts' knowledge[4]. The amount of research done on process tailoring to date can be considered small.

It is shown that knowledge reuse can improve efficiency and effectiveness of process tailoring[5]. Case-based reasoning is adopted to facilitate reusing the cases to customize the target process [6, 7]. However, any two projects are different, so a process successfully applied to one project may not work in another[4]. Partitioning the tailoring knowledge by process driver has much more reusability and flexibility than the case. The knowledge based inference technique is also utilized in [7] to derive process. Every process driver is supported or deactivated by a set of activities. The selected activities are integrated to generate process. But it is very troublesome to combine activities one by one. Its conflicts resolution is achieved by constraining selecting incompatible drivers simultaneously. Such a disposal is not reasonable in practice. Karlsson[8] utilizes the concept of Configuration Packages which are pre-made reusable configurations of a base method suitable for a characteristic. Combining configuration packages will result in overlapped activities and increase the overload of tailoring effort. He just simply adopts priority-based policy and leave human to deal with conflicts.

RUP itself contains configuration activities, which create a Development Case. But these activities are not sufficient, at least not considering reusability of tailoring knowledge.

7. Conclusions and Future Work

No single process is suitable for all software projects. The process framework must be adapted to the specific context, which requires substantial up front effort. Reuse of the tailoring knowledge can drastically improve the effectiveness and efficiency of tailoring.

This paper proposes a method for process tailoring based on the concepts of process driver and process tailoring package. Partitioning tailoring knowledge by process driver is propitious to narrow the focus at a time and improve reusability. In particular, the process tailoring package externally defines the changes to the process framework, which provides more flexibilities than directly modifying process framework. The way of applying process tailoring packages to process framework is more efficient than that of combining activities required by process drivers. Moreover, the decision model and the algorithm proposed provide the strong support for conflict checking and resolving.

The meta-model proposed in this paper is based on the Software Process Engineering Specification v1.1 (SPEM)[9]. The forthcoming SPEM v2.0 plans to separate Method Contents from Process. More dedicated analysis should be taken to deal with the new change.

Abstract

In this paper, we present a process for linking organizational training efforts with defects causal analysis in software development organizations. The process is being implemented in a CMMI maturity level 3 organization. Since causal analysis is not an expected process area at maturity level three, key success factors for the implementation of the process are identified and analyzed. The conclusions were tested in this software development organization. In order to do that, a pilot project was selected and training was implemented to support the process. The training results are analyzed in order to validate the overall approach. The resulting work provides a guideline for implementing causal analysis in lower maturity organizations and establishes that the implementation is viable in the target organization.

1. Introduction

Organizations nowadays invest large amounts of money in their training programs. Just in the United States, organizations invest an average of U$S 100 billion annually [1]. Organizations invest in training under the assumption that higher trained employees will result in higher quality products and reduced costs.

Nevertheless, in spite of all this investment and effort, organizations have not been so successful at providing consistent data that will link the investment on organizational training to organizational results.

Kirkpatrick's four levels of training evaluation establishes a framework against which organizations can measure up its investment in training. Kirkpatrick's four levels are called: *Reaction,* where trainees feelings towards the training are measured; *learning,* were trainees acquired knowledge is measured; *Transfer,* in which a measure of the amount of the Learned knowledge as actually put to use in the work; and *Results,* were impact to the organization's bottom line results is measured.

In this paper we propose a process for an organizational training department within a CMMI [2] maturity level 3 (CMMI L3), that addresses this problem. Our objective is to design a training process that is able to present results at Kirkpatrick's "Results" level [3].

The key aspect for the successful implementation of our process is the capability of the organization in defects causal analysis. Since the Causal Analysis and Resolution (CAR) process area belongs to maturity level 5 in the staged representation of the CMMI model, we want to make sure that the implementation of some causal analysis specific practices is possible in a level 3 organization.

In the following section, we provide an overview of the target organization, followed by our process proposal for the training department. Then in section 4, , we provide an analysis of the current state of causal analysis research. We specifically focus on linking causal analysis to organizational training. We finally provide data on the implementation and validation of causal analysis sessions within a maturity level 3 organization.

2. Brief description of the target organization and its infrastructure

The organization we are working with has recently obtained a maturity level 3 rating. It is a software factory that provides customized software solutions to in-shore and off-shore customers. Its development offices are located in Uruguay, and it has sales offices in the Caribbean and Mexico.

In the past two years, the organizational training department has invested - in US dollars - the equivalent to 7% of billable working time of their software developers. As a result, the training department needs to show the organization the return of its investment.

A Microsoft Office SharePoint Server supports the organizational measurement system. The SharePoint Server allows for the interoperation with other Office tools, for instance Microsoft Access is used for data analysis needs and the front end for data recollection is usually a Microsoft InfoPath form. The organization defect tracking system is one example.

Currently, the training department is using the described tools for its measurement needs. However, its data repository is not yet linked to the defect tracking system.

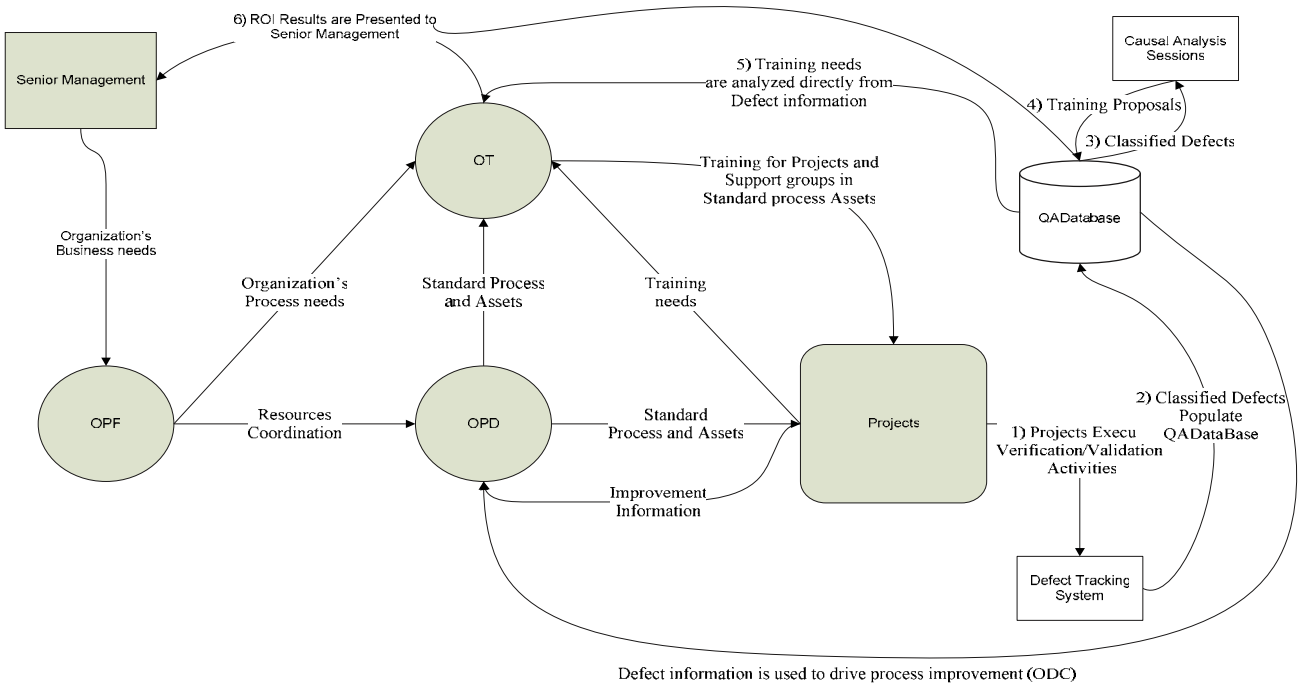

Figure 1 Overview of the Proposed Process

3. A description of our proposed process

This section describes the process we are deploying in order to link organizational training results to defects causal analysis. The idea is to make use of the information available at a CMMI L3 organization. Specifically, we want the training department to take advantage of the data available in the organization's defect tracking system. The purpose is that the training department will monitor the defect data in the system and will interpret the data as the training needs of the organization's development projects. The training department will use this information to plan training interventions specifically tailored to the development projects needs. We expect that those interventions will have positive results in the projects quality, and that those results will be noticeable in a reduction of the number of defects.

Figure 1 uses the diagram from the CMMI basic process management areas [2] in order to help us illustrate our process (items which come from the original CMMI diagram are shown in grey color, items from our proposal are left in white).

The first requirement of our process is that the defect tracking system must support a classification scheme that will allow for easier data analysis. IBM's Orthogonal Defect Classification (ODC) [4] is an example of one of such schemes, and the one we have used as reference. ODC is described in section 5.1.

In this process, when developers execute Verification and Validation activities they are required to classify the defects they log into the defect tracking system (arrow **1**). During the course of the projects life cycle, the execution of Validation and Verification activities will populate the Defect Tracking System database (QADataBase) with classified defects (arrow **2**).

At every project's milestone, the development team (arrows **3**) holds causal analysis meetings. The objective of these meetings is to provide the training department with training proposals. The idea is that developers will take the classified defect data (arrow **3**) from the QADatabase and identify which training they would have needed in order to prevent some of the mistakes that triggered the defects (arrow **4**).

The training department will use both the classified defects from the QADatabase and the outputs from the causal analysis sessions in order to plan the training interventions (arrow **5**).

Arrow **6** represents the ultimate goal of this proposal, which is the ability to show results in terms of Return on Investment (ROI) [5]. Return on Investment is interpreted as a Kirkpatrick's "Results" level measurement. Return on investment can be calculated by taking into account the defect reduction that should be noticed after the training department intervention. We expect to use the ROI classical formula to calculate ROI:

$$ROI = \frac{100 * (Benefits - Costs)}{Costs}$$ [5].

As a first step into the implementation of this process, we will turn our attention to validate arrows **3** and **4** of this cycle. First, we will present a systematic review of available literature about the implementation of causal analysis process area in lower maturity organizations. Our objective is to see if there have been previous attempts at

implementing causal analysis in a context similar to the one we have described. If the review is successful, we will turn our attention into developing and validating a consistent classification scheme within the organization.

4. A review of causal analysis methodologies

Since Causal Analysis and Resolution (CAR) is a CMMI L5 process area, we cannot expect to see a CAR process deployed in a level 3 organization. Yet, the causal analysis meeting is the critical success factor of our process since the output of the causal analysis meeting (arrow **3**) is one of the inputs that the training department will need in order to plan and deploy the training interventions.

A systematic review [6] of the causal analysis bibliography was carried out. Our objective was to answer these two questions: **A)** Has anybody else tried to implement CAR at a CMMI L3 organization? **B)** What are people doing with the results of the CAR meeting?

Table 1 shows a summary of the results of the systematic review on the implementation of causal analysis in lower maturity organizations.

Table 1 Summary of the reviewed literature

Authors	Is it a Lower Maturity (L2 or L3) Organization?	Purpose of CAR analysis
Buglione, L et al. [7]	Yes	N/A just the challenge of implementing it at lower maturity organizations
Bhandari, I et al [8]	No	Process Improvement
Card D. N. [9]	No	Process Improvement
Card D. N.[10]	No	Project Defect Profile
Card D. N.[11]	N/A	Cost Saving by Defect Reduction
Mitzukami D.[12]	No	Project Defect Profile
Lezak M et al. [13]	No	Process Improvement
Fredericks M et al[14]	No	Process Improvement
Norman E.F. [15]	N/A	Defect Prediction
Bibi S. et al [16]	N/A	Project Defect Profile and Defect Prediction
Jacobs J. C. et al [17]	N/A	Project Defect Profile and Defect Prediction

In reference to our first question, we only found one reference [7] which shows that CAR can be implemented at a maturity level 3 organization (question **A**). The research done by Buglione and Abram [7], describes how it is possible to implement a CAR process area in organizations that have not yet achieved higher maturity rating. They base their implementation of the causal analysis meeting using Ishikawa (or Fishbones) diagrams [18] and defects have been classified using IBM's Orthogonal Defect Classification [4].

Finally, Table 1 shows that we have classified the results of Causal Analysis in three categories (question **B**). "Process Improvement" is the category that reports using Causal Analysis results as an input to process improvement initiatives. This use is aligned with [4] first proposal of ODC. The "Project Defect Profile" category represents initiatives that use defect data to compare the actual project to the historical projects database of the organization. They use Causal Analysis to understand deviations from the historical data and to implement corrective actions to their project and to the organization's process. In the "Defect Prediction", we have seen attempts to use artificial intelligence techniques to profile project's defects and to predict the number of remaining defects. Finally, "Cost Saving by Defect Reduction", means that the implementation of causal analysis can provide cost savings. All the results show the intended uses of causal analysis as they are recommended in the CMMI model. Unlike our research objective, none of the reviewed authors have linked causal analysis to training needs.

5. Development and Validation of the classification scheme

For a successful implementation of causal analysis session, the organization must develop a classification scheme that will enable developers to consistently classify defects. This section starts by presenting an overview of IBM's ODC taxonomy, which has served as the groundwork for our classification scheme. We then describe our implementation and our results.

5.1. Reference classification scheme: Orthogonal Defect Classification

At IBM [4, 20, 21] Defect Data classification has been used to drive Software Process Improvement initiatives. They call their process Orthogonal Defect Classification (ODC). Within the ODC context, developers classify defect data in orthogonal classifications. IBM proposes a taxonomy for defect classification based on the source of the defects:

- *Education*, in this category the developer did not understand some aspect of the product or the process. This

category is further divided into education in base code, education in new function, and other education, depending on what was not understood.

- *Communication*, in this category the developer did not receive the required information or the information was incorrect.
- *Oversight,* in this category the developer failed to consider all cases and conditions. Usually some detail of the problem or process was overlooked. The developer forgot something, had difficulty checking thoroughly, or did not have enough time to be thorough.
- *Transcript*. In this category the developer knew what to do and understood the item thoroughly but simply made a mistake. Transcription errors are typically caused by some problem in a procedure, for example, typing or copying a list of items.

In relation to ODC we have reviewed the work by [19], where they recognize the importance of having a classification scheme that is consistent with the organizations' tools and culture.

5.2. Classification Scheme implementation plan

The classification scheme was developed based on the advice in [19]. In their work, the authors recognize the benefits that the organizations can obtain if they take the time to develop their own classification scheme consistent with their information needs. As a result of this work, it was decided to develop a classification scheme that was suitable for our target organization. We divided the deployment plan in four major stages (as shown in Table 2). In the first stage, we developed the custom classification scheme. Secondly, the classification scheme was deployed to the organization through its defect tracking system (this is described in this section). Then, training in developing classification ability had to be implemented in order to achieve a reliable classification capability within the organization (described in the following section).

Table 2 Classification scheme deployment plan

Stage	Activity
Organizations Capability	Design and Validate classification scheme
Deploy Classification scheme	Modify defect tracking system
Training	Design and deploy classification training Evaluate training results

As we mentioned earlier, to minimize the rejection risk of the classification deployment, it is important that the classification taxonomy was consistent with its information needs and culture[19]. A custom classification was developed with the help of the practitioners. Furthermore, the researchers established equivalence between the organization's classification and ODC (see Table 3[1]).

The organization was already using a defect tracking system whose defect states were the ones proposed by the Microsoft Solution Framework for CMMI Process Improvement [20]. Therefore, implementing the ODClike classification went seamless in the developer's culture. The new classification scheme had to be implemented into the defect tracking system front end (a Microsoft InfoPath form template), which required only 4 hours work.

Table 3 Example of the organization's defect classification scheme

Defect Category	Classification Criteria	ODC Category Equivalence
Product Integration Error	Interface implementation does not match specification. Changes are not transferred to lower layers. Data not transferred from lower layers.	Communication
Error in use or configuration of user interface controls	Controls 'Freeze'. Paging not working in DataGrids. DataGrids missing headers.	Education
…	…	…

5.3. Description of the classification training and its results

For a successful implementation of the causal analysis meetings the developers must be consistent in their defect classification across the organization. A training event was prepared for the pilot project's developers.

Three of the organization's developers attended training. One of the trainees (C1) was a senior developer of the organization. The other two developers had experience in the pilot project's product line. Moreover, since we wanted to simulate the turnover rate of the organization, we included a fourth individual (O) to our experiment. This fourth subject had no contact with the organization and was given no training in the classification scheme.

The training consisted on a 4-hour seminar split into 2 days. The seminar was prepared and given by one of the

[1] Since defect data can be sensitive to the organization, we were asked to show only what was strictly necessary to communicate our results. Hence, we decided not to include the full classification scheme here.

researchers. This kind of training is the standard training effort that this organization invests on a given process. The organization's training events of this kind are similar to the ones described in [21]. During the seminar, an explanation of the causal analysis meetings purposes was given to the trainees. The classification scheme was presented with a sample defect for each one of the 12 classification categories.

For training evaluation, we provided the trainees with a set of 31 defects which we asked them to classify. We wanted a measure of how reliable the classification was between the trained developers. For this objective we applied Cohen's Kappa [22] between each of the subjects following a process similar to the one shown in [19, 23]. Cohen's Kappa is a statistical measure of inter-rater reliability, it is used to compare the level of agreement between two subjects who are classifying the same data set. We also applied the Kappa correlation to the outsider (O), and to an expert classifier (E). Our intention was to measure how the untrained individual rated against the other subjects. Furthermore, we applied a Fleiss' Kappa [24] to the trained group, and to the trained group plus the untrained subject. Fleiss' Kappa is a statistical measure for assessing the agreement of a number of subjects classifying a fixed data set. We expect that the examination of the results will show that trained individuals score higher correlation values than untrained individuals.

Table 4 shows the results for every pair: E represents the expert rater (one of the analysts who helped develop the classification). C1 – C3 represent the trained developers and O represents the outsider. While Table 5 presents the Fleiss' Kappa results with and without the Outsider.

Table 4 Cohen's Kappa between subjects

Subjects	Cohen's Kappa significance	Subjects	Cohen's Kappa significance
E – C1	0,73	C1 – C3	0,47
E – C2	0,55	C1 – O	0,36
E – C3	0,52	C2 – C3	0,52
E - O	0,34	C2 – O	0,37
C1 – C2	0,62	C3 – O	0,30

Table 5 Fleiss' Kappa calculation results

Subject Group	K agreement
E-C1-C2-C3	0,53
E-C1-C2-C3-O	0,44

Table 6 presents the significance agreement intervals for both Cohen's and Fleiss' Kappas proposed by [25]. Based on this table, we set the objective for accepting developers' classification agreement in the "Substantial Agreement" interval or above.

Table 6 Kappa significance table for Cohen and Fleiss

Cohen's Kappa	Significance
< 0	Poor Agreement
0.00 – 0,20	Slight Agreement
0,21 – 0,40	Fair Agreement
0,41 – 0,60	Moderate Agreement
0,61 – 0,80	Substantial Agreement
0,81 – 1	Almost Perfect Agreement

Table 5 shows that the group did not achieve the target score, which is an indication of the effectiveness of the training. Nevertheless, the most remarkable result is that the inclusion of an untrained individual does not reduce the overall agreement significance.

The result on the exercise provides enough confidence in that the developers (C1-C3) are able to consistently classify defects according to the organization's classification scheme. Such results will enable the training department to process the causal analysis meetings output as input for specific training to the projects. In addition to this, results also show the importance of training for supporting the classification scheme.

The results in Table 4 show that training has effect on the subjects' ability to classify. This conclusion is drawn from Table 4 where we can see that trained subjects score higher agreement among themselves than when there are compared with the untrained subject. On the other hand, some of the trained subjects have failed to meet the 0,61 expected rate. We interpret this as an indication that training can be improved. This conclusion is supported by the fact that all three trained subjects scored correlations in the same significance category (between 0,47 and 0,62). In any event, the results have shown that with a 4 hour training regular developers classify 50% better that junior developers. And senior developers achieve a classification ability that scores substantial agreement in the correlation table. Finally, the comparison of the results with the untrained subject proves that training has impact on the classification ability of the developers. Taking into consideration the inclusion of the untrained subject shown in Table 5, it seems that the organization would do better to improve the efficiency of the training given, rather than achieving 100% training coverage of their developers.

6. Conclusions and future work

In this article, we have proposed a process that links defect causal analysis to the training department. The process enables an organizational training department to show its contribution to the bottom line results of the organization. We have taken the first steps into implementing the process and we have also conducted a verification of these first steps.

It was determined that the key point for the success of the deployment of the process was the causal analysis session. An effort was made to reviewing the current state of the implementation of causal analysis in lower maturity organizations. The result was that we were able to find research that shows implementing causal analysis in lower maturity organizations is possible.

We developed a custom classification scheme for the organization, and cost-effectively modified the defect tracking system to deploy it.

Training in that classification scheme was given to a pilot project. The results show that training improves the developers' ability to classify defects.

In conclusion, causal analysis meetings have been successfully implemented in a maturity level 3 organization. Previous experiences encourage us to affirm that an implementation of the Causal Analysis and Resolution process area can be achieved at a lower maturity organization. We are now developing the following steps to achieve a full implementation of the proposed process.

Abstract

Enterprise Applications (EA) are complex software systems for supporting the business of companies. Evolution of an EA should not affect its availability, e.g., because of a temporal shutdown, business operations may be affected. One possibility to address this problem is the seamless reconfiguration of the affected EA, i.e., applying the relevant changes while the system is running. Our approach to seamless reconfiguration focuses on component-oriented EAs. It is based on the Autonomic Computing infrastructure mKernel *that enables the management of EAs that are realized using Enterprise Java Beans (EJB) 3.0 technology. In contrast to other approaches that provide no or only limited reconfiguration facilities, our approach consists of a comprehensive set of steps, that perform fine-grained reconfiguration tasks. These steps can be combined into generic and autonomous reconfiguration procedures for EJB-based EAs. The procedures are not limited to a certain reconfiguration strategy. Instead, our approach provides several reusable strategies and is extensible w.r.t. the opportunity to integrate new ones.*

Keywords: maintenance, seamless reconfiguration, EJB

1. Introduction

Enterprise Applications (EA) are complex software systems for supporting the business of a company. According to Lehman's laws [10] software implementing real world applications like EAs must continually evolve, else their use and value would decline. The need for system evolution originates, e.g., from failures, inefficiencies or changes of the business or of the system environment that lead to new or changing requirements for EAs. Thus, system evolution can be categorized as *corrective* (removing software faults), *adaptive* (adjusting the system to the changing environment), or *perfective* (enhancing or improving the functional and non-functional system characteristics) (cf. [15, 18]). Due to the critical role of an EA within a company this evolution should not affect the availability of an EA and therefore the business operations. Otherwise, the company might miss business opportunities and loose reputation and trust. One approach to address this problem is the *seamless* reconfiguration, i.e., applying the relevant changes to the system while it is running. Except of delays in the response time reconfiguration should be transparent to the clients of the EA. This *post-deployment runtime evolution* can be seen as one critical challenge in software evolution [14]. To cope with this issue, the modularity of software systems, as proposed by the concept of *Component Orientation* (CO) [19], and the automation of system maintenance tasks, as described by the vision of *Autonomic Computing* (AC) [4, 8], can help. With the *mKernel* system [1, 2] a generic AC infrastructure is available that enables comprehensive management of component-oriented EAs that are realized with the *Enterprise Java Beans (EJB) 3.0* technology [3]. Based on *mKernel*, we provide a comprehensive set of steps, that are customizable and perform fine-grained reconfiguration tasks. These steps can be combined flexibly to generic and autonomous reconfiguration procedures for EJB-based EAs. Each of these procedures realizes a certain *reconfiguration strategy*, i.e., a certain way to perform a reconfiguration. Currently, our approach provides four reusable strategies that serve as templates for easing the planning and execution of a concrete reconfiguration.

The rest of the paper is structured as follows: Section 2 provides an overview to the background, namely system reconfiguration, CO and the AC infrastructure *mKernel*. Section 3 discusses related work, while section 4 presents our approach of reconfiguration procedures. Finally, the last section gives a conclusion and an outlook on future work.

2. Background

After introducing the basics of system reconfiguration, the concept of CO and relevant aspects of the EJB standard are presented. Finally, we describe how *mKernel* combines EJB with the vision of AC.

2.1. System Reconfiguration

The architecture of a software system is the *high-level organization of [its constituent] computational elements and the interactions between those elements* ([5], p.269). In this context, according to [13], there are two general approaches for software reconfiguration: *parameter adaptation* and *compositional adaptation*. The first one modifies variables of one or more elements that determine their behavior. The second one addresses structural reconfiguration through addition and removal of elements, including the manipulation of connections among them (cf. e.g. [9, 15, 17]). The weakness of parameter adaptation is that it allows only changes that were anticipated during development, because the elements have to provide the variables and react appropriately to their modifications. In contrast, compositional adaptation is intended for the dynamic and unanticipated reconfiguration of a system.

For carrying out a reconfiguration, two objectives are to be considered and desirable [9]. First, the reconfiguration should minimize the disruption to the system, i.e., the affected part of the system may notice delays but no failures, while the rest of the system should be able to continue its execution normally. Thus, reconfiguration should be carried out *seamlessly*. Second, a consistent state of the system must be preserved during and after reconfiguration. Consequently, a reconfiguration, like, e.g., the replacement of an element, may require to place the affected part of the system in a consistent state before structural changes are performed. A state is consistent if the affected elements are *quiescent* [9], i.e., none of them is currently engaged in servicing a request and none of them will initiate a request. Furthermore, no requests initiated by non-affected elements are forwarded to affected ones. To reach a quiescent state, requests that are currently serviced must be finished. New requests must be blocked except those which are needed to finish servicing ones. Otherwise, some elements are not able to reach a quiescent state and end up in a deadlock. Quiescence of the affected part of the system gives new elements the opportunity to be initialized in a state which is consistent with the rest of the system, and elements to be removed the opportunity to leave the system in a consistent state [9]. In case of an element replacement, this may include the need for transferring the internal state of a replaced element to a replacing one [15, 16].

How to apply changes are questions of reconfiguration strategies. In [16] the three strategies *Flash*, *Non-Interrupt* and *Interrupt* are presented. The *Flash* strategy reconfigures one element without concerning about other elements. Reconfiguration takes place immediately without handling existing interactions and the states of the affected elements. No state transfer is performed and existing connections to old elements are not updated. Therefore, these connections become invalid and are likely to cause errors. Finally, the system may become inconsistent. Consequently, *Flash* does not always perform a seamless and consistent reconfiguration. Nevertheless, it can be used, amongst others, for parameter adaptation or for reconfiguring elements not being critical for the consistency of the application. In contrast, the other strategies preserve consistency of the system and perform a seamless reconfiguration. The *Non-Interrupt* strategy supports the exchange of elements without the need for quiescence, hence reducing system disruption significantly. Both elements, the old one that is going to be replaced and the replacing one, are active. An intercepting facility forwards requests of already existing sessions to the old one and requests of new sessions to the replacing one. After all sessions on the old element have finished, it can be removed and only the new element is used. This strategy does not require a state transfer. It requires that the two elements can be used concurrently. The *Interrupt* strategy transfers the affected part of the system into a quiescent state before reconfiguration takes place. The states of the affected elements and existing connections between elements are handled, such that, e.g., an element replacement can be performed without causing any failures. After reconfiguration, the affected part of the system is released at once from the quiescent state, such that it can be assured that all elements and connections are reconfigured appropriately, before resuming their execution. Comparably with the other strategies, an advantage of requiring quiescence is that, e.g., an underlying database is not used during quiescence, which enables its consistent modification or transfer. Consideration of strategies is important to find the best way to reconfigure a system.

2.2. Component Orientation

The concept of *Component Orientation* (CO) [19] is a paradigm for the development of software systems in a modular way through functional decomposition. Such systems are composed of modules, called *Components*. A component encapsulates a certain functionality and provides it through contractually specified *Interfaces*. A component may use services from other components through their provided interfaces. An interface required by a component is called *Receptacle*. Consequently, a component-based system can be seen as a collection of loosely-coupled modules which collaborate among each other through their interfaces. Furthermore, a component can be deployed independently and is subject to composition by third parties [19]. Thus, CO addresses the complexity during development and deployment by modularity of requirements, architectures, designs, implementations and deployments. This modularity supports the partial reconfiguration of component oriented systems.

The *Enterprise Java Beans* standard (EJB), version 3.0, [3] is a component standard for the realization of component-oriented EAs on top of the *Java* programming language. It defines a sound component model that is based on so called *Enterprise Beans*, or *Beans* for short. There are two types of beans considered in the standard, namely *Message Driven Bean* and *Session Bean*. The former one is intended to be accessed through asynchronous message passing, and the latter one provides interfaces to access its encapsulated functionality. Session beans can be either *stateless* or *stateful*. An instance of a stateful session bean is exclusively used by a single client and retains its client-specific *Conversational State* across multiple invocations. In contrast, an instance of a stateless session bean is not exclusively used by a client. Moreover, each invocation from a client on the same reference may be executed on different instances. Thus, all instances of one stateless session bean are equivalent, and their states are client independent. Receptacles can be declared for session and message driven beans through *EJB References*. These can be connected to interfaces provided by session beans. Beans may be customized through *Simple Environment Entries* which can be interpreted as a kind of property. Before deploying beans, they must be configured, i.e., their properties must be set and their corresponding receptacles and interfaces must be connected. As unit of deployment the EJB standard defines the *EJB module* that must contain at least one bean. In the EJB context, parameter adaptation is performed through setting bean properties, and compositional adapta-

tion through (un)deploying modules and manipulating connections between beans. However, after the deployment of a module into an *EJB Container*, the runtime environment for components, the configurations of beans can not be changed.

2.3. Autonomic Computing and mKernel

The vision of *Autonomic Computing* (AC) [4, 8] addresses the management of systems at runtime. Its basic idea is to assign low level, administrative tasks to the managed system itself to disburden human administrators. The system manages itself according to the goals specified by the administrator. Autonomous management covers the four aspects *self-healing*, *self-protection*, *self-optimization*, and *self-configuration*. The last aspect addresses reconfiguration explicitly. Furthermore, each aspect can be mapped to at least one of the different kinds of system evolution discussed in section 1, namely corrective, adaptive, and perfective.

The *mKernel* system [1, 2] provides a generic AC infrastructure for EJB-based autonomous applications. It includes a comprehensive *Application Programming Interface* (API) of *sensors* and *effectors* through which the managed application can be inspected and manipulated by a higher level facility. Through this API, *mKernel* provides a reflective view, the *meta level*, of the managed application, the *base level*. Both levels are causally connected [11]. This reflective view enables the management of the application at three different levels of abstraction. The *Type Level* addresses information regarding types of the constituting elements of the managed application, i.e., artifacts being the result of development. The *Deployment Level* concentrates on a concrete configuration of the managed application that is deployed into a container. Finally, the *Instance Level* addresses the bean instances and interactions among them. With this multi-level view, subtle management operations are possible. As discussed in section 2.2, the EJB standard limits the configuration of bean properties and connections among beans to the deployment time, but *mKernel* enables the modifications of them at runtime. Together with supporting the lifecycle of EJB modules, *mKernel* provides runtime support for parameter and compositional adaptation. Nevertheless, the EJB specification is not violated or restricted by *mKernel*. Developers of EJB modules do not have to follow special guidelines beyond those of the EJB standard during development to enable the manageability of modules through *mKernel*. Thus, the developer can solely focus on the application logic while a preprocessing tool weaves the sensors and effectors into the EJB module. This approach maintains the idea of *Separation of Concerns*. Furthermore, *mKernel* is realized as a plugin for an existing EJB container and does not require any adjustments of the container implementation.

3. Related Work

Our approach to seamless reconfiguration is inspired by the work of Rosa, Rodrigues and Lopes [16] who present a framework for message-oriented systems that supports a fixed set of reconfiguration strategies. In contrast to their work, our approach is extensible w.r.t. the integration of new strategies. Moreover, the replacement of strategy elements is supported which provides additional flexibility. We support separation of concerns, because developers of EAs do not have to consider reconfigurations during development. Finally, the deployment and instance level are explicitly addressed, especially the transfer of conversational states of stateful session bean instances is supported. Our work addresses a different application area, namely EJB-based EAs.

Göbel and Nestler [6] extend the EJB specification by adding one more bean type, namely a composite bean. This composite encapsulates runtime adaptation by selecting different sub-components of the composite. Thus, the developer must consider this extension to the standard and only anticipated reconfiguration is possible that depends on the internals of the composite. Jarir, David, and Ledoux [7] enhance the EJB container to provide limited reconfiguration by intercepting calls to impose user-defined functionality. More possibilities are provided by Rutherford et al. [17], though their work is restricted to reconfiguration at the deployment level. They consider the management of the deployment lifecycle of modules and the modification of properties and of connections of beans. Nothing is said about the handling of bean instances, i.e., replacing bean instances together with their possible conversational states is not considered. In contrast, Matevska-Meyer, Olliges, and Hasselbring [12], who confine reconfiguration to redeploying modules, recognize the problem of the state transfer. They conclude that stateful beans are not safe to structural changes and provide no solution. Finally, the research group of the *Peking University Application Server* (PKUAS) [20] has implemented an own EJB container that incorporates the necessary technological facilities for updating modules including bean instances and state transfer. Thus, they consider the deployment and instance level. But they do not support higher-level facilities, like reconfiguration strategies that may simplify the role of administrators.

4. Autonomous Reconfiguration Procedures

Our approach to seamless reconfiguration of EJB-based EAs covers parameter and compositional adaptation. To meet various reconfiguration needs we identified and provide a comprehensive and complete set of customizable and reusable *steps*, that are described in table 1. The first column contains identifiers for the steps. The second column covers a short description of the particular step. Each step performs a special reconfiguration task, like, e.g., the deployment of a module (step a) or the establishment of connections between beans (step l). Steps are realized by so called *executors* that are based on the *mKernel* API. This is depicted on the left hand side in the reconfiguration model in figure 1. Our implementation provides default executors for all steps, except the step that is intended for reconfiguration of databases. Nevertheless, administrators have the freedom to provide *custom executors* for arbitrary

ID	Step	dep.	F	NI	I	I/NI
a	Deployment of the new EJB module. Setting the *Simple Environment Entries* and connecting the *EJB Reference* of its beans.	/	1	1	1	1
b	Declaration of the quiescence region which comprises those beans or whole modules that must be quiescent at a later point in time. For module replacement, this region is the module which is going to be replaced.	/	-	-	2	2
c	Start tracking and collecting session bean instances of beans of the quiescence region to get to know the instances that are handled with step f.	b	-	-	3	3
d	Initializing the quiescence, i.e., initializing the blocking of calls on the instances of beans of the quiescence region. The region becomes quiescent after finishing current calls.	b	-	-	4	6
e	Waiting until the quiescence region becomes quiescent.	d	-	-	5	7
f	Extracting the state of stateful session bean instances being collected because of step c.	c, e	-	-	6	8
g	Extracting the database that underlies the quiescence region.	e, f	-	-	7	-
h	Transfer or modify the database.	g	-	-	8	-
i	Starting of the new EJB module.	a	2	2	9	4
j	Modifying (optional) and injecting the states, being extracted at step f, to newly created instances of the corresponding stateful session beans of the new EJB module.	f, h, i	-	-	10	9
k	Publishing the references of the new bean instances that have been the target of the transfer of step j. Client components holding references to replaced stateful session bean instances are provided with the corresponding new reference to the replacing instance.	j	-	-	11	10
l	Re-route connections that are newly established. The source of the these connections are client components of the new/old EJB module and the target of these connections shifts from the beans of the old EJB module to the beans of the new EJB module.	h, i	3	3	12	5
m	Re-route already existing connections, i.e., clients of the old module holding references to bean instances of the old module are provided with new references to bean instances of the new module. In case of an I or I/NI this step only considers connections whose targets are bean instances which have not been transferred. Connections to transferred bean instances are already covered by step k. In case of NI this step is optional and only consistently applicable if the target of the connection is a stateless session bean instance.	h, i	-	4	13	11
n	Release the quiescence region, i.e., blocked calls and eventually blocked bean instance lookup requests are released and continue executing through using the reference already held before quiescence or the reference provided in steps k, l or m.	d, h, k, l, m	-	-	14	12
o	Stop and optionally undeploy the old EJB module if the old module is not used any more, or in case of the F strategy, should not be used any more through existing connections.	g, k, l, m	4	5	15	13

Table 1. Reconfiguration procedures and their steps

steps replacing the default ones. In this way, special requirements for reconfiguring concrete applications can be fulfilled.

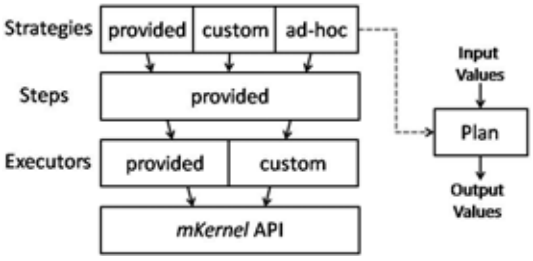

Figure 1. Reconfiguration Model

The provided steps are the basis for the *strategies* (see figure 1). Therefore, steps can be combined into generic and autonomous reconfiguration procedures. A procedure must fulfill the dependencies between its constituting steps. The third column of table 1 contains the steps each step depends on transitively. A '/' depicts that the particular step does not depend on any other step. Starting a new EJB module, e.g., requires that the module has been deployed before, therefore step i depends on a. Nevertheless, as some steps may be optional, corresponding dependencies need not to be met. For the case, that no state transfer is necessary, steps c, f, j and k can be omitted, and the step of stopping the old EJB module (o) does not depend on step k, but only on g, l and m. Consequently, these dependencies are influenced by a concrete arrangement of steps that may skip optional steps and by the concrete modules and beans each step is addressing. However, dependencies can be used to find basic restrictions in ordering the steps or potentials for parallel execution of steps. There exists, e.g., no dependency between the steps a and b, such that they can be executed in arbitrary order or even in parallel. The reusability of each step, the flexibility in ordering the steps and the possibility to omit optional steps enable various combinations of steps into generic reconfiguration procedures. Each procedure realizes a certain

reusable reconfiguration strategy. Therefore, administrators can develop *custom* strategies, that may be derived from others or that may be completely new ones. Even, a dynamic arrangement of steps during runtime is possible, resulting in *ad-hoc* strategies (see figure 1). Our approach provides the four strategies *Flash* (F), *Non-Interrupt* (NI), *Interrupt* (I), and *Interrupt/Non-Interrupt* (I/NI). Besides the first three ones, already presented in section 2.1, we identified I/NI as an additional new strategy for replacing modules. It is a mixture of the strategies I and NI. Its idea is that the new and old module are running concurrently, but newly created sessions are forwarded to the new module and start processing immediately. Already running sessions on the old module will not run until they finish, like it is done with the NI strategy. In contrast, they are driven into a quiescent state and their instances of the stateful session beans are transferred to the new module, where finally the sessions continue their processing. The advantage of I/NI is that system disruption is minimized because newly created sessions are not blocked from servicing requests. Therefore, the underlying database must be usable by both modules concurrently. Furthermore, the old module is removed from the system consistently.

In the following, we discuss in detail how the four strategies F, NI, I and I/NI can be applied for the case of replacing an EJB module with an alternative implementation. Therefore, each of the last four columns of table 1 describes a realizing procedure for the corresponding strategy. The entries of these columns are to be read as follows. A step that is not applicable or available within a strategy is denoted with a '-'. Otherwise, the number indicates the position of this step within the procedure.

For the F strategy only the deployment level is relevant since existing bean instances and connections among them are not handled. The other strategies distinguish between already existing connections and newly established connections of bean instances, hence considering the instance level of the application. Re-routing a connection before it is created is always possible. Re-routing existing connections is feasible if the target of the connection is a stateless session bean, because the states of stateless session bean instances are client independent (see section 2.2) and both beans, replaced and replacing one, provide the same functionality. However, if the target is a stateful session bean, an existing connection can only be modified consistently if the conversational state is transferred to the corresponding target instance, otherwise the client-specific state would get lost. As described in section 2.1 a state transfer requires quiescence of the affected beans, i.e., *all* instances of the affected beans must be quiescent. Reaching quiescence is simplified by the EJB standard because bean instances are per definition non-reentrant and are not allowed to perform any kind of thread handling. Quiescence is performed by the steps b, d, e and n. Another motivation for quiescence is the need to transfer or modify the database (steps g and h) that underlies the modules, i.e., the old and the new module must be either quiescent or in a stopped state. This is addressed by the I strategy. In summary, a state transfer (steps c, f, j and k) is only required if stateful session beans are involved and an I or I/NI strategy should be used. Without state transfer and database reconfiguration there is no need for quiescence, hence F or NI are the preferable strategies.

For each step being part of a concrete strategy an executor must be assigned. A step executor may define input and output parameters. Inputs represent information required for an appropriate execution and information about execution results are provided through outputs. Outputs can be mapped to inputs of subsequent executors. E.g., our executor implementation for step f outputs the extracted conversational states which are used as inputs for the executor of step j. At strategy level, inputs can also be specified. These can be connected to those executors inputs for which no matching outputs are given. Likewise, outputs can be defined for a strategy that provide information about execution results of an instantiated strategy to an administrator. Therefore, executor outputs can be connected to strategy outputs. To sum up, a concrete strategy consists of a set of steps together with their executors, specifications of inputs and outputs at the strategy level, and mapping specifications between parameters. In addition to the dependencies described in the third column of table 1, these mappings may introduce additional dependencies. A strategy is *valid* if there are no circular dependencies and if all executor inputs are connected either to strategy inputs or outputs of preceding executors. As long as the dependencies are fulfilled, the order of steps may change within a procedure. Thus, it is conceivable that a strategy is realized by several procedures, i.e., different orders of steps. The procedures described in the last four columns of table 1 reflect the provided implementations. For a concrete reconfiguration need, an administrator must provide a reconfiguration plan, i.e., a strategy must be chosen, instantiated and configured. Consequently, the plan consists only of the selected strategy and of values for strategy inputs (see right hand side of the figure 1). During execution, parameter values are injected to the relevant step executors. Therefore, the reconfiguration can be executed without further interaction need. Thus, an administrator only needs to know *what* a strategy is doing, but not *how* it is realized.

Our current implementation supports all four aforementioned strategies to replace one EJB module with an alternative implementation of this module. The reconfiguration plan for each strategy requires only the identifiers of the replaced module and of the replacing module type as input values to perform the reconfiguration autonomically. Nevertheless, the following restrictions must be fulfilled.

1. The replacing module must provide implementations for at least those interfaces that are provided by the replaced module and referenced by clients. This implies that the replacing module must fulfill the same contracts specified by these interfaces as the replaced module.
2. Each interface identified through restriction 1 must be implemented by exactly one session bean inside both, replaced and replacing modules.
3. For all required *EJB References* of each of the session beans providing at least one of the interfaces identi-

fied through restriction 1, there must exist appropriate providers. An appropriate provider is a session bean which is not part of the replaced module. If the provider is part of the replacing module, this restriction must hold recursively. All *EJB References* of providers not being part of the replacing module must be connected to interfaces, recursively.

4. For each bean of the replaced module, there exists one bean in the replacing module that provides at least the same interfaces w.r.t. restriction 1.
5. For stateful session beans, the state transfer at instance level is only performed for those fields of the replaced bean - regardless of their access modifiers - for which there exists a matching counterpart in the replacing bean. In this context, two fields are matching if they have the same name and type in both, the replacing and the replaced beans.

Though these restrictions are imposed on modules, the alternative implementation of the replacing module may eliminate failures in the behavior of the replaced one or it may be a more efficient implementation. Additionally, the integration of new functionality through adopting new or enhanced interfaces by the replacing module is possible.

5. Conclusion and Future Work

With this paper we presented a flexible approach to seamless reconfiguration of EJB-based EA that need not to be anticipated during EA development, hence it maintains the idea of separation of concerns. By providing generic and reusable procedures an administrator is freed from handling fine-grained reconfiguration tasks for each reconfiguration need. Instead of prescribing how a reconfiguration should be applied, the administrator can choose between several strategies. Thus, the role of the administrator is reduced to selecting an appropriate strategy and creating a reconfiguration plan that configures a generic procedure for a concrete reconfiguration need. The reconfiguration is performed autonomically.

As future work, it would be desirable if a mixture of the presented strategies could be applied for the replacement of a module, i.e., a strategy is applied only to a subset of beans of the module instead to all of its beans. Thus, disjoint subsets of beans can be reconfigured individually. Perhaps, this can be even broken down to the instance level. Finally, first considerations are made to weaken the restrictions of our current executors, e.g., to enable the replacement of n modules with m modules. Additionally, we investigate x-to-y relations for the bean replacement instead of only x-to-1 relations.

Abstract

Code duplication is a common software development practice that introduces several similar or identical segments of code, or code clones. In addition, there is currently a trend towards the use of multiple languages in the development of software systems. While there has been much work on clone detection and increased interest in studies of multi-language software systems, there have been no studies of code clones that span multiple languages, which we term cross-language code clones. In this paper we describe an approach for cross-language clone detection. We then introduce a tool, which is based on the CodeDOM library that is included with the Microsoft .NET Framework, to demonstrate the existence of cross-language clones in a real software system that contains both C# and Visual Basic.NET source code. Because our clone detection algorithm operates on a tree structure, other tree-based clone detection algorithms could be substituted in the implementation of our tool.

1. Introduction

Code duplication is a common software development practice that introduces several similar or identical segments of code, or *code clones*, and has many forms: language construct recurrence, pattern or paradigm adherence, framework reuse, and copy-paste replication. There are some advantages to duplicating code; developer productivity can be improved through the use of copy-paste to quickly replicate functionality. However, there are also important disadvantages to duplicating code; program comprehensibility, maintainability, and correctness can all be adversely affected by code duplication practices, particularly copy-paste replication. For example, when a change is to be made to a duplicated piece of code, a developer must determine whether the change should be made to all duplicate instances (clones) of that code. If the developer makes an incorrect determination, or accidentally misses a duplicate instance, then a bug is introduced.

Because code clones can have a negative impact on system quality, techniques and tools to eliminate code clones have been proposed. For example, techniques for automatic refactoring have been described [3, 5] and tools to guide manual refactoring [12] and to allow meta-level refactoring [4] have been developed. However, studies have shown that some code clones are inherent and that their elimination is not always desirable [15, 16]. Therefore, additional techniques, such as linked editing [38], are needed to mitigate the unneccessary maintenance costs associated with code clones [11].

Irrespective of the benefits or drawbacks attributed to a code clone or a category of code clones, techniques and tools to detect code clones are needed, and much work on clone detection has been performed. These techniques and tools use as inputs a variety of program representations, including source code [1, 2, 8, 14, 25], parse or abstract syntax trees [5, 9, 13, 19, 20, 37, 39], abstract semantic graphs [28], and program dependence graphs [17, 22]. Furthermore, these techniques and tools use a variety of matching approaches, including string or token comparison [1, 2, 8, 14], metric comparison [28], hashing [5], subgraph isomorphism [17, 22], feature vectors [19, 13], frequent item sets [25, 39], suffix trees [20, 37], and structural abstraction [9]. Direct comparisons and evaluations of some of these techniques and tools are provided in the literature [6, 33].

While several of the aforementioned clone detection techniques can be adapted to multiple languages [32] and some of the aforementioned clone detection tools accept more than one source language (for example, CCFinder [14] can detect code clones in Java, C, C++, C#, Visual Basic, and COBOL programs), all of the techniques and tools focus on detecting same-language code clones, that is, code clones for which each associated code segment is written in the same source language. However, there is currently a trend towards the development of heterogeneous soft-

ware systems in which multiple languages are used. The Microsoft .NET Framework [29], which leverages a common byte code format and virtual machine to allow programs written in different languages to interact, is a central actor in this trend. While this trend has caused increased interest in studying multi-language software systems [18, 27, 26, 30, 35], there are currently no approaches for detecting code clones that span multiple languages or studies of such clones.

In this paper we describe an approach for detecting code clones that span multiple languages, which we term *cross-language code clones*. Our approach is complementary to other clone detection techniques, as we are focused primarily on issues associated with detecting cross-language code clones and not on the mechanics of clone detection. We also introduce a tool, C2D2, that implements cross-language clone detection for the .NET Framework. We then apply C2D2 to two subsystems of a real, open-source software system, Mono™ [31]. Our results demonstrate the existence of cross-language code clones, specifically code clones that span the C# and Visual Basic.NET languages.

The rest of the paper is organized as follows. In Section 2 we provide background information about the libraries that we use to implement our cross-language clone detection system, C2D2, and in Section 3 we provide an overview of C2D2. In Section 4 we describe a case study and report our results. Finally, we discuss related work in Section 5 and conclude in Section 6.

2. Background

In this section we provide background information about the Code Document Object Model (CodeDOM) and NRefactory. Both are libraries that we use to implement our cross-language clone detection system, C2D2.

2.1. CodeDOM

The Microsoft .NET Framework includes the Code Document Object Model (CodeDOM) library, which provides a language-independent metamodel for representing source code [7]. CodeDOM exists primarily to allow developers of programs that emit source code, such as the Visual Studio.NET forms designer, to emit source code in multiple programming languages from a common representation. A CodeDOM graph is a graph of CodeDOM nodes that represent the logical structure of source code and can be used both to generate source code in any language for which an implementation of the `ICodeGenerator` interface is provided.

CodeDOM is similar to other metamodels for abstract syntax trees [10, 21] but is more similar to the Dagstuhl Middle Metamodel (DMM) [23] and the Common MetaModel (CMM) [36]. Like the DMM and the CMM, CodeDOM provides classes that represent many common object-oriented language constructs, including namespaces, type declarations (classes, structs, and enumerations), methods, fields, exceptions, and control statements. Also like the CMM, CodeDOM provides classes that represent statements and expressions, and is extensible. The expressiveness of CodeDOM is limited by the necessity of providing the option to generate code in any language in the .NET-family. Thus, CodeDOM can express only constructs that are available in all .NET languages.

Language constructs that are not directly supported by CodeDOM can be represented using a generic node, or "snippet" node. However, in many cases, source code can be restructured to avoid the use of snippets. For example, the switch statement is not present in all .NET languages, but can be restructured as a series of `if` statements. Such a restructuring ensures that the desired functionality can be achieved across all .NET languages.

2.2. NRefactory

Microsoft implements the interfaces in the CodeDOM library that allow a developer to populate a CodeDOM graph programmatically, but they do not implement the interfaces that would allow a developer to populate a CodeDOM graph from existing source code. The SharpDevelop IDE [34] includes the NRefactory library, which provides parsers for both C# and Visual Basic.NET; each of these parsers builds an internal abstract syntax tree (AST) representation of the input program. The `CodeDomOutputVisitor` class of NRefactory traverses the internal AST to produce a CodeDOM graph that represents source code that is semantically equivalent to the source code provided as input to the parser. However, because the expressiveness of the CodeDOM is limited, the source code generated from the produced CodeDOM graph may not be syntatically identical to the original source code.

3. C2D2

In this section we present our cross-language clone detection system, C2D2, including an overview of the system, a description of changes we made to NRefactory, and the details of our clone detection algorithm.

Figure 1 illustrates an overview of the C2D2 system, which takes as input one or more C# or Visual Basic.NET source files and produces as output a listing of detected clones. The source files, which are shown in the upper left of the figure, are read by the convertor component, which is shown towards the lower left of the figure. The convertor component converts each source file to a CodeDOM graph

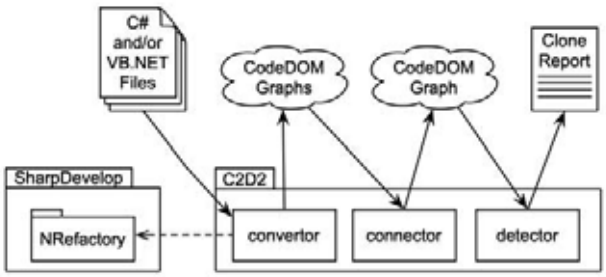

Figure 1. Overview of C2D2. *Dashed lines represent "use" dependencies. Solid lines represent data flow. Tabbed files are provided by the user. Clouds represent internal data structures. Lined files are generated by the system.*

by passing it to the NRefactory library, which is shown in the lower left of the figure. The connector component, which is shown in the lower middle of the figure, connects the collection of CodeDOM graphs produced by the convertor component to form a unified CodeDOM graph. The detector component, which is shown in the lower right of the figure, detects clones in the unified CodeDOM graph produced by the connector component. Output of the detector component is a clone report that lists the detected code clones.

3.1. Changes to NRefactory

We made several changes to the NRefactory library to fix bugs and to provide new functionality. With these changes, the CodeDOM graphs produced by the NRefactory parsers are usable for clone detection. Our corrections and additions to the NRefactory code are located primarily in the `CodeDomOutputVisitor` class. For example, in C# the `using` keyword can be followed by either an expression or a statement; however, only the expression case was handled by the version of NRefactory that we downloaded (version 2.2.0.2532). We added code to handle the statement case.

The parsers provided by NRefactory annotate some (but not all) AST nodes with line and column numbers, but do not propogate this information to the produced CodeDOM graphs. However, CodeDOM allows graph nodes to be annotated with a dictionary of user data via the `UserData` property. We leveraged this property to add line and column numbers (along with other auxilary data provided by the NRefactory lexers and parsers) to the nodes in the CodeDOM graph.

Our efforts to correct and enhance the NRefactory library are ongoing. Despite our efforts, there remain C# constructs that are either not properly parsed or not properly translated to CodeDOM; we are not yet able to obtain a CodeDOM graph for NRefactory due to these deficiencies. Nonetheless, our initial efforts allow the CodeDOM graphs produced by our modified version of NRefactory to be used for our feasibility study.

3.2. Clone Detection Algorithm

We utilize a hybrid token/tree-based algorithm for clone detection. Tree-based detection algorithms tend to be slower and more complex than token-based algorithms, so we wished to use a token-based algorithm to complete our feasibility study of cross-language clone detection. However, our input structure is a tree, not a token stream; thus, we created a hybrid token/tree-based algorithm.

The first step in our algorithm is to traverse the tree that underlies the unified CodeDOM graph and to create and store a string token for each leaf node in the tree. We perform the traversal depth-first to allow each interior node in the tree to access the tokens of its children during the traversal. An interior node stores the tokens of its children in a list and in prefix order. After traversal of the tree is complete, the list in the root node contains the token for each node in the tree, and so on down the tree. During the traversal, we also store each tree node in a list of nodes of the same type; one list exists for each CodeDOM node type.

Our matching algorithm is based on the Levenshtein distance algorithm [24]. The Levenshtein distance between two strings is the minimum number of character insertions, deletions, or substitutions required to transform one of the strings into the other string. We adapt this algorithm to work on lists of tokens representing CodeDOM nodes (recall that each CodeDOM node in the tree, except for a leaf node, contains the list of tokens for its children), which in turn represent code segments. We determine the minimum number of token insertions, deletions, or substitutions required to transform one list of tokens into the other list of tokens. We store our results in a data structure that stores the number of tokens cloned and the percentage matching (cloning) between two lists of tokens (code segments).

We only apply our matching algorithm on CodeDOM nodes of the same type. This is equivalent to only applying the algorithm on AST nodes of the same type, or to only attempting to match code segments of the same syntactic form. By intelligently applying our matching algorithm we reduce the complexity of the clone detection process and greatly improve performance. In addition, we eliminate the possibility of detecting a clone that crosses a block boundary; thus, we retain a key advantage that tree-based clone detection approaches have over token-based approaches.

Our matching algorithm takes four parameters. The first parameter specifies a minimum number of tokens that a list may contain to be considered, and the second parameter

		Percentage Matching					Tokens Matched							
	Total	30–40	40–50	50–60	60–70	70–100	0–10	10–20	20–30	30–40	40–50	50–60	60–70	70+
# of Clones	8,029	7,347	361	188	10	0	0	805	4,328	2,590	278	25	3	0

Table 1. Cross-Language Clones. *The number of cross-language clones detected by C2D2, categorized by percentage matching and by tokens matched.*

```
static public void EmitInt (ILGenerator ig, int i)
{
   switch (i){
   case -1:
      ig.Emit (OpCodes.Ldc_I4_M1);
      break;
   ...
   default:
      if (i >= -128 && i <= 127){
         ig.Emit (OpCodes.Ldc_I4_S, (sbyte) i);
      } else
         ig.Emit (OpCodes.Ldc_I4, i);
      break;
   }
}
```

```
Shared Sub EmitLoadI4Value(ByVal Info As EmitInfo, \
                           ByVal I As Integer, \
                           ByVal TypeToPushOnStack As Type)
   TypeToPushOnStack = \
      Helper.GetTypeOrTypeBuilder(TypeToPushOnStack)
   Select Case I
      Case -1
         Info.ILGen.Emit(OpCodes.Ldc_I4_M1)
      ...
      Case SByte.MinValue To SByte.MaxValue
         Dim sbit As SByte = CSByte(I)
         Info.ILGen.Emit(OpCodes.Ldc_I4_S, sbit)
      Case Else
         Info.ILGen.Emit(OpCodes.Ldc_I4, I)
   End Select
   Info.Stack.Push(TypeToPushOnStack)
End Sub
```

Figure 2. Example Cross-Language Clone. *A portion of a cross-language clone detected by C2D2. The left side of the figure lists a C# code segment from* `mcs/constant.cs` *and the right side of the figure lists a Visual Basic.NET code segment from* `vbnc/source/Emit/Emitter.vb`*. The full clone spans lines 805–855 of* `mcs/constant.cs` *and lines 1384–1414 of* `vbnc/source/Emit/Emitter.vb`*, and has a percentage matching of 58 (69 of 118 tokens matched).*

specifies the corresponding maximum number. These parameters can be used to reduce the number of matches attempted by the algorithm; please note that these parameters specify the numbers of tokens a list may contain to be considered by the algorithm and not the numbers of tokens that a clone may contain. The third parameter specifies a minimum percentage matching. This parameter can be used to filter clones that do not reach the specified percentage of similarity. Finally, the fourth parameter specifies whether to attempt to detect same-language clones (in addition to cross-language clones).

4. Case Study

In this section we describe a case study used to evaluate the feasibility of our approach. We use the C# and Visual Basic.NET compilers from Mono [31], version 1.2.6, as the test case. We chose these compilers because they are open-source and are part of a large, multi-language software system. Furthermore, as compilers for a common back end (the .NET runtime environment) they are likely to have common functionality in their code generators.

The C# compiler, mcs, consists of 38 C# files that contain 49,216 lines of non-blank, uncommented, non-preprocessed source code. The Visual Basic.NET compiler, vbnc, consists of 422 Visual Basic.NET files that contain 52,161 lines of non-blank, uncommented, non-preprocessed source code. Thus, our test case totals 460 source files and 101,377 lines of source code. Before running C2D2 on the test case, we configured it as follows: minimum number of tokens (50), maximum number of tokens (200), minimum cloning percentage (30), and attempt to detect same-language clones (no). We performed all experiments on a workstation with an AMD Athlon™ 64 X2 3800+ processor and 1 GB RAM; the operating system is Microsoft Windows XP Professional SP2 32-bit. Using the above configuration and the test case as input, the total execution time for C2D2 is 21 minutes and 23 seconds (wall clock time).

Table 1 summarizes the results of the execution. A total of 8,029 cross-language clones were detected; however, 7,708 of the detected clones had a percentage matching of less than 50, leaving only 198 clones with a percentage matching of 50 or greater. Of those 198 clones, only 10 have a percentage matching of 60 or greater and none have a percentage matching of 70 or greater. At first glance, these results do not appear to demonstrate the existence of meaningful cross-language clones. Yet, the example clone illustrated

in Figure 2 shows that percentage matching is a potentially misleading metric for cross-language clones detected using our algorithm. Figure 2 illustrates a cross-language clone that consists of a segment of C# code and a segment of Visual Basic.NET code. If it were not for the stack manipulation performed in the Visual Basic version of the code then the functionality would be identical. This example clone is a *type 3* clone [6], i.e., a clone in which identifiers have been changed and statements have been changed, added, or removed (added in this case). However, the percentage matching for the clone is only 58% (69 of 118 tokens matched), which might seem low.

Despite the discovery of the cross-language clone illustrated in Figure 2 and others, when compared to the results of other clone studies, the number of detected clones with a significant percentage matching appears to be low for the amount of code included in the test case. There are several possible explanations for this. First, as noted above, percentage matching seems to be a misleading metric for evaluating cross-language clones detected using our algorithm. Second, Mono simply might not have many cross-language clones; this seems likely given that different projects within Mono often have disparate development teams. However, this would indicate that study of additional multi-language software systems is warranted. We plan to undertake such studies in the future. A third possibility is that C2D2, while capable of finding some cross-language clones (as demonstrated above), might miss other cross-language clones. This could be due to the clone detection algorithm employed. Again, this would indicate that further study, including applying more advanced tree-based clone detection techniques, is warranted.

5. Related Work

In this section we discuss related work, which we divide into two categories: (1) studies of clones and (2) studies of multi-language software systems.

5.1. Studies of Clones

Many techniques and tools for clone detection exist. These techniques and tools operate on a variety of program abstractions, including strings [1, 2, 8], tokens [14, 25], trees [5, 9, 13, 19, 20, 37, 39], and graphs [17, 22, 28]. Because our approach detects clones on a tree structure, other tree-based clone detection algorithms could be substituted for the one we present.

Studies investigating the presence of code clones in single-language software systems have found significant amounts of duplicated code within these systems. These studies, known as clone coverage studies, suggest that it is not uncommon to have over 20% cloned code in a software system. For example, CCFinder detected almost 30% cloned code in version 1.3.0 of the JDK [14], and CP-Miner detected over 22% cloned code in version 2.6.6 of the Linux kernel [25]. In addition, one study reported over 59% cloned code in a COBOL payroll application [8].

5.2. Cross-Language Studies of Multi-Language Software Systems

There is currently a trend towards the development of heterogeneous software systems in which multiple languages are used [18]. This trend has caused increased interest in studying multi-language software systems. Topics of interest include modeling, usability, tool support, as well as maintenance processes, which would include clone detection and evolution.

Linos, et al. [27] and Moise and Wong [30] present studies of cross-language dependencies found in software systems written in C/C++ and Java. Strein, et al. [35] present an approach to cross-language program analysis for refactoring and a prototype tool that handles both C# and Visual Basic.NET; however, they do not leverage CodeDOM for their implementation. Finally, Linos, et al. [26] present an approach to computation of metrics on MSIL (Microsoft Intermediate Language). Their ultimate goal is to determine whether computation of metrics at the MSIL level is as effective as computation of metrics directly on source code.

6. Conclusions and Future Work

The current trend towards the use of multiple languages in the development of software systems introduces new challenges for software comprehension and software maintenance. Many techniques and tools for clone detection, elimination, and removal have been described in the literature, and some of this literature addresses the problem of applying these techniques and tools to software systems written in a variety of languages. However, none of these techniques or tools have been applied to multi-language software systems with a focus on detecting code clones that span multiple languages.

In this paper we introduced an approach for detecting code clones that span multiple languages, which we termed *cross-language code clones*. Our approach complements other clone detection techniques, as it is focused on issues of detecting cross-language code clones and not on the mechanics of clone detection. We described an approach for cross-language clone detection and presented a tool, C2D2, that implements cross-language clone detection for the .NET Framework. Our experimental results demonstrate the existence of cross-language code clones, specifically code clones that span C# and Visual Basic.NET.

As future work we propose to enhance the usability and interoperability of C2D2 by producing output files that can be read by existing clone visualization systems, to integrate more advanced tree-based clone detection techniques into C2D2, and to perform more extensive studies of multi-language software systems.

Abstract - Maintaining and supporting the software of an organization is not an easy task, and software maintainers do not currently have access to decision support systems (DSS) to evaluate strategies for improving the specific activities of software maintenance. This article presents a DSS which helps in locating best practices offered by a software maintenance maturity model (S3^{m}). The contributions of this paper are: 1) to instrument a maturity model with a DSS tool to aid software maintenance practitioners in locating specific best practices that could help them answer their questions.

I. INTRODUCTION

Knowledge transfer of a large number of best practices, described in a maturity model, has proved difficult [1]. This is especially true during the training stage of an assessor or a new participant in a process improvement activity. It is also challenging to quickly refer to, or access, the right practice, or subset of practices, when trying to answer specific questions during or after a process maturity evaluation.

The software maintenance maturity model **S3^{m}** contains a large number of software maintenance concepts and information which are structured in many successive levels [2], [14]. The first level is labelled 'process domains level', and regroups the maintenance practices in 4 process domains (*process management*, *maintenance request management*, *software evolution engineering* and *support to software engineering evolution*). Each process domain is broken down into one or more key process areas (KPAs). These KPAs logically group together items which conceptually belong together. As an example all training related practices are grouped into one KPA. A KPA is further divided into *roadmaps* with one or more *best practices*, spanning five maturity levels. The complete **S3^{m}** has 4 domains, 18 KPAs, 74 roadmaps and 443 best practices. It would be beneficial to have a decision support system (DSS) to help access this complex structure and large amount of information. A potential solution to this problem would be to develop a decision based system for the **S3^{m}**. This DSS could be available for both maintainers and maintenance clients. The proposed modelling of a software maintenance DSS was based on the van Heijst methodology [3], which consists of constructing a task model, selecting or building an ontology [4], mapping the ontology onto the knowledge roles in the task model and instantiating the application ontology with this specific domain knowledge. According to van Heijst, there are at least six different types of knowledge to be taken into account when constructing such a system: tasks-goals, problem-solving methods, task instances, inferences, the ontology and the domain knowledge (see Fig.1). Van Heijst uses the different types of knowledge in a more generic way than we do in this document.

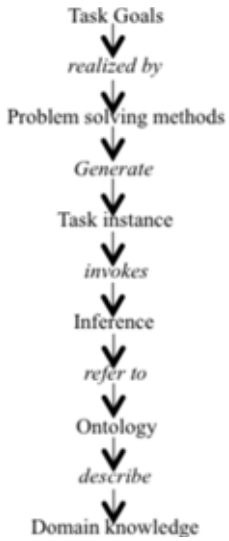

Fig.1. The different components of knowledge models [3]

For van Heijst, domain knowledge refers to a collection of statements about the domain [4]. The domain of this specific research is software maintenance, and it is divided into 4 process domains. Examples of statements are presented in section 3. At a high level, the ontology refers to a part of the software maintenance ontology [5] presented in section 4. The problem solving methods and tasks are described at length in section 5. The tool environment and conclusion, as well as future work, are presented in sections 6 and 7. Section 2 begins by presenting the goals of the **S3^{m}** architecture.

II GOALS OF THE *S^{3M}* ARCHITECTURE

The **S3^{m}** was designed as a customer-focused benchmark for either:

- Auditing the software maintenance capability of a service supplier or outsourcer; or
- Supporting the process improvement activities of software maintenance organizations.

To address the concerns specific to the maintainer, a distinct maintenance body of knowledge is required. The **S3^{m}** is also designed to complement the maturity model developed by the SEI at Carnegie Mellon University in Pittsburgh [6] by focusing mainly on practices specific to software maintenance. The architecture of the model locates the most fundamental practices at a lower level of maturity, whereas the most advanced practices are located at a higher level of maturity. An organization will typically mature from the lower to the higher maturity level as it improves. Lower-level practices must be implemented and sustained for higher-level practices to be achieved.

III *S^{3M}* ARCHITECTURE AND KNOWLEDGE STATEMENTS

Software maintainers experience a number of problems. These have been documented and an attempt made to rank them in order of importance. One of the first reported investigations was conducted by Lientz and Swanson [7]. They identified six problems related to users of the applications, to managerial constraints and to the quality of software documentation. Other surveys have found that a large percentage of the software maintenance problems reported are related to the software product itself. This survey identified complex and old source code which was badly documented and structured in a complex way. More recent surveys conducted among attendees at successive software maintenance conferences [8] ranked perceived problems in the following order of importance (see Table 1). These are also examples of knowledge statements about the domain of software maintenance. Key to helping software maintainers would be to provide them with ways of resolving their problems by leading them to documented best practices.

TABLE I
TOP MAINTENANCE PROBLEMS [8]

Rank	Maintenance problem
1	Managing fast-changing priorities
2	Inadequate testing techniques
3	Difficulty in measuring performance
4	Missing or incomplete software documentation
5	Adapting to rapid changes in user organizations
6	A large number of user requests in waiting
7	Difficulty in measuring/demonstrating the maintenance team's contribution
8	Low morale due to lack of recognition
9	Not many professionals in the field, especially experienced ones
10	Little methodology, few standards, procedures or tools specific to maintenance
11	Source code complex and unstructured
12	Integration, overlap and incompatibility of systems
13	Little training available to personnel
14	No strategic plans for maintenance
15	Difficulty in meeting user expectations
16	Lack of understanding and support from IT managers
17	Maintenance software running on obsolete systems and technologies
18	Little will for reengineering applications
19	Loss of expertise when employees leave

There is a growing number of sources where software maintainers can look for best practices, a major challenge being to encourage these sources to use the same terminology, process models and international standards. The practices used by maintainers need to show them how to meet their daily service goals. While these practices are most often described within their corresponding operational and support processes, and consist of numerous procedures, a very large number of problem-solving practices could be presented in a DSS which would answer their many questions about those problems. Examples are presented in section 6. Maintenance client problems could also be linked to these internal problems because of the impacts it can occur. When using the software maintenance ontology in the DSS, it was necessary to consider the structure of the maturity model relationship between the many process domains, roadmaps and practices. This problem is addressed next.

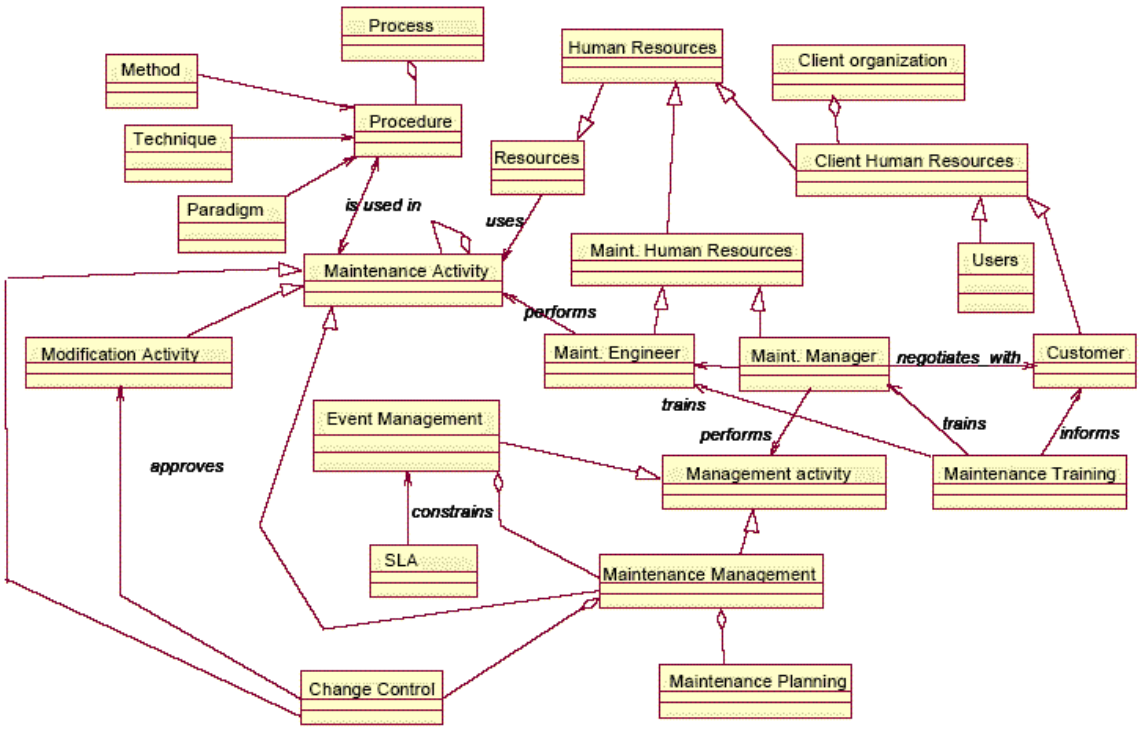

Fig.2. Part of the software maintenance ontology of (Kitchenham and et al., 1999)

IV ONTOLOGY OF THE SOFTWARE MAINTENANCE BODY OF KNOWLEDGE

We elected to implement only a subset of the ontology developed by Kitchenham et al. [5] and Ruiz et al. [9] for the initial trial of this research project. The Kitchenham ontology was chosen because its author is well known in Software Engineering maintenance. Other software maintenance ontologies could also be used [9], [10] and [11] to enhance the Kitchenham at al. proposal. Fig. 2 describes the different maintenance concepts considered surrounding a software maintenance activity. Software maintenance is highly event-driven, which means that some maintenance activities are unscheduled and can interrupt ongoing work. This subset of the ontology represents many, but not all, the concepts involved in responding to the questions related to the first problem identified by Dekleva [8]: "Managing fast-changing priorities". Maintainers agree that this is the most important problem they face. How can they handle the fast-changing priorities of the customer? Solutions to this problem are likely to be found by using many paths through the maintenance concepts of the ontology. Navigation through these concepts should lead to associated concepts which are conceptually linked and likely to contribute to a solution, like the need for better event management, change control, maintenance planning, Service Level Agreements, maintenance manager negotiation, training, procedures, and so forth. Many more concepts must be involved to contribute to all aspects of the solution, but our purpose is to show the utility of a DSS in the software maintenance domain, and it therefore starts with a constrained number of concepts. Maturity models typically include the detailed best practices that could be of help in solving this type of problem. The main issue is that the best practice locations and their interrelationships are hidden in the layered architecture of the maturity model, specifically in its process domains, KPAs and roadmaps. It is therefore necessary to find a way to link this layered architecture with the maintenance concepts of the ontology and proceed to analyze the tasks required to build a DSS to support the maintainers in their quest for solutions. The next section describes the navigation concepts that have been implemented in ***S3[m]DSS***. The user of the DSS navigates using a sequence of tasks that will lead him through a further sequence of tasks.

V HIGH LEVEL VIEW OF S^{3M} DSS

In [3], the first activity in the construction of a DSS is the definition of task analysis. Task analysis begins, at a high level, with a definition of an index of terms. This index includes words commonly used in software engineering (see Figure 3). From this index, a subset of

more restrictive words is identified. This subset is a list of keywords recognized specifically in software maintenance. Each keyword is then connected to one or more maintenance concepts. A maintenance concept, in software maintenance, is a concept found in the Software Maintenance Body of Knowledge and ontology (see Fig. 2). Every maintenance problem identified by Dekleva [8] has been translated into a case problem and connected to the software maintenance ontology. Each case problem is then linked to a set of themes (questions) which help the user of the DSS to navigate into a part of the maturity model that will propose recommendations in the form of best practices. The link between the maintenance concepts and the maturity model is made in the themes concept. Themes are questions which have been developed to hop from node to node in the ontology. A close look at Fig. 2 reveals that the themes concept can combine different maintenance concepts and, finally, create a set of recommendations of the maturity model. For every best practice, there is a linked theme (or choice) from which the user can select (also called facts) which will lead to a final specific set of recommendations. This 1-1 matching between theme and recommendation will contribute to a composed set of recommendations directly adapted to the user context. Above all of this, a distinction between internal maintenance engineers and maintenance client has been made. We think that the same problems are involved for both side but we need to adapt the way we ask. In this case, when a maintenance client uses the system, themes are adapted to his understanding.

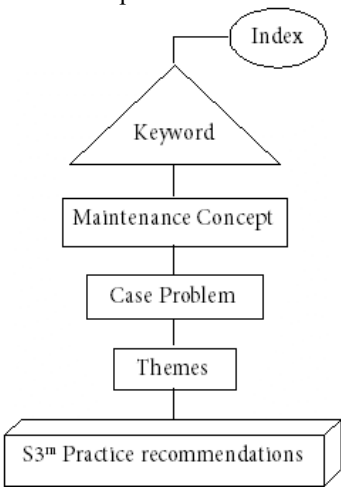

Fig.3. High-level view of S3^m

Provided recommendations are some kind of invitation to his maintainer to follow different rules. This could both help maintenance enterprise but also client one.

Expanding the 6 high-level tasks in Figure 3, we propose 12 detailed tasks which will help identify a subset of best practices related to the S3^m.

VI DSS TOOL TECHNOLOGY

Next we will explain the technology used as well as an overview of the design of the DSS. Then we will demonstrate how this DSS can be used to help a user answer a question and how an expert populates a complete case problem.

A. Technology and design

The ***S3^{m}DSS*** was built using Java, Java Server Pages, JavaScript, CSS and HTML technologies. This combination of technologies was selected for its easy access via the Internet.

TABLE II
DSS QUESTIONS

#	Questions
A	Are there training plans for to new maintenance engineers about generic topics like management and processes activities?
B	Do maintenance engineers periodically update their knowledge associated with the software and its infrastructure they maintain?
C	Are maintenance engineers trained and motivated to perform well when using the processes/services and their support role?
D	Is there some training communication with customers offered to software maintenance engineers?
E	Do you use any internal benchmarking data to guide the training of maintenance resources?
F	Does the maintenance organisation have a training budget?
G	Are there plans describing the training needed for each maintenance position and application software?
H	Is there training time planned?
I	Do senior maintainers familiarise new employees?
J	Are training needs defined for both technical and management responsibilities for each development project?
K	Do people working on the pre-delivery and transition receive the training deemed appropriate by the software developer?

Behind that, a SQL Server database was added in order to manage the knowledge base. This choice was justified by the lack of reactivity that XML parsing proposed before. The architecture is based on a 3-tiers

model providing easy maintainability and is composed of a presentation layer, a business layer and DAO layer. The business layer design has been split into 2 parts: the first part regroups all the controlling servlets and the second parts regroup all the business methods. Servlets assure proper communication between the presentation layer and the business layer while the business methods communicate with the DAO layer.Currently, more than 550 words and 70 keywords have been introduced into the DSS. Five maintenance problems identified by Dekleva have been introduced and took 17 hours to complete.

We estimate that there is still 2,000 hours required to populate the knowledge base for all the ***S3m*** practices for maturity 0, 1 and 2. The DSS has 3 different interface types: administrator, expert and user. The administrator interface manages access rights to the DSS, while the expert interface offers experts the option of adding new index words, keywords, concepts, cases, themes and recommendations. The next section will demonstrate how the DSS helps a user answer a specific question: How can I improve a maintainers training?

B. Helping a user answer a question

First of all, the user enters a word that will identify a suggested keyword that represents the topic he is interested to obtain answers for. As an example, the user enters: *training*. This keyword will guide the DSS to the most closely related KPA and roadmap concepts of its database. Currently, the DSS presents the following keyword: *maintenance training* as a feedback. In this same feedback the DSS presents the maintenance concepts, which are related to this KPA and roadmap, to the user.

It also presents the concepts in order of priority. This is done using a percentage of relevance linked to each concept. The expert had previously established this percentage. The user is then asked to choose one or multiple concepts, *maintenance human resources* in our example. The DSS presents the case problems associated with this maintenance concept selected to the user. It will present the case problems in order of priority to the user. A percentage of relevance is also related to each case problem. The expert has also previously established this percentage. The user chooses one or multiple case problems that represent the closest is current problem, ex: *little training available to maintenance engineers* in our example. With this case problem, there are 11 themes presented to the user in the form of questions (see Table 2). The user will find facts for each practice (theme). He can answer yes or no to any of the themes. In function of the facts chosen, the system composed a set of recommendations to the user. Figure 4 shows how the DSS will recommend the following solution (simplified for this paper): RecSet.

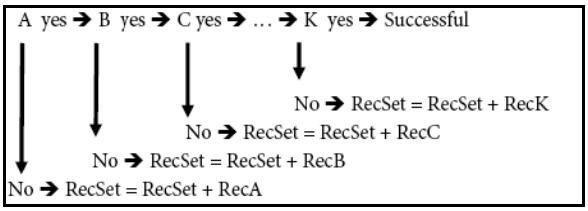

Fig. 4: DSS recommendation mechanism

Figure 5 (next page) shows an example of the user layout in the previous case problem. The user layout is made up of 4 dynamic tables representing all the concepts we discuss before.

Each table is displayed step by step by user selection and associated with a help function. In the top of the layout, a toolbar has been inserted to start every research by typing a word into the system or selecting a keyword. Next will show in practice how a maintenance expert can enter a case problem into the DSS.

VII EXPERT INTERFACE

Fig. 5 (next page) show an example of the expert layout. This layout asks experts to add, modify or delete high level view elements. Expert can also add a complete case to the DSS by respecting the following recommendation, question, case problem, maintenance concept, keyword and word order because of the links between elements. Below the top table, a form is proposed where expert can fill information like element name, help content or links with upper or lower elements.

All existing elements are accessible by conventional html lists and can be added very easily by selecting and pressing a button. When validation button is pressed, an additional form shown in Fig. 6 appear. Experts can then complete association percentages between linked elements. Note that experts can use HTML mark-ups into recommendation text to add hyperlinks, lists or tables.

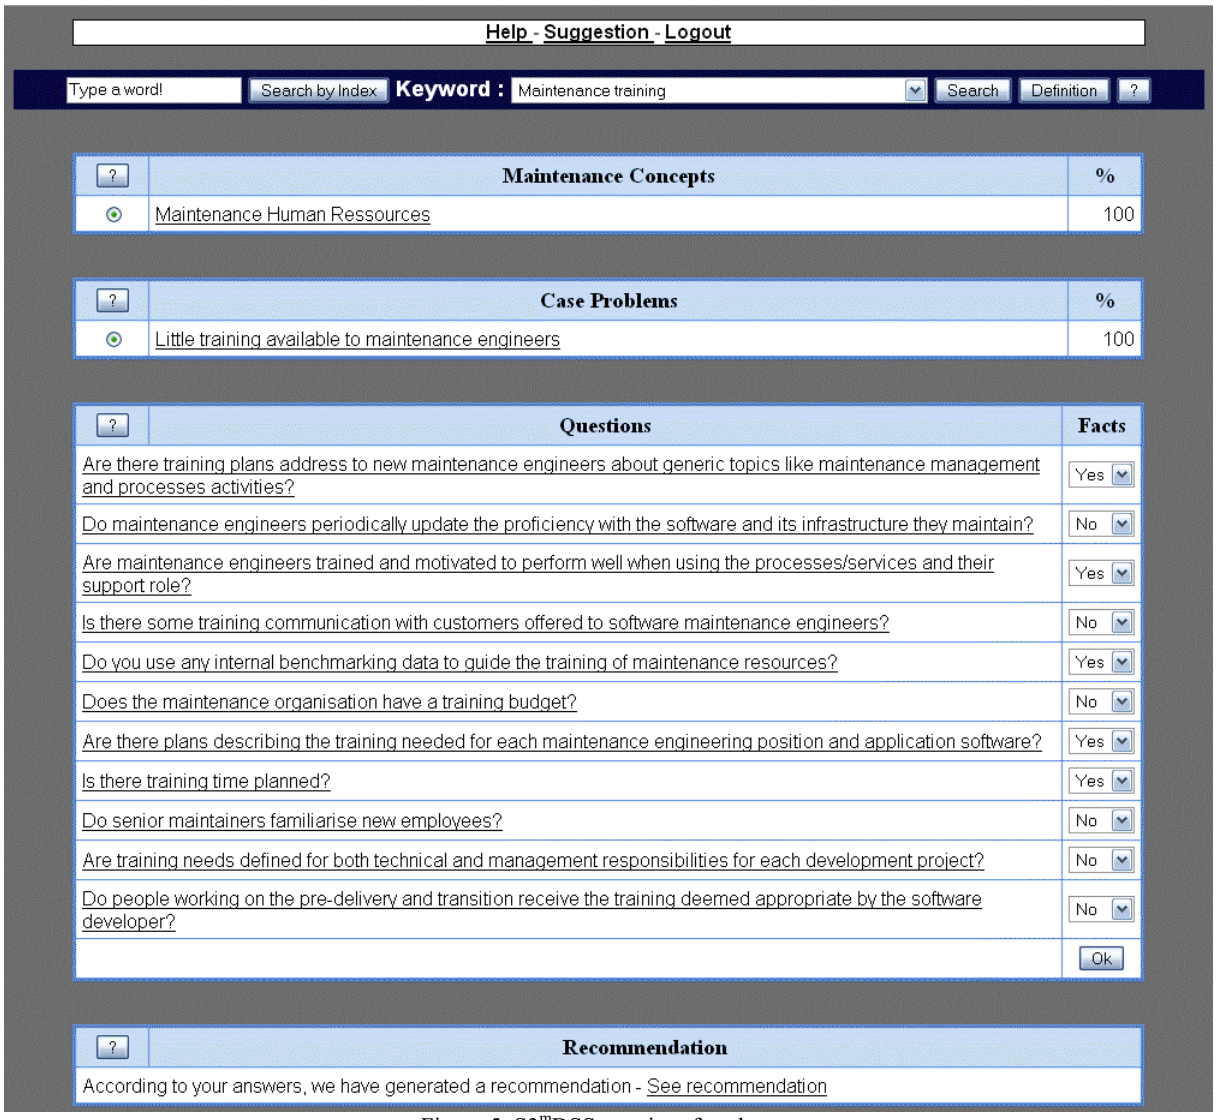

Figure 5: S3^{m}DSS user interface layout

X Conclusion and Future Work

Identifying the best practices in a maturity model is a difficult task, considering their number and the multiple possible answers associated with each of them. Our proposal is that a DSS could help in finding an appropriate recommendation. The next step in this research project is to populate the DSS, validate the results with experts in the domain and determine whether or not the DSS is a useful support tool for training on the content of the maturity model. The **S3^{m}DSS** is a working prototype and is available on **http://www.s3m.ca**. Future work will consist of first creating a higher level representation of the key users, customers, maintenance managers and maintenance engineers concerns. This will be helpful for users to navigate first in all the software maintenance problems before they can drill down to a specific area. Second tasks will be to enhance the number of maintenance problems and insert examples of how the case problem. A case problem is an example of what other companies have done to solve a specific issue. We have been tracking the usage of the DSS for 2 years now and can report on its usage. Although users will be able to find a recommendation there is little evidence that this information is helpful in their daily work. More validation is required to see if a DSS in this very unstructured and low maturity domain could yield any benefit to an organization. More research will be conducted this year with the help of master students from the FUNDP from Belgium.

Odyssey-MEC: Model Evolution Control in the Context of Model-Driven Architecture

Chessman Corrêa Leonardo Murta Cláudia Werner

Federal University of Rio de Janeiro
COPPE - System Eng. and Computer Science
{chessman, murta, werner}@cos.ufrj.br

ABSTRACT
Model-Driven Development aims to use models as first class artifacts in software development. Therefore, the need to control model evolution in this context became as important as to control the evolution of source-code. In Model-Driven Architecture, a target model is generated from a source model through a transformation process. Consequently, there is a relationship among them. However, these models may evolve independently due to modifications, making them inconsistent with each other. In this scenario, traditional versioning is fundamental, but it is not sufficient to control the evolution of different interconnected models that represent the same software. In this paper, we propose a server side transformation, synchronization and versioning approach to control the evolution of models.

Keywords
Version Control, Model Versioning, Model-Driven Development, Model-Driven Architecture, Model Evolution.

1. INTRODUCTION
Model-Driven Architecture (MDA) is the Object Management Group (OMG) framework for **Model-Driven Development** (MDD) [18]. One characteristic of this approach is the generation of a target model from a source model using a transformation engine. It means that the software is represented by different models, most of the time in different abstraction levels.

In large software projects, multiple people assuming specific roles and located at different places may modify related models independently. For example, a PSM (Platform Specific Model) generated from a PIM (Platform Independent Model) may need to be modified because it does not have all the necessary details to derive the source-code. In other words, models may need to be updated in order to be used to generate other models or source code.

Since these models are related with each other, modifications applied to a model may create inconsistencies between them. However, as these models represent the same software, inconsistencies cannot be allowed. For example, inconsistencies between PIM and PSM introduce some difficulties to generate PSMs tailored to other platforms. This is especially true if PIM level changes are made in PSM instead. In this case, the generation of PSM to a new platform would not have PIM details that exist in the other platform. It means that if a MDD project aims to create software for different platforms, PSMs of each platform have to be consistent with the corresponding PIM and with PSMs of other platforms. It is also true for models in the same abstraction level.

Model versioning is essential to control model evolution. However, if source and target models are versioned independently, there will be no guarantee that they are consistent with each other. Since these models have to evolve together, versioning is not enough to control their evolution in MDA context. Therefore, these models have to be synchronized before versioned.

Models synchronization is achieved from round-trip engineering through bidirectional transformations that preserve previous versions of existing models. However, if a synchronization tool is not automatically executed, software engineers may forget to use them, leading to inconsistent models.

Based on these facts, this paper proposes a server side model transformation, synchronization and versioning approach to control model evolution in MDA.

The rest of this paper is organized as follows. Section 2 briefly describes the Model-Driven Architecture. Section 3 discusses the key aspects of our approach. Section 4 presents some related works. Finally, the conclusion and future work are presented in Section 5.

2. MODEL DRIVEN ARCHITECTURE
OMG was inspired by constantly shifting infrastructures, requirements changing, and new emerging technologies to create the **Model-Driven Architecture** (**MDA**) [18]. This approach considers models as first-class development artifacts and uses them not only for understanding and commu-

nication, but also for design, construction, deployment, operation, maintenance, and modification of a system.

2.1 MDA Models

MDA specifies four kinds of models: **Computation Independent Model** (CIM), **Platform Independent Model** (PIM), **Platform Model** (PM) and **Platform Specific Model** (PSM) [18]. **CIM** represents the system requirements. It takes into consideration domain concerns, such as the vocabulary used by the domain practitioners. CIM represents a view of the system without computational details. **PIM** is a view of the system considering computational solutions that aim to be generic to any platform. Thus, it represents a system that can be tailored to multiple platforms, assuming that these platforms are compatible to the architectural styles adopted in the corresponding PIM. **PM** provides the technical concepts, requirements, and services of a specific platform. **PSM** is a view of a system considering the platform details. It can be seen as a merge of PIM and PM, augmented by some changes specific to the target platform.

2.2 Model Transformation

Model transformation is the process of creating a target model from a source model of the same system. Although it could be made manually, the MDA approach aims at automating this operation. This is a key factor to the increasing MDA adoption over traditional software development.

In **forward engineering**, a model-to-model transformation uses the CIM and other information to generate a PIM. Subsequently, another model-to-model transformation combines PIM and PM to create the corresponding PSM. Finally, PSM is used by a model-to-text transformation to generate the source-code to the specific software platform.

A model transformation uses **mappings** to create target model elements from source model elements. Mappings provide specification of how one or more target elements are derived from source elements. It also may have mapping rules based on specific **marks**, like stereotypes and tagged values. For example, a PIM class with the stereotype <<*entity*>> may generate an EJB (Enterprise JavaBean) class for the JEE[1] platform.

During model generation, the model transformation should also generate the **record of transformation**. It includes the **traceability links** between source and target model elements and informs which parts of the mapping were used during the generation. It is an important resource to support synchronization.

It is important to notice that CIM, PIM and PSM are in different abstraction levels. This mean that CIM-PIM and PIM-PSM transformations are vertical transformations among different abstraction levels. However, it is also possible to generate models in the same abstraction level through horizontal transformations, such as PIM-PIM and PSM-PSM.

2.3 MDA Application

The application of MDA is relatively simple. It can be divided into two main phases: infrastructure setup and transformation. The infrastructure setup starts with the creation of mappings based on a platform or a set of platforms. These mappings will be used by transformations. In addition, the marks to be applied on a PIM may also be defined, usually through a Profile [19].

After this initial setup, the software engineer uses a modeling tool to create a model (e.g., a PIM). Afterwards, that model may be marked according to the available Profiles. Finally, the transformation is executed, using the mappings and the marked model to generate the corresponding model (e.g., a PSM) and the record of transformation.

This scenario focuses on forward engineering. However, it is also possible to occur reverse engineering transformations, generating a PIM from a PSM.

3. ODYSSEY-MEC

In this section we introduce Odyssey-MEC (Odyssey for Model Evolution Control), a server side transformation, synchronization and versioning approach to control MDA models evolution.

In the following, we detail our approach presenting its architecture, model infrastructure, model repository, model versioning, model transformation, record of transformation, element search, and model synchronization.

3.1 Architecture

The architecture of the approach is shown in Figure 1. It has four types of repositories: Transformation Mappings, PIM, PSM, and Record of Transformation. The **Transformation Mappings Repository** (TMR) stores the transformation mappings to be used by the transformation engine. These transformation mappings are created by a transformation engineer, as specified by Bacelo et al [1]. **PIM and PSM Repositories** store PIMs and PSMs, respectively. It is worth to notice that these repositories persist versioned models. Moreover, each platform has its own PSM repository. **Record of Transformation Repository** (RTR) stores the Record of Transformations (RT).

Our approach comprises three main components to control model evolution: Odyssey-VCS [15, 17], Odyssey-MDA [1], and a synchronization engine (SE). It also uses a Transaction Manager (TM) component to control the synchronization and versioning process in a transaction context. The

[1] http://java.sun.com/j2ee/1.4/docs/tutorial/doc/index.html

Odyssey-VCS component is used for model versioning and the Odyssey-MDA component for model transformation.

Odyssey-VCS has hooks that execute the TM and the SE when a model is checked in. SE uses Odyssey-MDA to generate target models, and Odyssey-VCS to access the models to be synchronized and their versioning data. It also uses RT as an auxiliary resource to synchronize the models. Finally, an Odyssey-VCS client is used to communicate with Odyssey-VCS server (it can be any CASE tool that exports models through XMI 2.1 format). Odyssey-VCS client communicates with Odyssey-VCS server through Web Services [4].

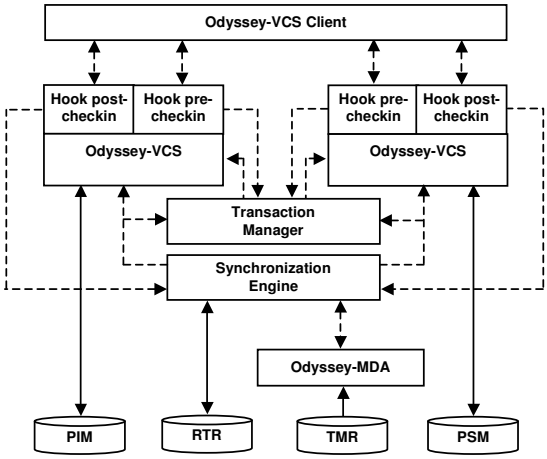

Figure 1. Odyssey-MEC Architecture

3.2 Model Infrastructure

OMG chose UML (Unified Modeling Language) as the standard modeling language for MDA. Therefore, our approach controls the evolution of UML models.

Although OMG uses MOF (Meta Object Facility) as UML meta-model, Odyssey-MEC uses the Eclipse Ecore meta-model [5]. The use of Ecore instead of MOF is not an obstacle to control the evolution of UML models because EMF uses XMI (XML Metadata Interchange) [20] for externalizing UML models. Client tools just have to use the same XMI version used by EMF (version 2.1).

3.3 Model Repository

Model repositories are used to store models. In our case, it is necessary to store all versions of a model to control the model evolution.

Due to the lack of versioning repositories for EMF, we adopted Odyssey-VCS as our versioning component, as detailed in Section 3.4.

3.4 Version Control

Version control is a key resource to control the evolution of models during development and maintenance. It is used to generate a history of model versions and maintain information like when, why, and who has made modifications. This history of model versions and modification information are stored in a repository. The basic functionalities of version control systems are: check-in (save a model into the versioned repository), check-out (get a model from the versioned repository), merge (join two models) and detect conflicts (identify concurrent modifications that cannot be resolved)[2].

Our model-based version control component is Odyssey-VCS. This component has a client/server architecture and offers all the requirements discussed above. It uses the EMF reflective API to support the versioning of any UML model element[2]. It can also execute external code trough hook implementation.

Odyssey-VCS works at fine-grained model versioning. This means that it is capable of identifying a new version of any UML model element. When a model element is composed from other model elements, if one of these elements is changed, the composing model element also receives a new version number. This is propagated recursively up to the outer model element, frequently a model package.

3.5 Model Transformation

Model transformation depends on a set of mappings and rules to create elements in a model from elements of another model. There are different ways to generate a new model using transformations [18]. Some existing approaches to model-to-model transformations are: ATL (ATLAS Transformation Language) [11], Triple [3], OptimalJ [7]. UMT [16], UMLX [8], and Odyssey-MDA[1]. A further discussion about transformation can be found in [21].

One of the requirements for controlling model evolution is the support for bidirectional transformations. This means that transformations should be able to generate PSM elements from PIM elements, and PIM elements from PSM elements. This feature is needed because different people may be working over different models, and new elements inserted in a PSM may have to be represented in its corresponding PIM. From the approaches presented above, ATL [11] and Odyssey-MDA [1] allow transformations in both directions. However, ATL requires the writing of a particular transformation mapping for each direction. On the other hand, Odyssey-MDA allows the specification of bidirectional transformations in the same mapping. In addition, it is also shipped with a tool for model marking, named ModelMarker. Due to that, we adopted Odyssey-MDA as our transformation engine component.

[2] A model element is any UML element defined in its metamodel, for example, a class, attribute, operation, component, association, etc.

Odyssey-MDA is capable to execute vertical and horizontal transformations. Therefore, although this paper is focused in vertical transformations, our approach can also be applied to control the evolution of models at the same abstraction level.

3.6 Record of Transformation

A record of transformation (RT) [18] is used to identify source models from target models and vice-versa. This is a very important resource to synchronize models, as it helps to identify existing model elements that have to be updated instead of being overwritten. Traceability links are particularly important for the synchronization activity when some relevant information is lost during the transformation [22].

In Odyssey-MEC approach, RTs are represented as a Traceability Links (TL). This is an Ecore model element that we created to reference the source and target model elements and the mapping that was used to generate the target element. Traceability links are generated by our Odyssey-MDA component during model transformations. Since more than one source or target model may be involved in transformation, it is possible that more than one traceability link references the same source element or target element.

3.7 Transaction Control

The synchronization and versioning of source and target models should be performed in a transaction context. In other words, if one of these steps fails, the whole process has to be canceled to avoid model inconsistencies.

To solve this problem, we adopted a Transaction Manager (TM) component that implement a two-phased transaction commit. When a model is checked in, the Odyssey-VCS pre-checkin hook uses TM to verify if there is any existing transaction in progress. If not, it asks for a new transaction and informs Odyssey-VCS that the model can be versioned. Odyssey-VCS starts its own transaction to create the model version. After versioning the model, Odyssey-VCS executes the post-checkin hook. This hook initiates the transformation and synchronization process. During this activity, other Odyssey-VCS instances may start their own transactions, as well as RTR. If all Odyssey-VCS instances finish their transactions successfully, TM navigates trough all Odyssey-VCS instances asking them to confirm their transactions. This also happens with RTR. Finally, the global transaction is confirmed.

3.8 Element Search

The versioning process depends on finding prior element versions. The synchronization process depends on finding PIM and PSM elements that have a trace relationship. Due to that, our element search occurs in two dimensions: time (different versions) and space (different models).

UML model elements are identified in XMI files by unique identifiers. Unfortunately, most tools do not preserve the value of these ids when models are exported. Therefore, this identifier cannot be used do identify model elements. To solve this problem, Odyssey-VCS uses a unique identifier as a tagged value.

The Odyssey-VCS meta-model has an element called Version. This element represents a version of a UML model element, and stores some versioning data, such as the element version number. It also has references to the UML model element it represents and references to the prior and next versions. Therefore, there is a list of versions for each element, which constitutes the element version history. This version history is useful to find prior and next versions of an element. However, due to the use of separate repositories for PIM and PSM, elements in different models have their own version history.

The combination of version history list and traceability links can be seen in Figure 2. Together, these two references make it possible to freely navigate from one version to another and from an element of a model (e.g., PIM) to another element of another model (e.g., PSM). This capability supports the versioning and synchronization processes discussed in Section 3.9.

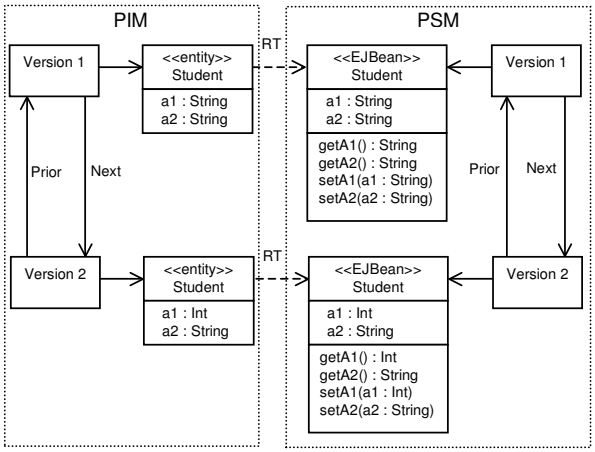

Figure 2. Version, PIM and PSM references

3.9 Model Synchronization

Interrelated models have to be consistent with each other. Therefore, it is necessary to synchronize them during development and maintenance, but preserving prior modifications. The ability to automatically synchronize models without information loss is called **roundtrip engineering** [22], and the lack of this ability usually leads to legacy systems [13].

Odyssey-VCS is designed to control the evolution of independent models. It means that this component alone is not capable of controlling the evolution of models that have

traceability links among them. Therefore, it is necessary to adopt a synchronization engine together with Odyssey-VCS. This synchronization engine is triggered by Odyssey-VCS hooks.

The synchronization engine, which is a component of Odyssey-MEC, depends not just on PIM and PSM version control information, but also on existing record of transformations of prior PIM and PSM versions. It also depends on Odyssey-MDA to generate models.

When a model is checked in, Odyssey-VCS tries to create a new version of the model. The Synchronization Engine (SE) is executed only if there is no version conflict during the versioning process. This avoids synchronization effort in cases of conflicts. If there is no conflict, SE selects the transformation mapping to be used and sends it to Odyssey-MDA, together with the new model version that was checked-in. Odyssey-MDA generates the target model (TM) and the RT of each target element, and returns them to SE. SE uses Odyssey-VCS of the target element to verify if there is any existing version available. If no previous version is found, SE considers the target model as a new model. In this case, SE checks in the target model using the Odyssey-VCS repository designated to it.

If there is an existing version of the generated target model, SE has to pre-process it in order to allow Odyssey-VCS to match the model with its prior version. This pre-processing starts with the recovery of versioning information. After that, the versioning information is interwoven into the generated target model.

This pre-processing process is composed of the following steps: (1) SE navigates trough all elements of the generated target model; (2) Using the traceability link, SE finds the related source model; (3) SE searches for the most recent version that has a traceability link dependency to an element of the target model; (4) When this element is found, SE retrieves its version information and puts into the respective generated target model element.

After the process is finished, SE checks in the model. It is worth to notice that, at this moment, the generated target model has all the necessary versioning information to allow Odyssey-VCS to interpret it as a new version of a model under version control. The generation of a new version of the model element means that the differences between the existing version and the checked-in version were merged. In other words, the synchronization was performed. If some conflicts occur during this merge process, all the operations are canceled.

When a source element has traceability links to more than one target element, the part of the transformation used to generate the target element is used to identify the correct element. This information is specified together with the traceability link that exists between the source and target models.

4. RELATED WORK

Gîrba et al. [10] proposes Hismo as a meta-model based solution to control model versions. However, this approach does not take into consideration synchronization and does not support UML models.

Matheson et al. [14] proposed an architecture for capturing models evolution in MDD. They suggest the use of a repository centric solution that is independent from client tools and stores model versions and their relationships in fine granularity. XMI is proposed as the data exchange mechanism for UML artifacts, and it uses XML and XML Schema to specify the transformation specifications. Besides the similarities with our approach, nothing was mentioned about the execution of model synchronization and model versioning.

There are some other researches [6, 9, 12] that take model evolution into consideration in some different ways, but do not consider versioning and model synchronization, as we do in our work.

5. CONCLUSIONS

This paper presented an approach to control the evolution of MDA models considering the model synchronization and versioning in a client/server architecture. Therefore, any CASE tool that can export models using XMI format is a potential client to Odyssey-MEC.

The way that PIM and PSM are versioned in Odyssey-MEC eliminates the need of any special mechanism to synchronize them. This synchronization is made when Odyssey-VCS merges the model that is being checked in with its last available version.

The client/server architecture of Odyssey-MEC makes it possible to implement distributed MDD using the MDA approach. The automatic model synchronization avoids the errors that can be introduced during manual synchronization. It also guarantees that models will always be consistent.

Although this paper focused on PIM and PSM, models in the same abstraction level may also be generated, synchronized and versioned. This can be done via horizontal transformation definitions during the MDD project creation. Moreover, we were mostly focused in this paper on PIM and PSM synchronization and versioning. Therefore, only two abstraction levels where considered. However, the approach works with unlimited abstraction levels. In this case, a PSM can be considered a PIM for the next abstraction level. It is also possible to support PSM for multiple platforms.

Currently, Odyssey-MDA works just with static models (i.e., class and component models). It means that Odyssey-

MEC cannot synchronize dynamic models, such as sequence model. Nevertheless, Odyssey-VCS can still be used to version control these models, but without synchronization among them. Moreover, the current version of Odyssey-MDA is able to deal with just one model as input and generates another model as output. Therefore, Odyssey-MEC supports model evolution in a one-to-one basis.

Our next step is to evaluate the proposed approach by applying some selected cases that will take into consideration conflict resolutions, forward and reverse transformations, transformation mapping change, etc. The results will be evaluated through precision and recall analysis [23], comparing them to the expected values.

As future work, we intend to: (1) expand our support to CIM and source-code; (2) develop an additional tool to help de visualization of MDA models evolution during the project execution and system maintenance; (3) control the evolution of transformation mappings and register in the RT the version of the transformation mapping used during the transformation; (4) expand our support to other UML models, such as the behavioral models; (5) modify Odyssey-MDA to receive and generate more than one model; and (6) use rules do control modifications that can be applied on interrelated models.

Analyzing the Impact of Attribute Noise on Software Quality Classification

Andres A. Folleco
Taghi M. Khoshgoftaar*
Lofton A. Bullard

Abstract

A ubiquitous problem in software quality classification is the presence of noise in measurement data. Noise can have a tremendous effect on classification performance. Relatively few studies, and none in the software quality estimation domain, have considered the impact of noisy attributes on classifier performance. This study investigates the impact of attribute noise on the performance of 11 software quality classification models. Noise was injected into seven real-world software measurement datasets, initially relatively free of noise. Attributes were ranked based on their KS statistic to determine their predictive significance. Those with higher rankings were injected with noise, in order of decreasing KS statistic. If the number of attributes injected with noise exceeded a threshold value found in this study, the classification performance deteriorated.

Keywords: attribute noise, random forest, software quality classification.

1 Introduction

The presence of noise in data is a recognized problem in software quality initiatives [11]. Noise can significantly affect the results and conclusions obtained from classification performance studies. For example, in the software quality estimation domain, models are built to distinguish program modules that are likely to contain faults (fault prone or fp) from those that are not fault prone (nfp). It is common in mission critical systems [8], that the misclassification of fp modules can threaten property and/or lives.

Relatively few studies, and none in software quality classification, have considered the impact of attribute noise on classification performance. A considerable number of studies in the data mining and machine learning field have focused solely on the impact of class noise on classification performance. In this study, we injected domain realistic attribute noise into seven class-imbalanced[1] real-world software engineering measurements datasets, initially relatively free of noise. The datasets were relatively cleansed of inherent noise before the injection of simulated attribute noise. Injecting noise into a dataset that already contains noise can bias any empirical conclusions. Thus, the experiments in this study were carefully designed to ensure result accuracy and robustness. The attributes selected for noise injection were ranked based on their KS statistic to determine their class prediction significance. Those with higher rankings were injected with domain realistic noise, in order of decreasing KS statistic [6].

The experimental results demonstrated that when the number of attributes injected with noise was five or more, or approximately 39% of the 13 independent attributes, the impact on classification performance became more important in this study. On the other hand, all classifiers had relatively minimal impact on their performances when one, two, three, or four of the most significant attributes were injected with noise. This performance behavior provides evidence that having moderate levels of attribute noise in software measurement datasets is not nearly as important to classification performance [11].

1.1 Related Work

Studies considering the impact of attribute noise on software quality classification have not been found. Often, related studies in other domains have suggested that in many cases, eliminating instances with class noise will improve classification accuracy [3, 7]. Further, very few of these studies have investigated the impact of attribute noise [18] on classification performance. Typically, handling attribute noise is more difficult than class noise [14, 18]. Class noise occurs when a program module is labeled as belonging to a class different than the one implied by its attributes, e.g., $fp \rightarrow nfp$ or when $nfp \rightarrow fp$. Often, eliminating instances which contain attribute noise is counter-productive, because other attributes belonging to the deleted instance can still contain valuable information. Zhu and Wu [18] pointed out an important fact from real-world data: the class information is usually much cleaner than commonly assumed; and it is the independent attributes that usually

[1] In binary classification, if one of the two classes has more program modules, then the data is considered imbalanced relative to the class.

contain more noise. Our previous work [10] determined similar findings, corroborating the importance of measuring the impact of attribute noise on classification. In this study, we used 11 classifiers and two performance metrics to investigate the impact of attribute noise on software quality classification performance. No other related study has used this many classifiers to investigate the impact of attribute noise. In fact, to our knowledge, similar comprehensive experimental procedures to those used in this work have not been reported in any other related studies.

The remainder of this paper is organized as follows: Section 2 describes the 11 classifiers used. The experimental methodology is provided in Section 3. Experimental results are presented in Section 4, and the conclusion is provided in Section 5.

2 Classifiers

Every classifier used was implemented in the Weka tool [17]. Default parameter changes were done only when classifier performance improved significantly. *C4.5* [13] is a benchmark decision tree learning algorithm. Two different versions of the C4.5 classifier were used. C4.5D uses the default parameter settings in Weka, while C4.5N uses no decision-tree pruning and Laplace smoothing [16]. The *random forest* (RF100) classifier [2] uses bagging and the 'random subspace method' to build an ensemble of randomized decision trees which are combined to produce the final prediction. RF100's 'Number of Trees' parameter was changed to 100 from its default value of 10. *K nearest neighbors* [1] (kNN) classifiers were built with changes to two parameters. The 'distanceWeighting' parameter was set to 'Weight by 1/distance'. Two different 'kNN' classifiers were built using $k = 2$ and $k = 5$ and were denoted '2NN' and '5NN', respectively.

The *support vector machine* (SVM) classifier called SMO in Weka had two changes to the default parameters: the complexity constant 'c' was set to 5.0 and 'buildLogisticModels' was set to 'true'. By default, a linear kernel was used. For a *Multilayer perceptrons* (MLP) classifier (a type of neural network), the 'hiddenLayers' parameter was changed to '3' to define a network with one hidden layer containing three nodes, and the 'validationSetSize' parameter was changed to '10' to cause the classifier to leave 10% of the training data aside to be used as a validation set to determine when to stop the iterative training process. *Radial basis function networks* (RBF) are another type of artificial neural network. The only parameter change for RBF was to set the parameter 'numClusters' to 10. *Naive Bayes* (NB) utilizes Bayes's rule of conditional probability and is termed 'naive' because it assumes conditional independence of the features. *Logistic regression* (LR) is a statistical regression model for categorical prediction. *RIPPER* (Repeated Incremental Pruning to Produce Error Reduction) is a rule-based classifier and is named JRip [4] in Weka. The default Weka parameters for these three classifiers were not changed.

3 Experimental Design

3.1 Experimental Datasets

The datasets used are from seven NASA software projects: JM1, CM1, MW1, PC1, KC1, KC2, and KC3 which were obtained from the NASA Metrics Data Program (MDP). Instances represent software modules with 21 software measurements. Classifiers were built using 13 primitive metrics[2] as independent variables and a module-class (binary) as the dependent variable, i.e., fp (fault-prone) or nfp (not fault-prone). The minority class is represented as the positive or fp class, while the majority class is represented as the negative or nfp class.

The RBCM noise filter was applied to these datasets in order to identify and remove subsets of noisy instances [9]. Table 2 provides details about the seven initial datasets and their respective cleansed versions. In this table, the #P column contains the number of positive (fp) examples, while the #N has the number of negative (nfp) examples. The %P column provides the percentage of positive examples relative to the total number of examples in a dataset, e.g., PC1 originally contained 1107 instances, of which 6.87% were fp. After cleansing, 703 total instances remained of which 7.54% were fp. The cleansed datasets were used in this work. These datasets were subjected to a methodical and carefully designed noise cleansing process described in [9] (also see Van Hulse [15] for a detailed discussion of the noise cleansing procedure).

Table 3 shows the classification performance across all classifiers obtained using each of the cleansed datasets. According to the AUC and KS performance metrics, the best classification performance was obtained by using JM1. The

[2] The other metrics are derived from the 13 primitive ones in Table 1

Table 2. Dataset characteristics

	Initial			Cleansed		
Data	# P	# N	% P	# P	# N	% P
JM1	470	2393	16.42	235	2210	9.61

MW1	0.9767	7	MW1	0.9428	7
Avg	0.9896		Avg	0.9616	

second best performance was obtained using KC1, and the worst performance was obtained using MW1. The average values ('Avg' row) across all the cleansed datasets and classifiers were used as a baseline reference for performance comparisons. Note that all datasets have nearly perfect performance by the classifiers, further supporting the fact that the datasets have been cleansed of noise significantly.

3.2 Performance Metrics

Traditional performance measures such as classification accuracy, or its complement, misclassification rate, are inappropriate when dealing with the classification of class imbalanced data. When as few as 1% of examples belong to the positive class, a classifier can achieve an accuracy of 99% by simply labeling all examples as belonging to the negative class. In a domain such as software quality classification, however, such a model is useless. Instead, two performance metrics that consider the ability of a classifier to differentiate between the two classes were used. The Kolmogorov-Smirnov statistic [6] measures the maximum difference between the empirical distribution function of the posterior probabilities of instances in each class.

The second metric used was the Receiver Operating Characteristic curve [12] (ROC). ROC curves graph true positive rates on the y-axis versus the false positive rates on the x-axis. The resulting curve illustrates the trade-off between detection and false alarm rates. Often, performance metrics consider only the default decision threshold of 0.5. ROC curves illustrate the performance across all decision thresholds. For a single numeric measure, the *area under the ROC curve* (AUC) is widely used, providing a general idea of the predictive potential of the classifier.

3.3 Noise Injection Procedure

The attributes selected for noise injection were identified by the KS test at a 5% significance level [9]. The KS two-sample test is a non-parametric statistical significance test [5]. It is useful in determining the fp and nfp discriminative quality of the attributes under consideration. The greater the KS statistic for an attribute, the better is its discriminative quality for segregating the fp instances from nfp instances. Noise was injected at five levels - 10%, 20%, 30%, 40%, and 50%. Noise was first injected into the most significant predictive attribute, creating a total of 35 derived datasets from the seven cleansed datasets. The derived datasets from each cleansed dataset contain a different amount of corruption in that attribute. The next 35 datasets were obtained by corrupting both the most and second most significant attributes. This procedure was repeated until the seven most significant attributes were corrupted. The results of six attributes injected with noise were excluded from this study because of similarities to the results obtained when seven attributes were used. A noise level of 10% implied that the values for the selected attributes were corrupted for 10% of the instances. The corruption was obtained by replacing the given value with a randomly selected value reflecting an instance of the opposite class, i.e., nfp or fp. For a given injected noise level, the nfp and fp proportions of the instances injected with noise was approximately the same as the nfp and fp proportions of the given dataset. For example, if the given dataset had a proportion of 70:30 for nfp:fp instances and if 100 instances were injected with noise, then those 100 instances would consist of 70 nfp and 30 fp instances.

3.4 Experimental Design Summary

The models were trained using the derived datasets from the cleansed datasets. 10-fold cross validation was used to build and test the models. The datasets were broken into 10 partitions, where nine of the 10 partitions were used to train the model, and the remaining (hold out) partition was used to test the model. This was repeated 10 times so that each partition was used as hold out data once. In addition, 10 independent repetitions of each experiment were done to avoid any bias that may occur during the random selection process and to ensure the statistical significance of the results. The results reported in the following sections represent the average of these repetitions. Noise was injected in up to seven of the most significant attributes from each dataset. There were five levels of noise, 10%, 20%, 30%,

Table 4. Overall Impact of Attribute Noise

	Clean	1-attr	2-attr	3-attr	4-attr	5-attr	7-attr
AUC	0.9896	0.9875	0.9856	0.9812	0.9794	0.9651	0.9504
KS	0.9616	0.9506	0.9429	0.9310	0.9268	0.8987	0.8542

40%, and 50%, eventually injected into these attributes. Based on these experimental parameters, there were a total of 231,000 models built and evaluated.

4 Experimental Results

4.1 Noise Impact on Classification Performance

Table 4 contains the impact of attribute noise on classification performance averaged overall datasets and learners. The column labeled 'Clean' contains the performance values obtained when using the cleansed datasets. The column labeled '1-attr' contains the performance values overall learners and datasets when the most significant attribute was injected with noise. The rest of the columns (labeled '2-attr,' '3-attr,' '4-attr,' etc.) show the performance values when noise was injected into two, three, four, five, and seven of the most significant attributes. Both metrics showed that when there were five attributes injected with noise (in the column labeled '5-attr') a relatively large drop in classification performance occurred. If we compare the performance values from the 'Clean' column to the rest of the performance values from the other columns, we can clearly see the relative large performance decline in column '5-attr'. Furthermore, the largest performance losses were 4.0% for the AUC and 10.7% for the KS metric. These losses were obtained by calculating the percent difference between the 'Clean' baseline and the '7-attr' column values.

Tables 5 and 6 contain the impact on each classifier's performance overall datasets and noise levels as the number of attributes injected with noise increased. The best performing classifier (RF100) is bolded. Both tables show declining classifier performance as the number of attributes with injected noise is increased. Note that the right most column in these tables (showing seven corrupted attributes and labeled '7-attr') has the lowest classification performance. The only exception to this trend in both tables is observed in Table 5. In this table, SVM is bolded to show its performance improvement when noise injection increased from five to seven attributes. SVM's unusual performance using JM1 can be used as an example of a classifier with unexpected results in a particular case study and it is further explored in Figure 1. Note that all classifiers maintained very good performances when one, two, three, or four of the most significant attributes were injected with noise.

Figure 1 shows SVM's performance based on the average KS metric (in the y-axis) when using the derived datasets from the best performing dataset, JM1 (AUC results are similar but not shown due to space limitations). The x-axis has the number of attributes injected with noise per injected noise level. At the lowest level of injected noise, 10% (labeled at the bottom of the figure), SVM had its largest performance loss when noise injection was increased from four to five attributes. In contrast, SVM had a relatively large performance improvement when noise injection was further increased from five to seven attributes. The classification performance was nearly perfect for the first four attributes with injected noise, regardless of the level of noise. In comparison to the other noise levels (separated by the solid vertical lines in Figure 1), 20%, 30%, 40%, and 50%, SVM recorded its best performance at the highest level of noise, 50%. This unusual SVM performance can be partly explained as an anomaly in the performance of this classifier when using the derived datasets from JM1. Under no other experimental scenario did SVM's (nor any other classifier's) performance resem-

4.2 Noise Impact on Classifiers

In this section we investigate the impact of attribute noise on each of the 11 classifiers averaged over all datasets, all noise levels and all attributes injected with noise. The impact on performance using the JM1 and MW1 datasets is also presented. Note that there are small disagreements between the AUC and KS values in Tables 7, 8, and 9. In general, the top two or three performing classifiers have very close values and rankings. This observation is also true for the two lowest performing classifiers. The tables have the same column format showing (from left to right) the classifier name, the AUC_c value obtained from the cleansed datasets, the AUC_n value obtained from the derived datasets with injected noise, the derived ranking (R_n) based on AUC_n, the KS_c value obtained from the cleansed datasets, the KS_n value obtained from the derived datasets with injected noise, and the corresponding ranking (R_n) from KS_n. The best ranked classifier (RF100) is bolded in the tables which are ordered by AUC_n ranking.

Table 7 shows the impact of noise by the lower AUC_n values when compared to those values from AUC_c. The same trend is observed in the KS values. The rankings are based on the AUC_n and KS_n values respectively. The best performance was obtained by the RF100 classifier, regardless of the levels of noise, number of significant attributes with injected noise, dataset used, or metric used. The second best performing classifiers were 5NN (as ranked by the AUC_n) and SVM (by the KS_n). The classifiers most affected by attribute noise were RBF and RIPPER.

Table 8. Performance of Classifiers using JM1

	AUC_c	AUC_n	R_n	KS_c	KS_n	R_n
RF100	1.0	**0.9991**	**1**	1.0	**0.9962**	**1**
5NN	1.0	0.9988	2	1.0	0.9941	3
2NN	1.0	0.9986	3	1.0	0.9926	4

RIPP	0.9370	0.9010	10	0.8966	0.8132	10
RBF	0.9519	0.8907	11	0.9085	0.7995	11

Tables 8 and 9 show the performance of the classifiers when using the derived datasets from JM1 and MW1 (see Table 3 for datasets details). Both tables show the impact of attribute noise by the lower AUC_n values when compared to those values from AUC_c. The same trend is observed in the KS values. The rankings are based on the AUC_n and KS_n values respectively.

Table 8 shows RF100 as the best performing classifier, followed by 5NN (for AUC_n) and LR (for KS_n). The classifier most affected by noise was SVM. Recall that both SVM and 5NN had the second best overall performance in this study. We explained SVM's performance when using JM1 in the previous section with a particular emphasis on the line plot shown in Figure 1. On the other hand, Table 9 shows RF100 as the best performing classifier, with SVM and 5NN as the second and third best classifiers re-

spectively. RBF and RIPPER had the lowest classification performance. These results agreed with the performances presented in Table 7 and were very similar to the results observed from KC1, KC2, KC3, PC1, and CM1. The results from these datasets were not presented due to space limitations.

5 Conclusions

The quality of the software measurement data is of paramount importance to software quality classification. As the levels of attribute noise increased, every classifier's performance decreased. This behavior was observed by the decline in the recorded AUC and KS values. Furthermore, when the number of significant attributes injected with noise increased, the classifiers' performances decreased. A threshold for this number of attributes was identified that when reached or exceeded, it drastically affected classification performance. The threshold value was determined to be five attributes, or approximately 39% of the 13 attributes in the datasets. In contrast, all classifiers had minimal impact on their classification performance when one, two, three, or four of the most significant attributes were injected with noise. This performance behavior implies that moderate attribute noise is not as concerning to classification performance as class noise. To our knowledge, this is the first software quality classification study to report such important empirical results.

The AUC and KS values were used to determine the best and worst performing classifiers. The empirical results conclusively demonstrated that the random forest ensemble classifier obtained the best and most consistent classification performance in every experimental scenario. The second best classifiers were SVM and 5NN. The classifiers most affected by attribute noise were RBF and RIPP. Based on these results, we strongly recommend the random forest classifier for software quality estimation. Even though SVM had very good overall classification performance, when the JM1 dataset was used with SVM, we observed the worst classification performance. At the lowest level of injected noise, 10%, SVM had its largest performance loss. This loss was observed in the KS and AUC values when noise injection was increased from four to five attributes. On the other hand, SVM had a relatively large performance improvement when noise injection was further increased from five to seven attributes. In comparison to the rest of the noise levels, 20%, 30%, 40%, 50%, SVM recorded its best performance at 50% (see Figure 1). These results emphasize the importance of using high quality data and carefully designed comprehensive experimental procedures.

Future work will include the investigation and comparison of the results obtained from the injection of class noise. Further research will consider both attribute and class noise, and will include additional software measurement datasets.

Abstract

A timely software defect prediction activity is a useful tool in improving the quality and reliability of software-based systems. Such a model provides the quality improvement team with a guidance on which program modules, prior to system testing and deployment, should be allocated the limited re-inspection and quality improvement resources. Among existing software fault prediction techniques, artificial neural networks are effective in extracting the complex relationship between the different software measurements of program modules and their associated defect data. We present an innovative neural network model that alleviate the various problems associated with the traditional back-propagation neural network models. The proposed Adaptive Resilient Propagation Neural Network (APROP) model for software defect prediction is investigated with a case study of a real-world high assurance software system. The APROP defect prediction model is compared with the traditional back-propagation neural network, and those results indicated a significant improvement in fault prediction. A comparison with a non-neural network model, Multiple Linear Regression, further validated the improved fault prediction of the proposed model. The APROP model is not limited to software defect prediction, and can be applied for other estimation problems during software development, such as identifying critical test cases for regression testing.

1. Introduction

Assuring good software quality and reliability is essential to any software development project, especially for high assurance and mission-critical software systems. In software engineering practice, various techniques and processes are used improving the quality and reliability of software products. Some of those techniques include software inspection [6], software redesign [11], formal requirements analysis [16], and knowledge-based software quality models [3, 8, 15]. This paper focuses on the latter approach to software quality improvement.

It is known that the presence of software errors and faults has a direct impact on the achieved level of quality and reliability of software-based systems. Hence, reducing the presence of software faults in program modules is a practical way to assure an improved level of software quality. Knowledge-based software engineering includes quantitative software quality estimation modeling and analysis. A software quality prediction model is typically built by training a machine learner (prediction model) on known software measurements and defect data collected from a prior release or previously developed system. Upon validation, the trained software quality model can be applied to predict the unknown defect data for program modules of the currently under-development project.

The characterization of defect data (software quality) varies from project to project, and depends on goals of the software quality improvement team. In some cases, software quality is expressed and evaluated in terms of membership of program modules to different quality-based groups, such as high-quality and low-quality. In other instances, software quality is expressed and evaluated in terms of number of faults associated with different program modules. In some other analysis, the amount of code churn required to fix a reported problem is used to express and evaluate software quality. We focus on number of faults in a program module as the primary characteristic of software quality.

We present an innovative artificial neural network model that overcomes several shortcomings of traditional neural networks, and investigate its performance and viability as a software quality prediction model. To demonstrate its bet-

ter performance for software fault prediction, the proposed Adaptive Resilient Propagation Neural Network (denoted as APROP) is compared with the traditional steepest gradient artificial neural network (denoted as ANN). We also compare the APROP model with a non-neural network software quality model; and for that purpose, we use the Multiple Linear Regression (denoted as MLR) prediction method.

The APROP neural network model is investigated with a case study of software measurement and defect data obtained from a real-world military command, control, and communication system. We build three software fault prediction models, i.e., based on the APROP, ANN, and MLR models. The three models are compared for statistical significance in their relative prediction performances. It is shown that the proposed Adaptive Resilient Propagation Neural Network model provides significantly better fault predictions compared to both ANN and MLR models.

While other algorithms and models have been used for software fault prediction, the focus of this paper is limited to presenting the APROP model as a viable and practical alternative to the traditional back-propagation neural network. We also include MLR in our comparison with APROP; however, a comprehensive comparison with other prediction algorithms and models is out of scope for this paper – in part due to paper size considerations. The application of our APROP model is not limited to fault prediction, and can be extended to predict other attributes in software project development, e.g., identification of critical test cases for regression testing.

The remainder of the paper is structured as follows: Section 2 summarizes key related work in the literature; Section 3 presents the Adaptive Resilient Propagation Neural Network model; Section 4 summarizes Multiple Linear Regression which we compare with the APROP model; Section 5 describes our case study, and analyzes the obtained empirical results; and, Section 6 concludes our paper and includes suggestions for future research directions.

2. Related Work

A perfect software development environment would include software quality improvement activities being applied to all program modules. However, limited resources available for re-inspections and quality improvement require a targeted allocation of those resources for maximum software quality improvement. The output of software quality estimation models are predictions that a development team can utilize to identify high-risk or low-quality program modules in the system. Knowledge-based software quality estimation models generally include software quality classification models [5, 9], software fault prediction models [2], and module-order models [7].

A software quality classification model aims to maximize return on quality improvement activities by guiding in predicting which program modules are fault-prone or not-fault-prone. A software fault prediction model estimates the number of faults a given module for use as a guide to target available resources to program modules that are likely to have more faults. Finally, a module-order software quality model provides the quality improvement team with a quality-based ranking of program modules which can then be used for targeted software quality improvement efforts.

In the literature, one can find various methods and techniques that have been investigated for building software quality estimation models, including decision trees [9], regression [15], case-based reasoning [3], soft computing methods [7, 18], artificial neural networks [17], etc. This paper does not include an extensive coverage of various software quality prediction methods, as it is beyond its scope. However, readers are provided with sufficient background material in the cited references.

3. Adaptive Resilient Propagation Network

Artificial neural networks (ANN) are systems that are deliberately constructed to make use of some organizational principles resembling those of the human brain. ANN have been studied for a long time since Rosenblatt [13] first introduced single layer perceptrons. For multilayer neural networks, back-propagation [10, 14, 19] is the most popular training algorithm.

We designed an adaptive resilient propagation neural network (APROP) based on the resilient propagation, adaptive learning rate, momentum, and structure optimization technique to overcome the inherent disadvantages of slow training speed, large memory usage, potential diverge training problems, and local minimum associated with back-propagation algorithms.

A typical neural network has the input layer, a numbers of hidden layers, and the output layer. Figure 1 shows a feedforward multilayer neural network. The traditional back-propagation algorithm adjusts the weights and basis by application of a gradient to compute the influence of each weight in the network with respect to a cost function E.

$$\frac{\partial E}{\partial w_{ij}} = -\sum_{k=1}^{p}(d_i^{(k)} - o_i^{(k)})f'(net_i^{(k)})x_j^{(k)}$$

However, training a multilayer network is usually a time-consuming process, and it is not easy to achieve the global optimal solution. Many algorithms have been proposed to speed up the learning process and achieve better solutions. For example, Martin Riedmiller and Heinrich Braun [12] proposed adapting the partial derivative of weights to optimize the learning process. APROP differs from traditional

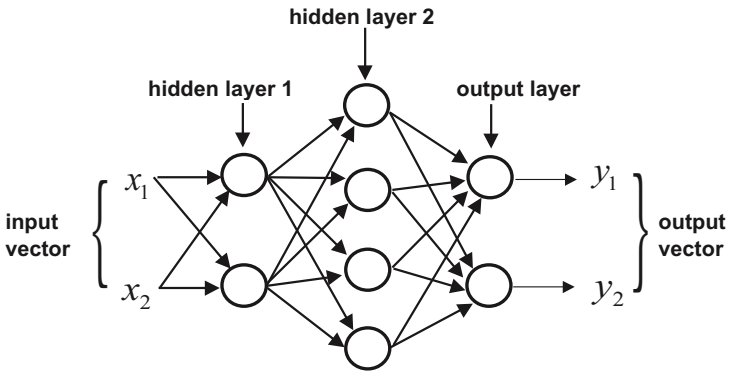

Figure 1. A feedforward neural network

resilient propagation networks in that both its learning rate and changes in weight derivatives are adaptive, and a growing method is used to automatically search for the optimized structure. Making both learning rate and the weight derivatives adaptive, and optimizing structure of networks can achieve better prediction and a faster and more stable learning process.

In summary, the ARPROP learning algorithm can be outlined in the following way. Consider a network with H layers, $h = 1, 2, ..., H$, and let net_i^h and o_i^h denote the net input and output of the ith unit in the h layer, respectively and w_{ij}^h denote the connection weight from o_j^{h-1} to o_i^h. Suppose the network has m input nodes and n output nodes. There are p pairs of training pairs $\{(\mathbf{x}^{(k)}, \mathbf{d}^{(k)})\}$ where $k = 1, 2, ..., p$.

1. Initialization: Choose a learning rate r, maximum epoch number and training goal E_{goal}. Randomly select weights and basis for each neuron.

2. Training loop: Apply the kth input pattern to the input layer $(h = 1)$.

3. While not done: the whole set of training data has been cycled through once.

   (a) Forward propagation: Propagate the signal forward through the network using

   $$o_i^h = f(net_i^h) = f\left(\sum_j w_{ij}^h \, o_j^{h-1}\right) \tag{1}$$

   for each i and h until the outputs of the output layer o_i^h have all been obtained.

   (b) Output error measurement: Compute the error value and error signals ∇E_i^h for the output layer:

   $$\begin{aligned} E &= \frac{1}{2}\sum_{i=1}^{n}(d_i^{(k)} - o_i^h)^2 \\ \frac{\partial E}{\partial w_{ij}} &= -\sum_{k=1}^{p}(d_i^{(k)} - o_i^{(k)}) f'(net_i^{(k)}) x_j^{(k)} \\ \nabla E_i^h &= r * \frac{\partial E}{\partial w_{ij}} \end{aligned}$$

   (c) Error back-propagation: Propagate the errors backward to update the weights and compute the error signals ∇E_i^h for the preceding layers:
   For all weights and biases

   $$\begin{aligned} \nabla w_{ij}^h(n+1) &= f_{adapt}(\frac{\partial E}{\partial w_{ij}}(n), \nabla w_{ij}^h(n), \\ &\qquad \frac{\partial E}{\partial w_{ij}}(n+1), r) \\ w_{ij}^h &= w_{ij}^h + \nabla w_{ij}^h(n+1) \end{aligned}$$

   where f_{adapt} is an adaptive function.

   (d)

   $$\nabla w_{ij}^{h-1} = f'(net_i^{h-1} \sum_j w_{ij}^h \, \nabla E_i^h)$$

   where $h = H, H-1, ..., 2$.

   (e) update learning rate according to $r = \frac{0.01}{1+e^{-1.4*E}}$

4. One epoch iteration: End while

5. Stop training check: If the total error reach the training goal E_{goal} or the epoch reach the set maximum, stop training, otherwise go back to the training loop for the next epoch.

The above APROP is for a fixed-node hidden layer ANN. If the hidden layer units are few, however, the ANN's learning ability is reduced, and the ANN may not converge and can not remember any learning pattern. On the other hand, if the hidden layer units are too many, the unnecessarily complex network can easily result in over-fitting of the software quality model. Hence, we empirically tried to find an optimal number of hidden layer units for the ANN by changing the number of nodes in hidden layer until the best prediction quality was achieved.

Initially, the number of hidden layer units was made equal to that of input nodes and then the number of nodes in hidden layer was changed until the best prediction quality was achieved. The input data was randomly divided into two subsets: (1) training data used to train the neural networks, and (2) validating data used to test the training quality. The structure of the neural network that had the best training result was chosen.

4. Multiple Linear Regression

Multiple linear regression is a statistical method for estimating a dependent variable as a function of independent variables [1]. The model is based as an equation where the dependent variable (number of faults in our study) is expressed in terms of predictors (software metrics in our study), and is generally given by,

$$\hat{y}_i = a_0 + a_1 x_{i1} + \cdots + a_p x_{ip}$$
$$y_i = a_0 + a_1 x_{i1} + \cdots + a_p x_{ip} + e_i$$

where, $x_{i1}, \ldots, x_{ip}$ are the independent variables values, $a_0, \ldots, a_p$ are the parameters to be estimated, $\hat{y}_i$ is the dependent variable to be predicted, y_i is the actual value of the dependent variable, and $e_i = y_i - \hat{y}_i$ is the error in prediction for the ith case.

The software measurement data is initially subjected to statistical analysis for removing any correlation existing between independent variables and to remove insignificant independent variables. The process of determining the independent variables which are significant is known as model selection, and several methods exist. They are forward elimination, stepwise selection and backward elimination. Here, stepwise regression is used. Stepwise regression [1] selects an optimal set of independent variables for the model. In this process, variables are either added or deleted from the regression model at each step of the model building process. Once the model is selected, the parameters $a_0, \ldots, a_p$ are then estimated using the least squares method.

Table 1. Software Product Metrics

Symbol	Description
η_1	Number of unique operators.
N_1	Total number of operators.
η_2	Number of unique operands.
N_2	Total number of operands.
$V(G)$	McCabe's cyclomatic complexity.
N_L	Number of logical operators.
V	$N \log_2(\eta_1 + \eta_2)$ is Halstead volume
$\widehat{N}$	$\eta_1 \log_2 \eta_1 + \eta_2 \log_2 \eta_2$ is Halstead length.
LOC	Lines of code.
ELOC	Executable lines of code.
PROCS	Number of procedures in a package.
COM	Number of command lines.
BLNK	Number of blank lines.

5. Software Project Case Study

5.1. System Description

We studied a large military command, control and communication system implemented in Ada. The software system was developed in a large organization by professionals using the procedural programming paradigm. The fault/defect data from problem tracking reports generated during the system integration and test phase. The defect and software measurement data is aggregated at the module level, where a program function or method is considered a program module. The number of faults (Y) in a program module is the dependent variable in our software quality research, and is predicted by a set of software metrics collected for the system.

The software metrics used in our case study are shown in Table 1, and include Halstead's, McCabe's and Statement-related product metrics [4]. The type and number of metrics used for the case study system were primarily governed by their availability, internal workings of the project, and the data collection tools used. Other metrics, including software process were not available. The use of the specific software metrics in our study does not advocate their effectiveness; hence, a different project may consider a different set of software measurements for analysis [3].

The case study data consisted of all 282 program modules measured by the development team. To create an independent evaluation dataset, we apply data splitting and randomly partition the original dataset into two subsets. The fit or training dataset consisted of two thirds of the program modules, while the remaining one-third formed the test (evaluation) dataset. Using an independent set for model evaluation provides unbiased software quality prediction results. Table 2 provides some summary statistics

Table 2. Statistics for number of faults

Statistic	Fit Data	Test Data
# Modules	188	94
Min.	0	0
Max.	29	42
Mean	2.27	2.56
Std. Dev.	4.65	5.88

on number of faults for the program modules in the fit and test datasets.

5.2. Performance Metrics

The performance accuracy of a given fault prediction model is evaluated with respect to the following metrics computed for the test dataset: *Average Absolute Error* (AAE), *Average Relative Error* (ARE), and the percentage of estimates that are within 20% (PRED(20)) and 25% (PRED(25)) of the actual number of faults value. With respect to the AAE and ARE performance metrics, lower values indicate better fault prediction accuracy. With respect to PRED(20) (or PRED(25)), a model with perfect fault prediction ability would have a PRED(20) (or PRED(25)) of 100% implying that it would estimate within 20% (or 25%) of the actual number of faults, 100% of the time.

The AAE and ARE metrics are given by, AAE $= \frac{1}{n}\sum_{i=1}^{n}|y_i - \widehat{y}_i|$, and ARE $= \frac{1}{n}\sum_{i=1}^{n}\left|\frac{y_i - \widehat{y}_i}{y_i+1}\right|$, where n is the number of modules in the test data, y_i and $\widehat{y}_i$ represent the actual and predicted number of faults, respectively. In the case of ARE, since the actual number of faults may be zero, we add a "1" to the denominator to avoid division by zero.

5.3. Empirical Results and Discussion

We applied the multiple linear regression model (MLR), APROP, traditional steepest gradient neural network (ANN) on the case study data, respectively. The multiple linear regression model in this section predicted number of defects in the software modules. These predictions were based upon a selection of principal components after conducting principal components analysis for 95% variance. The first step of model selection was followed by fitting the model, and finally analyzing of the quality of fit and prediction accuracy of the software fault prediction model.

Stepwise regression selected $V(G)$, N_L, η_1, η_2 at the 5% significance level. The following model was obtained using the least-squares estimation technique.

$$Y = 0.054 + 0.0306\,\eta_2 - 0.0318\,V(G) + 0.2310\,N_L - 0.0425\,\eta_1$$

Table 3. Prediction Accuracy for Models

Models	AAE	ARE	PRED(20)	PRED(25)
MLR	1.787	0.700	57.4%	57.4%
ANN	2.064	0.710	60.0%	60.6%
APROP	1.159	0.513	70.2%	71.3%

Each variable (software metric) in the model was significant at $\alpha < 0.04$. The quality of fit of the trained software quality model was indicated by an $R^2 = 0.738$. Application of the model to the test dataset yielded an average absolute error of 1.787, i.e., AAE = 1.787.

In order to be consistent with the multiple linear regression, the neural network model used the same independent variables ($V(G)$, N_L, η_1, η_2) as the multiple linear regression model. We built two neural networks. One is APROP and the other is a traditional steepest gradient neural network (ANN). We compared prediction performances of the models based on the AAE, ARE, PRED(20), and PRED(25) values computed for the test dataset. Table 3 shows that APROP performed better than the other two methods.

Toward verifying the improved performance of APROP against MLR, we conducted a paired t-test with AAE as the response variable. The hypothesis test is formulated as, $\mu(Y_{MLR})$

$$H_0 : \mu(Y_{MLR}(\mathbf{x}_i) - Y_{APROP}(\mathbf{x}_i)) = 0$$
$$H_A : \mu(Y_{MLR}(\mathbf{x}_i) - Y_{APROP}(\mathbf{x}_i)) <> 0$$

A 95% confidence interval of {0.065, 1.190} for the mean difference between MLR and APROP doesn't include a zero, suggesting a significant difference between them. An observed $t = 2.21$, which is greater than the critical value $t_{1-\alpha\,;\,n-1}$, where $\alpha = 0.05$ and $n = 94$ (the number of program modules in the test dataset) in this case study – hence, $t_{0.05\,;\,93} = 1.66$. The *p*-value for this test is 0.029. The small p-value further suggests that the data are inconsistent with $H_0 : \mu(d) = 0$, that is, the two AAEs are not close to zero. Therefore, we reject the null hypothesis H_0, and concluded that APROP's AAE is significantly lower than MLR's in this case study.

We also conducted a paired t-test, with AAE as the response variable, to evaluate the significance of APROP's fault prediction accuracy compared to that of ANN. The hypothesis test is once again formulated as,

$$H_0 : \mu(Y_{ANN}(\mathbf{x}_i) - Y_{APROP}(\mathbf{x}_i)) = 0$$
$$H_A : \mu(Y_{ANN}(\mathbf{x}_i) - Y_{APROP}(\mathbf{x}_i)) <> 0$$

The 95% confidence interval for mean difference between ANN and APROP is $(0.046, 1.763)$, which doesn't include a zero and $t = 2.09$ is larger than critical value. Hence, we reject the null hypothesis H_0, and conclude that the

APROP model significantly reduces the AAE metric in this case study.

6. Conclusion

A software defect prediction model can aid the software quality improvement team in conducting a more focused quality improvement by identifying program modules likely to have more defects. We presented the Adaptive Resilient Propagation Neural Network as a valuable alternative to the traditional back-propagation neural network model for software defect prediction. The proposed APROP model is shown to yield statistically significant performance improvement compared to both the traditional back-propagation neural network model and the multiple linear regression model.

The black-box characteristic of artificial neural network models make them less attractive to analysts, including software practitioners. Hence, one has to consider both model-comprehension and model-accuracy when determining which defect prediction model to use. When it comes to absolute reduction of latent software faults, accuracy of a defect prediction model should be more important. When it comes to assessing the intricacies of the software development process, a white-box software defect prediction model is more attractive. As there is no one-solution-fits-all for software defect prediction, the analyst should consider various models (including APROP) and decide which one best suits their project's quality improvement goals.

Future work will include: additional case studies with other real-world software projects toward further validation of the benefits obtained by the APROP model; developing ways to further improve the architecture and performance of the APROP model; and, extending the APROP model for other software engineering prediction problems.

Evaluating the Accuracy of Call Graphs Extracted with the Eclipse CDT

Nicholas A. Kraft and Kevin S. Webb
Department of Computer Science
The University of Alabama
Tuscaloosa, AL 35487, USA
{nkraft,kwebb}@cs.ua.edu

Abstract

The Eclipse open source development platform has garnered significant attention in recent years, largely due to its extensible plug-in architecture. Many plug-ins that analyze program source code have been developed in academia and industry; the majority of these plug-ins have used the Java Development Tools (JDT) to analyze Java source code. However, Eclipse also provides the C/C++ Development Tooling (CDT), which has now reached version 4.0. If the CDT is to become as successful a basis for implementations of static analyses as the JDT, then the challenges of using the CDT to build such static analyses must be investigated. In this paper we present an evaluation of the accuracy of call graphs extracted with the CDT. We present a CDT-based subject system and a gcc-based oracle system, and we evaluate the subject system using the oracle system. Our evaluation gives special attention to features of C programs that often cause difficulty for lightweight parsers, such as the one provided by the CDT. These features include function pointers, macros, and conditional compilation. Our results identify areas where the CDT still needs improvement, but also demonstrate the feasibility of using the CDT as a basis for more advanced static analysis tools.

1. Introduction

Most modern integrated development environments (IDEs) use a *plug-in architecture*, that is, an architecture in which tool builders can augment the base functionality of the IDE by defining extension modules (or plug-ins). Eclipse [4], Microsoft Visual Studio [16], and NetBeans [19] are all examples of IDEs that use this architecture. Many researchers have exploited these IDEs, especially Eclipse, to implement new techniques, such as static analyses of program source code. Because these IDEs provide commonly required infrastructure components, including parsers and static representations of source code, researchers can focus their efforts on implementing their techniques. In addition, these IDEs allow researchers to more easily distribute their work to practitioners as well as to other academicians.

Eclipse is an open source development platform that has garnered significant attention in recent years — largely due to its extensible plug-in architecture. Dozens of publicly-available and commercial plug-ins are available for Eclipse, including nearly 40 for analyzing program source code.Perhaps the most well known feature of Eclipse is its Java IDE, the Java Development Tools (JDT); most, nearly all, Eclipse plug-ins that perform static program analyses are based on the JDT. However, Eclipse also provides a C/C++ IDE, the C/C++ Development Tooling (CDT) [5], which has recently become more robust and has now reached version 4.0.

The CDT provides two parsers (for C and C++, respectively), each of which is hand-written with recursive descent technology, performs neither type-checking nor semantic analysis, and constructs a static internal representation from program source code. The internal representation for each language models common language extensions, such as GNU and Microsoft extensions, through the use of special, dialect-specific nodes. The CDT also provides an indexer that attempts to resolve all bindings, although binding resolution is not based on language semantics and is not as accurate as type-checking or semantic analysis.

If the CDT is to become as successful a launching point for implementations of static analyses as its breatheren the JDT, then the challenges of building such static analyses using the CDT must be investigated. In this paper we leverage the CDT to extract call graphs from the source code of C programs and evaluate the accuracy of the extracted call graphs by comparing them to call graphs extracted with an oracle system. We selected the call graph for this accuracy evaluation because it is a fundamental static program analysis that is needed to perform more advanced analyses such as interprocedural data flow analysis. This evaluation will be useful to other researchers who wish to understand the

current capabilities and shortcomings of the CDT with regard to the implementation of static program analyses.

The rest of the paper is organized as follows. In Section 2 we provide background information about the program representations and the tools that we use to perform our evaluation. In Section 3 we provide an overview of the CDT–based system that we evaluate and the gcc-based system that we use as our oracle. In Section 4 we describe our accuracy evaluation and report our results. Finally, we discuss related work in Section 5 and conclude in Section 6.

2. Background

In this section we briefly describe the program representations and the tools that we use to perform our evaluation. The three program representations that we describe are *static program representations*, that is, they can be constructed from the program source code without using dynamic (run-time) information. The tools that we describe, along with the CDT, serve as the bases for the tools which we developed to perform our evaluation.

2.1. Static Program Representations

An *abstract syntax tree* (AST) is a pruned parse tree from which nonterminals, keywords, punctuation, and other nodes and edges that do not affect the semantics of the program have been omitted. The AST is constructed by most parsers in lieu of an unabridged parse tree and is the most pervasive static program representation. An *abstract semantic graph* (ASG) is an adorned AST to which nodes and edges that represent semantic information about the program, such as edges from variables to their declarations and edges from type uses to their definitions, have been added. The ASG is often the output of a compiler front end and contains a wealth of information — one can construct many other static program representations using only the information found in an ASG [11].

A *call graph* is a directed graph in which the nodes represent the functions in a program and the edges represent the potential calls to those functions. For example, given two functions f_0 and f_1, an edge (f_0, f_1) appears in the set of edges if there is a potential call to f_1 by f_0. The call graph for a program is a directed acyclic graph (DAG) if the program does not use recursion. A call graph extracted from program source code is called a *static call graph*, while a call graph extracted from a running program is called a *dynamic call graph*.

In strictly first-order procedural languages, call graph extraction is straightforward; at each call site the target of the call is directly evident from the source code. However, in C (and C++), function pointers complicate call graph extraction. Semantic information, such as type definitions and bindings, are required to determine the target of a call made through a function pointer. Furthermore, the lax syntactic rules of C can make calls made through function pointers difficult to distinguish from normal calls if certain conventions are not followed.

2.2. GENERIC

The C/C++ compiler from the GNU Compiler Collection, gcc, uses an ASG to facilitate recognition, analysis, and optimization of a program. Since version 3.0, gcc has provided, via a command line flag, a facility for writing the ASG for a translation unit to a text file. The schema for the ASG representation stored in these text files, known as TU files, is called GENERIC [15]. Several researchers have used instances of GENERIC to perform program analysis, comprehension, and visualization tasks [1, 9, 10, 14].

The g^{4}re tool chain [12] includes a library, generic, that provides parsing, storage, traversal, and serialization facilities for working with GENERIC ASG instances. The input to generic is a TU file, and the output is a gzipped XML encoding of the input file or an in-memory representation of the ASG. The TU file parser is implemented with a flex scanner. A simple node list data structure stores the in-memory representation, and several parameterized methods traverse the leftmost child right sibling (LCRS) tree that underlies the ASG.

3. Systems

In this section we describe the two systems that we created for our evaluation: the *subject system* and the *oracle system*. In Section 3.1, we describe the subject system, which uses the AST provided by the CDT to extract call graphs. In Section 3.2, we describe the oracle system, which uses the ASG provided by gcc and the generic library to extract call graphs. Both systems extract call graphs for C programs.

3.1. Subject System

Figure 1 illustrates our subject system, which is an Eclipse plug-in that takes as input a C program consisting of one or more C files and produces as output an XML file containing a call graph. The C files, shown in the upper left of the figure, are read by the CDT, which is shown in the lower left of the figure. For each C file, the CDT produces one AST; the CDT provides a Visitor [7] base class from which other plug-ins can inherit to traverse the in-memory representation of each provided AST instance.

The cgce plug-in, shown in the lower right of Figure 1, extends the CDT and other essential Eclipse components (some of which are elided from the figure for clarity). The

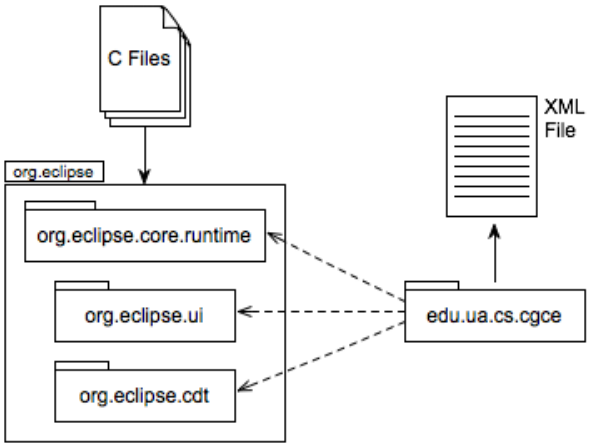

Figure 1. Overview of Subject System (cgce).
Dashed lines represent "use" dependencies. Solid lines represent data flow. Tabbed files are provided by the user. Lined files are generated by the system.

cgce plug-in extends the Visitor base class provided by the CDT to perform its AST traversals; during the traversals, cgce collects and stores information about functions and function calls. The CDT provides AST instances, not ASG instances, so cgce must manage a symbol table to resolve names; we built a partial symbol table to store information about scopes, functions, and function pointers. The symbol table that we manage allows cgce to detect calls to function pointers that the CDT call hierarchy cannot; in addition, the performance impact introduced by the symbol table is negligible.

After processing the information gathered during the visit to create a call graph, the cgce plug-in writes the call graph to an XML file, which is shown in the upper right of Figure 1. The XML file stores the call graph hierarchically by file and function; optionally, cgce can filter the call graph by either of these criteria before the XML file is written. In addition, cgce can filter the call graph based on the location of the callee function.

The cgce plug-in is full-featured and provides much more functionality than is described in the previous paragraphs. Using cgce, a user can, within Eclipse, explore the call graph in a hierarchical view or double-click the hierarchical view to jump to the definition of a function or to a function call. In addition, cgce can produce a dot [8] file that can be used to graphically view the call graph outside of Eclipse.

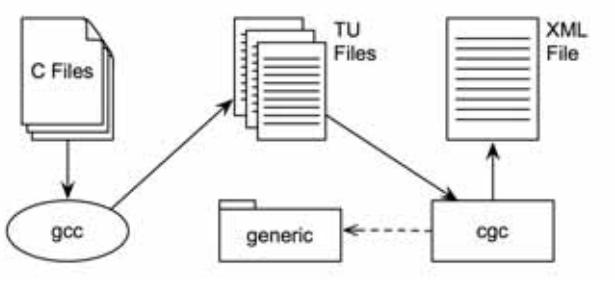

Figure 2. Overview of Oracle System (cgc).
Dashed lines represent "use" dependencies. Solid lines represent data flow. Tabbed files are provided by the user. Lined files are generated by the system.

3.2. Oracle System

Figure 2 illustrates our oracle system, which takes as input a C program consisting of one or more C files and produces as output an XML file containing a call graph. The C files, shown in the upper left of the figure, are read by gcc, which is shown in the lower left of the figure. For each C file, gcc produces one TU file; the resulting set of TU files, shown above center in the figure, is the input to the cgc program.

The cgc program, shown in the lower right of Figure 2, uses the generic library, which is shown below center in the figure, to read TU files. The Visitor pattern [7] is used by cgc to traverse the in-memory representation of each ASG instance that it obtains from the generic library. During the traversals, cgc collects and stores information about functions and function calls. After processing this information to create a call graph, cgc writes the call graph to an XML file, which is shown in the upper right of Figure 2. The XML file format produced by cgc is the same as that produced by the subject system; the filtering capabilities of cgc are also the same as those provided by the subject system.

4. Accuracy Evaluation

In this section we describe our accuracy evaluation of call graphs extracted with the CDT. In Section 4.1 we describe our technique, including the scope of our accuracy evaluation and the rationale for our oracle system. In Section 4.2 we describe our experimental setup. Finally, in Section 4.3 we list the results of our experiments.

4.1. Technique

Researchers have given much attention to extracting accurate and precise call graphs for the C language [3, 17].

Were it not for function pointers, call graph extraction for the C language would be straightforward; thus, this attention has focused on function pointers. However, before techniques for extracting call graphs in the presence of function pointers can be applied, accurate information about functions, function pointers, and function calls (including those through function pointers) must be obtained. In this evaluation, we focus on determining whether this (accurate) information can be obtained using the CDT.

In this evaluation, our oracle system, cgc, is gcc-based; in particular, cgc extracts call graphs for C programs using the ASG provided by gcc. Our rationale for designating cgc as the oracle system is based on an argument similar to the one used by Murphy, et al. [18]. The argument is as follows: during compilation, gcc builds an ASG and uses that ASG to generate executable code; if the generated executable code is correct then the ASG from which it was generated must be correct. Given that gcc is an industrial-strength compiler and that it is used to compile a myriad of widely-used programs, we can assume, with some confidence, that the executable code generated by gcc is correct, and, therefore, that the ASG used by gcc to generate that executable code is also correct. Because cgc simply gathers information from the ASG provided by gcc, we can reasonably designate it as our oracle system.

In addition to using our oracle system to evaluate the accuracy of our subject system, we used the call hierarchy view included with the CDT to validate our subject system. There are limitations to the functionality of the call hierarchy view. For example, it does not build a call graph for the entire program, but rather for one function at a time. To ensure that we were correctly extracting all available information from the CDT, we used the call hierarchy view as a reference during development of our subject system. However, please note that, as described in Section 3.1, our subject system manages a partial symbol table. Thus, our subject system is able to extract more information about calls to function pointers than the call hierarchy view.

4.2. Experimental Setup

We performed all experiments on a Dell™ OptiPlex™ 755 workstation on which we installed the Slackware 12.0 operating system. We created all TU files with gcc version 3.3.6. We used Eclipse version 3.3 and Java version 1.6.0_01 to develop and to execute our Eclipse plug-in. We wrote an XSLT stylesheet to extract results from the XML output files; we applied the stylesheet with Saxon-B version 8.9. Finally, we formatted and compared the resulting data using a series of simple bash scripts.

We use the Apache HTTP Server [2], version 2.2.6, as the test case for our evaluation. We chose Apache because it is mature, open-source, widely-used, and makes extensive use of function pointers, which are a key element of our evaluation. In addition Apache makes extensive use of macros and conditional compilation, both of which are often difficult for lightweight parsers, such as those included in IDEs, to handle properly.

	System	Subject	Oracle
User Functions	Defined	2,497	2,497
	Undefined	21	21
	Subtotal	2,518	2,518
Library Functions	Subtotal	671	666
Functions	Total	3,189	3,184

Table 1. Function Declaration Information. *The number of user functions and the number of library functions reported by each system. A function is a user function if it is declared in one of the source files for the test case and a library function if not.*

The Apache source tree contains multiple support libraries, but we selected only files from the `modules`, `server`, and `os` directories. Moreover, we only selected Unix-specific files from the `modules` and `os` directories and only selected files specific to the `prefork` version of the `mpm` module. Finally, we did not select any test modules from the `modules` directory. When generating the TU files for the oracle system, we configured Apache to include all available features.The test case resulting from our selections and configuration consists of 212 files, including 61 header (`.h`) files and 151 source (`.c`) files. The total size for the test case is approximately 89K lines of non-commented, non-preprocessed lines of source code (NCLOC).

As discussed in Section 3.2, the XML file format produced by the oracle system is the same as that produced by the subject system; furthermore, the filtering capabilities of both systems are also the same. Before performing our experiments we configured each system to remove from its extracted call graph all functions declared outside of the 212 files that comprise our test case, including all function calls found within those functions. Note that we did not remove calls to functions declared outside of the 212 files in the test case as long as the function in which the calls were made was not removed.

4.3. Results

Table 1 lists data about function declarations reported by the subject system and the oracle system. A function declaration is categorized as a user function if it is declared in one of the 212 source files for our test case; otherwise, it is categorized as a library function. Furthermore, a user function is categorized as defined if a corresponding function body was found or as undefined if no corresponding func-

Calls to Function Pointers	Subtotal	515	525
Calls	Total	16,241	16,218

Table 2. Function Call Information. *The number of calls to functions and the number of calls to function pointers reported by each system. A call to a function is categorized as user or library depending on whether it was a call to a user function or a library function.*

tion body was found.

The data in Table 1 indicates that the CDT-based subject system is in near total agreement with the gcc-based oracle system with respect to the nodes in the call graph. The only discrepancy is in the number of reported library functions; this discrepancy is a result of the way that the subject system detects library functions. The subject system reports information about a library function only when that function is the target of a reported function call. Thus, the discrepancy in the data from Table 1 is an artifact of a misreported function call(s); a more detailed explanation follows.

Table 2 lists data about function calls reported by the subject system and the oracle system. A function call is categorized as a call to a function if the target of the call is a user or library function; otherwise it is categorized as a call to a function pointer. Furthermore, a call to a function is categorized as user if the target of the call is a user function or as library if the target is a library function.

The data in Table 2 indicates that there are function calls which the subject system does not properly recognize. In particular, the subject system reports 33 extra calls to library functions and 10 too few calls to function pointers. Upon further investigation, we discovered that some of these differences were not the fault of the subject system, but rather of the oracle system. These differences all resulted from inlining; in total, 24 calls to `strlen` with a literal string parameter were inlined by gcc. However, we also discovered flaws in the CDT centered around function pointers.

Next we discuss a C construct that is problematic for the CDT and, hence, our subject system. On line 990 of the file `server/vhost.c`, a parameter `func_cb`, to the function `ap_vhost_iterate_given_conn` has type `ap_vhost_iterate_conn_cb`, which is an alias type (`typedef`) for a function pointer. A call to `func_cb` on line 1024 is not recognized by the CDT as a function call; however, our subject system does correctly determine that there is a function call on line 1024. Unfortunately, due to the limited information in the partial symbol table, our subject system does not correctly report the call as a call to a function pointer, but rather reports the call as a call to a library function. Calls to function pointers that are passed as parameters account for six (6) of the extra calls to library functions listed in Table 2. In addition, such calls account for the five (5) extra library functions listed in Table 1.

We have accounted for 30 of the 33 extra calls and 6 of the 10 too few calls to function pointers reported by our subject system. The remaining three extra calls are caused by problems the CDT has dealing with a combination of function pointers and macros, namely with a macro expansion that defines a function pointer variable and a later call through that variable. Curiously, this problem only appeared three times, and was properly handled in other cases. Nevertheless, this combination of a macro and function pointer accounts for the three remaining extra calls to library functions and three of the four remaining too few calls to function pointers reported by our subject system. As in the previous paragraph, while our subject system misidentified these calls as calls to library functions, the CDT did not recognize the function call at all.

Finally, on line 106 of the file `server/util_pcre.c`, there is a call of the form `(pcre_free)(preg->re_pcre)`. The CDT does not recognize the function call, and the partial symbol table managed by our subject system lacks the information necessary to identify the call. This is due to the function pointer `pcre_free` being defined in a library header file, which our subject system ignores. We have now accounted for all of the differences listed in Table 2.

5. Related Work

In this section we briefly review literature that relates to our work. There are two primary categories of research about call graphs: (1) extraction and (2) evaluation. We briefly review this research, and we then review tools that use the CDT to extract call graphs.

Milanova, et al. [17] apply the FA pointer analysis by Zhang et al. [21] to the extraction of call graphs for C programs with function pointers. They compare a call graph extracted using this analysis to the most precise call graph that can be extracted with existing pointer analyses. They conclude that the FA analysis can provide precision comparable to that of more expensive pointer analyses. Atkinson [3] describes a technique to improve the precision of extracted call graphs for C program with function pointers. The technique is parameterized by a pointer analysis and is safe (it does not degrade the accuracy of the extracted call graph). The supplied pointer analysis is augmented by function type information, and potential calls through function pointers are filtered based on the results of the (improved) pointer analysis. The focus of both of these techniques is on improving the precision of extracted call graphs, not on extracting the accurate information needed to implement these

techniques.

Murphy, et al. [18] describe the most comprehensive study of static call graph extractors to date. They empirically compare call graphs extracted from three software systems written in C by nine call graph extractors and present both quantitative and qualitative findings. In addition, they define a design space for static call graph extractors. Their argument for their oracle system is similar to our argument for our oracle system; however, their oracle system is not based directly on a compiler. Instead, their oracle system is based on a source-to-source translation tool that is based upon an obsolete version of gcc.

Lhoták [13] contributes a call graph difference search tool. The tool ranks edges in the call graph by their likelihood of causing significant differences among call graphs. In addition, the author describes a complimentary viewer that highlights certain differences among call graphs. Furthermore, the author presents the ranking algorithm implemented by the first tool and describes the results of a case study. The focus of the case study is determining imprecision in a static call graph by comparing it to a dynamic call graph for the same program; the subject language for the case study is Java.

We are aware of two other tools based on the CDT that extract call graphs for C programs. The first of these tools is the CDT itself. The most recent version of the CDT, version 4.0, includes the call hierarchy view, which shows the user the callers of a function. However, the call hierarchy view operates on only one function at a time – it does not build a call graph for the entire program. The second tool is the Eclipse Parallel Tools Platform (PTP) [6]. Recoskie and Tibbitts [20] reported on the static analysis capabilities of PTP, including a call graph extractor. However, they did not report on the accuracy of the call graphs that they extract.

6. Conclusions and Future Work

In this paper we presented an accuracy evaluation of call graphs extracted with the Eclipse CDT. We built a subject system and an oracle system, and we evaluated the subject system using the oracle system. In our evaluation, we used the Apache HTTP Server as our test case, because it is open-source, is mature, is widely-used, and makes extensive use of function pointers, macros, and conditional compilation. Our evaluation can be viewed as a (partial) accuracy evaluation of the AST produced by the CDT, and therefore, as a (partial) accuracy evaluation of the C parser from the CDT. The results of our evaluation show that the parser is extremely robust, even in the presence of heavy use of function pointers and the preprocessor.

We plan to use the CDT to build a more comprehensive source code analysis tool for the C language. We envision a general purpose tool that will complement the existing features of the CDT, as well as the Eclipse Parallel Tools Platform (PTP). Our goal is to facilitate comprehension and maintenance tasks of large software systems written in C, including the Linux kernel and the GNU Compiler Collection.

Abstract

This paper introduces a case study that was carried out in a small Finnish software development organization. The aim of the study was to evaluate possibilities for establishing tool support for tracking software developers' working time. The organization wants to improve their project management and effort estimation processes and they need a lightweight, tool-based approach for collecting and reporting the working time data. We propose a categorization for different types of time tracking tools and perform an evaluation of tools from different categories. Requirements for the tools and evaluation criteria are derived both from literature and the case company. DESMET method is utilized to rank the tools.

1. Introduction

Software measurement aims at providing quantitative information about development processes in order to estimate effort, time and costs that are required to produce a software product. The measurement process itself includes a wide variety of activities and specific metrics. Resource estimation is one of the first key elements to implement when establishing a predictable software development process.

Estimates are typically based on historical data, and recording, storing and analyzing process data is a challenging task. Ensuring the accuracy of the data is even more difficult, because different people can report the same data differently. Software development is human-centric, creative work, and measuring such phenomenon always requires some assumptions to be made. However, measurement is a necessity if an organization wants to systematically manage and improve their development processes.

Software tools can make the resource estimation task easier by automating calculations and providing means for collecting and storing the data [8]. This paper gives an overview to time tracking tools that are available for software developers. Furthermore, we introduce a classification of time tracking tools and present an evaluation of selected tools with the DESMET method. The tool evaluation is a part of a case study investigating deployment of software measurement tools within a small software development organization.

The rest of the paper is organized as follows. Chapter two introduces the research that have been done in the area of time tracking tools. Chapter three describes the research setting of this study.

2. Related work

Version control systems and bug tracking databases have been identified useful tools for getting information of software development projects in order to make effort estimations. [1, 13] Reliable effort estimation is crucial for estimating cost and schedule of a project, and helps in risk assessment. For cost estimation, several expert-based techniques [11] and algorithmic models, such as COCOMO [2] have been introduced. Effort estimation models can also have indirect benefits in predicting the number of defects in software and helps in making decision when to stop testing, for example [14]. Algorithmic estimation models are usually addressed to large projects. More lightweight methods exist for making estimates in small or individual-based projects. Such methods are the Personal Software Process (PSP) [5] or LEAP toolkit [6], for example.

Several studies suggest that establishing a software measurement successfully requires an adequate tool support. Tools for automatic data collection and use of persistent measures database are often listed among

the essential success factors of a measurement framework. Examples of the articles and studies highlighting the importance of correct tools for measurement include [4, 17], for example.

Especially the PSP approach has given inspiration to many time tracking tools, including Process Dashboard (http:// processdash.sourceforge.net/), PROM [19], Hackystat [9] and Jasmine [18]. In PSP, measurement and analysis of historical development data is in key role in making estimates of effort and product quality.

There is a wide variety of time tracking and effort estimation tools. Even a spreadsheet application can provide the basic set of templates and reports. In the other end are sensor-based tools that can collect data automatically and provide an extensive selection of analysis reports based on the data. It may also be useful to integrate process guidance and experience base into the measurement tool [18].

Johnson et al. [6] introduce three generations of tool support for gathering metrics on individual software developers' work. The first generation is manual data collection, developers logging their effort, size and defect information in printed templates and forms. The second generation includes more automated tools such as Process Dashboard, where users can record data through a relatively convenient user interface and the tool provides different types of analyses on the data. The third generation means fully automated measurement, in which developers do not have to worry about data logging or analysis.

Tools can also have some disadvantages, such as context switching. The need to continuously change between product development and process recording software may cause inaccuracies in the data and decrease the motivation to use the tools. Fully automated data collection tools eliminate the need for context switching. However, fully automated tools cannot necessarily recognize breaks in developer's work correctly, and it may be needed to correct automatically recorded data later on. Concerns on privacy is another challenge with automation. [8]

3. Research setting

The case organization is a small division of a large multinational company developing embedded systems. The division that participated in the study is a software development unit of about 20 software designers.

A study project for investigating time tracking systems was established because the organization wants to forecast the durations of their future projects. The products of the company are getting more software intensive and more attention has to be paid to the software development processes than before.

The purpose of the study was to investigate commercial and freeware solutions available for tracking the work time of software developers. Currently the organization utilizes simple time card system for that purpose. It is connected to the access control so that on arrival an employee clocks in for a specific project number and the system marks the working hours for that project. This system, and the information it provides, is not adequate for the company's needs in future. The current system stores only information about the projects the employees are currently working on and how many hours they have spent on each project. Even though the current system keeps record of the working time on the project-basis, the information is not detailed enough to really help in planning future projects and estimating project schedules and costs. The current system does not support reporting on what specific tasks of the project designers are doing. Such information would be necessary in order to monitor the development effort and identifying possible problems in the development process. For example, distinguishing design, implementation and testing efforts from each other is essential for evaluating the quality of both product and process.

The case organization wishes to establish a historical development database with the new time tracking system. Based on the historical data, schedule and effort estimates could be made more accurately than at the present. Furthermore, the estimation can be targeted more precisely regarding the phases of the development and individual tasks within a project.

For the purposes of this study the reference framework used in the tool comparison is DESMET [12]. It is a two-part methodology for comparatory evaluation of tools and methods in a given context for a specific purpose. The first part of the DESMET method includes the selection of an appropriate evaluation method, and the second part the actual methods and their descriptions. From the quantitative, qualitative and hybrid evaluation methods available we chose the qualitative feature analysis, which was most feasible given the research setting.

Although the actual tool tests weren't designed and conducted as a part of a process utilizing the DESMET method in the first place, it is used here to structure the empirical findings. On the other hand, the feature analysis selected as the evaluation method is usually conducted based on the literature and documentation available for the evaluation object. Therefore this

study, while using the test reports from the case company tool evaluation tests, can be seen as fulfilling the signs of a DESMET feature analysis.

It should be noted that the DESMET is designed for the industry, to aid in selecting the best suited tool or method for that context from the given set of candidates. In this case the context is an industrial case which is also a source for a part of the tool requirements, so the use of the DESMET method is justifiable also in this academic study.

4. Features used in evaluation

From the nine basic processes included in a feature analysis, the tool selection and its results are described in more detail in the next section. This chapter discusses the selection of required features for the tools to be evaluated, their prioritization and their scoring system. The level of rigour required cannot be affected in this study, since the only available source of information for the evaluator is the written test documentation. Responsibility of carrying out the evaluation is rather trivial in this case, and the analysis of the evaluation results is presented in the results and discussion section.

As feature analysis supports feature groups, hierarchies and refinements, this study uses it to classify the requirements on the main level to two different groups: those identified by the case company and those identified by the test team with the aid of some scientific literature. [e.g. 3, 7, 8, 9, 16] Summary of the requirements – which have been considered as features that are studied from each tool in this study –

Table 1. Case-company originated features for a tool to be evaluated in feature analysis.

Classification	Description	Priority
Data mgmt.	Access to database is controlled	1
Data mgmt.	Database stores relevant modifiable raw variables	1
Data mgmt.	All data stored in a web/intranet-server database	1
Functional	Free choosing of project and phase worked on	1
Functional	Worktime input must be possible also “after-the-fact”	1
Functional	At least worktime calculations must be automated	1
Functional	Tool must support customisable projects and phases in them	1
Functional	Tool must support recording and reporting times/phase, times/project, times/user	1
Functional	Time granularity must be represented accurately (hours and minutes)	1
Functional	Support for multiple simultanious users	1
Functional	Privacy of personal data among developers	2
Functional	Both estimated and actual times are supported and they can be compared	2
Interface	Time tracking must be done by pushing start/pause/stop -button(s)	1
Interface	Support for existing operating systems	1
Interface	Support for multiple common file formats (XML, HTML, txt)	1
Interface	Compatibility with existing systems	2
Reporting	Reports are accurate, stable and reliable	1
Reporting	Data collected: project, phase, people, start time/phase, end time/phase, total times	1
Reporting	Reports based on historical data	1

Table 2. Literature-based features for a tool to be evaluated in feature analysis.

Classification	Description	Priority
Functional	Data is modifiable and importable/exportable	1
Functional	System informs the user about status and events	2
Functional	System should support mistake-free data collecting	2
Interface	System should be customizable for expected types of changes	2
Usability	System should not allow the user to forget the use of the system	1
Usability	Tool usage must be as unobtrusive as possible (few minutes / day)	1
Usability	High overall usability, especially on the features used most often.	1
Usability	minimum need of investments and involvment from management	2
Nielsen	System should speak the user's language	1
Nielsen	Consistent use of terms and concepts.	1
Nielsen	Minimize the amount of things the user needs to remember	1
Nielsen	Flexibility for tailoring, efficiency for both beginners and experts	1
Nielsen	preventive error -approach	1
Nielsen	provide help and documentation	1
Nielsen	Provide easy exits	2
Nielsen	Informative error messages	2
Nielsen	Minimalistic design	2
Nielsen	give feedback to user	2

are presented in Table 1 and Table 2. Each feature is also attached with a scoring scheme, against which each evaluated tool is ranked. For this study, a simple yes/no scoring scale is adopted, indicating just the presence of a feature in the tool without analysing the level of the implementation of the feature. Priorities (indicated with 1 and 2 in Tables 1 and 2. Priority 1 is of higher priority) for each feature were devised along the requirements by the case company.

Both main categories of features are further divided into feature classes. These classes indicate if the feature in question is mainly related to the domain area –functionality of the system, how the data is managed by the system, what kind of interfaces the system has to other systems as well as the user, how the system handles reporting of its data to different users, and what kind of usability the system has. Generic usability heuristics are incorporated into these features in the form of Nielsen's heuristics [15, 16].

5. Tool evaluation

For any evaluation framework to produce usable results, an object of analysis is required. In this case the DESMET method being comparative, a selection of different tools is used. Based on initial set of requirements (simple, multi-user tool for Windows platform that has a free trial version available), some tools were searched, found and selected to be evaluated. By all means all possible project management and time tracking systems were not tested, from initial searches ten tools were selected for further testing.

For this study, a representative sample of those ten tools was attempted to find. This was done by categorizing the tools according to their method of gathering data, as per classification devised by the testing [8, 10]. The categories for the tools were based on the way the systems gather their data, the so-called level of time tracking: manual, system-based, recording-based or fully automatic tracking.

Manual tracking consists of methods that involve the user writing times manually into some form of log, like a timesheet, and then delivering those timesheets to her supervisors. It has the advantage of being a very flexible method, but also error-prone and time-consuming way of tracking data.

System-based tracking is partly automated way of data gathering, where each user submits her timesheet to a system that allows supervisors to generate reports from user data. It has the benefit of being more real-time than completely manual method and fairly cheap as well as easy way, but suffers from potential compatibility problems with existing systems and its reliability is in the end down to the user and how accurately she fills her timesheets.

Recording-based tracking can also be described as start-pause-stop -tracking, due to the fact that systems that incorporate this method usually do so by providing user with a user interface to start, pause and stop the tracking with a single press of a button. From the state of the tracker timesheets are automatically filled, and reports generated as in system-based tracking. Advantage of this method is that it provides somewhat more reliable user data than system-based trackers, since the filling of the timesheet is done more simply and promptly when relevant – there's no need for user to remember exact times when the system does it automatically. As with any method, this also has some drawbacks: Since it may distract the user from other, more thought-intensive tasks at the time, the motivation to use the system may not be high, thus causing inaccuracies in collected data. Also the monitoring of the time spent working away from the computer is difficult, and usually must be done in a way very similar to the system-based tracking method.

Completely automated tracking systems usually function by attaching sensors or similar hooks to different software tools that are used by the developers as part of their development work. From the usage statistic acquired via those sensors time and possibly also other metrics can be calculated. On the obvious positive side this way of collecting data is completely unobtrusive and therefore suffers no inaccuracies due to use of the tracking tool itself, but is more inaccurate in its way of gathering off-computer working time. In addition, the problem of resolving the quality of actual work done (if any) while the sensors register activity in tool usage remains problematic.

From the above categories, the following tools were selected for this evaluation as being the most representative of its class: For system-based trackers and as sort of a "de-facto baseline" MS Project is evaluated. For SPS-systems the Process/Team Dashboard is used for evaluation, and Dovico Timesheet is included as a system combining the system- and SPS-approaches. Automatic systems weren't tested with the case company, and thus are evaluated here based solely on academic and possibly other literature, are represented by the University of Hawaii's Hackystat. For completely manual way of tracking data no tool is selected – since it doesn't necessarily use any.

Table 3. Total features passed for each tool grouped by feature category.

	MS Project	Dashboard	Dovico	Hackystat	Max. available
Functional	8	12	12	9	12
Nielsen	6	8	9	8	10
Interface	2	5	5	4	5
Usability	1	3	3	4	4
Database	0	0	3	2	3
Reporting	2	3	3	2	3

6. Results and discussion

The last phases of the feature analysis consist of analyzing the results and presenting them to interested parties. In this case the presentation is done via this paper, and the analysis we will provide here. All of the five tools in this evaluation were assigned a true/false value for each of the features identified to be relevant. There were no predefined acceptance threshold of values, but it was understood that the tool that had the most desired features supported was the one that thecase organization would consider to be selected. The results are portrayed in table 3. Each row in the table represents one class of features that were analyzed. On the columns for those rows are the numbers of features that were present in each tool, columns therefore representing the tools in the evaluation. One of the columns is labeled as "Max. available", which represents the maximum number of features that were analyzed in each category. Compared to these maximum values we can see that none of the tools fulfils the requirements completely. Biggest deviations from the maximum values are in the database and usability feature categories. These are the topics that the tool developers should pay attention to in order to make their products more appealing to the industrial users. On the other hand all tools scored well in the functional and reporting feature categories.

When comparing the individual tools, it is evident that MS Project that is probably the most widely-used project management tool does not compare well to the maximum values. Full automation as provided by the Hackystat tool has also some shortcomings. These problems stem from the fact that you cannot automate all aspects of time tracking. The main issue with the Hackystat tool concerns data collection capabilities. It is not easily possible to track time while user is doing work away from the computer. The Dovico Timesheet and Project Dashboard are quite similar, which is not too surprising since they represent the same SPS-tool category in this evaluation. Main differences between these two are in the database support they provide and in usability characteristics. Although usability is rather subjective measure, the support for relational databases is surely something that industrial users desire.

It seems that a well-implemented SPS-type of tool is better than current fully automated systems for time tracking, but if full automation could be implemented with more comprehensive time tracking support it would be the best solution. This, as well as better SPS-tool implementations are something that should be investigated in further studies. In this study the case organization decided to evaluate and pilot the Dovico Timesheet tool more closely. The choice was made between the Dashboard and Dovico Timesheet, but the usability of the latter was perceived to be better.

This kind of evaluation benefits the case organization, because it focuses attention to the process of effort estimation and time management, and thus improves both of them via the "Hawthorne-effect". A well-argumented tool selection fixes these processes as well to some extent, but isn't enough by itself.

Finally, the DESMET method works well for this kind of evaluation, but if more than one person is involved in defining the features and scoring them, it is very likely that issues of subjectivity and difficulties in communication arise. Especially the interpretation of the meanings behind feature descriptions has to be communicated carefully. If the communication difficulties can be overcome an evaluation using the DESMET method is very well suited for collaboration and knowledge exchange between academia.

7. Conclusion

This study draws together requirements for time tracking tools from a case company and relevant academic literature. We found that a systematic approach for evaluating the tools based on these

requirements is beneficial even though an ideal tool would not exist. Requirements definition, evaluating the tools and reflecting the entire process of effort estimation and time management helps the organization to identify potential process improvement areas.

We suggested a classification for time tracking tools, partially based on literature and partially on empirical observations during this study. Based on the experiences gained from this case, instead of manual or system-based approaches to time tracking, we suggest either a well-implemented fully automated tracking tool or a more comprehensive support via a SPS-tool to be explored when selecting a time tracking tool.

The tool support for time tracking is an actively studied area, but there remains a number of issues that need further investigation. Before a fully automated tool that covers all phases of data collection is developed, the time tracking data is as accurate as the people that track it.

Abstract

Resource modeling is an important aspect of real-time systems. However, resource modeling and resource constraints are found to be lacking from majority of real-time specification language. RealSpec real-time specification language is proposed with language constructs for defining and manipulating both abstract data structuring and hardware system resources. The paper provides details of abstract data resources along with examples. The well known dining philosophers' problem is specified to demonstrate language resource modeling features.

1. Introduction

Resource modeling and constraints are an important aspect of real-time systems [1]. The timing behavior of a real-time system depends not only on delays due to process synchronization, but also on the availability of shared resources [2]. As with timing constraints, specifying physical resources and constraints on those resources required by a computation has a key role in determining the performance, quality, and correctness of computation in real-time systems. Even though Lee et al. pointed out the lack of resource modeling consideration in the context of process algebra formalism [2], the issue seems to be equally prevalent for most real-time specification techniques. The lack of resource modeling was also highlighted by a comparison of real-time specification techniques [3]. A real-time specification should provide a highly integrated and time-constrained resource modeling approach along with interaction protocols in a platform independent way [4, 5]. In addition, the specification should provide the primitives to control and to keep track of resource utilization.

This paper presents process and resource modeling concepts and constructs in RealSpec, a real-time specification language based on the functional dataflow language Lucid [6]. In doing so, the language semantics of Lucid are extended to include complex data types with functions, a concept necessary for defining resource objects. The selection of Lucid was made to satisfy language design goals of functional computation model, declarative nature, and freedom from implementation bias. Moreover, Lucid supports high parallelism by design with every equation within a program representing parallel executing data flow nets. The remainder of the paper is organized in the following sections. Section 2 provides a synopsis of the Lucid dataflow programming language. Section 3 briefly discusses the semantic extensions to Lucid to add user defined algebras and objects. Section 4 introduces RealSpec specification language. Section 5 presents resource modeling concepts in RealSpec. Section 6 applies process and resource concepts to the specification of the dining philosophers' problem. Section 7 summarizes the paper.

2. Lucid Dataflow Programming Language

Lucid [6] is a functional dataflow programming language based on Landin's Iswim language [7]. The statements in a Lucid program are equations defining streams and filters, not commands for updating storage locations as in the case of traditional imperative programming languages. Hence, Lucid is a definitional language. The equations in a Lucid program are assertions or axioms from which other assertions can be derived using the Lucid axioms and rules of inference [8]. Hence, Lucid provides a formal system where proofs of programs can be carried out [8]. The Lucid programmer states exactly the output of a program, but only suggests or indicates the

computations to be performed. The variables in Lucid are regarded as dynamic objects and their values are simultaneously updated at each computation step. The following is a simple Lucid program example:

```
a + b
   where
      a = 2;
      b = 5;
   end;
```

In the above program the **where** clause is an expression together with a set of definitions of variables used in the expression.

Lucid allows functions to be defined by equations where the equations within the **where** clause can use other functions or variables defined in the clause. The expression defining a function can also use the same function so that recursive definitions are also possible:

```
fac(p)
   where
      fac(n) = if n < 2 then 1
            else n * fac(n-1) fi;
   end;
```

There is no requirement that a variable or function be defined before it is used. In general, the order of the definitions in a clause is irrelevant.

The simplest conditional expression in Lucid is the primitive if-then-else. For example, the following program takes two input streams x and y and outputs a stream consisting of the maximum at each index value:

```
max(x, y) = if x <= y then y else x fi;
```

If x and y have values <5, 2, 10, 21, 7,…> and <3, 9, 9, 13, 15,…>, respectively, then the output stream would be <5, 9, 10, 21, 15,…>.

Lucid provides a binary operator **fby** (followed by) for abstract iteration over sequences. The two arguments of this binary filter are combined by taking the first component of the first argument and appending to it the stream corresponding to the second argument. For example, if x and y are two streams <x_0, x_1, x_2, …> and <y_0, y_1, y_2, …>, respectively, then x **fby** y would be the stream <x_0, y_0, y_1, y_2, …>. For example,

```
x
   where
      x = 1 fby x+1;
   end;
```

This program defines x (the output) to be the stream <1, 2, 3, 4, 5,…>, an infinitely varying sequence. The first argument of **fby** primes the pump that permits successive future values to be generated.

The binary operator **asa** (as soon as) computes by repeatedly reading in pairs of values of its two arguments until, if ever, the second argument has the value *true*. Assuming a *true* is eventually read then the value taken by the **asa** operator will be the value of the first argument corresponding to the *true* value of the second argument. For example, if x = <0, 1, 2, 3,…> and y = <false, true, false, true,…>, then

```
x asa y = <1, 1, 1,…>
```

The next section provides extensions to Lucid semantics for resource modeling.

3. User Defined Algebras and Objects in Lucid

Lucid is based on a few fixed algebras such as integers, reals, Booleans, and strings. However, in order to be able to represent resources, Lucid needs to be enhanced to include user defined algebras for representing complex data types. Based on the Iswim family of languages [7], data objects may have operator nets or filters in addition to a set of variables. A Lucid program then would be an operator net for this "data with operator net". Each instance of input and output would be some form of this data with a specific internal state based on the values of its member data types and the internal operator nets. Thus, the instance variables of a data object must themselves be full-fledged Lucid streams resulting in streams of data objects which contain a stream of data objects that are followed by potentially an n number of streams [9]. This concept is demonstrated below for a data object d with an internal instance variable x, where t′ is the time index for d stream and d_i represent object d with an updated state based on its internal instance variable and manipulation functions. For each d_i, the internal instance variable x goes through a sequence of values indexed by t″:

	t′=0	t′=1	t′=2 …
	d_0	d_1	d_2 →
t″=0	a_0 ↓	b_0 ↓	c_0 ↓
t″=1	a_1	b_1	c_1
t″=2	a_2	b_2	c_2
…			

Lucid is based on the unconventional idea that computations do not terminate. The input to a Lucid program which runs indefinitely is the infinite history of the values 'fed into' it, and the output is the infinite history of all the values produced [6]. Lucid, however, allows writing programs whose actual output is finite. To terminate a Lucid program, a special symbol **eod** (end-of-data) is output that closes the output stream and

terminates the program normally. For example, the program

```
3 fby 5 fby eod
```

will put 3 and 5 on the standard output and then terminate. The semantics of the member functions of data objects with internal streams is defined using the terminated streams. Each call to a local function will result in the data object function to be evaluated based on the local **where** clauses followed by an implicit **eod**. RealSpec uses the terminated stream semantics for data object member function calls.

4. RealSpec: An Executable Specification Language Based on Lucid

The following section introduces basic concepts of the RealSpec executable specification language.

4.1. Active and Passive Objects

Two types of objects are modeled in RealSpec: active and passive. Active objects are those which instigate an action and are responsible for handling control to other objects. Active objects can change their own states and may utilize services of other passive objects. Active objects have their own execution threads. Passive objects are those which do not have their own execution thread instead these passively wait for other objects to require their services. Passive objects are usually activated on receiving messages from other objects. RealSpec uses active objects to model system processes and passive objects to model system resources.

4.2. System Definition

A system construct is used to model a system in RealSpec. The system construct provides a context for the rest of the specification and consists of the declaration of system resources, statically defined processes, process and thread creation order, and global system level functions. A system definition in RealSpec is specified using a system construct:

```
system s {
   resources { … }
   processes { … }
   functions { … }
}
```

4.3. Process and Thread Objects

A process object is defined using a process construct. A process construct consists of the keyword **process** with process name followed by process body within curly brackets. The body of a process definition may consist of declaration for primitive data variables, other active or passive objects, and a set of process functions. The functions in a process are Lucid-like declarative assertions. For example, a process `factorial` that contains a single function calc`fac(int n)` to calculate factorial can be defined as follows:

```
process factorial() {
   calcfac(int n)
      where {
         fac(int x) = if x < 2 then 1
            else x * fac(x-1);
      }
}
```

A process has a single execution thread by default. However, a process may have as many threads as possible. Multiple threads can be defined as part of a process definition. In the example below, `x` gets the value of `x+1` if the executing thread is `th1`, indicated by the property `pid`, otherwise `x` gets the value of `x*2`:

```
process p() threads th1, th2 {
   … x = 1 fby if pid == 0 then x+1
       else x*2; …
}
```

The processes can also communicate with each other via message passing using a pair of send and receive thread functions. The message communications can either be synchronous or asynchronous. In the following example of synchronous message passing with timeouts, `p1` blocks for 50 microseconds and `p2` blocks for 75 microseconds:

```
process p1() {
   … p2.send(data) @tout 50 us; …
}

process p2() {
   … x = p1.receive() @tout 75 us; …
}
```

5. Resource Modeling in RealSpec

RealSpec supports modeling of system resources. These resources consist of abstract data structure such as semaphore, mutex, array, stack, and queue, and hardware resources such as signal, analog IO, memory, communication channel, and timer. The hardware resources are the representation of various system and hardware elements along with mechanisms for manipulation of these resources by the specification processes and functions. This paper focuses on the abstract data resources.

Users can define new resources using a resource construct. A resource construct consists of the keyword **resource** with resource name followed by resource body within curly brackets. The body of

resource consists of resource variable definitions and resource functions. The variables and functions may appear in any order.

```
resource <name>(<parameters>) {
   <resource variables>
   <resource functions>
}
```

Once defined, resources must be instantiated before these can be used. The instantiation may be at the system level, process level, or within other resources.

Semaphore and Mutex Resource: Semaphore resource is defined for process and thread synchronization. The resource is used to protect shared resources and critical regions. The semaphore resource is defined with two functions **`wait`** and **`signal`**, a private integer counter, and a private queue of threads. The parameter `value` is passed in by users as the initial counter value at declaration. The optional parameter `pol` may be used by users to define sleeping thread wakeup scheme. RealSpec supports two wakeup schemes, first-come-first-serve and priority based, defined as constants. The resource is defined using following schema:

```
semaphore(int value, int pol =
   FCFS_BASED) {
   int counter = value;
   int policy = pol;
   list pidqueue = [];
   bool wait(generic p);
   bool signal();
}
```

Consider an example where there are two rows of ballroom dancers, leaders and followers, waiting in two queues, A and B, before entering the dance floor. When a leader arrives, it checks to see if there is a follower waiting. If so, they can both proceed. Otherwise, the leader waits. Similarly, when a follower arrives, it checks for a leader and either proceeds or waits. This problem can be represented in RealSpec by two semaphores, `leader` and `follower`, both of initial size zero:

```
semaphore leader(0);
semaphore follower(0);
process p1 {
   dance() asa (leader.wait(p1)
      asa follower.signal());
}
process p2 {
   dance() asa (follower.wait(p2)
      asa leader.signal());
}
```

If the leader arrives before follower, the leader signals the follower which increments follower's count and leader goes to sleep as soon as follower signal is successful since leader count is zero. When a follower arrives, the follower signals the leader which wakes up the leader. The follower counter is already greater than zero, so the follower proceeds to dance. The leader wakes up, checks the counter to be greater than zero, decrements it and also proceeds to dance.

The mutex resource structure is identical to semaphores with the difference that mutex private counter value is always zero or one.

Stack Resource: A stack, also called a LIFO (last-in-first-out), resource in RealSpec is defined by following schema. The stack resource is multi-thread safe by using internal semaphores and mutex resources.

```
stack(int value, int pol=FCFS_BASED)
{
   list slist = [];
   semaphore available(size, pol);
   semaphore occupied(0, pol);
   mutex m(pol);
   int size = value;
   generic operator<<(generic x, generic p);
   generic operator>>(generic p);
   int items();
   bool full();
   bool empty();
   generic top();
}
```

The stack is internally modeled using a list variable `slist`. Two semaphores `available` and `occupied` are used for controlling read from empty stack and write to a full stack. A mutex resource `m` is used to lock and unlock stack access for a thread. The write operator (<<) adds an item `x` to the top of the stack as soon as the thread `p` writing to the stack locks the stack. The calling thread is put to sleep within the available semaphore if the stack is full. Likewise, the calling thread is put to sleep within the mutex `m` if the stack is locked by another thread. The write operator returns the updated stack. The read operator (>>) works in a similar manner and returns the item at the top of the stack. Consider following specification example using stack for evaluating a simple arithmetic expression written in postfix notation. The **`is current`** declaration is used for nested iteration by "freezing" each individual expression in the input stream into the variable `in` for parsing and evaluation.

```
stack s(10);
evaluate(input) = calc(s, in)
   where {
      in is current input;
      calc(s, n) = if n == nil
         then s >> result
         elseif isdigit(hd(n))
         then calc(s << hd(n),tl(n))
         else calc(op(s, hd(n)), tl(n));
      op(s, c) = case c of {
```

```
            '+': s << (s >> two + (s >> one));
            '-': s << (s >> two - (s >> one));
            '*': s << (s >> two * (s >> one));
            '/': s << (s >> two / (s >> one));
         }
      }
```

Queue Resource: A queue resource in RealSpec is bounded to a fixed number of items meaning that it has a specific capacity. Moreover, like stack, the queue resource is multi-thread safe by using internal semaphores and mutex resources. The queue resource has a similar schema as the stack. The operations of the write (<<) and read (>>) operators are different such that << writes to the end of the queue and >> reads from the front of the queue.

Array Resource: RealSpec provides single dimension array resource. The array resource is multi-thread safe by using internal mutex resource. The array resource is defined by following schema:

```
array(int value, int pol=FCFS_BASED)
{
   list alist = [];
   mutex m(pol);
   int size = value;
   generic operator<<(generic x, generic p);
   generic operator>>(generic p);
   generic operator[](int index);
}
```

The write (<<) and read (>>) operators work in the same manner as in stack and queue except that the write or read is performed at the array location identified by the index operator []. The following example uses arrays to perform selection sort of a stream of numbers sequences. The example assumes that the input sequences have ten or less numbers. The example also assumes that the input sequence has already been read into the array `a`.

```
array a(10);
ssort(a, items) = a asa k == 0
   where {
      A is current a;
      k = items-1 fby k-1;
      a = A fby swap(a, imax, k);
      imax = imax asa j == K+1
         where {
            K is current k;
            A is current a;
            j = 1 fby j+1;
            imax = 0 fby
               if (A[j]>>a) > (A[imax]>>b)
               then j else imax;
         }
      swap(a, imax, k) = …
   }
```

6. Dining Philosophers in RealSpec

Dijkstra invented the *dining philosophers problem* as a synchronization problem [10]. Imagine that five philosophers sit around a circular table with a plate of spaghettis. However, there are only five forks available. Each philosopher thinks. When a philosopher gets hungry, the philosopher sits down and picks up the two forks that are closest to the philosopher. If a philosopher can pick up *both* forks, the philosopher eats for a while. After a philosopher finishes eating, the philosopher puts down the forks and starts to think. The classic problem is used as a specification example for RealSpec so focus can be directed on the specification in RealSpec rather than the problem itself. Also, it is assumed that the duration between picking up left and right forks is zero avoiding deadlock.

The problem is specified in RealSpec by declaring five forks as **`mutex`** resources shared between five philosopher process threads `p1` to `p5`. The five forks are defined as a list constant by enclosing within the [% and %] brackets. A philosopher process is defined that consists of five threads with eat and think functions. When a process is created, all defined threads are automatically created and start simultaneous execution. Each philosopher represented by the five threads p_i is defined by the value of the function `eatandthink()`. The function `eatandthink()` is recursively defined in the **`where`** clause as an equation with initial value of `eat` followed by the value of `think` which in turn is followed by the call to `eatandthink()` to represent repeatability of eating and thinking for each philosopher. A philosopher starts eating as soon as the philosopher has forks and the duration of the eating is specified using temporal operator **`@dur`**. The philosopher tries to lock two adjacent forks represented by two adjacent mutex from the `forklist`. If both forks are locked, the philosopher starts eating; otherwise the thread is suspended until both forks are available. The `think` function works in the similar manner but does the opposite things. The function unlocks the right fork as soon as the left fork is unlocked followed by thinking for duration `thinktime`.

7. Summary and Future Work

The paper presented RealSpec executable specification language in general and resource modeling concepts in in particular. RealSpec real-time specification language is based on the functional, declarative, dataflow programming language Lucid. The abstract data resources were discussed in detail and the resource concepts were applied to specify the dining philosophers' problem. A language compiler is currently under implementation to be able to execute and debug specifications of real-time systems in

RealSpec by extending existing Lucid compiler.

Abstract

Change impact analysis plays an important role in software maintenance. It allows evaluating the possible effects of a change. We present, in this paper, a static technique supporting predictive change impact analysis for object-oriented systems and associated tool. The technique uses a model based on control-call flow graphs obtained by static analysis. The control-call flow paths, generated in a compacted form from the model, are used to predict change propagation. The technique we present has been compared, according to several criteria (quality of precision and performance), to two static impact analysis techniques (call graph and slicing based techniques). We used several versions of a Java project (JMOL). The results are reported and discussed in the paper. We also give an overview of the environment we developed to support the proposed approach.

1. Introduction

Maintenance is widely recognized as a very costly step of the software development process [2, 3]. Two basic activities of software maintenance are [1]: the comprehension of the system and the evaluation of the effects of a change. To understand the potential effects of a change, a developer must first understand how the system works [4]. To reduce the important costs of software maintenance, it is necessary to ease the change management process using approaches that allow, among others, evaluating the potential effects of a change [5, 6, 7, 8, 9]. Furthermore, the complexity of interdependencies between components of a software makes this task even difficult [10, 11, 12]. A change to a software, however small, can lead to unexpected ripple effects [13].

Change impact analysis, often called *Impact Analysis*, plays a crucial role in this context. It allows developers and managers to evaluate the possible effects of a change to the source code of a program [15, 16]. Impact analysis information can be used to plan changes, to execute changes, as well as to follow the effects of a change [14]. One of the main goals is to insure, in an iterative process, the consistency of a system before and after a change was implemented [17, 18, 19]. Impact analysis is often used to evaluate the effects of a change after it was implemented [13]. However, more proactive approaches could use impact analysis techniques before it is implemented [5, 13]. In this way, they would allow developers assessing and choosing, among several ways of implementing a change, the solution presenting the lowest estimated impact. Predictive approaches give a global overview of the required efforts in terms of costs and planning [4, 13]. Barros et al. [1], among other authors, discussed the importance of determining the effects of a planned change before it is implemented. The predictive analysis of an impact requires, however, that the maintainers specify the approximate location where the planned changes will be implemented. Impact analysis techniques can be divided into two major classes [5]: traceability and dependence analysis techniques. Impact analysis techniques can be dynamic such as [13, 14, 24, 26], static such as [4, 10, 21, 22, 27, 29], or techniques combining both static and dynamic analysis such as [23]. We focused in this paper on static dependence analysis techniques.

We present a static technique supporting predictive change impact analysis for object-oriented systems and associated tool. The technique uses a model based on control-call flow graphs (a reduced form of control flow graphs) obtained by static analysis of the source code. The atomic instructions of a control flow graph that do not contain method calls are ignored. The control-call flow paths, generated in a compacted form from the model, are used to predict change propagation. Working at the method level granularity makes the analysis more appropriate in practice [13]. We conducted an empirical study using several versions of a Java large project (JMOL). The observed changes were collected from its successive versions. The technique we present has been compared, according to several criteria (quality of precision and performance), to two static impact analysis techniques (call graph and slicing based techniques). The sets of potentially affected classes, returned by the three techniques after a given change, were compared to the observed changes. The results are reported and discussed in Section 5.

The remainder of the paper is organized as follows. Section 2 presents an overview of call graph and slicing based impact analysis techniques. The impact analysis technique we propose is presented in Section 3. Section 4 gives a brief overview of the developed tool. Section 5 presents the empirical study we conducted and discusses the obtained results. Finally, we give some conclusions and future work directions in Section 6.

2. Related work

Impact analysis based on call graphs [21] considers when a procedure P is modified, all the procedures called by P (directly or indirectly) as potentially affected. Impact analysis, in this way, can lead to imprecise results [13, 23]. In fact, we cannot determine, from a simple call graph of a procedure P, what are the conditions related to the propagation of the impact of a change from a procedure to the other procedures. Moreover, call graphs cannot capture the propagation of an impact resulting from the return to a procedure [13]. This weakness was also discussed in [23]. Call graphs capture the local structure of potential calls. They ignore, however, the other aspects related to their control. The behavior of calls is much more complex that call graphs indicate. The first experimentation we conducted and discussed in [27], which focused on a partial comparison between the proposed technique and call graphs based techniques, confirmed the conclusions of several other researches. It was limited, however, to an analysis of the size of the returned impact sets and has not assessed their quality in terms of precision. We implemented, for the needs of our experimentation, two versions of call graph based impact analysis (direct and indirect).

Program slicing was introduced by Weiser in [30] to support debugging and program comprehension. The proposed algorithm is based on an analysis of data flow in a control flow graph. It determines the parts of a program that are potentially affected by the values of the variables of a slice criterion [35, 18, 36]. Two sets of data are defined: defined variables and referenced variables, for each node (instruction) of the graph [31]. The Weiser algorithm was adapted by several authors [32, 33, 29]. Bishop [34] focused on the improvement of the performance (time) of impact analysis using traditional slicing techniques. Others authors [18, 13, 14] assessed the performance of static forward slicing and particularly the size of the returned sets of potentially affected parts of a program after a change. Wang et al [18] discussed the role of program slicing in a ripple-effect process. They implemented a prototype for the analysis of Cobol programs using backward and forward slicing. They concluded, after several experimentations, that the indirect propagation returns a too large set of potentially affected elements compared to a direct propagation. Furthermore, according to [18], it is preferable to analyze iteratively the direct results when performing a change process. However, Wang et al. [18] did not explore the quality of precision of the returned results. They did not precise whether the direct results are better, in terms of quality of precision, compared to those obtained indirectly. Law et al. in [13] conclude that static slicing can be costly in resources and can return imprecise results when dynamic behaviors are analyzed. Moreover, program slicing is difficult to implement [37]. An implementation of forward slicing based on the approach of Weiser [30] was realized in our work. We implemented, in fact, a version of static forward slicing similar to the definition of *Data Slicing* of Zhang et al. [38]. The algorithm we implemented focuses on the identification of methods containing one or several paths of impacted data. Starting from a control flow graph, we adjust the intra and inter modular data dependence links between the different atomic instructions (irreducible instructions) of a method.

3. Control-call flow graph based impact analysis

Definition 1 : A control flow graph (CFG) is a directed graph. The nodes of the graph represent decision points (if-then-else, while, case, etc.), an instruction or a sequential bloc of instructions. A sequential bloc of instructions S is a sequence of instructions such that if we execute the first instruction, we are sure to execute the others, and always in the same way. A directed arc links node N_i to node N_j if it is possible to execute the instruction corresponding to N_j immediately after the one associated to node N_i. The arcs of the graph indicate the control from one node to another.

Definition 2 : A control-call flow graph (CCG) is a control flow graph from which the nodes representing instructions not leading to calls are removed.

Let us consider the example of method M given in figure 1.1. S_i represents a sequence of instructions that do not contain method calls. Figure 1.2 gives the body of method M reduced to calls. The corresponding call graph is given in figure 1.3. Finally, figure 1.4 gives the corresponding control-call flow graph. The proposed technique is organized in several steps.

Fig. 4. Some control-call paths.

Step 1. Construction of control-call flow graphs: The control-call flow graphs, corresponding to the different methods of the program, are extracted by static analysis of the source code.

Step 2. Generation of compacted control-call paths: From the control-call flow graphs, we generate the control-call paths in a compacted form. Starting from the compacted paths, we can generate the set of reduced control-call paths by eliminating unfeasible ones. The compacted paths allow informing on the dynamic behavior of a program. This represents an advantage relatively to dynamic approaches that attempt to obtain these paths by analyzing and compacting execution traces. Figure 2 gives the synthesis (control reduced to calls) of several methods that we consider to illustrate our approach. Figure 3 presents the compacted control-call paths corresponding to the methods of figure 2. We use several notations to express the control in the call sequences. The notation {*sequence*} expresses the iteration in the execution of the sequence (or part of a sequence). The sequence in { } can be executed 0 or several times. The sequence (*sequence 1* / *sequence 2*) expresses an alternative in the execution of the two sequences. The sequence [*sequence*] expresses the fact that the sequence between [ ] can be executed or not. Figure 4 illustrates some of control-call paths that can be deduced from figure 3.

Step 3. Impact Analysis: Our technique considers, if we plan a change on a method M, solely the impact that can be propagated through any control-call flow path including method M [27]. This principle was already used in [13]. Any method called after M, called by M, and any method calling M is included in the set of potentially affected methods.

4. Iterative Impact Analysis: A Supporting Tool

We developed a tool (JIAT: Java Impact Analysis Tool) as a plug-in for the Eclipse development environment. Others authors have also implemented their impact analysis tool using the Eclipse API [23, 39]. It allows, in fact, the creation of *Abstract Syntax Tree* (AST), which facilitates the analysis of the code of a project. Their use makes also the tool independent from the version of the Java language. The architecture of the developed tool is given in figure 5. The tool compiles, using Eclipse environment, a set of AST for a given project. Then, the CCG engine converts the AST in standard CCG structures for each method of the project. Finally, the analysis engine uses the set of CCG to generate the control-call flow paths and capture the potentially affected classes (methods). The analysis process is done in three steps:

Change location: The tool allows the user to indicate the location of the planned changes. This is done by positioning the cursor in a method from the Eclipse's Java file editor. An example is given in figure 6.

Analysis of change propagation: The user asks the tool to do a change impact analysis from the position of the cursor. The tool compiles the CCG and gives different views of the results.

View of the results: The results are presented in two different forms: textual and graphic. The textual view can be interpreted as a list of affected classes and methods (figure 7). Figure 7 shows two windows: the first one shows the class or the method that will be modified and the second one shows the set of classes (methods) that could be impacted. The graphic view, shown in figure 8, allows the user to have a global view of the extent of the propagation of the change.

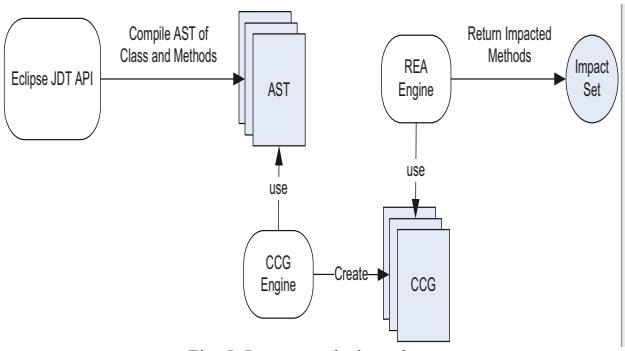

Fig. 5. Impact analysis tool.

```
public static BaseAtomType get(int atomicNumber) {

  Enumeration iter = typePool.elements();
  while (iter.hasMoreElements()) {
    BaseAtomType at = (BaseAtomType) iter.nextElement();
    if (atomicNumber == at.getAtomicNumber()) {
      BaseAtomType atr = get(at.getRoot());
      return atr;
    }
  }
  return null;
}
```

6. Location of a change.

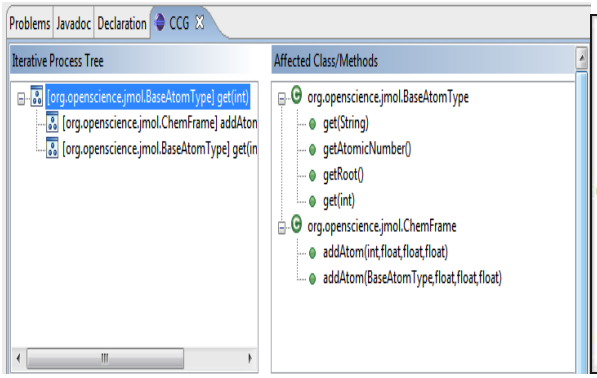

Fig. 7. Presentation of the results in textual form.

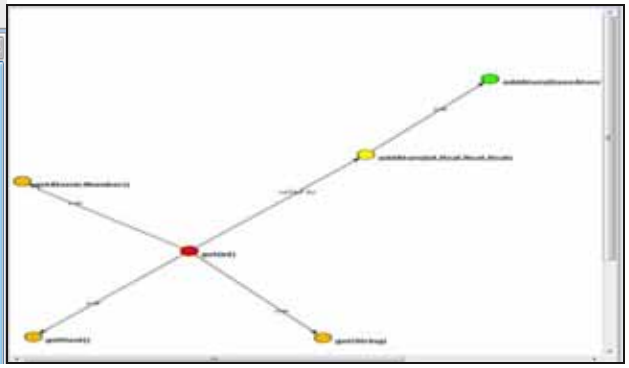

Fig. 8. Presentation of the results in graphic form.

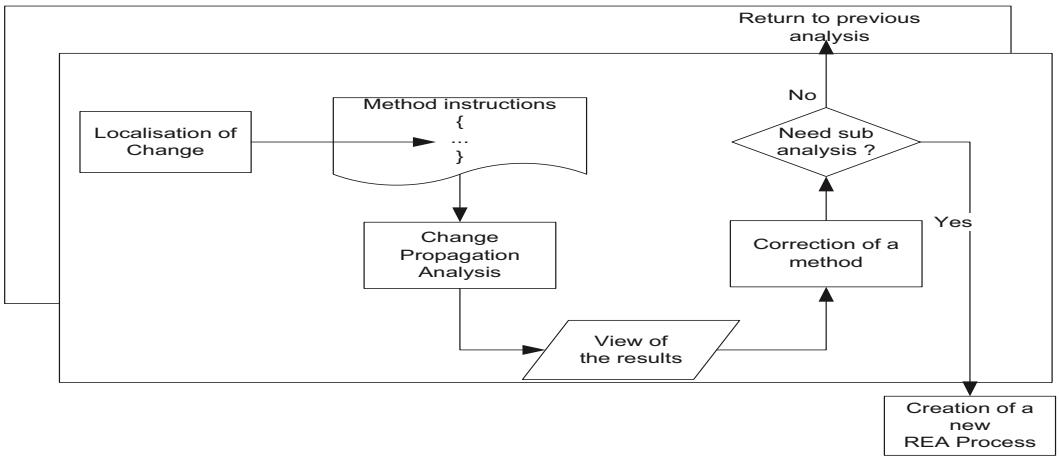

Fig. 9. Iterative process for the construction of impacted sets.

The visualization of the propagation can be done, according to the choice of the user, in two different ways: the first shows the parts of the code that are directly affected, and the second shows the parts that may be affected indirectly. The user can select a class (method) in the list of affected classes (methods) (figure 7, window 2) and restart the analysis process. He can also return to a previous state by selecting another class (method) in window 1. We consider, for simplification reasons, solely the set of elements (classes, methods) that are potentially affected directly following a given change. The set of impacted elements is constructed iteratively (figure 9). In this way, the technique avoids managing eventual large sets that can contain several non impacted elements. In the process, only the elements that can be affected directly following, for example, a modification to a method M_i are considered. Let us suppose that this set is noted I_{Mi}. If after the modification of M_i, another method M_j belonging to I_{Mi} needs an adaptation, we can repeat the process that consists on constructing the corresponding I_{Mj} set. This process is repeated iteratively until there are no more impacted methods by the change. In this way, we avoid considering, for regression testing, a relatively large set of methods that do not actually need to be tested again.

5. Case Study

5.1. Methodology and data collection

We conducted an empirical study using several generations of an open-source Java project (*JMOL*, available on www.*sourceforge.net*). JMOL is a free application for the visualization of molecules for students, educators and researchers in chemistry and biochemistry. The project represents a concrete case study and was used, among others, in [40]. The goal is, in particular, to determine the precision of the considered approaches in identifying the right impacted classes (methods) after a change. In a first step, we identified between two successive versions of JMOL the different instantiated changes. The observed changes from one version to another of JMOL were collected. We applied the selected approaches: Call Graph (CG), Control-Call Graph (CCG) and Forward Slicing (FS). The sets of potentially affected classes (methods), returned by the three techniques, were compared to the observed changes. The three techniques were also compared using some performance criteria. Our experiments followed a methodology similar to the one used in [25]. We extended it by assessing the performances of the three approaches.

Identifying changes and impacted classes: We compared (repeatedly for each version), using the binary comparison tool of Eclipse, two major successive versions of JMOL to identify the methods (classes) changed from one version to the other. This allowed us to extract, for each version, the set of changed methods (classes). Moreover, when a programmer makes a change (initial change) on a method for example, it is possible that other methods will be modified (adapted) as a consequence of the initial change. These changes (propagation) must be identified. To identify the initial changes, we combined the use of the binary comparison tool of Eclipse with a manual analysis of the code. This task was not easy to perform.

Filtering the elements that do not induce propagation: To construct adequately the set of elements that were really affected, from one version to another, it is important to filter the elements that do not generate a propagation of change such as it is mentioned in [25]. Several changed methods where ignored according to some criteria such as: reformatting the code (adding spaces, empty lines), changing informative elements (changing comments), etc.

5.2. Used metrics

Hassan et al. [25] defined two metrics to compare ripple-effects analysis approaches. They proposed the metric *recall* defined as the percentage of the number of elements identified by an approach (*PO*) on the number of elements that were really changed. This measure indicates the sensitivity of the approach. For example, a *recall* of 0.3 signifies that the approach has correctly identified for example 30% of the modified classes, but 70% of the classes really modified were not identified. They proposed also the *precision* measure defined as the percentage of elements correctly identified by the approach (*PO*) on the total number of identified elements (*P*). For example, a *precision* of 0.5 implies that for two classes returned by an approach, one of the classes is not really impacted by a change.

5.3. Results and discussion

Collecting and analyzing data on changes from JMOL for the assessment of three approaches was not easy. Our experiments have been limited to the seven first versions of the software, which presently count about 10 versions. The collected data were significant enough to allow us to complete our experiments. Table 1 gives some descriptive statistics on the different versions of the project. We can observe, among other things, that the size (number of lines of code) has gone from 18357 to 30288. This represents an increase of 65%. The number of classes was 237 and is now 315 (33%). The number of methods has gone from 1073 to 1732 (61%). The transition from version 1 to 2 was not retained, because there was not enough data.

Table 2 summarizes the obtained results. The three evaluated approaches (implemented for Java programs) are shown in the table: CG_i (indirect call graphs), CG_d (direct call graphs), CCG (control-call flow graphs) and FS (forward slicing). Column *C* indicates the number of changed classes between two versions. The total number of observed changes is 121. Column *P* notes the total number of classes that each approach returned and column *PO* notes the classes that were correctly identified by each approach. CCG obtains a better sensitivity with a *recall* of 32%, higher than FS (22%), and CG_d (30%). However, FS obtains a *precision* of 58% where CCG obtains 48%. CG_i has the lowest *precision*. CCG gives better results than CG_d by having a better *precision* and *recall*. Compared to FS, CCG is less restrictive in its analysis.

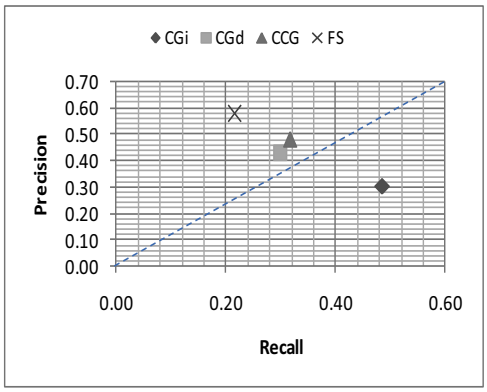

Diagram 1. "Recall" vs "Precision": class level.

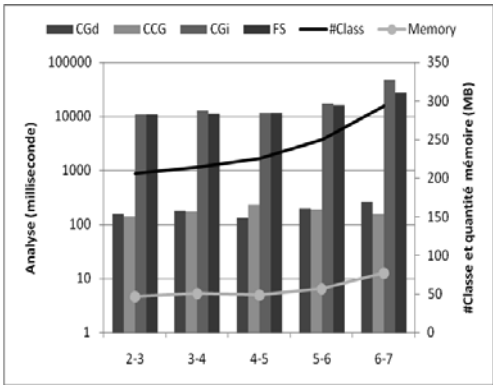

Diagram 2. Analysis time compared to the number of classes and quantity of memory used by revision.

Moreover, Zhang et al. report in [38] that they observe a very short distance (in instruction granularity) of the impact propagation by doing a dynamic FS. We also observed a small distance for static FS. Diagram 1 gives a global view on the sensitivity and precision of the approaches. The more an approach follows the diagonal line, the more its results are balanced (*sensitivity* and *precision*). The more the approach is close to the higher right corner, the more it is effective. FS obtains a high *precision* compared to the other approaches, but obtains a low *recall*. CG_i obtains the best *recall.* It also obtains the worst *precision*. CG_d obtains a better precision compared to CG_i, but a low sensitivity. CCG seems to be more effective than the other techniques. It gives results more balanced than the other approaches (sensitivity and precision - closest to the top right corner of the diagram).

Table 3 reports on time, in milliseconds, for the creation of an Eclipse AST structure for each approach, as well as analysis time, which include the creation of their respective dependence structures. The use of memory of each approach is also noted for each experiment. From the reported results, we can observe that on average the creation of an AST takes 2 seconds. Both direct approaches obtain the fastest results on analysis, which is approximately 1/10 of seconds and is relatively fast. For CG_i and FS techniques, the analysis time is very imposing. On average, they both take 19 and 15 seconds respectively to give a result. To do 5 analyses CG_i and FS take more than a minute, while CG_d and CCG techniques take less than one second. The quantity of memory used is similar in all approaches. This is due to the intensive use of Eclipse's AST to implement the approaches. CG_i seems to be using more memory than the others. The creation of matrices to determine the indirect relations could explain a higher use of memory. In diagram 2, we show also the required time (left axis). Visually, it seems that there exists a link between the increasing number of classes from one revision to another, the required time to complete an analysis, and the average quantity of memory used for all approaches. The more there is information to analyze, the

more the memory required by each approach increases. This remark is also true for the required time. Furthermore, the direct approaches are largely faster than the indirect approaches and seem more or less influenced by the increased number of classes between revisions.

6. Conclusions and future work directions

We presented, in this paper, a static technique supporting predictive change impact analysis for object-oriented systems and associated tool. The technique uses a model based on reduced control flow graphs (control-call flow graphs) obtained by static analysis of the source code. We compared it according to several criteria (quality of precision and performance) to two static impact analysis techniques (call graph and slicing based techniques).

We performed an empirical study using several versions of a Java large project (JMOL). The obtained results show that CCG and FS techniques are more precise than CG based approaches. Moreover, CCG obtains a better sensitivity than FS. However, FS obtains a better precision than CCG. CCG seems to be more effective than the other techniques. It gives results more balanced than the other approaches (sensitivity and precision - closest to the top right corner of the diagram). On the performance level (analysis time), CCG is much faster than FS. In a general manner, and taking into account the criteria used for the assessment of the techniques, CCG technique seems presenting a good compromise relatively to the other techniques. The present study has also confirmed the relevance of taking into consideration the control flow and data flow in impact analysis. The unification of the two approaches would be an interesting way to explore.

Moreover, the tool supporting our approach can be used to evaluate, by successive simulations of changes, their estimated impact sets. This possibility allows choosing, among several solutions for implementing a given change, the one having the lowest estimated impact. This presents an advantage compared to the FS approaches which are applied generally after a given change is implemented. As future work, we plan to: (1) Extend our technique to take into account data flow, (2) and experiment the new model.

Abstract

The rise of agile methodologies and open source software has led to the creation of several new tools designed to help software engineers construct better applications. One particular emphasis of these new tools is the creation of unit tests. This paper describes a qualitative assessment of the reverse engineering capabilities of three unit testing tools (Agitar Software's Agitator, and the open source tools JUnit and EasyMock) for Java programs. The focus of the assessment is largely on how the unit testing tools can assist in understanding existing code. The assessment is structured using an existing Reverse Engineering Environment Framework (REEF). The results of the assessment suggest that unit testing tools can indeed aid software engineers in understanding Java programs.

Keywords: program understanding, reverse engineering, unit testing, qualitative, assessment, REEF, Java

1. Introduction

One area of software engineering tool functionality that has grown rapidly over the past few years is that of unit testing. This is due, in part, to the growing popularity of Agile methodologies such as Extreme Programming [9] or Scrum [12]. Many of these development methodologies place a strong emphasis on the developers creating robust unit test suites (often even before the code itself is written) and executing these tests frequently. Numerous tools, both commercial and open source are available for creating unit tests. While these tools have an established reputation for aiding in developing unit tests, there are other uses to which they can be put as well – in particular, they have inherent abilities to aid program understanding by reverse engineering.

This paper assesses the reverse engineering capabilities of unit testing tools from the perspective of a developer trying to gain understanding of an existing program (in particular Java program for this research). A reverse engineering framework REEF [14] is used to assess the capability of program understanding of these tools. The assessment is qualitative in the sense that the unit testing tools are not evaluated according to absolute ability, but rather according to the types of reverse engineering activities that they support. The unit testing tools that are considered in this paper are quite popular: Agitator (from Agitar Software) [6], Junit [3], and EasyMock [1].

The next section of the paper briefly describes background for this research. Section 3 describes the Reverse Engineering Environment Framework (REEF), the instrument that it used to structure the assessment. Section 4 describes the three unit testing tools examined as a part of this study and the results of the evaluation performed. Finally, Section 5 summarizes the paper and discusses possible avenues for future work.

2. Background

Unit tests examine individual pieces (or *units*) of a system. Units are generally classes or methods in a typical object-oriented program, and unit tests focus on the functionality contained within the unit. These tests simply check that the unit behaves in the manner it was designed. Unit tests are generally written by developers in conjunction with the code that comprises the unit being tested. Traditionally, developers have been reluctant to create unit tests, to the lament of the testers on those projects. Little tool support existed that was used in practice, and developers had no training or support materials for creating these tests.

The emergence of agile methodologies brought a change to all this. Most agile methodologies put a strong emphasis on creating and maintaining a suite of unit tests to serve as a "safety net" to ensure that making changes to the code (either to fix bugs or add new functionality) does not break existing functionality. Test Driven

Development (TDD) is one form of agile software development where the developer creates a single unit test that fails. Then, the developer creates the simplest code possible to make the test pass (without breaking the others). Once the test passes (along with all the other existing tests), the developer refactors the code to clean it up, and then repeats the cycle, starting again with a single test.

This pre-coding creation of unit tests serves as a design method. Since the tests usually exist in a separate class than the code they test, creating the test forces the developer to think about the interface his or her code provides from the perspective of using it from another class. It also encourages the developer to identify the domains of applicable values for the code, and the circumstances that should cause exceptions. Another benefit of unit tests often cited by proponents is the idea of tests as documentation for the system. Since all code can be tied back to a particular test that required the code to be added, and the tests are executed with each change to the code, these tests are kept in sync with the code. They also serve as examples of what is expected of the code – both for inputs and outputs, and for exceptional conditions.

Both of these benefits are aided by and foster a deep understanding of the program. The initial designing of the code that goes into creating the test instills the understanding in the original developer, and this understanding then gets encapsulated in the unit tests, where it is ready for future developers to quickly regain when they have to work with the code. With the tools facilitating this degree of program understanding, it follows that these tools may be useful not only for developing a system, but also for reverse engineering it once it has been developed.

3. The REEF

Space limitations on this paper preclude an in-depth description of the REEF's entire structure here; the interested reader is referred to [16] for more information. The framework classifies reverse engineering tools across five major dimensions: cognitive model support, reverse engineering tasks, canonical activities, quality attributes, and miscellaneous characteristics. This paper focus on reverse engineering tasks, canonical activities, and quality attributes only.

There have been a number of assessment instruments developed whose goals include an evaluation of the capabilities inherent in reverse engineering tools to support activities related to program understanding (e.g., [7],[8],[10]). The REEF has been used to examine several different applications domains (e.g., [15][17][18]). This paper represents the first time the REEF has been used in the context of unit testing.

Reverse Engineering Tasks

The REEF identifies five reverse engineering tasks as being the most important ones to consider. These tasks are program analysis, plan recognition, concept assignment, redocumentation, and architecture recovery. Program analysis is pattern matching at a syntactic level, plan recognition is pattern matching at a semantic level in the programming level domain, and concept assignment is pattern matching at a semantic level in the application domain. Redocumentation is the recreation of documentation for an existing system, while architecture recovery recovers the overall design (architecture) of the existing system.

Canonical Activities

The activities of reverse engineering can be organized into three main groups: data gathering, knowledge management, and information exploration . These groups are derived from the classification of the artifacts manipulated by reverse engineering into three categories. Artifacts can be data (factual information); knowledge (data along with relationships and rules derived from that data); and information (knowledge which is communicated based on a contextual selection from all available knowledge).

Quality Attributes

Practitioners often refer to the attributes as the "-ilities" as many of the attributes share that suffix. Dependability, reliability, and usability are all examples of a quality attribute. The REEF includes three of these attributes as measures on which to compare tools: applicability, extensibility, and scalability. Applicability examines the subset of application and implementation domains to which a given tool applies. Extensibility looks at the mechanisms a tool provides for its end user to extend and customize the tool's capabilities, and scalability looks at how well a tool can handle projects of increasing size and complexity.

4. Assessment

Consider the following scenario: a developer is tasked with understanding a Java program. This system may or may not have much in the way of accurate documentation, and it is the developer's task to perform some maintenance action on the system. Because schedules are tight, the developer needs to get the required understanding of the system as quickly as

possible, and ideally, there would be some method of capturing the understanding to make it easier for the next person who has to maintain the system.

The tools discussed in this section can help with this task. Although the tools are primarily for unit testing, they do have varying degrees of reverse engineering capabilities that can be used in support of program understanding. This section describes an assessment of these capabilities according to the REEF.

4.1 Agitator

Agitar Software's Agitator is a tool designed to "agitate" code in order to find bugs in the code. This agitation involves executing the code with various inputs that are automatically generated by the tool. While the code is being executed, Agitator makes observations of conditions which are always or often true of the code. These observations are then presented to the user who determines which are supposed to be always true. The observations that are supposed to be true are promoted to assertions, and all further agitation runs of the code check that the defined assertions always hold true. Assertions can be assigned within specific contexts of the application (so that a path that generates an exception could have a different set of assertions than a normal path through the code).

Reverse engineering tasks

Program Analysis. Agitator focuses on individual methods of the classes it is testing and the parameters of those methods. It also allows outcome partitioning of the assertions. An outcome partition is one possible path through the code. By default, Agitator provides outcomes for the normal path through the code and any exceptions it encounters while executing the code. Additional outcomes can be created, however, lending support to more complex situations and allowing for more fine-grained assertions to be made about the code. Both this partitioning of outcomes and the partitioning of the assertions by class and method are examples of tasks that can be categorized as a type of program analysis. In both cases, it aids in the understanding of the program by narrowing the engineer's focus to one small part of the code, and the assertions that are relevant to that one part.

Plan Recognition. Another reverse engineering task that Agitator supports is plan recognition. The rules that define where the experts are applicable serve as patterns that the tool then matches against the system. These rules allow filtering based on the names of classes or the inheritance hierarchy of the code before an applicability check is performed. This applicability check can then apply any programmable criteria to determine if the expert applies to the project, class, or method being examined. Essentially, the rules are defining the clichés to which the expert is relevant.

Redocumentation. A third reverse engineering task supported by Agitator is redocumenting the program through the creation of observations and assertions. As observations are made and assertions identified about the program under certain circumstances, these assertions can then be recorded in Agitator. While it is difficult to get the assertions out for use in other formats, Agitator does provide the benefit of rechecking these assertions on demand. This is particularly useful as changes are made to the application–if a change is made to an application that violates one of the assertions, it is found during the next agitation run.

Canonical activities

Data Gathering. Agitator supports data gathering by the static analysis of applying the experts to the code and applying rules of coding style to the code. In addition, Agitator performs dynamic analysis of the system while the code being examined is executed and the observations are being made about the code. This feature aids in the act of reverse engineering as well, by displaying the observations that it finds to be true or almost always true (along with the values for which an observation was not true).

Knowledge Management. The discovery element of knowledge management is supported through the creation of observations. As Agitator observes things about the application, it may reveal information or patterns that even the original developers did not recognize. Agitator also helps in the evolution of knowledge about the system, particularly as the system changes. With a click of the mouse, the code can be re-agitated. During this process, all the existing assertions are verified to still be true, and new observations may be made. These new observations or failing assertions may reflect updated information about the code (thus replacing old information) or they may reflect bugs that have been introduced into the application.

Information Exploration. Agitator supports information exploration by navigating through the information about the code using the considerable navigation capabilities built into Eclipse. Another element of the information exploration activity is that of analyzing the information. For reverse engineering, Agitator largely does this through the assertions and observations, though its flagging of code style violations also does some analysis as well. The final element of this activity is that of the presentation of information.

Agitator has multiple ways of presenting its information —via Eclipse views displaying different aspects of the agitation process, via graphical display within the source editor itself, indicating how much coverage was achieved by the agitation and presentation of information through its Management Dashboard (a set of generated Web pages providing overviews of the project).

Quality attributes

Applicability. Agitator only works for programs written in Java. Because it is developed, marketed and priced as a commercial software package, it is more applicable to projects that have a substantial tools budget, rather than the majority of open source or freeware software being developed. Agitar does remedy this to some extent by agitating some common open source code and making the dashboards available for these projects on their website.

Extensibility. Agitator exists as a set of Eclipse plug-ins. Because of this, it is possible to augment the functionality of the tool by installing one or more of the many existing Eclipse plug-ins [5]. Agitator also provides a high degree of end-user programmability. While it provides many built-in factories and experts, it also includes APIs so that end-users can develop their own instances of these components as their project requires them. It is also possible for additional assertions to be created, using a Java-like syntax. This allows the end user to program in assertions that are not based on observations.

Scalability. Agitator scales to large projects fairly well. Since each set of assertions applies to a single outcome partition of a single method, and agitation is done per class, it is feasible to have many classes and methods while still focusing on just one at a time.

4.2 JUnit

JUnit is an open-source tool created by Erich Gamma and Kent Beck, and is a member of a family of tools collectively referred to as "xUnit" that span a variety of programming languages. JUnit provides a set of methods the developer can use to assert certain conditions on the code. These assertions typically are based on return values of methods in the code, but may also involve other aspects of the environment or the system being tested.

Reverse engineering tasks

Program Analysis. JUnit's main function is to execute tests against the application being tested. Each time these tests are run provides an instance of the reverse engineering task of program analysis. The tests analyze the program, indicating what's working as expected and what is not. For reverse engineering, this is useful if the tests were created along with the code. It is also useful if maintenance has begun and changes are being made to the code.

Redocumentation. The agile development community argues that the code in the unit tests serves as documentation and they are examples of how to call into the methods being tested and a complete set of unit tests illustrates the boundary conditions and constraints to which the system is subject. With this idea of tests as documentation, creating unit tests for an existing system can be categorized as an element of the redocumentation reverse engineering effort. At the end of the creation process, an artifact (the test suites and cases) remain to serve as documentation for the code, reducing the time required for later engineers to work on the system.

Canonical activities

Data Gathering. The results of executing the tests also serve as a source of data for the canonical activity of data gathering. The tests serve as dynamic system examination, and give insight into what works or what hypotheses are correct.

Knowledge Management. JUnit's tests also serve the canonical activity of knowledge management. They can be used to organize knowledge that has already been obtained by grouping tests of similar functions or contexts together. The tests can also be used to discover additional knowledge about the application through the encoding of hypotheses in the tests. As the tests pass or fail, they confirm or disprove the hypotheses. Each of these results adds to the knowledge available about the system. The tests can be used to encapsulate experience about the system once it is gathered. These tests can either be pre-existent (created when the code was originally written, as in TDD) or created based on the results of other experience capture activities.

Quality attributes

Applicability. The xUnit family works with many languages and each individual tool applies in much the same way as described above. JUnit, in particular, works with Java programs. By itself, it can be used for the public and default level methods and fields of a class. However, add-ons are available that extend the tool's reach to GUIs and private members [11].

Extensibility. JUnit is released as an open source tool which means that anyone can download the source code and extend the tool as they desire. It is also possible to extend the default classes (through add-ons), leaving

the core JUnit code as is, and thus increasing the potential user base for additional functionality.

Scalability. As with Agitator, JUnit tests focus on no more than one unit each (and often there may be several tests for that unit). This means that the only issue with performance scaling is one of the time involved, both to develop the tests and to execute them. Large suites of JUnit tests may take 5-10 minutes to execute, but usually the tests run in less time than that.

4.3 EasyMock

EasyMock is an open-source tool written by Tammo Freese. It serves as more of a support tool for unit testing than a tool for executing unit tests. EasyMock allows its users to create a mock object which functions as a proxy for a real object that is unavailable, unpredictable, or otherwise difficult to test.

Reverse engineering tasks

EasyMock's lack of standalone reverse engineering capabilities means that it does not directly perform any of the REEF's reverse engineering tasks. Instead, EasyMock supports the tasks of program analysis and redocumentation by allowing the engineer to focus on one piece of the application. It also provides the ability to better control the return values of subsystems (such as databases, for example) that make it easier to understand the error handling code present in an application.

Canonical activities

Data Gathering. EasyMock aids in the canonical activity of data gathering by performing dynamic system examination. When a test containing EasyMock code is executed, EasyMock examines the method calls made to the part of the system that is being mocked. It then validates these calls against the ones it was told to expect. This can be helpful in understanding the flow of actions in the system, particularly if the tests are developed in an evolutionary fashion where few or no expected calls are described, and each call that EasyMock reports is verified and then added to the test.

Knowledge Management. EasyMock provides a limited form of knowledge management. As the tests are created with accurate expected results, they store the knowledge of the order that went into creating the tests. As more method calls are discovered, the tests can be updated to reflect evolving knowledge about the system.

Information Exploration. EasyMock can aid information exploration. Each time an EasyMock test executes, it analyzes the inter-method calls being made into the portion of the system being mocked. It then confirms or disproves that these calls occur in the order and with the parameters that are expected.

Quality attributes

Applicability. EasyMock can be used on any Java application. Its design makes it much more suited to cases where interfaces are used and classes are passed into methods, and without the use of these language features, substantial code changes may be required to use the mock object created by EasyMock. These changes run the risk of introducing bugs into the code being reverse engineered, potentially taking the reverse engineer down a path away from program understanding.

Extensibility. EasyMock is released as open source software, meaning that anyone can extend its functionality by editing the code.

Scalability. Like the other tools in this paper, EasyMock focuses on units of code. This narrow focus allows it to scale well to a large number of units, though the time required for deploying and using the tool does increase with the number of units.

5. Summary

This paper described an evaluation of the capabilities of three unit testing tools in a situation where reverse engineering of a system was required. A summary of the canonical activity portion of the evaluation across all three tools is included in Table 1.

Our evaluation of these tools revealed that unit testing tools share several characteristics that make them useful for reverse engineering in aid of program understanding. For example, they have a narrow focus, which allows them to scale up to large systems fairly easily. The tools focus on units of code, which means that the tools have the capability to gain access the individual units. Because of the emphasis of frequent execution of the tests, unit testing tools often serve to encapsulate knowledge about the system that would otherwise be lost. This aids in future maintenance efforts by reducing the time it takes to get back up to speed.

Some areas that may prove useful to examine in the future is that of the variation in language focus amongst unit testing tools. For example, while the majority of the xUnit family of tools are modeled on JUnit, some tools are now beginning to evolve in different directions based on the capabilities of their base languages. Nunit [4], and TestNG [13] are trying to improve on the model presented by JUnit and may have different impacts on reverse engineering.

Finally, an area that could prove worthy of study is the opposite of this research: the application of reverse engineering tools to software testing. Since testers are gaining understanding of what a program does when they test it, it is quite possible that some of the tools of reverse engineering might prove very helpful to them.

Table 1: Canonical Activities

Estimating Event Lifetimes for Distributed Runtime Verification

Christos Kloukinas, George Spanoudakis, Khaled Mahbub
Department of Computing, The City University, London, EC1V 0HB, UK
{C.Kloukinas, G.Spanoudakis, K.Mahbub}@soi.city.ac.uk

Abstract

Runtime system verification has been proposed as a form of dynamic verification of software systems which can be applied in settings where complete static verification or exhaustive system testing is not practical. Runtime verification checks properties against runtime events generated during the operation of a system. Current approaches to runtime verification assume that runtime events are time-stamped by a single clock and, thus, can be totally ordered. They also assume that events are received by the reasoning engine in the same order as they have been produced. These assumptions are apparently true only in systems with a single clock. In this paper, we present the extension of a framework for runtime verification which can monitor distributed systems, in which events are produced by different components, each having its own clock.

1. INTRODUCTION

Runtime (or dynamic) system verification has been proposed as a complementary approach to static system verification and testing, which can enhance confidence in the correctness of system operations by monitoring and identifying violations of required system properties during the normal system operation [3][6][10]. Runtime verification is needed due to the inability to guarantee the completeness of system models that have been used for static analysis and the preservation of these models by system implementations. It is also useful as it is difficult to foresee all the different circumstances that may arise during the operation of a system and therefore guarantee that the assumptions, under which its correctness can be statically proved, hold at runtime.

Typically, platforms for runtime verification (e.g. [6] [9][11][20]) provide support for specifying formally the properties of a system that should be verified at runtime, identifying the events that should be available in order to assess if certain properties are satisfied, capturing these events at runtime, and checking for violations of the required properties.

The main limitation of existing runtime verification platforms is that they assume that the systems to be monitored consist of components running on a single machine. In such cases, the events of the system that is being monitored are: (i) time stamped by a single clock, (ii) totally ordered, and (iii) received by the monitor in the same order as they are generated by the system that is being monitored.

Whilst valid in the case of centralised systems, these assumptions do not necessarily hold in cases of distributed systems with components running on different platforms. In such systems, runtime events may come from distributed components operating with different time clocks. Furthermore, distributed system components may have different types of connections with the monitor and, therefore, generate events which arrive at the monitor with different communication delays and possibly in an order that is not the same as the order of their generation.

Thus, in order to check properties involving events from distributed components, a monitor would have to overcome two problems: (i) to synchronise the clocks of the various event sources, so that the timestamps of the different events can be ordered and compared to each other, and (ii) to establish until when a particular event needs to be stored, so that it can reason about the system properties in a sound way or, equivalently, to compute the required monitoring lifetime of each event.

Consider, for instance, the case of monitoring the availability of the communication channel between two components C1 and C2 of a system by ensuring that the dispatch of a request R from C1 (*Event-1*) will always be followed by the receipt of R by C2 (*Event-2*) within a specific time period. In this case, *Event-2* may arrive at the monitor before *Event-1* due to different communication delays in the relevant channels. Thus, when the monitor receives *Event-2* it will have to decide for how long it should wait for *Event-1* and wait for this event before dropping *Event-2* or otherwise it may report a false violation of the availability of the communication channel between C1 and C2. This would happen in cases where, after dropping *Event-2*, the monitor receives an *Event-1* corresponding to it.

In this paper, we present an extension of a dynamic verification framework described in [20] which addresses these problems. The original framework monitors systems against properties expressed in Event Calculus (EC) [19] and was initially developed to support monitoring based on events which are generated by a single source. The extension of the framework that we present in this paper enables it to monitor systems in which events are generated by distributed sources having different clocks and communication channels to the monitor.

The rest of the paper is organised as follows. In Section 2, we provide an overview of our monitoring framework and the language that it uses to specify monitoring properties. In Section 3, we propose a solution for

computing the lifetime of events that the framework receives from distributed sources and show how these lifetimes are used during monitoring. In Section 4, we give an overview of related work and, finally, in Section 5 we summarise our work and outline directions for further research.

2. MONITORING FRAMEWORK

2.1. Overview

As shown in Figure 1, the dynamic verification framework that we have extended consists of a *monitoring manager,* a *monitor,* a *Network Time Protocol (NTP) server*, and communicates with different event collectors attached to the components of the system that is being monitored.

The *monitoring manager* has responsibility for initiating, coordinating and reporting the results of the monitoring process. Once it receives a request for monitoring a specific set of properties, the manager checks whether it is possible to monitor them and, if it is, it sends the properties to be checked to the monitor, and starts listening to events which are generated by different types of external event collectors. These events are received via TCP/IP sockets and sent to the monitor.

After receiving events from the manager, the *monitor* checks whether they violate any of the properties given to it. The monitor is a generic engine for checking violations of EC formulas against a given set of runtime events. During monitoring, it also takes into account information about the state of a system that it derives from runtime events using a special type of EC formulas called *assumptions* (see Section 2.2). When a violation of a property is detected, the monitor records it in a *deviation database* which is polled regularly by the monitoring manager to retrieve detected deviations.

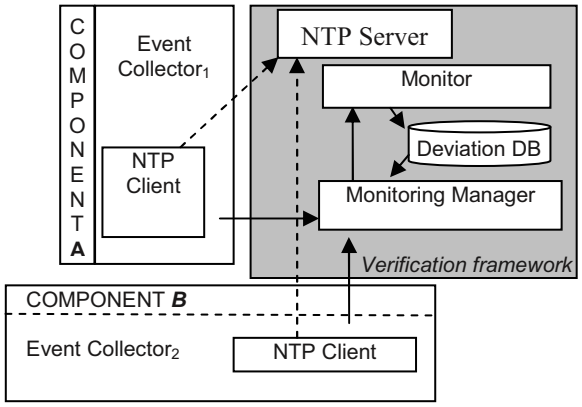

Figure 1 : Verification framework

The framework assumes that the components of the systems to be monitored have associated *event collectors* that can capture events during their operation and send them to the monitor. When a collector captures a runtime event, it wraps it into an envelope with additional information including the source of the event (i.e., the component where it was captured) and a timestamp indicating when the event was captured at the component.

To enable the synchronisation of event timestamps, the framework incorporates components that realise the *Network Time Protocol* [17] (i.e., a protocol based on the clock synchronisation scheme described in [12]). The implementation of this protocol allows event collectors to compute the difference of their clocks with the clock of the monitor at regular intervals. This difference is used to transform timestamps taken according to the clock of each collector into timestamps that express time in terms of the monitor's clock. This is achieved by implementing an *NTP client* at each event collector and an *NTP server* at the machine that hosts the monitor, as shown in Figure 1. The NTP clients call the NTP server at regular intervals to synchronise their clocks with the clock of the server. The use of NTP can synchronise distributed clocks at a very high level of accuracy since recent versions of NTP (version 4) use a resolution of less than one nanosecond.

2.2 Specification of Properties

As indicated in Section 1, in our runtime monitoring framework the properties to be monitored are expressed in a language based on Event Calculus (EC) [19]. EC is a first-order temporal logic language which can be used for representing and reasoning about *events* and their effects over time. An event in EC is an occurrence that takes place at a specific instance of time (e.g., invocation of a system operation, receipt or dispatch of a message) and may have an effect. The effects of events are represented by *fluents*. Fluents are conditions which may change over time (e.g. a condition indicating that a system has received a message) and are initiated and/or terminated by events.

The occurrence of an event in EC is represented by the predicate $Happens(e,t,\Re(lb,ub))$. This predicate denotes that an instantaneous event e occurs at some time t within the time range $\Re(lb,ub)$ (i.e., $lb \le t \le ub$) . The boundaries lb and ub that define time ranges are specified as linear expressions over time variables of *Happens* predicates in an EC formula of the form:

$$lb = l_0 + l_1 t_1 + l_2 t_2 + \ldots + l_n t_n$$
$$ub = u_0 + u_1 t_1 + u_2 t_2 + \ldots + u_n t_n$$

Given our focus on runtime system monitoring, the events we consider represent invocations of system operations, responses from such operations, or exchanges of messages between different system components. Thus, events have the following structure which captures the information required for monitoring such system interactions without affecting the overall expressiveness of the framework with respect to standard EC:

event(_id, _sender, _receiver, _status, _sig, _source)

In this structure:

- *_id* is a unique identifier of the event
- *_sender* is the identifier of the system component that sends the message represented by the event
- *_receiver* is the identifier of the system component that receives the message represented by the event
- *_status* is the processing status of an event (i.e. whether or not its processing has started when the monitor receives it)
- *_sig* is the signature of the dispatched message or the operation invocation/response represented by the event, comprising the operation name and its arguments/result.
- *_source* is the identifier of the component where the event was captured.

Fluents are defined as relations between objects of the form $rel(O_1, ..., O_n)$ where *rel* is the name of a relation which associates the *n* objects O_1, …, and O_n. The initiation or termination of a fluent *f* due to the occurrence of an event *e* at time *t* is denoted in EC by the predicates *Initiates(e,f,t)* and *Terminates(e,f,t)*, respectively. An EC formula may also use the predicates *Initially(f)* and *HoldsAt(f,t)* to denote that a fluent *f* holds at the start of the execution of a system and at time *t,* respectively.

The rules to be monitored at runtime are specified in terms of the above predicates and have the general form *body* $\Rightarrow$ *head*. The meaning of a rule is that if its body evaluates to true, its head must also evaluate to true. The *Happens* predicates in a rule which have no constraints for their lower and upper time boundaries are what we call "unconstrained" predicates. During the monitoring process, rules are activated by events that can be unified with the unconstrained *Happens* predicates in them. When this unification is possible, the monitor generates a rule instance to represent the partially unified rule and keeps this instance active until all the other predicates in it have been successfully unified with events and fluents of appropriate types or it is deduced that no further unifications are possible. In the latter case, the rule instance is deleted. When a rule instance is fully unified, the monitor checks if the particular instantiation that it expresses is satisfied.

An example of a rule that can be expressed in the EC language of our framework is given by the formula below:

Rule 1: $\forall$ _eID1,_C1,_C3:String; t1:Time
Happens(e(_eID1,_C3,_C1, REQ, authorise(),
_C3),t1,$\Re$(t1,t1)) $\Rightarrow \exists$ _eID2:String ; t2:Time
Happens(e(_eID2,_C3,_C1, REQ, authorise(),
_C1),t2,$\Re$(t1+1,t1+10))

This rule states that when an event *e(_eID1,_C3,_C1, REQ, authorise(), _C3),t1,*$\Re$*(t1,t1))* representing a call of the operation *authorise()* in a component *_C1* by a component *_C3* is dispatched, it must be followed by an event *e(_eID2, _C3, _C1, RES, authorise(), _C1)* represening the receipt of the call by *_C1* in no more than 10 time units after the dispatch of call. Thus, *Rule 1* expresses a bounded availability property for the communication channel between the component *_C3* and other components of the system (*_C1*) since it requires that the requests generated by *_C3* are transmitted within a bounded time period.

The unconstrained predicate in this rule is the predicate *Happens*(e_1^{C3}, *t1,*$\Re$*(t1,t1))*[1], since the lower and upper bounds of its time variable are defined without any references to other time variables in the rule. Thus, at runtime, new instances of *Rule 1* will be generated as soon as an event that can be unified with this predicate is received. Each of these rule instances will remain alive until it is fully unified or until no further unification of an event representing the receipt of a response of the call dispatched by *_C3* in the rule instance is possible.

Note that, as in the above example, our framework requires all the constrained predicates in a rule to have time variables with constrained upper bounds. This is to ensure that rules can be verified. For example, if the *Happens* predicate for e_2^{C1} in the head of *Rule 1* did not have an upper bound, then its absence would never cause the monitor to flag the rule as violated, since the monitor would always wait for some e_2^{C1} event at some point in the future.

3. COMPUTING LIFETIME OF EVENTS

As we discussed in Section 1, the problem that arises with the use of events which are generated by distributed sources is two-fold: firstly we need to synchronise the clocks of the different event sources so that the timestamps of the events that they generate can be comparable to each other and secondly we need to know until when we need to store a particular event in order to be able to reason about the system state and check rules. The clock synchronisation that is performed through the use of the Network Time Protocol (NTP) by our framework solves the first problem but not the second.

To appreciate the second problem, consider *Rule 1*, assuming without loss of generality that *_C3* and *_C1* denote both the source of the event and the clock of the source system component where the event was captured. As the occurrence of events of type e_1^{C3} in *Rule 1* is unconstrained, events of this type can instantiate the rule during monitoring. Unlike them, events of type e_2^{C1} are temporally constrained by e_1^{C3} events in the rule and cannot, therefore, create new instances of the rule; they can only be unified with existing rule instances.

[1] e_1^{C3} is an abbreviated reference to the event *e(_eID1,_C3,_C1, REQ, authorise(), _C3)*, in which the subscript denotes to the event ID and the superscript to the event source. Such abbreviated references are used in the rest of the paper in all cases where other event variables are not important.

Thus, if the monitor receives an event of type e_2^{C1}, in addition to unifying it with all the current instances of *Rule 1*, it must keep it until there is no possibility to receive an e_1^{C3} event that could be correlated with e_2^{C1} through *Rule 1*. This is necessary since if e_2^{C1} is dropped and later the monitor receives an e_1^{C3} event with an earlier timestamp than e_2^{C1}, it would report a false violation of *Rule 1*. The possibility of e_1^{C3} and e_2^{C1} events arriving at the monitor in the opposite order of their occurrence arises due to different (and dynamically changing) communication delays in the channels that connect C_1 and C_3 with the monitor or even attacks in these channels that can cause the loss of events. Whilst keeping events of type e_2^{C1} in this case is necessary for the soundness of the monitoring results, the monitor must also ensure that it keeps these events only for the maximum time that is necessary for the soundness of the results. This is because if the monitor keeps them longer the size of its event store will increase monotonically with a deteriorating effect on both the space and time required for monitoring. The maximum time point until when events e_2^{C1} would need to be kept by the monitor, in this example, can be established by finding the maximum value of the time variable t1 of e_1^{C3} events that satisfies the constraints: (1) $t1 \leq t2-1$ and (2) $t2 \leq t1+10$.

In general, for a rule with *n+1 Happens* predicates, there will be *2n+1* such inequalities to solve. This is because one of the rule predicates is unconstrained (the one firing the rule), the remaining *Happens* predicates contribute two inequalities each, and we need an extra equality to establish the exact value for the time variable of the event in question (t2 in our previous example with the e_2^{C1} events).

Figure 2 shows the algorithm for computing the lifetimes of an event. According to this algorithm, when an event *e* occurs, the set *R(e)* of rules which have predicates that can be unified with the event *e* is determined (this set includes rules that have event types which are the same as the type of *e* or supertypes of it). The set *R(e)* will include rules that may specify time constraints for the event that cannot be fully evaluated yet. Subsequently, the constraints of each rule in *R(e)* are identified and expanded with an equality expressing that the time variable of the predicate of the rule that has been unified with *e* is equal to the timestamp of *e* (step 2.a). Given the time constraint set that results from this process, the algorithm computes the maximum possible value for each of the time variables of the rule using the *Simplex* method [8] (step 2.b.i). Subsequently, it groups the different time variables according to the clock of the event source they are related to (step 3), and generates a set of all the conditions (*Lifetime(e)*) for computing the upper bound of the lifetime of *e* (step 4). A condition in *Lifetime(e)* states that *e* won't be needed after the last event that is seen from a channel which is relevant to *e* has a timestamp ($last\_observed(c_j)$) that is greater than the maximum possible value of the time variables grouped in this channel's group (see condition $last\_observed(c_j) > max_{t_i \in G_j}(max(t_i))$). The reason for using the timestamp of the last event that has been observed from a clock in the evaluation of the *Lifetime(e)* conditions is because events are communicated to the monitor through TCP/IP sockets which *guarantee* a FIFO transmission within the same component (clock)-monitor channel. The conditions in *Lifetime(e)* determine the lifetime of e since when their conjuction becomes true, the lifetime of *e* will expire.

Compute_Lifetime(e):

1. $R(e) = \{ r \mid r$ has a predicate p that can be unified with e$\}$
2. Forall $r \in R(e)$ do
   a. $CN_r = \{$time constraints of r$\} \cup \{$time variable of predicate p that matches e = timestamp of e$\}$
   b. Forall $t_i \in CN_r$ do
      i. Find $max(t_i)$ given CN_r
3. Group the time variables t_i into as many groups G_j as the different event sources (clocks) c_j in $R(e)$
4. $Lifetime(e) = \cup_j ((last\_observed(c_j) > max_{t_i \in G_j}(max(t_i))))$

Figure 2: Computing the lifetime of an event – I

In our previous example, if *Rule 1* is the only rule that is being monitored and an event of type e_2^{C1} is observed at t2=10, step 1 will produce the set $R(e_2^{C1}) = \{Rule\text{-}1\}$, step 2.a will produce $CN_r = \{t1 \leq t2-1, t2 \leq t1 + 10, t2 = 10\}$, step 2.b.i will produce the solutions $max(t1)=9$ and $max(t2)=10$ by finding the maximum value of t1 for which the constraints in CN_r are satisfied, and step 3 will produce two groups of time variables $\{t1\}$ and $\{t2\}$, for the two clocks C_1 and C_3, respectively. Finally, in step 4, the lifetime constraint set for e_2^{C1} will be established as:
$Lifetime(e_2^{C1}) = \{(last\_observed(C1)>10), (last\_observed(C3) > 9)\}$.

It should be noted that our algorithm uses the Simplex method, which has exponential complexity $O(2^n)$ (for a problem with *n* variables [8]), to find the maximum time of a time variable in *step 2.b.i.*, although there are algorithms with polynomial compexity (the worst case complexity of Karmarkar's algorithm [1], for example, is $O(n^{3.5})$). This is because for small numbers of variables, as the ones normally appearing in monitoring rules ($n \leq 10$), Simplex has better performance. Furthermore, the algorithm of Figure 2 computes the maximum value of a time variable for each rule separately, rather than combining them into a single larger problem. This is because the individual rule problems can be solved independently and a larger set of rules would take more time to solve due to the additional time variables (in general $2^n + 2^m < 2^{n+m}$ for $n,m \geq 2$). Due to this approach, once the individual rule systems have been solved, the different time variables that are associated with events

coming from the same clock need to be grouped together, as done in step 3 of the algorithm.

Note that at this step, the algorithm of Figure 2 assumes that the clocks/sources of the events in the rules are fully specified when a rule is matched with an incoming event. In the example of *Rule 1* this is the case, since the sender of an event e_2^{C1} (i.e. C3) is also the source of events e_1^{C3}. Thus, when *Rule 1* is matched with an e_2^{C1} event, the identity of C3 becomes known. However, there might be cases where the exact source of events that could potentially be matched with a rule is not known after the rule is matched with arrived events. Consider, for instance, the following rule:

Rule 2:

∀ _eID1, _eID2, _U: String; _C1,
_C3: Terminal; _C2: Component; t1, t2:Time
Happens(e(_eID1,_C1,_C2, REQ, login(_U,_C1),
_C1),t1,ℜ(t1,t1)) ∧
Happens(e(_eID2,_C3,_C2, REQ, login(_U,_C3),
_C3),t2,ℜ(t1,t2)) ∧ _C1 ≠_C3 ⇒ ∃ _eID3: String; t3:Time
Happens(e(_eID3,_C1,_C2, REQ-A, logout(_X,_C1),
_C1),t3,ℜ(t1+1,t2-1))

This rule requires that if a user *_U* logs in to a system *_C2* from a terminal *_C1* and later he/she logs in again from a different terminal *_C3*, he/she must have logged out from the former terminal before the second login. The rule effectively monitors cases where users are logged in from different terminals at the same time. When an event *e(_eID2,_C3,_C2, REQ, login(_U,_C3), _C3)* (or e_2^{C3} in our abbreviated form) arrives at the monitor, its lifetime will need to be estimated in reference to the maximum possible values of time variables *t1* and *t3*. In this case, however, the algorithm of Figure 2 does not work, since at step 3 it is not known which other terminals the user of e_2^{C3} may be using or, equivalently, which source clocks should be associated with the time variables *t1* and *t3*.

Compute_Lifetime(e):

1. *R(e) = { r | r has a predicate p which unifies with e}*
2. Forall $r \in R(e)$ do
   a. CN_r= {time constraints of r} ∪ { time variable of predicate p that matches e = timestamp of e}
   b. Forall $t_i \in CN_r$ do
      i. Find $max(t_i)$ given CN_r
3. Group the time variables t_i into as many group types TG_u as the different types of event sources c_u in *R(e)*
4. Forall group types $g \in TG_u$ do
   c. Forall the known sources *j* of type *g* do
      i. Create a group G_j and assign copies of the time variables of *g* to it
5. $Lifetime(e) = \cup_j \{(last\_observed(c_j) > max_{t_i \in G_j}(max(t_i)))\}$

Figure 3: Computing the lifetime of an event – II

To deal with such cases, we use an extension of the algorithm, shown in Figure 3. The extended algorithm initially groups time variables into groups corresponding to the types of the event sources that are associated with them in the rules. Then, for each of the source type groups, it finds all the sources of the particular type that are known to the system, creates different groups for them and assigns copies of the time variables of each source type to each of the source groups that were generated from the type. Thus, if it is known that the system that is being monitored with *Rule 2* has 3 terminals, the algorithm of Figure 3 will create different variable groups for each of these terminals and assign copies of the time variables *t1* and *t2* to each of these groups.

Having computed the *Lifetime(e)* constraint set, upon the arrival of an event *e* at runtime we use it to compute a vector with the maximum time values for *e* with respect to the different clocks related to it. For the ongoing example of *Rule 1*, the vector of e_2^{C1} would be < 10, 9 >. The event and its vector are then stored in the database of the monitor. Also, when a new event arrives at it, the monitor checks if the lifetime of some other events which depend on the clock of the new event has expired. The above process is shown in Figure 4.

1. Observe an event *e*
2. Update the global vector of observed clock values
3. Lifetime(*e*) = Compute_Lifetime(*e*)
4. Store *e* in the DB with its vector of different clock limits
5. Remove events from the DB if their clock limits have been exceeded

Figure 4: Using event lifetimes

4. RELATED WORK

Forms of dynamic verification have been developed and investigated in the context of program verification, safety critical, and service centric systems.

In program verification, research has focused on the development of programming platforms with generic monitoring capabilities, including support for generating program events at runtime (e.g. jMonitor [11]), embedding specifications of monitorable properties into programs and producing code that can verify these properties during program execution (e.g. monitoring-oriented programming [4] and [6]). There is also work focusing on runtime verification of requirements specifications [7]. However, metric time is not considered in [4], [6], [7] or [11]. Runtime monitoring methods have also been applied to autonomous safety critical systems [16], as the testing of such systems is difficult and resource consuming. In service-centric systems, dynamic verification has focused on monitoring *service level agreements* (SLAs) [2][20]. In safety critical systems, early monitoring methods focused on detecting timing failures and guaranteeing system responsiveness [9][15]. Though [15] supports timing constraints, it does not support distributed monitoring. The distributed

monitoring of [9] on the other hand does not support fluents or general expressions for time and does not clarify how the bound of the size of the event histories is decided. Event correlation has also been considered in [18] where event observers are produced as transducer automata recognizing and rewriting the input events. Compared to our framework, the approach in [18] does not support fluents or metric time.

The extension of the framework in [20] with the capabilities described in this paper makes it possible to verify complex properties, based on events captured from distributed sources, thus, exceeding the capabilities of other approaches.

5. CONCLUSIONS

In this paper we have presented extensions of the monitoring framework described in [20] that render it applicable to multi-clock distributed systems. Our extensions address two of the problems of distributed systems monitoring: (1) the need for synchronizing the clocks of different event sources so that the events they emit can be correlated, and (2) the estimation of the lifetime of events within the monitor in order to ensure that unknown transmission delays of other events that may need to be correlated with them will not affect the monitoring process. To address the first of these problems, we have incorporated an implementation of the NTP protocol in our framework. To address the second problem, we compute the maximum lifetime of an event by identifying, the constraints between the time variable of the event and time variables of other events that co-exist with it in rules and solving these constraints to find the maximum possible lifetime for the event using the Simplex method (see [12] for full details).

One possible optimisation of our solution is to statically solve all the linear constraint systems at initialisation, so as to only need to instantiate the specific values of the different timestamps associated with a new event and its related rules when the event arrives, instead of solving the corresponding linear system each time. This would require a symbolic solution of the linear constraints system instead of the more straightforward numerical solution which we currently employ. For this reason we have decided against the symbolic solution in the current implementation, and intend to examine this option once we have gained more experience with the behaviour of the current implementation in a distributed setting.

ABSTRACT

In this paper we present (1) a method for semantic search supported by ontological concept learning; and (2) a prototype multiagent system that can handle semantic search and encapsulate the complexity of such process from the users. Agents which conduct semantic search on behalf of a user, deploy ontologies to organize structured and unstructured documents in their corresponding repositories. The ontology for each repository is individualized and commitment to a common ontology is not required. The agents can improve their search capability by learning new concepts from each other. This method thus allows agents dynamically establish common grounds on concepts known only to some of them. The concept learning is realized by analyzing positive and negative examples from other agents, and/or taking votes in case of conflicts in the received knowledge by involving other agents again.

Index Terms — multi-agent system, semantic search, ontology, concept learning, semantic interoperability.

1. INTRODUCTION

In contrast with the traditional keyword search technology which purely depends on the occurrence of words in documents, semantic search denotes one or more concepts in the context of other concepts. Understanding the denotation of concepts can help retrieval part of search engine understand the context of search, the activity the users is trying to perform, thus drive expectations on the categories of documents [6]. The essence of semantic search is semantic interoperation towards denotation part in the search phrase. Nowadays, general denotation procedures are realized depending on ontology-oriented means, and ontologies adopted are usually evolved and maintained in a distributed way. Thus, multiplicity of ontologies raises the issue of integration and renders the communication between peers involved in a semantic search ineffective.

Establishment of a common ontology for a certain domain is one of the cornerstone among cooperative agents (peers) participating in semantic search. However, agreeing on a common ontology may not be realistic. In multi-agent systems (MAS) research concerning agents' communication, having a common ontology is only possible when the design rationale, the concepts and meanings assigned to the concepts as well as the context of applying the concepts are shared. In other words, the agents must be designed in such a way that all the domain concepts and their meaning (i.e. semantics) should be provided in advance. In heterogeneous MAS, for a single domain, usually there is no agreement on the ontology among developers, and for several domains, the potential ontologies are large, unwieldy and may lead to less resolution and higher abstraction.

Recently, the idea of having agents *learn* concepts from each other has been suggested as a solution to improve agent communication. For example, the work in [8] suggests a method for learning a language and the work in [9] has focused on interactions between two agents to learn a single concept. In our previous work, we have presented a method for agents to learn concepts from several peer agents [1-2] and a method for verification of the learnt concepts [5].

Euzenat in [4] defines semantic interoperability as the faculty of interpreting the annotations at the semantic level, i.e. to ascribe each imported piece of knowledge to the correct interpretation or set of models. Possible levels of interoperability needed to be considered when trying to understand an expression from other systems are in ascending order of semantic intensity:

- *encoding*: being able to segment the representation in characters;
- *lexical*: being able to segment the representation in words (or symbols);
- *syntactic*: being able to structure the representation in structured sentences (or formulas or assertions);
- *semantic*: being able to construct the propositional meaning of the representation;

- *semiotic*: being able to construct the pragmatic meaning of the representation (or its meaning in context).

This model resembles humans' natural communication style that each semantic level can be achieved only if the lower ones have been traversed. For example, people can exchange useful information only if they have chosen a language, and clarified meanings of concepts which are critical to the topic. The idea of layered semantic interoperability has already been applied to the WWW [3] and is directly applied in our architecture of layered semantic search.

In this paper we present a method and a system that uses the ontology learning in a multi-layer semantic search. The architecture and learning supported search mechanism will be explained through the prototype system in Sections 2 and 3. The implementation details are provided in Section 4 followed by an example in Section 5 and conclusions in Section 6.

2. LAYERED SEMANTIC SEARCH ARCHITECTURE

Based on the semantic interoperability model [4], we have devised the layered semantic search architecture as illustrated in Figure 1. In this model peers can communicate and conduct search at various levels. This layered architecture will reduce complexity by breaking complex semantic interoperability into smaller problems; it standardizes interfaces between adjacent layers; it facilitates modular engineering and development of search tools; and

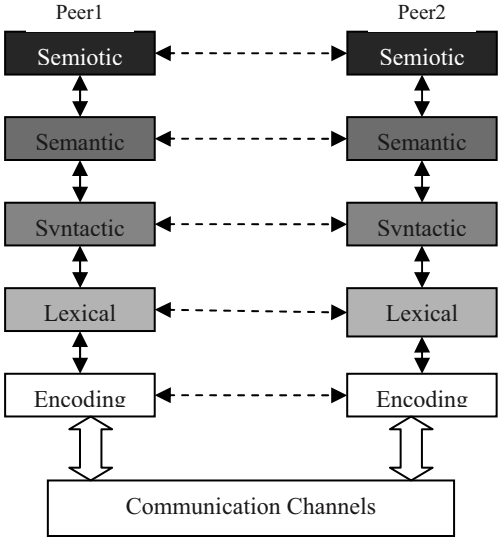

Figure 1. Architecture of layered semantic search

it accelerates evolution of technology.

The model puts some constraints on the communication between peers, namely:

1. One layer only talks with its peer layer on remote side under some agreements (or protocols). These agreements help both sides to settle natural languages, encoding standards for exchanging information, representation grammar of search phrase, etc.
2. A search phrase can be optionally initiated at any layer, then will be passed down, layer by layer, to the bottom layer (encoding layer). Each layer will add corresponding annotation information to the search phrase. Packaged phrase, finally, will be sent out.
3. Each layer can work relying on the ontology located on the same layer of semantics.

Definitions of functionalities of layers of semantic interoperability are given below.

The **encoding layer**, as base layer, defines encoding format of data exchange, thus implicitly defines the character sets of a natural language for exchanging a search phrase. ASCII and Unicode are mainly used as encoding formats. The **lexical layer** tokenizes the search phrase. At this layer, important identifiers of ontology components are identified. Functionality of this layer is not easily realizable for some natural languages such as Chinese because tokenization of sentences is a big issue due to the lack of explicit delimiter, except for punctuation, to separate each single word (or symbol). The **syntactical layer** identifies concepts by structuring words following grammar at query side, and it is capable of understanding the structured representation to extract concepts at responding side. The **semantic layer** provides ability to understand propositional meaning of the representation of search phrase. The **semiotic layer** provides ability to understand meaning of the representation of search phrase in a context (specific domain). The objective of this paper is to design and implement a prototype semantic search system to study annotation-learning workflow with focus on the lexical layer.

3. SYSTEM ANALYSIS AND DESIGN

The overview of prototype system for annotation-learning workflow within lexical layer is shown in Figure 2. In this system, software agents form a cooperative group to learn and search concepts. Each agent is responsible for a local unstructured data repository with a local ontology. The agents are responsible for organizing documents in their own repositories using any ontology they deem appropriate. The agents also communicate with each other to respond to search queries.

The system design assumptions, following the FIPA guidelines (http://www.fipa.org) are:

a) MAS is a close cooperative group. It means that there is, at least, one agent taking charge of registering service. Any other agent joining the group needs to register by offering its necessary information such service type and access point.
b) There is, at least, one agent that provides yellow page service to enable agents find each other.

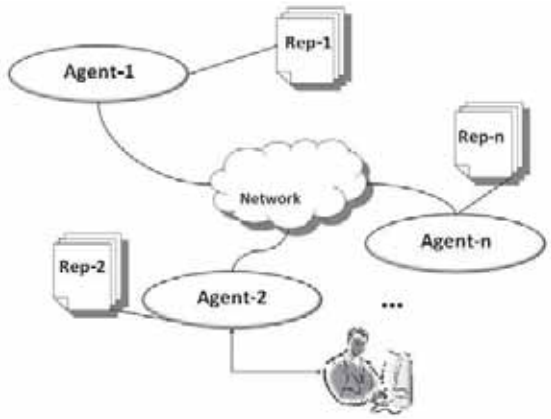

Figure 2. System overview

GAIA design methodology [10] is used to design the MAS. Each individual agent currently holds 4 roles: *Document Annotator*, *Concept Learner*, *Register Handler*, and *Concept Manager*. IBM's UIMA [7] is used to enable dynamical annotation of documents, and, therefore, enable classification of documents within their own repository. In a later phase, we will utilize an addition *Peer Finder* role to create an open cooperative MAS that enables agents automatically find each other. Details of the annotator and learner roles are explained below.

3.1. Document Annotator

Regular search usually is capable of finding tokens without any relationship between them. The tokens are not able to reflect domain-specific properties similar to atoms in early chemistry which are unable to retain chemical properties of a complex chemical substance.

The documents annotator in this project is aiming at annotating "molecules", special combinations of tokens, on which some well-defined constraints are applied. Creating such type of annotation, especially dynamically creating annotations is a fundamental role, not only for concept learning, but also for semantic search involving newly learnt concept. As the following formula describes,

$$\textit{Annotation} = F_{constraints}(token1, token2, \ldots).$$

Constraints can be, for example, window size, appearing order within certain window size of text, etc. The annotation process is depicted in Figure 3. The methods used in the annotation process are:

CreateConceptHierarchy([concept], keyword1, keyword2, …, CH1)
Annotator first creates a Concept Hierarchy (CH) using received series of keywords. This CH directly goes into the Annotation Engine (AE) to tell what is needed to be searched from the document repository.

CreateAnnotationEngine (Type1, AE1)
This method takes CH as a parameter to dynamically build Annotation Engine (AE) which is the algorithm's container.

DoAnnotation(Annotator1, Doc1, Doc2, …)
Once annotation engine is created, it will be run against repository to annotate and grab satisfying documents.

ReplyQuery(Annotated Documents, PositiveExamples, NegtiveExamples)
This method takes charge of replying to query. In this project, it also implements some specific filtering work such as selection of positive examples and creation of negative examples (see Section 3.2 for details).

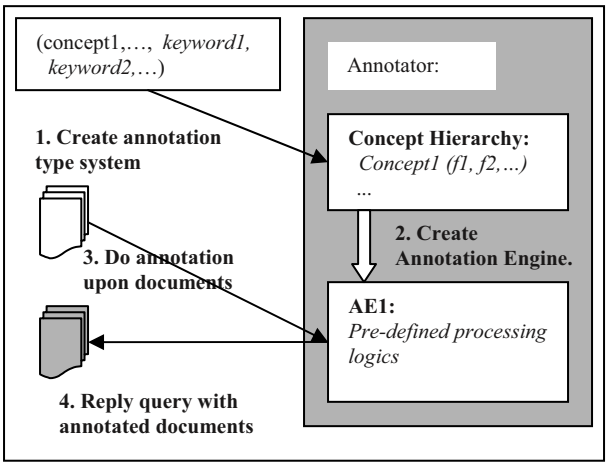

Figure 3. Process of Documents Annotation

3.2. Concept Learner

An agent knowing a concept is equivalent to having a defined classifier for that concept. The classifier is a binary function which decides whether a new incoming document belongs to (or explains) the concept. The *Concept Learner* role is used to generate this classifier.

We adopt a feature-based representation model to represent concepts. That is, each concept is composed of a set of features or keywords which are regarded as the best representation of this concept. For each concept, there exists a set of documents whose major topic belongs to this concept. Those documents are called positive objects for this concept. The list of features can be generated from the positive objects using a simple statistics method [11]. The similarity between a pair of concepts is defined as:

Sc_1,c_2: Similarity between concept c_1 and concept c_2

$Nc_1 \cap c_2$: Number of documents that belong to both concept c_1 and concept c_2 (with relevance degree greater that a defined threshold)

$Nc_1 U c_2$: Number of documents that belong to either concept c_1 or concept c_2.

Based on this definition for each concept set we have an ontology matrix as shown in Figure 4. The values in this matrix denote the similarity value between pairs of concepts. For example, the similarity value between c_1 and c_2 is 0.8, and there is no relationship between concept c_1 and c_3 since the similarity value between them is zero.

	c_1	c_2	c_3
c_1	1	0.8	0
c_2	0.8	1	0
c_3	0	0	1

Figure 4. Ontology Matrix

The learner is based on the training set available. For each concept, we select a set of positive objects (documents in this case) belonging to the concept and a corresponding set of negative objects using the ontology matrix. For example, if we want to create a classifier for concept c_1, we choose positive examples from the documents assigned to concept c_1. For negative examples, we choose documents which belong to concept c_3 because those documents do not represent concept c_1. This mechanism may not always lead to an optimum learning and we have investigated other algorithms [2]. Finally, using the positive and negative examples, we adopt a data mining algorithm to train and get the classifier for concept c_1.

3.2.1. Concept Learning Process

We illustrate the learning process using the following actions (see Figure 5).

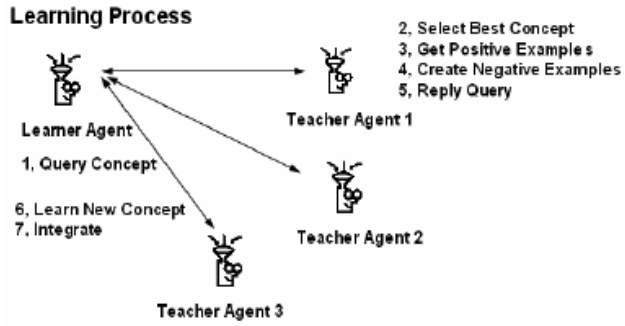

Figure 5: Concept Learning Process

QueryConcept ("keyword1", "keyword2", …)
The learner agent will start the concept learning by issuing action *QueryConcept* which will send the query to other agents. The parameters it takes are a list of keywords representing features of a potential concept.

SelectBestConcept ("keyword1", "keyword2", …)
On the receiver side, the agent first uses keywords to build annotator dynamically which then is used to annotate the candidate documents.

SelectPosEx(concept)
After getting the best concept and candidate documents associated to this concept, the receiver agent will select a given number of positive examples from the candidate documents.

CreateNegEx (concept)
The receiver agent also performs this action to produce a given number of negative examples for the concept based on the ontology matrix.

ReplyQuery(pi, ni)
The receiver agent i sends back the positive (p_i) and negative (n_i) examples to the learner agent.

Learn ((p1,n1), (p2,n2), …)
The learner agent will take all the documents transferred from the teacher agents as the training documents to form a new concept. We have examined various data mining algorithms such as Naïve Bayes and SVM. If there are any conflicting documents, they are dismissed. It means only documents which are agreed by all the agents are regarded as the documents under the new concept.

Integrate (concept)
With the new concept from the method *Learn*, the learner agent will assign a temporary name to it and suggests it to the administrator of the learner system. The administrator can approve the concept, assigns a meaningful name to it and add it to the local repository.

4. IMPLEMENTATION

4.1 System Architecture

Figure 6 shows the prototype system. Document Annotator is developed using IBM's UIMA (Unstructured Information Management Architecture) [7]. IDE Eclipse Europa is selected because it supports UIMA and Apache Tomcat http://www.eclipse.org/europa/) which is used to deploy document annotation service in this project. UIMA is featured by *type system* in which the data has a type and a set of *attribute*, *value* pairs [7], so that it is conceptually identical to concept from our point of view.

4.2. Document Annotator

The components to fulfill actions C*reateConceptHierarchy, CreateAnnotationEngine, DoAnnotation,* and *ReplyQuery* need to be built to form a complete Annotator. Central task is to deal with creation of type system.

4.2.1. Creation of Type System

According to type system definition specification [7], the first step is to build XML-based type system descriptor. Figure 7 shows an actual descriptor from the project. This is an aggregate type system which is composed of several basic primitive types. The lines enclosed by an oval represent one type definition which includes name, description, super-type name, and its features. UIMA provides APIs to build class components to dynamically adjust contents of descriptors and create a corresponding Java class.

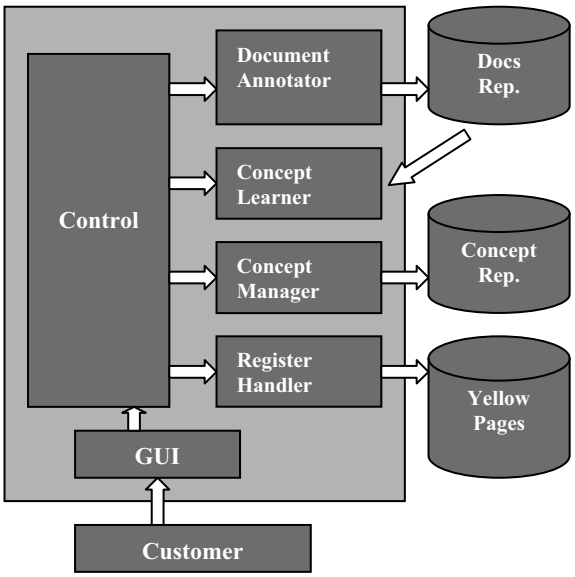

Figure 6. Architecture of Prototype System

4.2.2. Creation of Annotation Engine (AE)

Developer of an annotator has to implement a standard interface having several methods, such as *initialize()*, *process()* and *destroy()* to embed processing logic into it.

There are two ways for creator to tell *process()* method which types need to take and which types need to produce. One is manually creating a component descriptor which is XML-based document, like type system descriptor; another is using APIs that come along with UIMA to dynamically set this component descriptor. The latter is preferable because developer can select input/output type system at run-time. Immediately after the Annotation Engine is created, the *process()* will take over to scan documents and produce types as specified in AE descriptor.

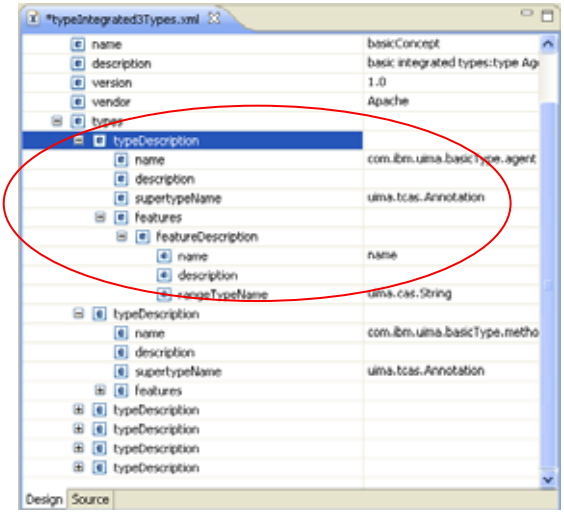

Figure 7. A Type System Descriptor

4.3. Concept Learner

The *Concept Learner* role is responsible for implementing action *Learn* which takes training documents as input, and produces concept classifier.

4.4. Concept Manager

Concept Manager role helps agent to manage set of concepts coming from three sources: newly learnt through training, selected by experts of specific domain, and newly learnt through semantic search. It need implement actions: *SaveConcept, RetrieveConcept.*

5. ILLUSTRATIVE EXAMPLE

To illustrate semantic search-learning process, here we provide a simple but illustrative example. In this scenario, three existing repositories of documents concentrating on software testing (R_{test}), object-oriented analysis and design (R_{oo}), and agent-based software engineering (R_{agent}) are created. Agent-based software engineering (R_{agent}) is considered as the local repository.

In the local repository there are several documents: some of them are about MAS methodology; some about other concepts. The initial status, as shown in Figure 8, tells that all documents, having not been annotated, are organized in flat structure.

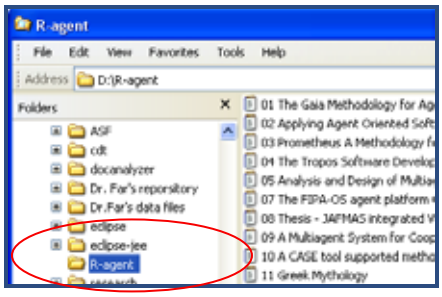

Figure 8. Snapshot of Initial Repository

Based on current status, a regular query, as shown in Figure 9, is initiated. In this case, a user wants to know "what the token Prometheus means in software engineering". Processing this query with no semantic search (as depicted by empty "Concepts" box in Figure 9) will return two documents, with completely different contents. The document 03 is talking about Prometheus MAS design methodology; meanwhile, the document 11 is about Greek mythology which is apparently not the one that user intended to receive.

To disambiguate search results, the agents will take the following steps to kick off a semantic search:

1. A concept learning routine is started to evaluate returned documents, through which new concepts, for example, "agent" (including its features) is identified; it then will be propagated within the group (see [11] for details).

2. Each agent, upon receiving this concept, will annotate its own repository. Annotation procedure re-categorizes repository by conforming to concept hierarchy. Figure 10 shows changes happened to repository R-agent.
3. New concepts will be added to the concept repository in order to support decoding query phrase, or searching.

Figure 9. Illustration of Regular Search Procedure

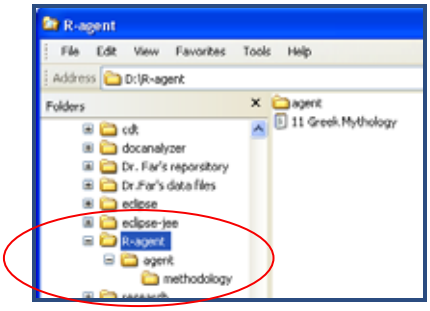

Figure 10. Snapshot of Annotated Repository

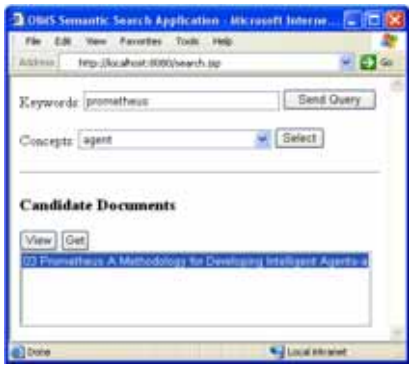

Figure 11. Illustration of Semantic Search Procedure

Once these steps are completed, a next round of search will start by involving the newly learnt concepts. Figure 11 shows a disambiguated result by sending query phrase consisting of both keywords and concepts.

From the procedure explained above, we can conclude that dynamical annotation guided by concept hierarchy is capable of categorizing the repository, consequently, making retrieval of documents more efficient.

6. CONCLUSION AND FUTURE WORK

In this paper we presented a method and a prototype MAS for semantic search-learning. This method is based on the architecture of layered semantic interoperability. The central procedure is composed of dynamical document annotation and concept learning mechanisms to solve the problem of semantic heterogeneity in distributed information management with minimum overhead and no need to commit to a common ontology. From the implementation, we can conclude that the semantic search supported by concept learning is a generative evolutional procedure. It is started by a regular search leading to learning a new concept. Then later the learnt concept is used in semantic search, and the search resolution will improve.

Future work includes implementation of the role *PeerFinder* which will lead to an open MAS. Also, research efforts will be put on organizing concepts into a hierarchy through learning. Finally, based on research achievements, we will propose a protocol for search on other layers of the semantic interoperability model.

Abstract—Program comprehension's importance as a research field has recently increased. In fact the task of understanding the working of a program roughly represents half of the maintenance costs. Our approach to software comprehension is to map the high level models of the system to the source code. The building of the models follows the technique proposed in the Unified Process (UP). The model recovery process, that has been presented elsewhere, rested so far on manual techniques. But to offer a real help to software maintainers, it should be automated. This papers presents the tools we built to automate the mapping of high level business and system models to the source code. These tools use artificial intelligence techniques to make heuristic search of the possible maps between the models. After having explained the way we solved the problem, the paper shows a comparison of the performance of the tool as compared to the manual application of the process on a real industrial software.

1. Introduction

It is commonly known that maintenance is the most expensive part in the life cycle of a software system; it represents between 60% and 90% of the total cost of a program [8]. It is less commonly known (yet extremely interesting) that almost two thirds of the maintenance cost are devoted to software comprehension or understanding [16]. The importance of program comprehension in maintenance comes from the nature of reengineering. In fact, before being able to restructure or re-implement a legacy program it is necessary to understand its working and its functional architecture [2]. During the process of implementing a program, developer's understanding of the program grows since they have to keep in mind which elements of the system satisfies what part of the specifications. Unconsciously, developers build a mental mapping between the problem domain elements (business domain or real world) and the elements of the system domain (source code) [20][23]. This mapping represents their understanding of the program being developped. This mental process agrees with the following definition of program comprehension [1]:

"A person understands a program when able to explain the program, its structure, its behavior, its effects on its operational context, and its relationships to its application domain in terms that are qualitatively different from the tokens used to construct the source code of the program."

The rebuilding of these mental mappings seems then necessary for program comprehension. It allows understanding of the system domain components by linking them to business domain components. The surprising fact is that most of the remarkable techniques for program comprehension or reengineering fail to take domain elements into account and focus mainly on the syntactical features of the programs [3].

A reengineering methodology, relying as much on the analysis of the properties of source code as on the existence of the mapping between the domain and the code is proposed in [3]. This methodology allows the construction of a "bridge" between the source code of a program and its analysis diagram (robustness diagram) as reconstructed from the specifications. It is important to note that this methodology has been empirically tested on a real life legacy system [14] leading to the next natural step: automating. This has been done using artificial intelligence and knowledge engineering techniques. This article focuses on these techniques and the results that have been obtained.

First, a brief reminder to our reengineering methodology is given in section 2. Then, Sections 3 and 4 focus on the system that has been built to automate the methodology. In section 5, we discuss the results comparing them, when possible, to the ones obtained manually by Jossi on the same system [14]. Section 6 presents the related work in domain-driven reverse-engineering and section 7 concludes the paper by explaining the future work.

2. Reengineering methodology

The methodology presented in [3] is based on the development process know as Rational Unified Process (RUP) [15]. Its goals are:

- To rebuild the domain and system models that a developer may have used during the forward engineering of the program.
- To construct a mapping between these models and the actual code of the system.

To tackle the reengineering problem in its greatest generality, the methodology considers the documentation of

the program as nonexistent and its original developers as unavailable. The lack of these two information sources forces the methodology to focus on the current state of the program and its actual users. In fact, even if the actual users of the program ignore everything about the implementation of the program, they represent an invaluable source of information on the business purpose and the features of the system. Then, the methodology suggests that actual users be consulted in order to gather information useful to rebuild the domain and system models.

Therefore, our reengineering methodology can be split in two phases, each one focusing in one of the two above-mentioned goals. To ease global comprehension, we refer to the normal way the RUP phases are developed as the "forward" direction (this is represented by the gray arrow in figure 1):

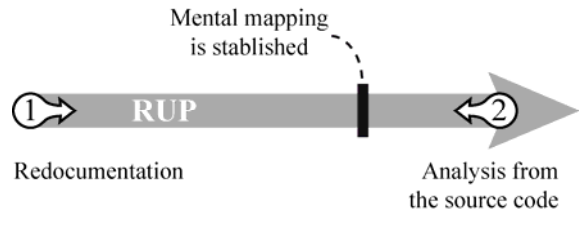

Figure 1: The two phases of our methodology.

The first phase focuses mostly on the re-documentation of the functional specifications of the program and their analysis. It is developed in the "forward" direction of RUP. In the second phase, we rebuild a mapping between analysis models and the source code of the programs. This is performed "backwards". The moment in the RUP timeline where these two phases meet might be seen as the moment in time where the mapping we're trying to rebuild was established by the original developers of the system. It is also the moment in time at which the maintainers of the program reestablish this knowledge.

A. First phase

The first phase focuses on re-building the business and system models. This ends up with the System Use-Case Model and the associated Analysis (Robustness) diagram. It follows the disciplines of the RUP:

- Reconstruction of the business models, Business Use-Case model and Business Analysis model.
- Reconstruction of the system models, the System Use-Case model and the Analysis (Robustness) diagram associated to every use-case.

The analysis diagram is built from the following analysis objects stereotypes [15]: Boundary (interface to the external world), Entity (information holder) and Control (orchestrator of the use-case's execution). Then, the above mentioned models allow us to establish the traceability links between the functional needs at the business level and the analysis objects that represent the corresponding system responsibilities.

B. Second phase

In this phase we concentrate on the mapping between the system models, especially the robustness diagram and the source code elements. By re-creating the links between the analysis objects and the classes of the programs we are able to close the traceability link from the high level business models and the implementation [4]. To create these links we use two kinds of techniques:

- **Static analysis:** this works on the static structure of both the source code and the robustness diagram. They are called static because they rest on the syntactic features of the elements.
- **Dynamic analysis:** this works on the features of the system that can only be observed at run-time. Most of this information concerns the interactions between the elements of the program, their frequency, their nature, and their order. By executing the system we will compare what actually happens inside the system with what was supposed to happen (as documented by the system models). We will then search for similarities that lead to the mappings.

We perform post-mortem dynamic analysis i.e. we generate an execution trace file during the execution of the system that we analyze off-line. One of the problems of dynamic analysis is to choose the scenario to execute on the system i.e. what action should the user perform for the execution trace to convey the required information [9]. Because of our approach, we concentrate on the recovered use-case of the system that represents what the users actually do with the system. Then, we gathered an execution trace for every use-case flow we recovered from the first phase of the methodology. This execution trace holds a sequence of operation invocations whose order is obviously *correlated* to the user manipulations. This observation is central to our reengineering methodology.

3. The platform

Three characteristics of both our methodology and the problem we are trying to solve had a strong impact on the way we implemented the platform:

1. We have described our approach to program comprehension as a forward and backward application of the RUP. Then, according to RUP, our methodology is iterative and incremental as well [4].
2. Most of the information used to rebuild the program and system models are gathered from the users. So, we cannot be sure of their accuracy.
3. Human reasoning is a logical process in which new information is obtained by evaluating previously known information [22]. Therefore, the platform should allow the revision of the old inferences in the light of new information.

By the way, it is interesting to note that the iterative nature of the RUP is at the same time necessary to the simulation of human reasoning. Indeed, obtaining new

information can be seen as one iteration of the simulation. Therefore, at each iteration, new information merges into the group of known information. These information units will be called *facts* from now on.

So far, it could seem that a production system (i.e. the artificial technique to simulate reasoning by production rules [17]) is all we need to perform the simulation. However, such a production system could not easily deal with uncertain facts. Then, our system should be able to revise its reasoning while new facts are generated by the production system. Consequently, we chose to adapt a TMS (Truth Maintenance System) [7] to control the production system as well as the set of facts produced and stored at each iteration. The TMS works with a Knowledge Base (KB) that holds all the facts generated by the production system. As we said, human reasoning generates new facts in an iterative fashion. This process could be decomposed into several smaller and simpler reasoning units which, together, perform the whole reasoning. These smaller reasoning units are called *inference rules* in the TMS paradigm.

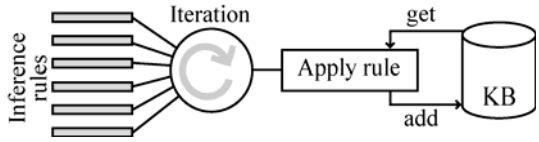

Figure 2: Our system components and process.

Figure 2 shows a representation of the elements composing our system: the KB and the set of inference rules. Its execution can be described as follows: the inference rules are applied iteratively on some of the facts in the KB, the facts produced by the inference rules are added to the KB at the end of each iteration. Then the TMS engine is responsible for assigning a level of certainty to each fact in the KB.

4. Mapping analysis objects to source code

There are two sources of information that are used to perform the search of the mappings:

1. The description of the use-case flows.
2. The execution trace gathered while executing the scenarios corresponding to the use-cases.

In fact, these are two representations of the same reality: the performance of a business function by the system. The first is located at the user level, the other at the system level. Since the operations of the system are called in the same order as the manipulation of the user, we should be able to correlate both representations. Use-case flows normally consist of a sequence of text-lines (steps) expressing the interaction of the user with the system and the response of the system. The information in this representation is not formalized thus leading to subjective interpretations. On the other hand, execution traces are made up of a sequence of operations called during the execution of the use-case, together with their actual parameters and returned values, making no room for misinterpretation. We considered that there were little chances to succeed in comparing both representations without first adding information to the use-case flows that would bring them closer to the elements observed in the execution traces.

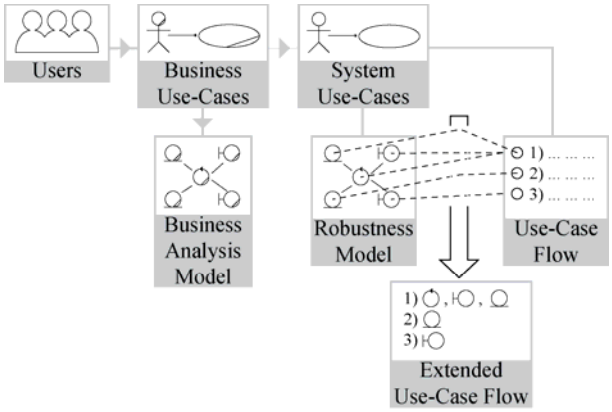

Figure 3: Building the extended use-case flows

Robustness diagrams are built by analyzing the use-case flows and determining which robustness diagram objects are involved at each step [15]. Most of the times, this mapping is not documented and generally lost because there is no need to keep it at the end of system development. In our case nevertheless, this relationship between use-case flow steps and analysis objects is exactly what we need to re-create. We then built the *extended flows* for each use-case containing, for each step, the list of the involved analysis objects. Figure 3 shows the process of building the extended flows.

Finally, from a close examination of the execution trace we realized that some of the modules are invoked all over the timeline of the execution. Since no objects exhibit such a behavior in the extended flow of the use-cases we pre-filtered the execution trace by removing these "omnipresent" modules since they are unmatchable.

A. Mapping the boundary objects

Boundary objects represent interfaces between the outside world and the system. The matching technique is to compare the positions of the occurrences of the boundary objects in the extended flow of the use-cases and in the execution trace. We should then be able to identify which source code components are likely to implement what boundary object. However, we cannot expect to observe an exact match, mostly because the density of occurrences is extremely different between the extended flows of the use-cases and the execution trace. Indeed, while occurrences in extended flows are a small multiple of the number of steps in a use-case flow, which stays generally under 50, the number of occurrences in a execution trace can easily count in thousands.

To bring the two descriptions close enough to find matches between their elements, two strategies are developed:

1. Bring down the number of occurrences of elements to analyze in the execution trace by filtering those that cannot implement a boundary object, based on syntactical considerations.
2. Summarize the multiple occurrences of a given element in the execution trace with a function computing the "density" of occurrence. This function allow us to bind an occurrence of the boundary object in the extended flow with the element of the execution trace that has the highest density of occurrence at the same moment in time.

Before talking about the actual implementation of these strategies, we need to clarify some of the terms used in our experimentation. The system on which our technique has been tested is an industrial package software. It is a fat-client kind of client-server system. The client is made of 240k lines of VB6 code. The server consists of 80k lines of PL/SQL code accessing an Oracle database. In this paper, for the sake of conciseness, we will concentrate on the reverse engineering of the client part of this system. The elements of the execution trace will be Visual Basic procedures invoked during the execution of the UC flows. These procedures belong to modules which represent the level of granularity we target in our mapping process: the analysis objects are mapped to VB modules.

The first strategy was performed manually by Jossi [14]. He manually selected, based on the extension of the file name, the modules in the source code that implement a window. This technique was easily automated on our platform, reducing from 363 to 12 the number of modules to look for in the trace file and from 27537 to 1954 the number of events to analyze in the execution trace. This filtering step has then become a proper inference rule in the production system. We now have to look for the mappings between the remaining modules and the boundary objects in the extended flows of the use-cases.

Our technique is to compute a measure of closeness between a module occurrence in the execution trace and a boundary object occurrence in the extended flow. First, we normalize the timeline of both descriptions, the extended flow and the execution trace, to the interval [0..1]. Every event will then take place in this normalized timeline. The closeness measure is not only computed on the base of the distance between occurrences but also on the following concepts:

- **Depth of the call:** since the robustness object in the extended flow of the use-cases are considered the key object implementing the behavior they should be readily visible in the execution trace. In other words they should not be deeply nested in the execution call chain. Then, we implemented the following heuristic: the deeper the invocation in the call chain, the less probable the match.
- **Coverage:** represent the extent of use of a module along the timeline. The more the spread of the occurrences of a module the larger the coverage. Therefore we favor modules whose occurrences are located in specific moment in time, over modules whose occurrences are evenly distributed along the timeline.

Finally, our closeness metric c is computed by the following formula where d, p and v represent distance, depth and coverage respectively:

$$c = \frac{1}{d}\left(\frac{1}{p}\right)^{K_1}\left(\frac{1}{v}\right)^{K_2} \qquad (1)$$

The values K_1 and K_2 have not yet been formally investigated so far. In our implementation, we empirically determined the best values by trial and error. The closeness formula computes the match between a single occurrence of a boundary object in the extended flow and an occurrence of a module in the execution trace. Next we must compute the match over the entire timeline of the execution of the use-case. In order to display the result as a graphic, we compute the moving average of the closeness value over the timeline. The result is presented in figure 4. The resulting value is called the "significance level" of a module to a boundary object. In this figure, the vertical axis represents the significance level of a particular module at the in time represented by the horizontal axis.

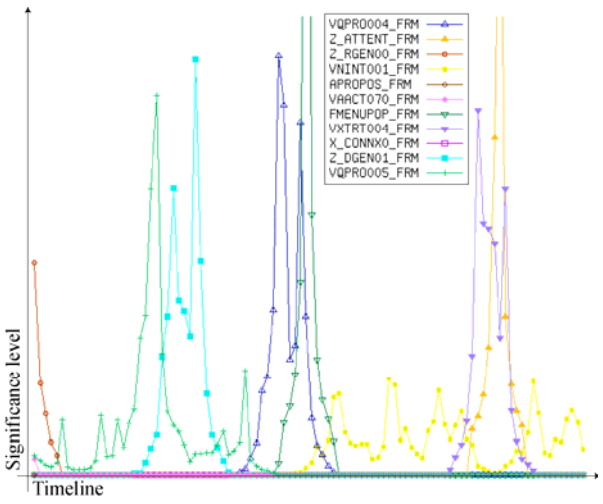

Figure 4: Significance levels for modules.

To establish the final mapping, we took each boundary object and computed, for every module, the mean of the significance value for each of the objects occurrences. We normalized the results for each boundary object so that their

sum was 1. This way we gave more importance to the high significant modules without overlooking the significance of other modules. The normalized values gave us a meaningful way of ordering the mappings between each boundary object and each module according to their likely match.

B. Mapping Entity objects

A first analysis of the modules used to access the tables has shown that all access went through the same few modules. In other words, there is no specificity of the modules to the entity objects of the robustness diagram. Therefore we decided that it would be more useful to re-create the mapping between the entity objects and the database tables that store the information represented by these objects. As before, we compared the occurrences of the objects in the extended flows of the UC and the table access in the execution trace. Then, we need to analyze the values of the parameters of the operations in the execution trace to find the strings corresponding to SQL queries. This activity has been automated by another heuristic rule.

Nevertheless, the mapping heuristic is different from the one we used to map boundary objects because:

1. The mapping of an entity object to a table can be observed as one global access or as many localized accesses. Therefore, coverage does not play any role in this mapping.
2. Unlike operations, there is no hierarchy of accesses to a table. Therefore, there is no equivalent to the depth of calls in the case of table access.

Distance between occurrences in the normalized timeline is the only measurement that we use in this rule to compute the closeness of the match. However, the mapping is much fuzzier in the case of database tables than modules because:

- The same table might be used to store several information items belonging to different entities.
- A table could be used in read mode to validate information stored in another table.

Therefore we decided to manage the match between the entity object occurrences and the table occurrence like the symptoms and illnesses in medical problem solving. In other words, the closeness between the object occurrences in the timeline and the table occurrence in the timeline is considered the symptom and a true correlation between both items (object and table) as the diagnosis. Then, we measure the specificity and sensibility of the relationship between the symptoms and the diagnosis as a way to evaluate the strength of the match. We proceed in two steps: first we compute the sensitivity then the specificity. To formalize the relationships between "symptoms" and "diagnosis", we use the following definitions:

- {T,O} represents the mapping between the table T and entity object O (i.e. the diagnosis)
- T | O represents the closeness between the positions of T and O on the timeline (i.e. the symptom). For the closeness to be true, the distance between the occurrence of the object and the table should not be larger than 5% of the timeline. We estimated empirically that a bigger distance would not let us to conclude anything.

Figure 5 presents the truth table for the closeness operator. We shall remark that the function is not defined in the case where p and q are both absent.

p	q	p|q	¬(p|q)
0	0	?	?
0	1	0	1
1	0	0	1
1	1	1	0

Figure 5: Truth table of the function of closeness $p|q$.

1st step: sensitivity: it is computed as the probability to observe a short distance between the table and the entity objects if these elements are truly correlated:

$$\{\mathrm{T},\mathrm{O}\} \rightarrow (\mathrm{T} \mid \mathrm{O})$$

In order to approximate this probability, we made the following supposition: the higher the probability of $(T \wedge \neg O) \vee (\neg T \wedge O)$, the less likely $\{T,O\}$. In other words: $(T \wedge \neg O) \vee (\neg T \wedge O) \rightarrow \neg\{T,O\}$

However, since $(T \wedge \neg O) \vee (\neg T \wedge O) \equiv T \oplus O$ and given that the meaning of $\neg(T \mid O)$ is $T \oplus O$ [1] (figure 5) we have: $\neg(T \mid O) \rightarrow \neg\{T,O\}$, which is equivalent to equation (2). This means that $P(T \oplus O)$ is the likelihood of $\neg\{T,O\}$.

2nd step: specificity: it is computed as the probability to not observe a short distance between the table and the entity objects if these elements are not correlated

$$\neg\{T,O\} \rightarrow \neg(T \mid O)$$

Or equivalently: $(T \mid O) \rightarrow \{T,O\}$

In order to compute this probability we assumed the following: the more probable $(T \mid O)$, the more likely $\{T,O\}$. Within this assumption, the probability of $\{T,O\}$ can be approximated by probability of $(T \mid O)$, which is the probability of $(T \wedge O)$ (figure 5).

By combining these two metrics we can build a formula that, applied to every couple (table; entity object), gives us measure of the likelihood of a true correlation between them.

Let P_1 be the value of $P(T \oplus O)$ (sensibility) and let's P_2 be the value of $P(T \wedge O)$ (specificity). We combine these two results through the following equation of the certainty of a match between T and O:

$$c = K \cdot P_2 - P_1 \qquad (2)$$

K is a constant allowing us to give more or less importance to P_2 according to the specific situation at hand.

[1] This holds because we are not interested in the cases where both instances, T and O are absent.

5. RESULTS

In order to evaluate the performance of our heuristic-based matching system we compared its results for the mapping of the boundary objects to the ones obtained manually by Jossi [14]. It must be noted that all the mappings produced by our engine are weighted by the certainty of the match. This is not the case in the manual match performed by Jossi. Therefore, we cannot directly compare a set of weighted matches to individual matches obtained by hand. Then, we compared the most likely matches produced by our engine to each match obtained manually.

Our system produced 14 mappings and the manual match 16. The comparison between both techniques has shown that 13 mappings were the same. This means that:

- Our system was able to correctly establish 81% of the manual mappings.
- From the 14 selected mappings made automatically, 93% were correct.

Table 1: Comparison of the manual and automatic mappings.

Table 1: Comparison of the manual and automatic mappings. shows the mappings that were obtained by Jossi and by our automated system. At the same time, it shows, by highlighting them, the mappings that are different between the results of both techniques.

The mapping between tables and entity objects was not performed by Jossi because of the high quantity of information to process. Jossi limited his investigation to the search of the modules that performed the accesses to the database. It is not possible then to compare the results of the inference engine with any previous results, as we did in Table 1. Therefore, to analyze these results, we will compare them to our expectations:

- A mapping should be created between tables and objects whose occurrences are *often* close on the timeline.
- A mapping should not be created between tables and objects which are *often* far from each other on the common timeline.

Figure 6 presents the results of the mapping of entities to tables. The vertical axis represents the different tables. The horizontal crosses shows the moment in time where the table is accessed. The horizontal axis represents the timeline on which we set the occurrence of the entity objects. For example {entity1,T4} and {entity2,T3} satisfy the first expectation. The candidate mapping {entity2,T4} is rejected because their occurrences are close on one part of the timeline only (about 0.6 in the normalized timeline). In fact they are more often far from each other than close.

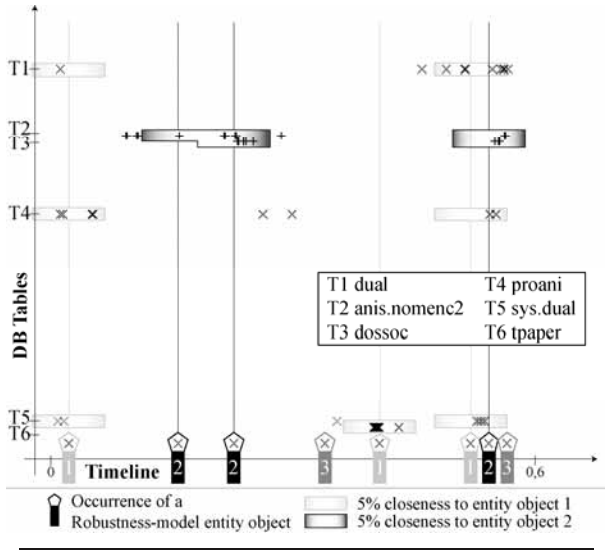

Figure 6: Results of the mapping of entities to the tables.

The tolerance to non-matches is controlled by the parameter K. This let us keep {entity2,T2}, although there are some non-matches along the timeline, but reject {entity3,T5} because:

- T2 occurrences didn't happen close to the occurrences of any other entity object than entity2. Therefore, the mapping was a lot more likely for entity2 than for the other entities.
- T5 occurrences are close to more occurrences of entity1 than entity3. Therefore, T5 was mapped with entity1 with a higher value of certainty than with entity3.

6. RELATED WORK

Domain models have long been acknowledged as a good way to improve reverse engineering and program understanding [19][18]. For example, in their Pioneering work, DeBaud and Rugaber [6] and DeBaud [5] used an executable domain model in the form of an object oriented framework. This framework represents the concept of the domain and helps the search for the corresponding concept in the programs. Then, each time a concept is identified in

the program being reengineered, the corresponding class of the domain is instantiated representing the result of the reverse-engineering [6]. From this experiment, DeBaud [5] remarked that domain models can efficiently guide software artifact comprehension. However, their structure is somewhat subjective and depends on the application. In other words, in the same domain, many different "models" can be represented. Therefore such a model must be flexible to account for all the variations of the domain concepts used in the program. Moreover DeBaud highlighted the difficulty to match the granularity of both the program code elements and the domain model. In particular he mentioned the difficulty raised by the delocalization of the concept in the program i.e. the lines of code referring to a concept are often noncontiguous. It must finally be noted that the domain model used in this work represents programming concepts not business concepts. This approach is quite similar to the work of Gold [12] who, in its HB-CA system for concept assignment used a knowledge base of programming concepts. In this work also, the domain model does not represent business concepts but programming concepts. For example, the experiment reported refers to programming notions such as "read file", "write file", "compute value". Using this knowledge, HB-CA is able to identify the segments of the source code where files are written, read etc. Later, the problem of non-contiguity of the source statement dealing with a concept was solved by Harman, Gold et al. by using slicing techniques [13]. Rugaber and Stirewalt used a formal specification using an algebraic specification language to model both the domain and the program being reverse-engineered [18]. Their main purpose is to evaluate the effort needed to reverse-engineer a program. Then they build the model of the program and, using a code generator, they generate a new system from the formal specification. If the generated system is "close enough" to the original system, the model of the system is considered adequate. They can afterwards evaluate the reengineering effort based on this model of the program. However, to construct it, they first build a domain model that gives them expectations for the concepts that might be represented in the code. Then they build the program model. Next they link the program model to the domain model, an operation called "interpretation". These connections help to understand the system purpose and how the code fulfils that purpose. The approach taken by Gall, Weidl and Klotsch [10][11][24] is to build an object model of the main domain abstraction implemented in the code, using all documentation and expert advice available. This is considered the domain model. Then the source code is analyzed to find candidate software objects. Finally the two sets of objects are matched using a similarity factor based on syntactic (name) and semantic (data type) properties. Human expertise is required to solve the many ambiguities that arise during this process. Their experiments have shown that the amount of code that the system could match against some domain concepts is limited. In fact many program elements are left without finding a suitable mapping. The conclusion we can draw from this work is that the code associated to the entity objects in a given program only represents a limited part of the total amount of code.

7. CONCLUSION

The heuristic techniques we used to automate the match between the objects of the robustness diagram and the programming elements produced very encouraging results. The main findings are:

1. The manual match between the objects in the robustness diagram and the elements of the implementation of the system can be automated.
2. The result obtained show that the automatic match can outperform the manual match especially if the quantity of information prevents any manual match to be done.
3. The implementation based on a production system coupled with a TMS is a workable solution. In particular, the processing time is reasonable with respect to the amount of information to process. In particular the processing of a trace of more than 25'000 events took less than a dozen of seconds in all our experiments.

This system has been developed in Java as an Eclipse plugin. It has been linked to a UML modeler so that the re-constructed models of the program can be used as input to the heuristic matcher. Future work ideas include:

- Extend the mapping engine to deal with higher abstraction models built with the RUP methodology like the Domain Object Model representing the key abstractions in the domain.
- Extend the specificity / sensibility metrics to all domain model objects.
- Improve the certainty calculation to better take into account the iterations between several use-cases and their partial matches.

Abstract

Objective: This paper aims to generate explanations from a series of data points obtained from a decision support system called ReleasePlanner® for supporting product release planning and considered to be a black box.
Method: Concept analysis is applied to 1085 data points received from running 10 scenarios of a real world product release planning project with 35 candidate solutions generated by ReleasePlanner®.
Results: Three main results are obtained: (1) patterns between inputs and outputs; (2) impact of individual input parameters on outputs; and (3) sensitivity level of outputs in dependence of inputs.
Conclusion: Concept analysis is shown to be a feasible technique for gaining more insight into the structure of results obtained from a black box input-output system, such as, but not limited to, ReleasePlanner®.

Keywords

Explanations, concept analysis, product release planning

1 Introduction

Product release planning involves decision making on assigning features to different releases for incremental software product development. It must simultaneously consider several aspects, such as conflicting stakeholder priorities and objectives, feature interdependencies, and resource and risk constraints [15]. A decision support system called ReleasePlanner® [13] has been developed to support decision makers in the complex release planning process. It is based on computationally efficient optimization algorithms for the generation of a set of alternatives solution having a proven degree of optimality.

However, the findings from a series of experiments conducted with ReleasePlanner® users revealed that they were reluctant to accept the solutions advised by this tool [6]. Similar observation has also been made on other systems [4] [10]. It was concluded in [1] that the major problems are not technical problems, but people problems in which people have very limited understanding on the support they get from decision support systems. In addition, according to [2], product release planning problem is classified as a wicked problem [14] which is hard to be precisely formulated. Thus the procedure needed to solve product release planning problems (as demonstrated in ReleasePlanner®) is more complex and requires more in depth explanations to achieve good user understanding on the tool support and its solutions.

How can we facilitate better understanding of the ReleasePlanner® solutions? In this paper, a data analysis technique called concept analysis [11] is applied for this purpose. It is applied to investigate data within a specific product release planning problem and identifies hidden relationships between the project inputs and outputs. In particular, three types of relationships are analyzed:

- Patterns between the input and output attributes
- Impact of individual input attributes on the outputs
- Sensitivity level of the outputs to the inputs

The answers to these three research questions provide additional knowledge that is currently unavailable to users of the ReleasePlanner® system. As a result, the users' acceptance and trust level on the tool and its solutions is expected to be improved.

The remainder of this paper is organized as the follows. Section 2 gives an overview of product release planning and the related decision support tool ReleasePlanner®. Section 3 introduces the background of concept analysis. In Section 4, a sample product release planning project is investigated to demonstrate the application of concept analysis. Section 5 analyzes and interprets the results in the context of the three stated questions. Finally, Section 6 summarizes the research and outlines future research.

2 Product Release Planning

Many formal approaches have been proposed for product release planning, such as incremental funding method [5], cost-value approach [9], planning software evolution with risk management [8], and hybrid intelligence (EVOLVE*) [15]. The latter is used in this paper. This section gives a short overview of this approach to the extent necessary to understand and judge the results obtained from concept analysis presented later in this paper. More details on the method are available from [15].

2.1 Technical Formulation

In incremental product development, the goal of product release planning is to select from a set of features $F = \{f_1,\ldots,f_n\}$ and to assign them to one of K possible releases each of them having a weight (relative importance) of ξ_k ($k = 1\ldots K$). A release plan is described by vector x with

decision variables $\{x(1),\ldots,x(n)\}$, where $x(i) = k$ if feature f_i is assigned to release option $k \in \{1,\ldots,K\}$; and $x(i) = K+1$ otherwise (i.e. the feature is postponed).

Two types of feature dependencies are considered: coupling and precedence relationship. A coupling $CC(f_i, f_j)$ indicates that both features f_i and f_j must be released jointly. A precedence $PC(f_i, f_j)$ indicates that feature f_i cannot be released later than f_j. Some features can be fixed to certain release by the pre-assignment $preassign\text{-}x(i)=k$, indicating that f_i is fixed to release k.

The planning approach considers T resource types for implementing the features. Capacities $Cap(k, t)$ relate each release k to each resource type $t \in \{1,\ldots,T\}$. Every feature f_i requires an amount of resources of type t $r(f_i, t)$. Thus, each release plan x assigns feature f_i to release k expressed as $x(i) = k$, for all releases k and resource types t, must satisfy $\Sigma_{x(i)=k}\, r(f_i, t) \leq Cap(k, t)$.

A set of stakeholders $S = \{s_1,\ldots,s_q\}$ is involved in release planning. Each of them has a relative importance $\lambda \in \{\lambda_1,\ldots,\lambda_q\}$. It is a nine-point ordinal scale that provides differentiation in the degree of importance. The higher the importance value is, the more important the stakeholder is.

In brief, the purpose of release planning is to provide the most attractive features at the earliest releases to the most important stakeholders. For the purpose of this paper, $Value(s, f_i)$, $Urgency(s, f_i)$, and $Competitiveness(s, f_i)$ are the three attributes of a feature's attractiveness. Each feature can be prioritized from these three criteria with the value ranging from 0 to 9. These criteria are associated with the weights μ_1, μ_2, and μ_3, respectively.

The three prioritization criteria are the basis to formulate the objective of product release planning. The objective function $Utility(x)$ is defined as a linear combination of the priority votes of stakeholders related to these criteria:

$$Utility(x) = \sum_{k=1}^{K} (\xi_k \times \sum_{i:x(i)=k} \Pr iority(f_i))$$

where $Priority(f_i)$ is an aggregated priority of f_i defined as:

$$\Pr iority(f_i) = \sum_{s=s_1}^{S_q} (\lambda_s \times (\mu_1 \times Value(s, f_i) + \mu_2 \times Urgency(s, f_i) + \mu_3 \times Competitiveness(s, f_i)))$$

2.2 ReleasePlanner®

ReleasePlanner® [13] is a decision support system that aims at performing systematic product release planning based on computationally efficient optimization algorithms. Users are able to perform what-if analysis to pro-actively explore different scenarios defined by a sequence of inputs of the same project under investigation. In addition, the tool is capable of generating a set of diversified solution alternatives for each instance.

A series of studies on ReleasePlanner® revealed that its users tended to have higher confidence and trust on their manual solutions than the ones generated more efficiently by the tool [6]. The major reason is that the tool works in a black box manner and the rationale of solution generation is hard to understand by the users. This is even more complicated because the users usually investigate multiple scenarios with multiple solutions.

3 Concept Analysis

Concept analysis, firstly introduced in [17], is a theory of data analysis to identify conceptual structures among a set of data. It has been successfully applied to many fields [12], including in software engineering [11].

In this paper, concept analysis is investigated to address the three research questions presented in Section 1. Another two techniques, i.e. rough set analysis and dependency network analysis, have also been applied to explain release planning solutions by ReleasePlanner® [7]. However, they can only deal with the first two research questions and are not the focus of this paper. Detailed applications of these two techniques are available at [7].

3.1 Basic Terminology

Concept analysis investigates the relations R between a set of objects O, and a set of attributes A. The triple $C = (R, O, A)$ is called a formal context.

Def. 1 (Common Attributes and Common Objects): For any set of objects $\mathcal{O} \subseteq O$, the set of common attributes having the same attribute value is called common attributes related to $\mathcal{O}$ and is denoted by $ca(\mathcal{O}) = \{a \in A \mid \forall\, o \in \mathcal{O} : (o, a) \in R\}$. For a set of attributes $\mathcal{A} \subseteq A$, their common objects are $co(\mathcal{A}) = \{o \in \mathcal{O} \mid \forall\, a \in \mathcal{A} : (o, a) \in R\}$.

Def. 2 (Formal Concept): Each pair $c = (\mathcal{O}, \mathcal{A})$ with $\mathcal{O} = co(\mathcal{A})$ and $\mathcal{A} = ca(\mathcal{O})$ is called a formal concept. It demonstrates a pattern, i.e. relation, between $\mathcal{O}$ and $\mathcal{A}$.

Def. 3 (Concept Lattice): All formal concepts for a given context C are called a complete concept lattice in which concepts can be partially ordered. If $c_1 = (\mathcal{O}_1, \mathcal{A}_1)$ and $c_2 = (\mathcal{O}_2, \mathcal{A}_2)$ are two concepts in the context C, a partial order $c_1 \leq c_2$ can be defined whenever $\mathcal{O}_1 \subseteq \mathcal{O}_2$ and $\mathcal{A}_1 \supseteq \mathcal{A}_2$.

Def. 4 (Greatest Lower Bound and Least Upper Bound): The greatest lower bound of c_1 and c_2 is the concept with objects $\mathcal{O}_1 \cap \mathcal{O}_2$ and attributes held by all objects in $\mathcal{O}_1 \cap \mathcal{O}_2$. The least upper bound of c_1 and c_2 is the concept with attributes $\mathcal{A}_1 \cap \mathcal{A}_2$ and objects which have all attributes in $\mathcal{A}_1 \cap \mathcal{A}_2$.

3.2 An Illustrate Example

Applied to planning product releases, O constitutes the set of features F to be assigned to different releases. The input to and output from product release planning using ReleasePlanner® form set A. Figure 1 shows a simple example of concept analysis in this domain. The upper part is a data table of feature set $F = \{f_1,\ldots,f_4\}$ defined with the attribute set $A = \{a_1,\ldots,a_3\}$. In this table, the value of each attribute for each feature can be H, M, or L.

These values represent different value ranges. The lower part of this figure shows the corresponding concept lattice with all the concepts $\{c_1,\ldots,c_8\}$ and their order relations. In this lattice, the values of the attributes in each concept are also highlighted. Among all the concepts, c_1 is the most general one and c_8 is the most specific one. Some of the order relations among the concepts are $c_2 \leq c_1$, $c_3 \leq c_1$, and $c_7 \leq c_1$. From this figure, we can also identify the least upper bound and greatest lower bound of a set of concepts. For example, c_1 and c_4 are the least upper bound and greatest lower bound of c_2 and c_3, respectively.

	a_1	a_2	a_3		a_1	a_2	a_3
f_1	H	H	L	f_3	L	H	L
f_2	H	M	L	f_4	M	L	L

Figure 1: Example concept analysis

4 Applying Concept Analysis to Explain Product Release Planning Results

4.1 Sample Project

To illustrate the application of concept analysis to explain results generated by ReleasePlanner®, we investigate on a sample project based on the data from a real life product release planning problem. As a summary, this project is defined with the following inputs:

- $F = 31$ features $\{f_1, \ldots, f_{31}\}$ to be assigned
- $K = 2$ releases
- $S = 18$ stakeholders $\{s_1,\ldots,s_{18}\}$ with weights $\{\lambda_1,\ldots, \lambda_{18}\}$
- Prioritization criteria $Urgency(s,f_i)$, $Value(s,f_i)$, and $Competitiveness(s,f_i)$
- $T = 3$ types of resources $\{Res1, Res2, \text{and } Res3\}$

The full details of this project setting can be referred to http://pages.cpsc.ucalgary.ca/~dug/ConceptAnalysis. This project setting and the results obtained from it are taken as the baseline scenario. From this baseline, the tool user also generates another 9 scenarios that the user thinks to be the most important (but not necessarily the complete) scenarios for investigation. Together these 10 scenarios are used for what-if analysis which is useful and important for product release planning, as discussed in Section 2.2. For all these scenarios, in total 35 solutions are generated by ReleasePlanner® for later analysis.

4.2 Data for Concept Analysis

With the above project settings, each feature f_i in each solution is associated with a data point used for concept analysis (see Table 1). The selection of the attributes is based on the experience of manual analysis of several product release planning projects [15]. The first six input attributes are relevant to stakeholder votes which are considered in the objective function for planning. In particular, $ConfUrgency(f_i)$, $ConfValue(f_i)$, and $ConfComp(f_i)$ are the standard deviation between different stakeholders' votes for each feature f_i from the three criteria, respectively. They indicate the degree of disagreement among stakeholder opinions. The other six input attributes address resource utilization and criticality of features.

Table 1: Data defined for concept analysis

Input Attribute	Definition
$AverageUrgency(f_i)$	$AverageUrgency(f_i) = \frac{\sum_{S=S1}^{S18} \lambda_S \times Urgency(s, f_i)}{\sum_{S=S1}^{S18} \lambda_S}$
$AverageValue(f_i)$	(similar for $AverageValue(f_i)$, $AverageComp(f_i)$)
$AverageComp(f_i)$	
$RelConfUrgency(f_i)$	$\mathrm{Re}lConfUrgency(f_i) = \frac{ConfUrgency(f_i)}{AverageUrgency(f_i)}$
$RelConfValue(f_i)$	(similar for $RelConfValue(f_i)$, $RelConfComp(f_i)$)
$RelConfComp(f_i)$	
$Res_tUtiRatio(f_i)$ (t = 1, 2, 3)	$\mathrm{Re}s_tUtiRatio(f_i) = \frac{r(f_i, \mathrm{Re}s_t)}{\sum_{i=1}^{31} r(f_i, \mathrm{Re}s_t)}$
$Res_tCriticality(f_i)$ (t = 1, 2, 3)	$\mathrm{Re}s_tCriticality(f_i) = \mathrm{Re}s_tUtiRatio(f_i) - \frac{r(f_i, \mathrm{Re}s_t)}{\sum_{k=1}^{2} Cap(k, \mathrm{Re}s_t)}$
Output Attribute	**Definition**
$Release(f_i)$	$Release(f_i)$

Based on our previous experience on the analysis of these attributes, each attribute is discretized according to Table 2. The purpose of discretization is to scale attributes with continuous values to a nominal or ordinal scales.

Table 2: Discretization of the defined attributes

Input Attribute	Value Range	Discretization	
$AverageUrgency(f_i)$	A real number in [0, 9]	High	[6, 9]
$AverageValue(f_i)$		Medium	[4, 6)
$AverageComp(f_i)$		Low	[0, 4)
$RelConfUrgency(f_i)$	A real number in [0, 1]	High	[0.7, 1.0]
$RelConfValue(f_i)$		Medium	[0.4, 0.7)
$RelConfComp(f_i)$		Low	[0.0, 0.4)
$Res_tUtiRatio(f_i)$	A real number in [0, 1]	High	[0.10, 1.00]
		Medium	[0.05, 0.10)
		Low	[0.00, 0.05)
$Res_tCriticality(f_i)$	A real number in [-1, 1]	No	[0.00, 1.00]
		Low	(-0.01, 0.00)
		Medium	[-1.00, -0.01]
Output Attribute	**Value Range**	**Discretization**	
$Release(f_i)$	An integer in [1, 3]	Not necessary	

Based on the above definition and discretization, a table with 1085 data points (35 solutions with each containing 31 features) is obtained for later concept analysis. The complete table is available at the website provided earlier.

4.3 Concept Analysis of the Data

We used an open source library called Colibri/Java [3] to perform concept analysis. It builds a concept lattice which contains all patterns (concepts) for the data prepared in Section 4.2. We then implemented a tool to traverse the concept lattice to select only those patterns where the distribution of the output values significantly changed along the (subset) relations between these patterns. To test significance, we used Fisher Exact Value and Chi Square tests (significance level of p=0.01) [16]. Using our tool, two filtered lattices were generated that contain the patterns which affect the distribution of releases the most:

- Concept lattice #1 contains 64 patterns where the likelihood of assigning a feature f_i to release 1 is increased by at least 45%.
- Concept lattice #2 contains 1093 patterns where the likelihood of assigning a feature f_i to any release, i.e. 1, 2 or 3 (postponed), is increased or decreased by at least 30%.

The first lattice is essentially a part of the second one. The details of these lattices are available at the website given earlier and will be analyzed in depth in Section 5.

Table 3: Example record in the generated concept lattices

Context			*Res3Criticality(f_i)*_Low		
Var			*AverageComp(f_i)*_High		
Δ_R1	0.49	**Context_R1**	548	**Context+Var_R1**	118
Δ_R2	-0.3	**Context_R2**	339	**Context+Var_R2**	1
Δ_R3	-0.18	**Context_R3**	198	**Context+Var_R3**	0

Each filtered lattice consists of a number of patterns and transitions between these patterns in the form shown in Table 3. This table is read as, for all the 1085 cases in the dataset, the distribution of features f_i following the pattern of "*Res3Criticality(fi)* = Low" ("context" part) is 548 data points for release 1 ("context _R1"); 339 for release 2 ("context_R2"); and 198 for release 3 ("context_R3"). The pattern of "*Res3Criticality(fi*) = Low AND *Average Comp(fi*) = High" ("context" and "var") is supported by 118 data points for release 1 ("context+var_R1"); 1 for release 2 ("context+var_R2"); and 0 for release 3 ("context+var_R3"). The transition between these two patterns can be understood as a rule: adding "*Average Comp(fi*) = High" ("var") to the "context" part increases the likelihood of assigning a feature f_i to release 1 by 49% ("Δ_R1"), and decreases the likelihood to release 2 and 3 by 30% ("Δ_R2") and 18% ("Δ_R3"), respectively.

5 Analysis and Interpretation of Results

In this section, we analyze the two lattices generated in Section 4.3 from three perspectives: similarity of patterns, importance of input attributes, and sensitivity of outputs. The findings from these aspects contain new knowledge that reveals the underlying relationships between the inputs to ReleasePlanner® and its outputs, for the studied sample project. They can be used as explanations for this decision support system and its solutions.

5.1 Pattern Transitions and Data Similarity

Each generated concept lattice covers the most significant patterns discovered from the product release planning data used for concept analysis. These patterns are presented in the "context" part and of the different granularities, i.e. from the most general to the most specific. A general pattern can be transformed to more specific ones, and vice versa. By examining the generalization or specification relationships among these patterns, the transitions among the patterns become visible. In addition, the discovered patterns demonstrate the similarities shared among the data used for analysis. Data that are categorized under a same pattern are of the similarity as demonstrated by the pattern. For any two patterns that can be generalized to the same more general pattern, the two data sets supporting these patterns must be similar to each other in the way that is represented from the general pattern.

To illustrate the pattern transition and data similarity in this sample project, the concept lattice #1 is analyzed for simplicity. Any other lattices can be analyzed similarly.

Figure 2 shows the top four levels of patterns within this concept lattice and the transitions of these patterns. The complete transitions of all the patterns in this lattice can be referred to the website provided earlier. In this lattice, the most general pattern is #1, as shown in the very top of the figure. It can be specified to pattern #2, #3, and #4 at the second level. In this case, we say pattern #1 is the generalization of pattern #2, #3, and #4. On the other hand, pattern #2, #3, and #4 are the three specifications of pattern #1. Each of these three patterns can be further specified to other patterns until no more specific pattern can be found. For example, one of the most specific patterns is pattern #60. It follows the specification path of pattern #1→#3→#6→#41→#50→#60.

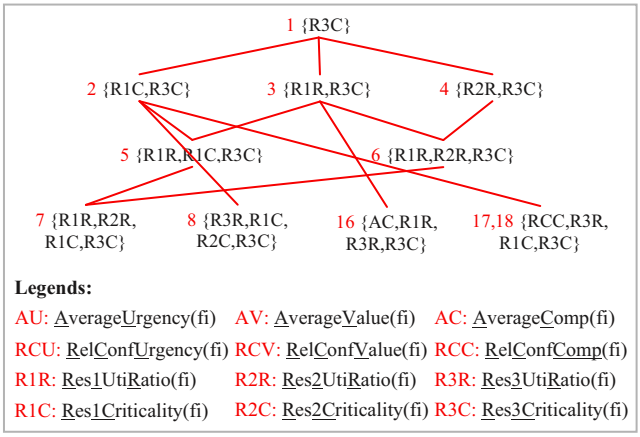

Figure 2: Transition of patterns (concept lattice #1)

Regarding the similarities shared among all the 1085 data used for the analysis, all these data are the same in terms of their values on the input R3C (*Res3Criticality(f_i)*), as illustrated through the most general pattern, i.e. pattern #1. More similarity is discovered from the data #1 to #715 and #869 to #930 because these data points also share the same value on the input attribute R1C (*Res1Criticality(f_i)*), besides on R3C. As a result, these data form a more specific pattern, i.e. pattern #2.

These results can be interpreted as a type of explanations on ReleasePlanner® solutions. If, in a solution, the release assignment of a feature is supported by general pattern(s) that are supported by a large number of data points, the users are more likely to accept such result. Otherwise, they might want to further improve the solution.

5.2 Importance Level of Inputs on Outputs

By examining all the found patterns ("context" part), we can identify each input attribute's importance level to the output attribute, in our case the release. The assumption is that the higher the number of the occurrence of an input in the patterns is, the more important this input is in determining the release value. However, an exception to this assumption is that this number cannot be as high as the total number of data used for analysis. The rational for this exception is given later.

For this purpose, we investigate the second concept lattice which provides more coverage than the first one on the patterns inherent in the data. Figure 3 summarizes the number of occurrence of each input in this concept lattice. *Res3Criticality(f_i)* appears to be the most important attribute. It is in all the patterns and has the same value. In other words, it has no influence at all on the distribution of release. *Res1Criticality(fi)* and *Res1UtiRatio(fi)* are important attributes which have different values. The least important ones are *AverageComp(fi)*, *AverageUrgency(fi)*, and *RelConfComp(fi)*. Other input attributes have medium level of importance.

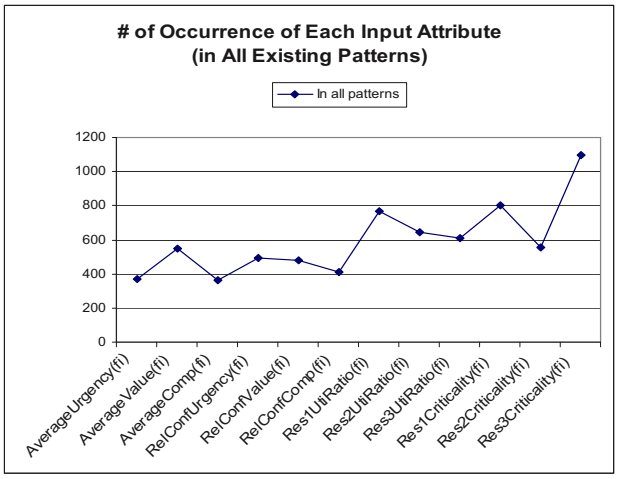

Figure 3: Importance level of each input on the output (concept lattice #2)

This part of the results provides the ReleasePlanner® users with the explanations by identifying a subset of all the defined inputs that play the most significant impacts on the tool when it generates solutions.

5.3 Sensitivity Level of Outputs to Inputs

The generated concept lattices also check if adding a new input attribute ("var" part) to the existing patterns ("context" part) would change the distribution of release. If the change is significant, this input is likely responsible for such change, i.e. the output is sensitive to this input. To observe the sensitivity of the output on each input, the second concept lattice is used for analysis again. In particular, we examine six types of how the "var" part may impact on the distribution of releases:

- R1/R2/R3 +0.30: increase by at least 30% in the distribution of assigning a feature f_i to release 1, 2, and 3, respectively
- R1/R2/R3 -0.30: decrease by at least 30% in the distribution of assigning a feature f_i to release 1, 2, and 3, respectively

For each input, we first count its number of occurrence in the "var" part of each record. For example, in the record in Table 3, the input attribute *AverageComp(f_i)* is in the "var" part with 118 cases supporting the impact of R1 +0.30. Therefore its number of occurrence in this record, for this type of impact, is 118. Then, by summing up such numbers for all the records of the same impact type, we obtain the total number of occurrence of this input. Figure 4 shows this number for each input based on the above calculation. We assume that the higher this number is, the more sensitive the output is to this input.

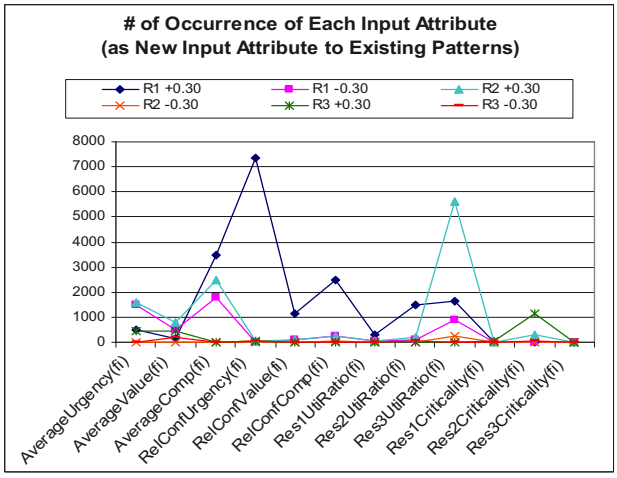

Figure 4: Sensitivity level of the output to each input (concept lattice #2)

From this figure, *RelConfUrgency(fi)*, *Res3UtiRatio(fi)* and *AverageComp(fi)* have the most significant impacts on the distribution of release. Specifically, release 1 is most sensitive to *RelConfUrgency(fi)* and *AverageComp(fi)* for at least 30% of increased distribution, and to *AverageComp(fi)* for at least 30% of

decreased distribution. Release 2 is most sensitive to *Res3UtiRatio(fi)* and *AverageComp(fi)* for at least 30% of increased distribution. But they usually have no impact as R2 -0.30 or R3 ±0.30. On the other hand, *Res1UtiRatio(fi)*, *Res1Criticality(fi)*, and *Res3Criticality(fi)* almost never contribute to any change by at least ±30% in any release. Although they occur the highest times in the patterns in Figure 3, their sensitivity levels are not as significant as at least ±30% and cannot be reflected in Figure 4. The other input attributes in general have medium level of sensitivity on the output attribute.

The above results explain some sensitivity aspects of the solutions generated by ReleasePlanner®. This kind of knowledge reveals the degree of impact from changing different input parameters. In case of uncertain data, the rule of thumb is that the more robust a solution, the higher chance of acceptance by the user.

6 Conclusions and Future Work

In this paper, a formal data analysis method called concept analysis is combined with statistical hypothesis testing to explain complex solutions recommended by ReleasePlanner®, a decision support system for product release planning. The results of our analysis of the data of individual release planning projects contain additional knowledge that is currently unavailable to the tool users. Specifically, such knowledge explains the underlying relationships inherent in the investigated data, in terms of the underlying patterns between the input and output data, as well as the importance and sensitivity levels of inputs on outputs. These explanations intend to achieve better understanding on the solutions of ReleasePlanner®, and therefore higher acceptance level from the user side. To demonstrate the application of concept analysis and statistical hypothesis testing, a sample product release planning project was investigated. Although the findings presented in this paper are specific to the sample project, the methodology of applying such analysis is generic (since it treats the decision support system as a black box) and can be applied to any other product release planning projects, or other software systems in which explaining complex solutions to users is necessary.

As a very important future work, empirical studies will be conducted with ReleasePlanner® users in order to justify the usefulness and effectiveness of the proposed method for explaining the tool's solutions. In addition, the results obtained from the concept analysis, as presented in this paper, only provides one type of explanations on ReleasePlanner® solutions and it is by no means complete. The explanations generated from this method are better to be used with other types of explanations (e.g. the ones discussed in [7]) that address the solutions from different aspects. Therefore we will also investigate on how these different types of explanations obtained from different techniques are complimentary to each other so that they can together provide the tool users with a more complete view of explanations on the tool and its solutions.

Acknowledgement

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Alberta Informatics Circle of Research Excellence (iCORE) for their financial support of this research. Many thanks are due to Daniel Götzmann and Christian Lindig who provided the Colibri/Java implementation.

Weighted Static Code Attributes for Software Defect Prediction

Burak Turhan, Ayse Bener
Dept. of Computer Engineering

{turhanb,bener}@boun.edu.tr

***Abstract*—It has been recently shown that defect predictors built on the combination of log-filtering, InfoGain attribute selection and Naive Bayes learner, outperform rule based learners. Naive Bayes is a well known statistical technique that assumes the 'independence' and 'equal importance' of attributes, which are not true in many problems. This paper addresses the 'equal importance' of attributes assumption of Naive Bayes. We show that with simple heuristics, relevant weights can be assigned to attributes according to their importance which improves defect prediction performance. Furthermore, our proposed heuristics have linear time computational complexities whereas choosing the optimal subset of attributes requires an exhaustive search in the attribute space. We compare the weighted Naive Bayes and the standard Naive Bayes predictors' performances on publicly available datasets both from Nasa and various small and medium enterprises (SMEs) in Turkey. Our results indicate that assigning weights to static code attributes may increase the prediction performance significantly, while removing the need for feature subset selection.**

I. Introduction

Quality of software is often measured by the number of defects in the final product. Minimizing the number of defects -maximizing software quality- requires a thorough testing of the software in question. On the other hand, testing phase requires approximately 50% of the whole project schedule [1], [2]. This means testing is the most expensive, time and resource consuming phase of the software development lifecycle. An effective test strategy should therefore consider minimizing the number of defects while using resources efficiently.

Defect prediction models are helpful tools for software testing. Accurate estimates of defective modules may yield decreases in testing times and project managers may benefit from defect predictors in terms of allocating the limited resources effectively [3].

Defect predictors based on linear regression, discriminant analysis, decision trees, neural networks, Bayesian networks and Naive Bayes classification have been analysed in previous research [4], [5], [6], [7], [8], [9], [10], [11]. Among these, Naive Bayes is reported to achieve significantly better performances than the other methods [8]. Naive Bayes assumes the independence and equal importance of attributes despite the fact that these assumptions are not true in many cases. Nevertheless, Naive Bayes has a good reputation for its prediction accuracy [12].

The number of research for relaxing the assumptions of Naive Bayes has significantly increased in recent years. These research focused on modifications to break the conditional independence assumption and weighting attributes [13], [14], [15], [16], [17]. All studies reported results that are generally 'not worse' than the standard Naive Bayes, while preserving the simplicity of the model.

For the attributes that are used for constructing predictors, some research prefer ranking the attributes for subset selection [18], [8], and some use a ranking criteria for attribute weight assignment [16], [19]. In fact, subset selection corresponds to 'hard' weighting of attributes, i.e. assigning 0 or 1 for attribute weights.

This paper attempts to tackle the assumption of "equal importance of attributes" of Naive Bayes in defect prediction context. Attribute weighting has been explored to some extent for other problems such as cost estimation. Auer et. al. employs attribute weigthing for analogy based cost estimation [19]. However, they assign *random* weights to project features and search for the optimal weigths. Similarly, neural network models for defect prediction have inherent attribute weighting. However, neural networks are non-deterministic and complex models that require optimization of the network structure together with many model parameters. Thus they require relatively large number of data samples for building a predictor. In practice, usually a limited amount of data is available. Further, the weights of the neural network model can not be easily interpreted especially in complex networks.

Furthermore, previous studies employ *feature subset selection* as a filtering step before learning a model. In brief, they label the available static code attributes as 'useful' or 'non-useful' based on some threshold determined by various attribute selection/ ranking methods. This approach, subsetting, has three disadvantages:

1. A threshold value should be set carefully either with extensive experimentation or manually.
2. An attribute labelled as useful is employed as if its degree of usefulness is the same as the rest of the useful attributes.

This research is supported in part by Bogazici University research fund under grant number BAP-06HA104.

3. An attribute labelled as non-useful:
   (a) may contain useful information, but is discarded by the threshold value.
   (b) may be useful in combination with other attributes, but the attribute selection/ ranking method discarded it [20].

In this paper we aim at removing these disadvantages introduced by feature subset selection. For this purpose, we propose attribute weighting along with several heuristics for determining the degree of importance of static code attributes. Recent research investigates integrating feature selection into generic classification models [21]. While not generic, our approach also integrates feature selection into Naive Bayes [17], [16].

Considering defect prediction, we claim that all static code attributes do not have equal effect on defect prediction and they should be treated accordingly. Our goal is to develop a methodology that permits the use of static code attributes in terms of their relevance to defect prediction. Menzies et.al. state that: *"how the attributes are used to build predictors is much more important than which particular attributes are used"* [8]. We also focus on *how* rather than which.

We reproduce the experiments on NASA datasets by Menzies et.al in order to construct a baseline for comparison. Furthermore, we include datasets collected from SME's, in order to justifiy the generalization of our results. We aim at combining the best practices of the above mentioned studies for constructing robust and accurate defect predictors. We use a weighted Naive Bayes classifier and construct heuristics for accurate attribute weight assignment. We propose to treat each attribute based on their estimated importance and we search for empirical evidence for the validity of our approach. Our results indicate that assigning weights to static code attributes may increase the prediction performance significantly, while removing the need for feature subset selection. Although the complexity of the proposed model is increased, we observe more stable results.

II. Methods

A. Weighted Naive Bayes (WNB)

Standard Naive Bayes derivation can be obtained by placing a special form of multivariate normal distribution, as the likelihood estimate in the Bayes theorem. By special form we mean that the off-diagonal elements of the covariance matrix estimate are assumed to be zero, i.e. the attributes are independent. In this case the multivariate distribution can be written as the sum of univariate normal distributions of each attribute (See Equation 1). In a classification problem we compute the posterior probabilities $P(C_i|x)$ for each class and choose the one with the highest posterior. In general the logarithms are used for computational convenience.

$$P(C_i|x) = -\frac{1}{2}\sum_{j=1}^{d}\left(\frac{x_j^t - m_{ij}}{s_j}\right)^2 + \log(\hat{P}(C_i)) \quad (1)$$

While assuming the independence of attributes, a weighting term can be introduced to reflect the relative importances of attributes. Then Weighted Naive Bayes can be written as in Equation 2 [16], [17].

$$P(C_i|x) = -\frac{1}{2}\sum_{j=1}^{d} w_j\left(\frac{x_j^t - m_{ij}}{s_j}\right)^2 + \log(\hat{P}(C_i)) \quad (2)$$

Now that we have introduced another parameter, we should find a way of estimating it accurately. For this purpose we propose 8 heuristics, which are explained in the next section.

B. Attribute Weight Estimation

We propose 8 heuristics mostly derived from attribute ranking techniques in order to estimate weights for the static code attributes. In all heuristics we compute the rank values for the attributes and then derive weights by normalizing over the sum of all rank values (See Equation 3). Thus, all weights are scaled to lie in the [0, 1] interval. A complete list of heuristics used in this research is given in Table I.

$$w_j = \frac{Rank(j)}{\sum_i Rank(i)} \quad (3)$$

First heuristics is based on the Principal Component Analysis (PCA), which projects the data points onto orthogonal principal axes such that the variance in each axis is maximized. We do not directly use PCA for dimensionality reduction. Rather, we claim that attributes with higher contributions for determining principal components should have higher weights in the prediction method. In our proposed heuristic, we use k eigenvalue and eigenvector pairs that correspond to the 95% of the proportion of the variance explained. Eigenvalues are written as $\lambda_1, \lambda_2, .., \lambda_k$ and eigenvectors are written as e_{id} where $i = 1..k, d = 1..D$ and D is the number of attributes. Then the weight of attribute d is estimated as a weighted sum of the corresponding eigenvector elements as given in Equation 4.

$$w_d = \frac{\sum \lambda_i e_{id}}{\sum \lambda_i} \quad (4)$$

Among proposed heuristics, GainRatio and InfoGain are mainly used in decision tree construction to determine the attributes that best splits the data [22]. Zhang and Sheng use the GainRatio heuristic for attribute weight assignment [16]. InfoGain is used in other studies for subset selection by ranking attributes [18], [8]. Our goal is to convert these ranking estimates into attribute weights. For this purpose we also evaluate OddsRatio, LogProb, ExpProb, CrossEntropy and Kullback-Leibler (KL) Divergence.

In defect prediction context, these heuristics correspond to the following: Given an attribute A,

- KL measures the similarity between the distributions of defective and nondefective modules. The more different the distributions, the higher the weight attribute A has.

TABLE I
LIST OF HEURISTICS USED IN THIS STUDY.

Heuristic	Equation
PCA	See text
Information Gain	$IG(x,A) = Entropy(x) - \sum_{a \in A} \frac{\lvert x=a \rvert}{\lvert x \rvert} Entropy(x=a)$
Gain Ratio	$GR(x,A) = \frac{IG(x,A)}{SplitInfo(x,A)}$, where $SplitInfo(x,A) = -\sum_{a \in A} \frac{\lvert x=a \rvert}{\lvert x \rvert} \log \frac{\lvert x=a \rvert}{\lvert x \rvert}$
KL Divergence	$D_{KL}(x,A) = \sum_{a \in A} p(x=a\lvert pos) \log(x=a\lvert neg)$
Odds Ratio	$OR(x,A) = \log \sum_{a \in A} \frac{p(x=a\lvert pos)(1-p(x=a\lvert neg))}{(1-p(x=a\lvert pos))p(x=a\lvert neg)}$
Log Probability	$LP(x,A) = \log \sum_{a \in A} \frac{p(x=a\lvert pos)}{p(x=a\lvert neg)}$
Exponential Probability	$EP(x,A) = \exp\left(\sum_{a \in A} p(x=a\lvert pos) - p(x=a\lvert neg)\right)$
Cross Entropy	$CE(x,A) = \sum_{a \in A} p(x=a\lvert pos) \log p(x=a\lvert neg)$

TABLE II
DATASETS

Name	# Attributes	# Modules	DefectRate (%)
CM1	38	505	9
PC1	38	1107	6
PC2	38	5589	0.6
PC3	38	1563	10
PC4	38	1458	12
KC3	38	458	9
KC4	38	125	39
MW1	38	403	9
SQ1	36	113	23
SQ2	26	286	5
SQ3	29	36	22
SQ4	26	1360	6
SQ5	26	1925	3

- OddsRatio measures wheter defective modules are more likely to occur than the nondefective modules.
- LogProb is the logarithm of the ratio of probability of a module being defective over probability of a module being nondefective.
- ExpProb is the exponentiation of the difference of probability of a module being defective and probability of a module being nondefective.
- CrossEntropy is the average number of bits needed to differentiate between the defective and nondefective module distributions.

Assigning weights with these heuristics takes linear time. On the other hand, ranking the attributes with these methods and then searching for an optimal subset requires both an exhaustive search in the attribute space and the evaluation of performance with each candidate subset. We expect to observe that the attributes that are discarded by the subset selection methods would have relatively small weights than the selected attributes.

III. Datasets

We have evaluated 13 datasets from different project domains. Among these, 8 public datasets are obtained from NASA MDP Repository [23]. These datasets are accepted to reflect the common industrial software engineering practice. However, in order not to restrict the experiments to datasets from a single company, we have also formed 5 more datasets (i.e. SQ datasets). These are collected from SME's in Turkey, which operate in different domains. These entities do not have any certification yet for their software processes, but some of them are in the process of certification and all are among the leading companies in their corresponding domains.

The projects in the SQ datasets include: embedded software from a leading whitegoods manufacturer, software for archieving media broadcasts for government audit, application software from a national science council, software for financial applications and telecommunication software.

Sample sizes of the projects vary from 36 to 5589 modules, which enables experiments in a broad spectrum of project sizes. Each NASA dataset has 38 attributes static code attributes (See [23], [8]). SQ datasets include 26 to 36 of the static code attributes available in NASA datasets. In both datasets modules with error counts greater than zero are assumed to be defective.

IV. Performance Measures

We have used probability of detection (pd) and probability of false alarm (pf) as the performance measures [8]. pd is a measure of accuracy for correctly detecting the defective modules. Therefore, higher pd's are desired. pf is a measure for false alarms and it is an error measure for incorrectly detecting the nondefective modules. pf is desired to have low values. Since we need to optimize two parameters, pd and pf, a third performance measure called balance is used to choose the optimal (pd, pf) pairs. balance is defined as the normalized Euclidean distance from the desired point (0,1) to (pd, pf) in a ROC curve [8].

Zhang and Zhang argue that using (pd,pf) performance mesures in imbalanced classification problems is not practical due to low precisions [24]. On the contrary, Menzies et.al argues that precision has an unstable nature and it can be misleading to determine the better predictor [25]. They also give examples of low precision predictors that are in use in SE industry. We also think that predictors with high pd rate can be practical even when they have high pf rate. Especially in mission critical and safety critical systems, detecting defects accurately with the cost of many false alarms is affordable [25], [26], [27]. Furthermore, we

believe that this strategy is still more efficient than using exhaustive testing. Thus, we argue that it would not defeat the purpose of defect prediction as Zhang and Zhang claims [24].

In addition, we would like to point out that balance performance measure should be used carefully for determining the best among a set of predictors. Since it is a distance measure, i.e. the distance of (pd,pf) to the optimal point (0,1), a specific balance value defines a quarter-circle on the ROC graph with radius of (1 - bal) and with the origin (0,1). So, predictors with different (pd,pf) values can have the same balance value. This does not necessarily show that all predictors with the same balance value have the same practical usage. As mentioned above, domain specific requirements may lead us to choose a predictor with a high pd rank although it may also have a high pf rank.

V. Experiment Design

We have compared the best defect predictor reported so far (log-filter, InfoGain attribute selection, standard Naive Bayes [8]) with the Weighted Naive Bayes classifiers constructed by our proposed heuristics on NASA datasets. Then we have evaluated the weighted Naive Bayes method on SQ datasets to show the applicability of the model in a wide range of company profiles. The experimental design follows the framework suggested as a baseline by Menzies et.al. [8]. We have also reproduced these experiments on NASA datasets for comparison purposes.

We have applied log-filtering on the datasets before we trained the predictor [8]. Then, we have used 10-fold cross-validation in all experiments. That is, datasets are divided into 10 bins, 9 bins are used for training and 1 bin is used for testing. Repeating these 10 folds ensures that each bin is used for training and testing while minimizing the sampling bias. Each holdout experiment is also repeated 10 times and in each repetition the datasets are randomized to overcome any ordering effect and to achieve reliable statistics. Overall, we have performed 10x10=100 experiments per heuristic for each dataset and our reported results are the means of these 100 experiments for each dataset. We have applied t-test with $\alpha = 0.05$ in order to determine the statistical significance of mean results. Since t-test assumes normal distribution, analysis can be misleading in case of skewness. In order to detect any skewness in the distribution of the results, we also include box-plots. All implementations are done in MATLAB environment.

VI. Results

(pd, pf, bal) results of 100 experiments for NASA and SQ datasets are plotted in Figure 1 and Figure 2 repectively. From these figures, we observe that Infogain(IG), GainRatio(GR) heuristics and standard Naive Bayes with log-filtering(LNB) outperforms other heuristics. These three methods show statistically significant performances than others in all datasets. Thus, we only tabulate these three methods' mean (pd,pf,bal) values in Table III and Table IV.

In NASA datasets, overall evaluation yields 5, 6 and

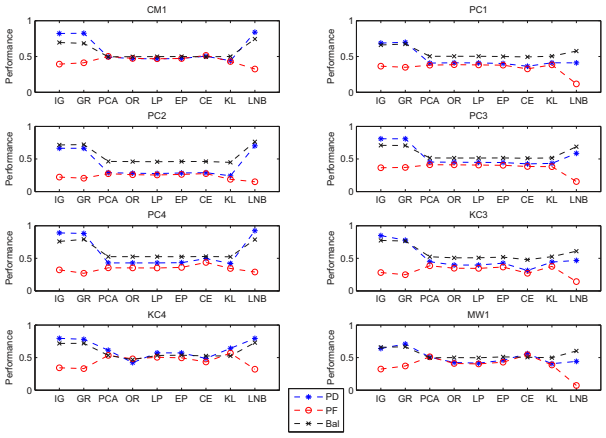

Fig. 1. Performance measures (pd, pf, bal) for Nasa datasets

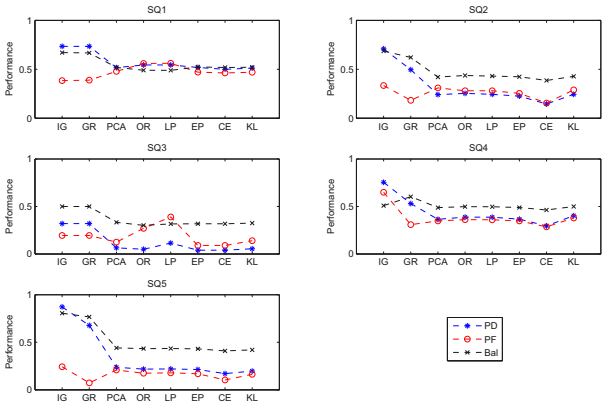

Fig. 2. Performance measures (pd, pf, bal) for SQ datasets

4 wins for InfoGain, GainRatio heuristics and LNB respetively. These results indicate that our proposed approach yields comparable and in some cases better results than the ones reported on these datasets so far. InfoGain and GainRatio heuristics achieve higher pd and pf values compared to LNB. We argue that the projects that require high reliability should have higher pd values. Since these datasets have this requirement, InfoGain and GainRatio based heuristics may be preferred over LNB.

In SQ datasets we observe a decrease in the average of all performance metrics. This stems from the bad predictions in SQ3 dataset. The results for SQ3 are (pd, pf, bal) = (32, 20, 50). Excluding SQ3 from the average enhances the results. On the other hand, SQ3 dataset includes only 36 modules whereas the number of attributes is 30. SQ3 results suggest that defect prediction becomes a harder task and it lacks the desired performance in small projects. However, this should be verified by testing on additional small projects.

Figure 3 shows the boxplots of 100 balance results for IG, GR and LNB. The leftmost and the rightmost lines in the boxes correspond to the 25% and 75% quartiles and the line in the middle of the box is the median. The notches around

Avg (-SQ3):	77	40	67	61	24	67

the median correspond to the 95% confidence interval of the median. We observe that the statistical signifinace of the means also apply for the medians of the three methods in most cases. We should also note that it is a sign of skewness if the medians are not centered between 25% and 75% quartiles. In most datasets, we observe such skewness. The dashed lines in the boxplots indicate 1.5 times of the interquartile range, i.e. the distance between the 25% and 75% quartiles. Data points outside these lines are considered as outliers. CM1, PC4, KC3 and MW1 datasets have relatively large number of outliers in this sense. Another observation is that the weighting results are more stable than standard Naive Bayes. Figure 3 shows that, in all datasets, the spread of balance values are less than or equal to that of Naive Bayes.

Figure 4 shows the same plot for SQ datasets. It is clearly seen that the behavior on SQ3 dataset is different from the others and the results are highly skewed due to the small number of data samples in this dataset.

VII. CONCLUSION AND FUTURE WORK

This paper presented an application of defect prediction built on weighted static code attributes. We have used several heuristics in order to estimate the weights of attributes based on their relative importance. These heuristics have linear computational times. We have evaluated our approach on Weighted Naive Bayes predictor, which is an extension of standard Naive Bayes. Our major contri-

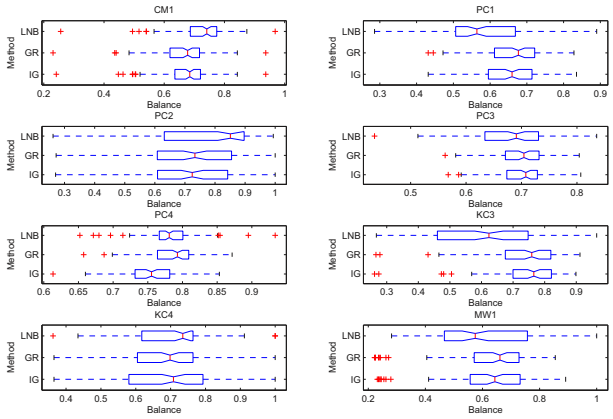

Fig. 3. Boxplots for Nasa datasets.

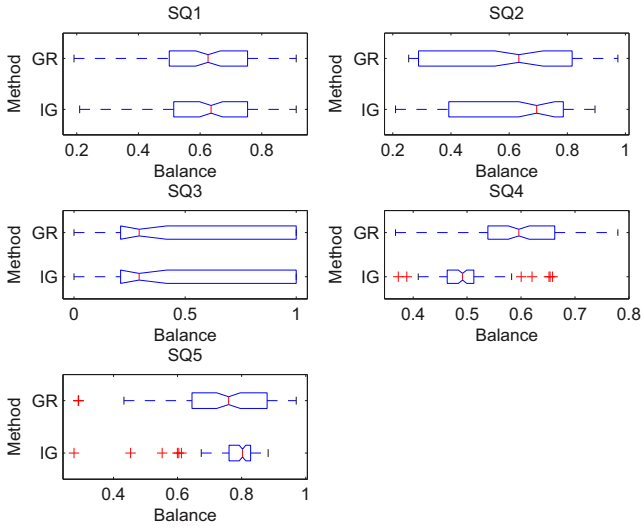

Fig. 4. Boxplots for SQ datasets.

bution in this research is to introduce a novel "weighted attributes approach" for defect prediction.

Condidering our motivation about the disadvantages of subsetting, we have eliminated the need for a threshold value, thus the most time consuming 'search for the optimal' step is avoided. All availabe attributes are used according to their estimated importances based on their discriminative power for defect prediction i.e. less important attributes are used with lesser weights. While some attributes seem to have greater importance than others for defect prediction, we believe in the notion that there is not a magical set of attributes to achieve the best performance. Moreover, automatic collection of static code attributes does not cost much. Therefore, we encourage to collect as many attributes as possible so that the weigthed scheme choses how they will be used. It would then be better to use all available attributes rather than explicitly throwing away a portion of collected data with subsetting.

Our proposed approach performs at least equaivalent and in some cases better than the currently best defect

predictor [8]. Although more parameters are introduced by the weights, the predictions are more stable. Finally, it has better time complexity and we generalize the results on both NASA datasets and datasets collected from various SME's.

Though some research stated against using static code attributes [28], [29], our results confirms the foundings of Menzies et. al.[8]. This shows the applicability of defect predictors based on static code attributes in a wide range of companies and projects.

We should note that our datasets include an extreme case (i.e. SQ3) with too few modules. We can comment that exceptionally small projects has highly skewed predictions with large variances. This is because there are not enough data samples to learn a stable theory. A future direction should be to focus on determining the necessary number of data samples for stable defect predictors.

From a software practitioner's point of view, these results are useful for detecting defects before proceeding to the test phase. In this sense, test resources can be managed more efficiently. Additionally, many companies in the software market develop their standards or make use of the best practices from industry, to determine the thresholds for static code attributes in order to guide developers during implementation. Our results indicate that the impact of changes in static code attributes to the defect rate varies for different attributes. Weights of the model can be interpreted as the attributes' contribution to the defectiveness of the modules and can be considered in code reviews.

One research direction is to examine the other assumption of Naive Bayes, which is the 'independence' of attributes assumption. We have ongoing research to address this problem by introducing multivariate distributions to defect predictors in order to model correlations between attributes.

Another future work is to measure attributes of module complexities by taking the software structure into account. Current static code attributes measure the complexites of modules independently, whereas these modules are not independent of each other. We think that attributes incorporating the communications among modules would lead better prediction performances.

Abstract. In this paper we present a simulation based approach to predict the expected probability distribution that describes the size of a software project in a given period in the future. Since the simulation strongly depends on historical information, we propose the collection of such data from version control systems, which are well-known and widely used in the industry. We discuss the information collection process and the simulation model that is built and executed based on such data. Finally, we present a case study in which we apply the proposed approach to estimate the size of a large software project on a three month time frame, comparing simulation results with other estimation procedures.

Keywords: software estimation, software economics, measurement and empirical Software Engineering.

1 Introduction

Size prediction is a hard problem for software projects. Many are the external and internal forces that can influence software growth, and the combined effect of such forces may prove difficult to model. Nevertheless, estimating future size is paramount as an early warning sign of missing milestones and the need to negotiate adjustment to project schedule and cost baseline. By predicting the size of a software project in the near future, a manager can identify whether the development team is productive enough to attain the functionality necessary to meet the next milestones within the desired time frame. So, the manager can plan team allocation on maintaining the software assets that are already constructed and the new functions to be built.

Two perspectives are usually explored when researchers propose a software project prediction method: (a) modeling the project and its influence factors in great detail, yielding complex simulation models that can be executed under distinct scenarios to provide insight on the future of the software project [1] [2] [3]; or (b) selecting a small group of relevant influence factors, deriving analytical formulations that explain the attributes under estimation based on data from past projects, and applying these equations to estimate the project at hand [4] [5].

While the first perspective demands knowledge about the software project to build the simulation models, the second perspective requires a selection criteria by which past projects are chosen to provide data to estimate the new one. Usually, this selection criterion is based on similarity, a subjective and ambiguous term whose interpretation may vary according to the different concerns people present about the project. Also, external drivers (such as consumer's expected delivery date and budget restrictions) may influence the selection of "similar" projects, favoring those whose data yield estimations for the current project within a feasible zone. Finally, there may be issues regarding which data about a past project is available, how such projects were characterized, and how the information was stored. Diversity on data formats, technology used, programming language, development team, environment, and so on, may require adjustments on the available datasets in order to make them useful for the new project.

In this paper, we propose a simulation based approach to predict the expected probability distribution for the size of a software project in a given period, based on information collected from the project itself. Our fundamental assumption is that the most similar project to the one requiring estimation is the project itself. Thus, past information about the project is probably the best estimator for its future performance. Version control systems, like CVS [6] or SubVersion [7], commonly used in many industrial software projects, provide the required information. The approach is related to the second project prediction perspective, since relevant factors collected from past data are used to predict the future of the software project. A case study regarding the application of the approach is presented and its limitations are addressed.

The remaining of this paper is organized in five sections. Section 2 presents concepts and definitions that support the collection of information from version control systems to feed the simulation model. Section 3 presents the proposed simulation model and how results can be drawn from it. Section 4 presents a case study where the proposed approach is applied to a large software project. Section 5 presents related work. Section 6 addresses some limitations of the proposed approach and, finally, section 7 draw conclusions and directions for future work.

2 Collecting Information from Version Control

Configuration management tools have become well known and widely accepted by the software industry [8]. The availability of free source tools for version control, the growth of outsourcing and geographically distributed development, and the need for larger development teams drive the use of version control systems in medium and large software projects.

Version control systems store every version of relevant artifacts that compose a software project, thus maintaining a history of changes done throughout the software life-cycle. Version information, such as comments about the changes that were made, completion date and developer in charge, are attached to each version of an artifact. Version control systems are commonly used to allow navigation and retrieval of different versions of source code modules, but research in the field is evolving to allow requirements, design documents, project plans, and every other document to be managed by these systems.

Therefore, over the years the central repository of a version control system becomes a rich source of time-related information about a software project. After some development time, the repository is populated and the information it holds can be used to estimate relevant attributes for the project. So, instead of relying on "similar projects", our approach uses information from the project itself to support estimation.

Before describing the simulation process that yields the probability distribution for project size in a given period, we need to formalize the information structure under the control of a version control system. A version control system manages several software project repositories. We define a software project repository (SPR) as the finite set of files (F_i) that compose a software project:

$$SPR = \{F_i \mid 1 \leq i \leq N\}$$

Each file composing a software project repository is described by the directory in which it is located and an ordered set of reviews (R_i). Each review ($R_{i,j}$) is described by a unique identifier, the developer who committed the review to the central repository, the moment when the commit operation was executed, a comment describing the changes, and the resulting source code.

$$F_i = (\text{directory}, R_i)$$

$$R_i = \{R_{i,j} \mid 1 \leq j \leq M\} \ \therefore \ R_{i,j}.\text{time} < R_{i,k}.\text{time}, \ \forall \ j < k$$

$$R_{i,j} = (\text{id}, \text{developer}, \text{time}, \text{comment}, \text{code})$$

Based on such definitions, we define the *size* function, which represents the size of a given file review. The function maps a concept from the space defined by the reviews of a given file to the space of natural numbers, where size is defined.

$$\text{size}(R_{i,j}): R_i \Rightarrow N$$

We also define the *current* operator, which returns the last review committed in a given moment for a given file. It allows us to define the size function against time, measuring the size of the current review in that moment.

$$\text{current}(F_i, t) = R_{i,j}$$

$$\therefore R_{i,j}.\text{time} \leq t, \ R_{i,j} \in F_i$$

$$\therefore \text{not} \ \exists \ R_{i,k}: R_{i,j}.\text{time} < R_{i,k}.\text{time} \leq t, \ \forall \ 1 \leq k \leq M$$

$$\text{size}(F_i, t) = \text{size}(\text{current}(F_i, t))$$

Finally, we define the *diff* and *growth* operators. The first calculates the nominal size change observed from time t_1 to t_2, $t_1 < t_2$, while the second calculates the percentile size change in the period.

$$\text{diff}(F_i, t_1, t_2) = \text{size}(F_i, t_2) - \text{size}(F_i, t_1)$$

$$\text{growth}(F_i, t_1, t_2) = \text{diff}(F_i, t_1, t_2) / \text{size}(F_i, t_1)$$

The selection of a metric to act as the size function is not trivial. Lehman suggests counting the number of source files as a size measure for large software projects [9], while Godfrey and Tu [10] use lines of source code to measure size. Moreover, [11] has shown that the number of source code lines is high correlated to the number of source files in large software projects and, therefore, these metrics grow at roughly the same rate. We decided to use lines of code because most size estimation procedures are directly related to this measure, such as [4, 5].

Nevertheless, collecting information from version control systems is a time consuming activity [12] that must be automated to scale to large projects with many thousands of files. We have developed a framework, namely JCVS, which is able to collect information from version control repositories and store such data to XML files or database tables. These are easier to query for project specific information than the poorly structured textual files that compose the version control repository. In the proposed approach, our major interest is related to the number of lines of code in the files' reviews, but the framework is capable of retrieving the source code itself and all the attributes presented in the former formulations.

3 The Simulation Model

The historical growth data about the files composing a software project can be analyzed as a time series, that is, a set of values observed in successive time intervals. Converting time series to probability distributions (by computing the number of times each value is repeated in the series) is a practical procedure to highlight the series' descriptive characteristics, such as average value and variance. Moreover, by analyzing the correlations among time series, we can describe how they behave together, that is, how a change in one series is reflected in the other.

We propose the use of Monte Carlo simulation to estimate the size of a software project in a given period based on correlated probability distributions derived from time series collected from the project's version control system. Monte Carlo simulation is a sampling technique that estimates probability distributions for one or more results, given distributions for a set of parameters. The simulation process requires: (a) a finite set of parameters with known probability distributions; (b) a finite set of results, whose probability distributions will be estimated; and (c) a model that states how given parameter values yield a value for each result. Monte Carlo simulation consists in several cycles, each generating a value for each parameter (according to its probability distribution), calculating results according to the rules and relations prescribed in the model, and annotating these results. After thousands of such cycles, thousands of values are

annotated for each result and their probability distribution can be derived from these values. Monte Carlo simulation is popular because it allows parameters to be described by any type of probability distribution (such as the normal or beta distributions) and model development does not require specific knowledge on statistics or how to apply operations upon probability distributions.

In our proposed estimation method, the parameters are parts of the software project, being characterized by probability distributions estimated from growth time series extracted from version control systems; the single result is the observed growth of the project; and the model prescribes that the growth of the project is equal to the sum of the nominal growth of its parts divided by project size. So, the definition for both parameters and model depends on how the project is broken into parts. Two restrictions apply to this decomposition: (i) it must be possible to collect growth time series for each part from version control systems; and (ii) high correlated time series must be grouped and treated as a single part[1].

The first restriction allows two decomposition strategies: to take each file composing the project as a part or to take selected groups of files as a part. However, the second restriction eliminates the first strategy, since for large projects there would be thousands of composing files. In such a situation, there is a large probability that there will be any two files, F_i and F_j, so that changes to F_i will be coincident to changes to F_j over time. This results in high correlation among these time series, breaking the second restriction. Thus, the remaining option is to divide the project into file groups and treat each group as a part.

In the context of the proposed method, we define a component as a group of files that are logically related to each other in a project (for instance, they represent distinct design aspects for the same concept or process). The project must be divided into a set of complementary components (C_k). We suggest using of the project's directory structure as a starting point for the division, refining it according to the distribution of project features among the source code distribution units (for instance, packages in an UML model). The final set of components must be so that each and every file in the repository pertains to one and only one component.

$$SPR = \{C_k \mid 1 \le k \le Z\}$$

$$C_k = \{F_i \mid 1 \le i \le N\}$$

$$\therefore \forall F_i \in SPR \Rightarrow \exists\, C_k : F_i \in C_k,\ 1 \le i \le N,\ 1 \le k \le Z$$

$$\therefore \forall F_i \in SPR,\ F_i \in C_k \Rightarrow \text{not } \exists\, C_l : F_i \in C_l,\ 1 \le i \le N,\ 1 \le k, l \le Z;\ l \ne k$$

Given these definitions, we can define the size function and the *diff* and *growth* operators for components. The size function is defined below. The definition for the *diff* and *growth* operators is straightforward.

$$size(C_k, t) = \sum_{i=1}^{N} size(F_i, t) \qquad \therefore F_i \in C_k,\ 1 \le i \le N$$

After dividing the project into components, we collect a growth time series about each component from the version control system. These growth time series are calculated by applying the following process: (a) build a time series for the size of each project file, collecting these data directly from the version control system, as presented in section 2; (b) sum up the time series for the files that compose each component, yielding a time series for the size of each component; (c) apply the growth operator in a weekly basis over each component size time series, resulting in a weekly growth time series for each component.

The weekly basis was selected since we expect that our approach will be used in medium or large size projects, where development time is measured in months or years. Using a monthly basis would leave few data points to build the component's probability distribution, while a day seems too small a period to measure changes in components' sizes. Further investigation is required to determine if the weekly basis can be generalized to any project, independent of its size or any other characteristic.

Next, the growth time series for each component must be analyzed to identify and eliminate outlier points. Such outliers are common in software development, and they are discernible as ripples in the growth time series as files are reused into the component (upward ripple), files are transferred to another component (downward ripple), developers delay the commitment of large changes to the central repository (upward ripple), or third-party code is put under version control (upward ripple). We observed that such ripples are more common early in the project life-cycle or during the transition phase of a service acquisition (such as third-party development). Since they do not represent the expected behavior for the project, these outliers must be eliminated before simulation.

Each weekly growth time series is then converted to a probability distribution that describes the component in the simulation process. Correlations among these time series are calculated and organized in a symmetric matrix where each row and column represents a component and each cell conveys the correlation among the components in its row and column. After sampling a growth value for each component in a simulation cycle, such values are applied to the correlation matrix in order to represent the joint behavior of growth in components. Thus, we have a set of correlated parameter values.

The simulation process also depends on the estimation period, that is, the number of intervals after a given date on which project size will be estimated. As data collection is established in a weekly basis, the estimation period (Δ) is also expressed in weeks. Each simulation cycle samples correlated parameter values Δ times, yielding Δ random weekly growths for each component (G_t). The size of the component after the estimation period is given by:

[1] When using Monte Carlo sampling with correlated time series, their correlations are organized in a symmetric matrix that must be positive defined. This property cannot be observed if two or more series present high correlation.

$$size(C_k, T+\Delta) = size(C_k, T) \cdot \prod_{t=1}^{\Delta}(1+G_t)$$

After simulating each component size Δ weeks ahead, project size is estimated by summing up the sizes of its components. So, each simulation cycle yields an estimated project size and an estimated size for each component. By executing thousands of cycles, the proposed approach yields a probability distribution for project size and a probability distribution for each component's size.

4 Case Study

This section describes the application of the proposed approach to a large scale system. The system is used by financial institutions and financial departments of non-financial companies to identify, analyze, and manage investments in market, over-the-counter, and hedge assets. It is under development since early 2005, with an average team of ten developers, using object-oriented and software component technologies. The software is developed using an incremental process and is currently composed of about 500 KLOC distributed along 1,931 source code files.

In this case study we were interested in addressing the ability of the proposed approach to estimate project size in the future, comparing the estimated size to the observed growth. We had version control data for the project since February, 2005 to September, 2007. We designed the case study so that such data was separated into two samples: data from February, 2005 to June, 2007 was used to parameterize the simulation model, while data from July, 2007 to September, 2007 was used as a test sample, being compared to results achieved from simulation.

Based on an assessment of its directory structure and a meeting with the system architect, the software project was decomposed into fifteen components. Six of these are under development since the project started (February, 2005), five others were started a year later (February, 2006), and the last four components were started about a year and a half after development was commenced (November, 2006). Though some components had version control data available since February, 2005, we decided to collect information only for the period when all components were under development (that is, from November, 2006 to September, 2007). This allowed us 34 weeks of sample data and 12 weeks of test data. Also, this period would better reflect the actual productivity, since the development team was smaller in the early stages of the project life-cycle. Table 1 presents the size (in KLOC) of each component after the 34 weeks of sample data (first row) and after the 12 weeks of test data (second row).

Table 1 - Component sizes after the sample and test data periods

aux	sdbb	sass	sinf	srep	sdec	svar	scfr
21,7	45,0	51,7	53,7	6,1	23,8	28,0	20,7
24,9	48,1	51,8	54,5	14,0	28,2	33,7	21,3

idbb	iass	iinf	irep	idec	ivar	icfr
24,5	19,5	47,3	10,3	20,7	50,8	13,2
25,8	19,8	53,1	12,4	22,5	57,5	13,2

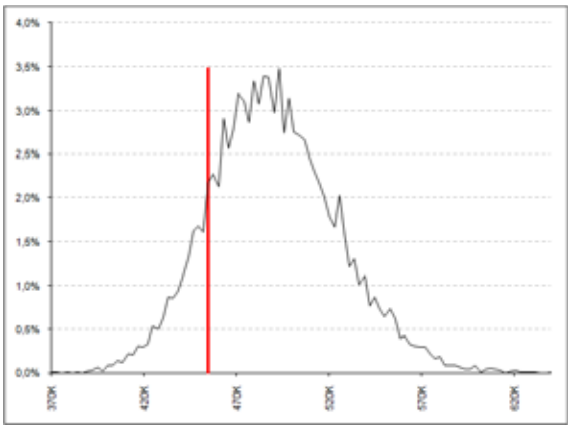
Next, we created the growth time series for the components, as presented in Section 3. By visually inspecting these time series, we observed some outliers and proceeded with an investigation with the system architect to understand whether these outliers were valid values that should be accounted for in the simulation or there were reasons for these large growth variations that should not repeat in the future. Therefore, we conducted a qualitative outlier elimination based on information gathered through interviews with the project architect, instead of a model based, quantitative outlier elimination procedure. This investigation revealed important issues about project components:

- The six components built from February, 2005 (*aux*, *sass*, *sinf*, *sdec*, *svar*, and *scfr*) were developed by reusing code from a previous version of the same system. So, their early development stages show high growth (thousands of KLOC added in a single week), which was not compatible with the effort dedicated to the components and could only be related to the inclusion of reused code. Therefore, data from the early development stages should be suppressed from the analysis. This was not an issue to the current case study (which used information from November, 2006 on), but was recorded as a lesson learned for field data collection;
- Two components (*srep* and *irep*) were developed by an external company, being integrated to the project's version control system later in their development process. So, the time series for these components present large ripples as new code is integrated monthly (due to a staged delivery schedule), instead of a smoother daily integration. Moreover, the maintenance of these components was transferred to the company within the test data period. So, the large growth ripples ceased and a moderate growth behavior was observed. This could not be projected by the components' time series, since they reflected a third-party development period. We decided to estimate project size without these components, thus eliminating their series from analysis;
- A component (*aux*) presented a "ladder style" time series: a week presenting high growth was followed by several weeks without development (that is, growth very close to zero). By enquiring the architect about this component, we discovered that it was composed by utilities classes, many of them reused from previous projects. The reuse of previous code justified the "ladder-effect" in the time series, as complete, quality code from other projects was injected into the version control repository. We decided to keep the component under analysis, eliminating a single very large ripple that made the component's size double in a single week.

After removing the outliers from the time series, we generated their probability distributions and calculated

their correlation matrix. The multivariate distribution was submitted to the simulation process, yielding future size distributions for each component. The distributions after 10,000 simulations are available at the URL http://www.uniriotec.br/~marcio.barros/seke2008/ index.html.

Figure 1 presents the probability distribution for project size 12 weeks after the sample data period, related statistical information, and a comparison to the observed size. The final project size (vertical line at 454.5 KLOC, excluding the *srep* and *irep* components) is within the boundaries of the probability distribution and close to the region determined by its first standard deviation from the average (469.7 to 510.1 KLOC).



Information	KLOC	Information	KLOC
Observed Size	454,5	Estimated Size	489,9
Std Deviation	20,2	Median	487,3
1st Quartile	465,5	3rd Quartile	511,8

Figure 1 - Probability distribution for future project size and related statistics

We compared this result with a projection of system size after 12 weeks using the growth of the whole system as a single time series. Over the 34 sample data points, the average growth for the whole system was about -0.91%, which yields an expected size of 376.8 KLOC after the 12 weeks of test data. Thus, the error between the simulation based estimation and the real system size after the test period was about 7%, while a projection of system size over the same period based on a single system growth time series would generate an error rate of about 17%.

We also compared simulation results to estimation based on exponential weighting the growth time series for the whole system, a usual estimation procedure in time series analysis. Exponential weighting uses a polynomial based on a factor (λ) by which observations are weighted. The polynomial is built so that recent observations have more weight than older observations. The estimated system growth (EG) is calculated as shown below.

$$EG = (G_t + \lambda.G_{t-1} + \ldots + \lambda^N.G_{t-N}) / (1 + \lambda + \ldots + \lambda^N)$$

$\therefore$ G_{t-K}: observed system growth on time t-K

By varying the lambda factor from 100% to 70%, we observed that estimation error for system size grows from 17% to 20%. Thus, correlations among component growth time series play a fundamental role to estimation, which is not captured by analyzing the single system growth path.

Analyzing the distribution for component sizes, we observed that *svar* presented higher growth than expected from past information, *idbb* presented lower growth, and *idec* presented less growth variations than observed in the time series. Questioning the architect about such results, we were informed that new features were recently added to the *svar* component (leading to higher growth than expected), and that sample data captured a phase in which new features were implemented in *idbb*, complementing features that were earlier implemented in the *sdbb* component (thus, test data represented an stabilization period for such component, presenting lower growth). Finally, the architect could not explain the large variability in the *idec* component in recent, test data.

Thus, analysis results provide indications that the proposed method may be useful to address project size in the future. Moreover, analysis indicates that it can elicit relevant questions about project component's evolution, useful to register project history and to predict future behavior for the software project.

5 Related Work

The most typical approaches for using version control data to provide insight upon a software project are based on visualization. Many approaches, such as the Seesoft tool [13], the Aspect Browser [14], and Augur [15], allow the visualization of dependencies among changes to a software project. Such tools usually summarize project information in line lengths and/or color codes, allowing thousands of data elements to be presented simultaneously on a screen. However, these tools are not yet able to draw conclusions from the data, leaving this task to the analyst.

Monte Carlo simulation has been used to draw the evolutionary path of specific uncertainties in software projects. Grey [16] and Hullet [17] present simulation methods to estimate project schedule and cost baseline. In [2], we see the use of Monte Carlo sampling to model uncertain results of a system dynamics model, according to probability distributions associated to its parameters.

To the best knowledge of the author, there is no attempt to use size information from version control systems to predict the future size of software projects. However, in a recent paper Kitchenham et al [18] addressed the benefits of using in-company estimation methods (that is, estimation models based on information from previous projects developed by the same company) instead of using cross-company methods. It was observed that, in some companies, in-company methods performed better than cross-company models, thus enforcing that in-project data may be useful for estimation.

6 Limitations of the Proposed Approach

Due to the nature of the information used to describe the parameters of the simulation process, the proposed

approach has some limitations. First, it is tightly related to the coding activity, since version control systems are usually used during such activity. However, we see growing interest on using such systems before coding, to store and evolve specifications, design diagrams, and other artifacts created during project development. As research in this direction unfolds, we probably will be able to use other artifacts to support estimation.

Second, the approach cannot estimate project size early in the life-cycle, since there must be "past information" upon the project. We suggest that analogy estimation, based on similar projects from the past, might be used to provide a first estimation for the project. This estimation can be refined as project information is made available in version control systems. The combination of analogy and project-based estimation strategies requires investigation and is a future perspective for our research.

We also believe that the usefulness of the proposed approach may vary according to the usage of different project life-cycle models. Project-based estimation is probably more useful when development is carried on using an incremental or spiral life-cycle model, in contrast to a waterfall life-cycle model, since the coding activity (and generation of version control information) starts earlier in the former models.

Other important aspect of the proposed method is that estimation is solely based on the production of source code lines. Though it may seem that many factors that influence the growth of a software project are overlooked, the method assumes that recent history will repeat itself in the near future. Thus, the same factors that affected recent production of source code lines will play their role again, affecting production in the estimation time horizon. So, we rely on a single relevant productivity indicator, assuming that it captures the influence of other factors.

7. Conclusions and Future Perspectives

This paper presented a simulation process to estimate the size of a software project in a given time horizon, according to information collected from the project's version control system. The project is divided into components, component size changes in the past are calculated from version control data, probability distributions are drawn to describe component growth dynamics, and Monte Carlo simulation is used to estimate the joint effect of these distributions upon project size.

Further investigation is being conducted to assess the usefulness of the approach under distinct development models. We intend to evaluate it under agile development, process-oriented organizations, and distinct life-cycle models. We also intend to provide better procedures for the component division and outlier elimination stages of the proposed approach. Moreover, since Monte Carlo simulation is computer intensive, we can study version control information on the perspective of time series models, such as auto-regressive (AR), moving average (MA) and integrated models (ARIMA).

Supporting Reusable Component Selection with Use Case Gap-Based Development Effort Estimation

Xin Zhou, Bonnie Ray, Chenhua Feng

Abstract

Reuse-based development effort is an important factor to be considered when selecting appropriate reusable components. However, it's rarely considered very seriously in current practice, as current methods for estimation of reuse development effort rely heavily on personal experience and different developers may provide very diverse estimates. In this paper, we propose a method - AREA (Asset Reuse Econometric Analysis) that enables systematic evaluation of development effort for a new software based on consideration of alternative reusable components. The core components of the method are a process guiding the evaluation and an algorithm for calculating the effort based on use case gap analysis between to-be developed new software and selected reusable components. A proof-of-concept implementation of AREA is introduced and the feedback acquired through its pilot with a solution development team in IBM's Global Business Solutions Center (GBSC) is presented.

Keywords: software reuse, reusable component selection, development effort estimation, use case gap

1. Introduction

Software applications are playing an increasingly critical role in supporting daily business, and there is widespread need for high quality software applications to be delivered in very tight time schedule. Software reuse has been considered a promising way for improving the quality and productivity of software development via leveraging validated reusable software components [1][2].

Among the issues and problems associated with software reuse, the selection of suitable reusable components from numerous candidates is a critical one [3]. The challenge is to achieve appropriate balance among multiple concerns: functional requirements, non-functional requirements, technical compatibility, financial issues, and so on. An overall reusable component selection process and some general criteria for assessing the suitability of potential reusable components are presented in [4]. A strategy for managing risks in the components selection is proposed in [5]. Kontio et. al present their COTS (Commercial Off-The-Shelf) selection method – OTSO and its case studies in [6][7]. Also there are requirement engineering based methods for COTS evaluation and selection, as introduced in [8][9]. These existing works mainly focus on systematic selection process, selection criteria definition technique, functional and non-functional requirement based selection, and decision making techniques. However, they rarely consider the potential development effort for developing the new software, leveraging a given set of candidate reusable components. The lack of careful consideration of reuse-based development effort may cause inappropriate selection of reusable components, which increases the possibility of higher cost and longer development lifecycle and counteracts the benefit of reuse.

In this paper, we present AREA (Asset Reuse Econometric Analysis), a method that enables systematic evaluation of the development effort for each candidate reuse approach based on alternative reusable components selection. The core components of the method include a process guiding the evaluation and an algorithm for calculating the effort based on analyzing the use case gap between to-be developed new software and selected reusable components. A proof-of-concept implementation is built for AREA and is currently being piloted with solution development teams working at IBM's Global Business Solutions Center (GBSC), from whom preliminary feedback has been acquired.

The remainder of this paper is organized as follows. Section 2 describes the AREA process and algorithm. Section 3 introduces a web-based AREA support tool. We report the pilot of AREA in section 4. In section 5, we conclude and propose some future works.

2. AREA Method

In this section, we will first describe the conditions on which AREA is intended to be applied. Then, the overall AREA process and the core use case gap-based development effort calculation algorithm are presented. Finally, we will give an illustrative example for better understanding of the method.

2.1. Assumptions

In present reuse practice, various public or private reusable component repositories [10][11] are set up to accommodate reusable component information and software developers search and/or retrieve reusable components for reuse based software development. To apply the AREA method, we assume that for each reusable component registered in the repository, the following affiliated artifacts can be found: its use cases, its implementation work products, the traceability between use case and work products providing information on which work products realize which use cases.

2.2. The AREA Process

Figure 1 describes the overall AREA process. There are four major steps in the process: searching reusable components, generating reuse approaches, calculating development effort for each reuse approach, and comparing all the reuse approaches considering their development effort.

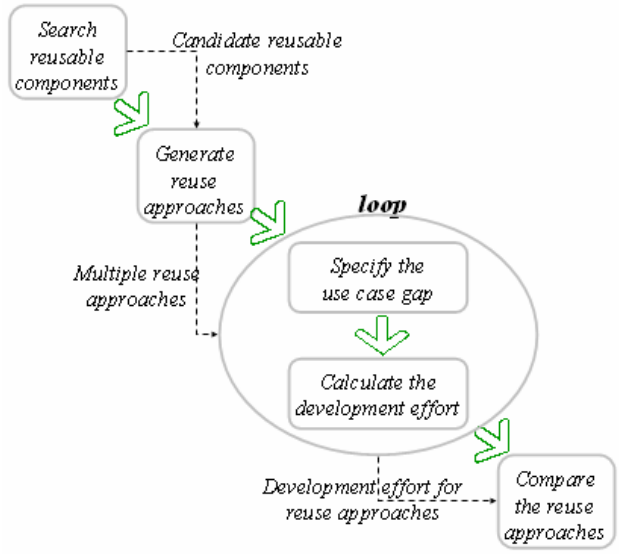

Figure 1: Overall AREA Process

First given the to-be developed new software, software developers search a reusable component repository for candidate reusable components that fully or partially realize the whole or partial requirement of the to-be developed software. For example, we might find three candidate reusable components for required function "xml parser written in java" and five candidate reusable components for requirement "logging".

In the second step, based on the search result, software developers can generate multiple reuse approaches. For example, in approach one, candidate reusable components a, b and c will be reused, while in approach two, candidate reusable components a, e, and f will be reused.

While generating the reuse approach, some factors are usually considered by software developers, including the to-be developed software's architecture design, the to-be developed software's technical constraints, and the interface compatibility of reusable components selected for this approach, etc. It's rare that a resulting reuse approach can exactly match the requirements of the to-be developed software. As a result, once we take one approach, further efforts are required to supplement new functions, to transform existing un-matched functions, and to remove unwanted functions, and the effort size depends on the degree of function added, transformed or deleted. In order to calculate the development effort, we need to clearly specify the gap between requirements of the to-be developed software and the existing functions of the individual components considered for reuse. As use case [12] has been widely adopted as an effective way to specify software functions, AREA recommends specifying the requirement gap with use case gap metrics.

Use Case Points (UCP) estimation method estimates software development effort based on external use cases specifying the software's functional requirements [13]. UCP method assumes that all use cases are to be developed from scratch. Use case points are assigned according to use case and actor's complexity and adjusted by a set of technical factors and environment factors. The final effort estimation is calculated by multiplying UCP by a statistical parameter PHperUCP (Person Hours per UCP). Experiments [14][15] reveals that this method is more accurate than expert estimation in industrial trials. Our work differs from this in that we estimate the development effort based on use case gap between to-be developed software and reusable components, instead of use case of the to-be developed software.

Table 1 provides a non-exhaustive list of the basic use case gap metrics.

Table 1: Basic Use Case Gap Metrics

Object	Metric Definition
Actor	(Weighted) Number of as-is actors
	(Weighted) Number of new actors
	(Weighted) Number of unwanted
	(Weighted) Number of to-be transformed actors
Event Flow	(Weighted) Number of as-is flows
	(Weighted) Number of new flows
	(Weighted) Number of unwanted flows
	(Weighted) Number of to-be transformed flows
Extension Point (EP)	(Weighted) Number of as-is EPs
	(Weighted) Number of new EPs
	(Weighted) Number of unwanted EPs
	(Weighted) Number of to-be

For a given use case of the to-be developed software, there are three scenarios when identifying reusable components. The first case is that it represents totally new functions and cannot find any similar reusable component use case. The second case is that there is one reusable component use case representing similar functions as it does. The third case is that there are multiple reusable component use cases which together provide similar functionality.

Based on the clearly specified use case gap, we will leverage the size and effort information of the reusable components selected in current reuse approach to calculate the potential development effort for the to-be developed new software taking this approach. Our ultimate purpose is not to provide a very precise estimation on the development effort for resource and schedule planning, but to provide software developers with an additional effort related dimension for reuse approach tradeoff. The effort calculation approach is detailed in the following section

2.3. The Effort Calculation Algorithm

For the convenience of algorithm presentation, we first define some notation as follows:

- The reusable components selected by current reuse approach are denoted as C_1, C_2, …, C_k
- The use cases of the to-be developed new software are denoted as T_UC_1, T_UC_2, …, T_UC_n
- The use cases of a reusable component C_i are denoted as R_UC_{i1}, R_UC_{i2}, …, R_UC_{im}
- The reuse relationship between to-be developed software use case and reusable component use case(s) is denoted as (T_UC_i, $Set\_of\_R\_UC_i$).
- The implementation work products related to a reusable component use case set Set_of_R_UCi are denoted as $WP_1\_UC_i$, $WP_2\_UC_i$, …

Considering the three scenarios about the similarity between T_UC and R_UC introduced in previous section, there may be none, one, or multiple reusable component use cases in $Set\_of\_R\_UC_i$. The development effort E for new software consists of the effort E_{new} for realizing those use cases without leveraging any reusable components and the effort E_{reuse} for realizing those use cases leveraging reusable components.

Formula 1:

$$E = E_{new} + E_{reuse}$$

Formula 2:

$E_{new} = \sum$ Effort of T_UC_i, where $|Set\_of\_R\_UC_i| = 0$;

Formula 3:

$E_{reuse} = \sum$ Effort of T_UC_i, where $|Set\_of\_R\_UC_i| > 0$;

For the effort of T_UC_i whose Set_of_R_UCi is empty, we still need software developers to manually input a development effort as there is no baseline for reference. Summing these effort values comes to E_{new}.

For the effort of T_UC_i whose Set_of_R_UCi is not empty, we will calculate it based on the historical development effort of the implementation work products it reuses. Suppose the gap between T_UC_i and $Set\_of\_R\_UC_i$ is denoted by P_{Ai}, P_{Ni}, P_{Ti}, and P_{Di}. More specifically, P_{Ai} denotes the percentage of $Set\_of\_R\_UC_i$'s actors/event flows/extension points that have the same counterpart from use case(s) in T_UC_i. P_{Ni} denotes the ratio of new actors/event flows/extensions points in T_UC_i to the total actors/event flows/extensions points in $Set\_of\_R\_UC_i$. P_{Ti} denotes the percentage of $Set\_of\_R\_UC_i$'s actor/event flow/extension point that has similar but not equal counterpart from use case(s) in T_UC_i. P_{Di} denotes the percentage of $Set\_of\_R\_UC_i$'s actor/event flow/extension point that has neither similar nor equal counterpart from use case(s) in T_UC_i.

The effort calculation for this kind of T_UC_i is defined by formula 4. Here, we make an assumption that reusing as-is from reusable components needs no effort.

Formula 4:

Effort of $T\_UC_i = (P_{Ti} * TF_i + P_{Ni} + P_{Di} * DF_i) * \sum$ Effort of $WP_j\_UC_i$, where $|Set\_of\_R\_UC_i| > 0$;

TF_i (Transformation Factor) is a number denoting the ratio of transformation difficulty to new development difficulty. For instance, a TF_i value 0.5 means that for use case T_UC_i, developing from scratch is twice as hard as transforming based on existing implementation work products. Similarly, DF_i (Deletion Factor) is a number to denote the ratio of deletion difficulty to new development difficulty.

2.4. An Illustrative Example

In this section, we will use an example to demonstrate the AREA process and calculation algorithm.

** Search Reusable Components*

Suppose the to-be developed software S has three use cases: T_UC_1, T_UC_2, T_UC_3. The candidate reusable components obtained from repository are C_1 (with one use case R_UC_{11}), C_2 (with two use cases R_UC_{21} and R_UC_{22}) , C_3 (with two use cases R_UC_{31} and R_UC_{32}) and C_4 (with one use case R_UC_{41}). The use case similarity relationship between the new software S and C_1, C_2, C_3, C_4 are shown in Table 2.

Table 2: Use Case Similarity Relationship

Use Case		*T_UC1*	*T_UC2*	*T_UC3*
C_1	R_UC_{11}	Yes	No	No
C_2	R_UC_{21}	No	Yes	No
	R_UC_{22}	No	No	Yes
C_3	R_UC_{31}	Yes	No	No
	R_UC_{32}		No	No
C_4	R_UC_{41}	No	Yes	No

Also, software developers can get the historical development efforts of implementation work products realizing C1, C2, and C3 from repository, as listed in Table 3.

Table 3: Historical Work Product Development Effort

Use Case		*Work Product*	*Development Effort*
C_1	R_UC_{11}	WP_{11}	20PHs (*)
C_2	R_UC_{21}	WP_{21}	45PHs
	R_UC_{22}	WP_{22}	30PHs
C_3	R_UC_{31}	WP_{31}	30PHs
	R_UC_{32}	WP_{32}	20PHs
C_4	R_UC_{41}	WP_{41}	25PHs

(* PHs means PersonHours)

** Generate Reuse Approaches*

Based on the preliminary analysis on above search results, software developers generate two alternative reuse approaches. For the first approach, C_1 and C_2 are reused. For the second approach, C_3 and C_4 are reused.

** Development Effort Calculation for Reuse Approach 1*

As in reuse approach 1, C_1 and C_2 will be reused by S, the software developers compare the use cases of S and those of C_1 and C_2. They get the values for use case gap metrics, as listed in table 4.

Table 4: Use Case Gap for Reuse Approach 1

	P_A	P_N	P_T	P_D
(T_UC_1, {R_UC_{11}})	60%	20%	20%	20%
(T_UC_2, {R_UC_{21}})	70%	30%	30%	0
(T_UC_3, {R_UC_{22}})	90%	10%	10%	0

Suppose the transformation factor $TF_1 = TF_2 = TF_3 = 0.6$ and deletion factor $DF_1 = DF_2 = DF_3 = 0.4$, then the calculation steps for reuse approach 1's development effort is:

(1) Effort of T_UC_1
= $(P_{T1} * TF_1 + P_{N1} + P_{D1} * DF_1) * \sum$ Effort of $WP_j\_UC_1$
= (20% * 0.6 + 20% + 20% * 0.4) * (20)
= 8 PHs

(2) Effort of T_UC_2
= $(P_{T2} * TF_2 + P_{N2} + P_{D2} * DF_2) * \sum$ Effort of $WP_j\_UC_2$
= (30% * 0.6 + 30% + 0 * 0.4) * (45)
= 21.6 PHs

(3) Effort of T_UC_3
= $(P_{T3} * TF_3 + P_{N3} + P_{D3} * DF_3) * \sum$ Effort of $WP_j\_UC_3$
= (10% * 0.6 + 10% + 0 * 0.4) * (30)
= 4.8 PHs

(4) E_{reuse}
= Effort of T_UC_1 + Effort of T_UC_2 + Effort of T_UC_3
= 8PHs + 21.6 PHs + 4.8 PHs = 34.4 PHs

(5) $E = E_{new} + E_{reuse}$
= 0 + 34.4PHs
= 34.4PHs

** Development Effort Calculation for Reuse Approach 2*

As in reuse approach 2, C_3 and C_4 will be reused by S, the software developers compare the use cases of S and those of C_3 and C_4. They get the values for use case gap metrics, as listed in table 5.

Table 5: Use Case Gap for Reuse Approach 2

	P_A	P_N	P_T	P_D
(T_UC_1, {R_UC_{31}, R_UC_{32}})	50%	20%	40%	10%
(T_UC_2, {R_UC_{41}})	80%	10%	20%	0
(T_UC_3, {})	/	/	/	/

Suppose the transformation factors $TF_1 = TF_2 = 0.6$ and $DF_1 = DF_2 = 0.4$, then the calculation steps for reuse approach 2's development effort is:

(1) Effort of T_UC_1
= $(P_{T1} * TF_1 + P_{N1} + P_{D1} * DF_1) * \sum$ Effort of $WP_j\_UC_1$
= (40% * 0.6 + 20% + 10% * 0.4) * (30+20)
= 24 PHs

(2) Effort of T_UC_2
= $(P_{T2} * TF_2 + P_{N2} + P_{D2} * DF_2) * \sum$ Effort of $WP_j\_UC_2$
= (20% * 0.6 + 10% + 0 * 0.4) * (25)
= 5.5 PHs

(3) E_{reuse}
= Effort of T_UC_1 + Effort of T_UC_2
= 24PHs + 5.5 PHs = 29.5 PHs

(4) E_{new} = Effort of T_UC_3 = 15 PHs, as estimated manually by software developers

(5) $E = E_{new} + E_{reuse}$
= 15 PHs + 29.5 PHs
= 44.5PHs

** Compare between Reuse Approach 1 and 2*

With the development effort calculation results gotten in previous steps, software developers can learn that reusing C_1 and C_2 for S will save 44.5 – 34.4 = 10.1 PHs effort than reusing C_3 and C_4. Although it's not the determinant factor for developers to select reuse approach 1, software developers can combine this factor with others (like the price for getting reusable components for each approaches, how developers skill availability for different approaches, and so on), to support more precise decision making.

3. Proof of Concept Implementation

3.1. High Level Architecture

As depicted by Figure 2, major components of the AREA support tool fall into four layers. Components in the representation layer provide software developers with the integrated interface for login, reuse approach design, candidate reuse approach tradeoff, and so on. This layer is implemented with JSP (JavaServer Pages)[16] and Struts[17], both widely available technologies.

Components in the application layer provide core functions, including user management, project management, alternative reuse approach management and estimation management. We use SCA (Service Component Architecture)[18] to implement the components in application layer.

Components in the data access layer provide convenient and stable database access interfaces for application layer components. iBatis[19] is used for the data access components implementation.

The repository implemented with DB2 provides persistent storage for user information, work product metrics, software project profiles, reuse approaches, etc.

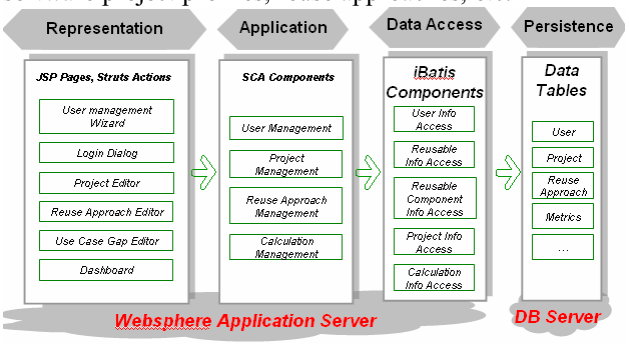

Figure 2: AREA Tool Architecture

3.2. Workflow

The architecture is designed to allow these functional components and tools to be accessed in the context of a collaborative workflow. Typically, a workflow would be started whenever new software is proposed for development. A project would be started to analyze the development effort for candidate reuse approaches. First a leading software developer would start a project for the to-be analyzed software, and assign other developers to work on the analysis using the Role assignment wizard. From that point, the leading software developer can monitor the project progress. The software developers assigned to different roles would perform the profiling and analytic tasks as prescribed in their role assignments. Figure 3 shows the screenshot for use case gap specifying task.

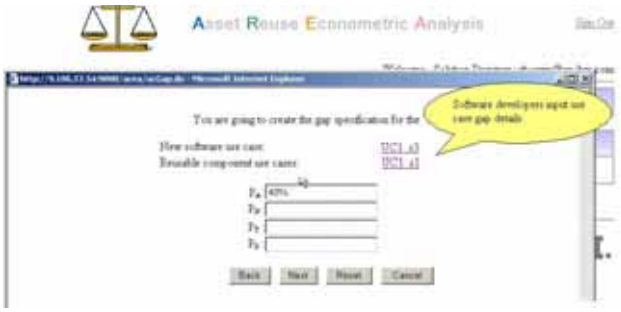

Figure 3: Specifying Use Case Gap

As prerequisite tasks are performed and completed, individuals assigned to dependent tasks would be notified that their tasks can and should be commenced. When the analytical tasks are completed, all the software developers can review the development effort calculation report and start reuse approach evaluation.

3.3. Dashboard

The tool provides an estimation effort dashboard to the software developers. The dashboard presents the components in each reuse approaches, the use case similarity relationship between new software use cases and reusable component use cases, the detail information about use case gap, the process and result of development effort calculation. Then, software developers can drill down into the details behind the effort result and understand the effort in a scientific way.

4. Pilot and feedback

Version 1.0 of the AREA tool is currently being piloted with solution development team working at IBM's Global Business Solutions Center (GBSC). The GBSC developers who use AREA tool comment that: in their previous reuse-based development practice, development effort estimation is not typically considered when selecting reusable components, as manual estimation of the development effort relies heavily on personal experience and different developers may give very different estimation. With the AREA tool and its backend method, the development effort calculation for candidate reuse approaches becomes more scientific and it's easier for them to come to an agreement on the result as the calculation process is explicit to all.

Also, the feedback from the pilot users drives new requirements for further method enhancement and tool development, which includes:

1) To extend the AREA method for considering Non-functional requirement gap between new software and reusable components while calculating the development effort.

2) To integrate the AREA tool with Rational Software Architect so that use cases, implementation work products,

and the traceability between them can be viewed in the native environment.

3) To allow customizable calculation for use gap P_A, P_N, P_T, and P_D based on basic use case actor, flow and extension point gap metrics.

4) To provide more intuitive and interactive reporting.

5. Conclusion and Future Works

In this paper, we present the AREA method, which enables systematic evaluation of development effort based on alternative reusable components selection. The core components of the method are a process guiding the evaluation and an algorithm for calculating the effort based on use case gap analysis between to-be developed new software and selected reusable components. A proof-of-concept implementation of AREA is built and being piloted with a solution development team working at IBM's Global Business Solutions Center (GBSC). Preliminary feedbacks reveal that the AREA tool and its backend method make the development effort calculation for candidate reuse approaches more scientific and it's easier for them to come to an agreement on the result.

In the future, we are going to enhance the method and tool according to suggestions acquired in present pilot, and continue the validation in more cases.

6. Acknowledgement

We thank Gopikrishnan Gopalakrishnan for leading the AREA trial and giving the feedback. We also thank Paul Borrel, William Tulskie and Liu Ying for illuminating discussions.

Abstract

Organizational resource constraints should be taken into consideration when making a software project plan, as resource problems are one of the main causes of software project failures. Most of the resource schedule methods focus on optimizing resource allocation for a fixed project schedule. There is a lack of methods that guides project schedule based on resource constraints. Human resource is the most important resource in software development. We suggest a project schedule method that can satisfy both the schedule constraints among tasks and organizational human resource availability. It can provide decision support for project managers in making practical project schedule, such as helping them to schedule project more effectively to ensure high resource utilization rate, and providing useful information for project plan modification and resource plan creation.

1. Introduction

A practical project plan is an important assurance for project success. According to IEEE standards [1-2] for SPMP (Software Project Management Plan), project schedule and resource allocation are the most important parts of SPMP. The project would finish on time only has enough resource been assigned. Resource problem is one of the primary causes of software project failures [3]. In order to enhance organizational competitive edge and to ensure high ROI (Return on Investment), how to use resource more effectively is the key problem to solve for those large, global-distributed software companies.

In *CMMI for Development Version 1.2*, project resource includes "*labor, machinery/equipment, materials and methods*" [4]. Different from traditional industry processes, software development processes mainly depend on human capability. Human is the most important and complicated resource. William R. Tracey, in *Human Resources Glossary* defines Human Resources as: '*The people that staff and operate an organization*' [5]. The importance of human factors in software development gained more and more attentions [6]. How to take full advantage of human resource is the pivotal question for software companies.

In software project management field, how to set up, monitor and control project schedule effectively based on resource constraints remains a key problem. That human resource belongs to more than one departments in matrix organizations (IBM, HP, …), dynamic project teams and multi-project environment make it difficult to get a high utilization rate of human resource:

1 The low visibility of human resource availability makes project schedule according to resource status difficult.

2 The size of the project and the complexity of human resource make estimating the duration of the project consistent with human resource availability difficult.

We suggest a project schedule method based on organizational resource availability. The method first describes organization's human resource availability and defines human resource constraints for a task, then schedules tasks while assigning human resource to the tasks. Some evaluation indicators and analysis approach for the result are also offered to help project manager to solve resource problem and improve the project plan. Because organization's resource availability is considered during making project schedule, the final project schedule is practical which can guide the software development effectively by avoiding potential resource problem.

2. Related works

PERT (*Program Evaluation and Review Technique*) and CPM (*Critical Path Method*) [7] help project

manager to schedule tasks based on the constraints among tasks and estimate the time limit for the project. These methods are widely used in industrial fields, but they do not consider resource constraints when scheduling tasks, the resource utilization ratio can not be ensured. The derived critical path is often unpractical.

Critical-Chain [8-9] takes resource into consideration based on CPM. But it focuses on project schedule control, not the scheduling method.

Human resource is the core resource of software companies. How to describe human capability and manage human resource effectively is the key problem of software project management [3] [10]. It seems that most of the researches [11] on resource schedule methods do not consider the characteristic of human resource for optimization.

We proposed software process modeling based on organization entity capability (OEC-SPM) [12-15]. Organization entities with similar capability are modeled as a Process-Agent. Some descriptions of human resource in OEC-SPM are adopted in this paper.

The work in this paper stands on organizational resource availability. We believe that a project schedule which conforms to organizational resource availability is a strong assurance for software project success.

The rest of the paper is organized as follows: Section 3 describes the two kinds of constraint in project scheduling. The method will be explained in section 4. In section 5, an example is offered to illustrate the usage of our method. Section 6 discusses the conclusion and future work.

3. Schedule constraints and resource constraints

3.1. Basic concepts

Some concepts in our research scope are described as following:

(1) Role and role set

RS (Role Set) = { $Role_1$, $Role_2$, $Role_3$ ⋯}

Role is the description of capability and responsibility of human resource when executing a task. For example:

RS = {Designer, Programmer, Tester}

(2) Task and project

Task is the low level work package in WBS [1-2]. Its cost, workload, duration, work product and resource requirement can be easily recognized. We define task as follows:

T (Task) = {**TN**, **R**, **ED**, A**PR**, **ISD**, **IFD**, **PSD**, **PFD**, **HRA, NHRA**}

TN is the *task name*. R indicates that only the person who has the *role* can execute the task. ED is the *estimated duration* of the task. APR is the amount of estimated human resource required by the task. ISD is the *ideal start date* of the task without considering resource constraints. IFD is the *ideal finish date* of the task without considering resource constraints. PSD and PFD stand for the *plan start date* and *plan finish date* of the task after resource allocation. HRA is the *human resource list assigned* to the task. NHRA is the *number of human resource assigned* to the task.

For example, T = {module C development, Programmer, 7, 4, 2008-3-26, 2008-4-1, 2008-4-1, 2008-4-9, {"jack", "tom"}, 2} means the task called 'module C development' needs four programmers to work together for 7days. The ideal start date is 2008-3-26, The ideal finish date is 2008-4-1. The plan start date is 2008-3-28, and the plan finish date is 2008-4-3. The task has two human resources assigned, they are jack and tom.

A software project consists of many tasks.

SP (software project) = { $Task_1$, $Task_2$, $Task_3$ ⋯}

(3) Human resource

Task will be executed by the assigned human resource. It will run normally only when the assigned human resource has the capability needed and has enough time. We describe human resource as follows:

HRS (Human Resource Set) = { HR_1 , HR_2 , HR_3 ⋯}

HR (Human Resource) = {**N**, **RS**, **WC**}

N (Name) is the name of human resource. RS (Role Set) contains roles that human resource can act as. WC (Work Calendar) is the time table of human resource. It indicates which days are free and which are occupied by tasks.

WC (Work Calendar) = { Day_1 , Day_2 , Day_3 ⋯}

Day = {Date, Task}

Day.Task = null indicates that the human resource is free on that day. Day.Task ≠ null indicates that the work day is occupied by the task.

Assumption1: It is assumed that ED and APR of a task is reasonable. Task schedule and resource allocation will follow these estimated values. The analysis and evaluation of the result are also based on them.

3.2. Schedule constraints among tasks

Definition1. T.Pre-Tasks: Other tasks which can impact T' schedule are defined as **T.Pre-Tasks.**

Constraints among tasks mainly lie in schedule constraints because of work products. They can be easily recognized by project manager. T.Pre-Tasks can be empty, which means the task is independent. When T.Pre-Tasks are not empty, each task in T.Pre-Tasks may have four kinds of schedule constraints (Table 1) with T. They are SS (start-start), SF (start-finish), FS (finish-start) and FF (finish-finish).

Table 1. Four kinds of schedule constraints

Type	Explanation	Figure
SS	B.PSD>=A.PSD	SF	B.PFD>=A.PSD.	FS	B.PSD>=A.PFD	FF	B.PFD>=A.PFD.	
T.Pre-Tasks can be divided into four sub sets based on the four constraint types. They are: **T.Pre-Tasks.SS**, **T.Pre-Tasks.SF**, **T.Pre-Tasks.FS**, and **T.Pre-Tasks.FF**. The tasks in each sub set have the same type of schedule constraint with T. The schedule of T should satisfy the following four SC (schedule constraints):

SC1. SS-All: T.PSD >= T.Pre-Tasks.SS.MPSD
MPSD (Max Plan Start Date) is the latest plan start date of all the tasks in the given task set.
SC2. SF-All: T.PFD >= T.Pre-Tasks. SF.MPSD
SC3. FS-All: T.PSD >= T.Pre-Tasks.FS.MPFD
MPFD (Max Plan Finish Date) is the latest plan finish date of all the tasks in the given task set.
SC4. FF-All: TPFD >= T.Pre-Tasks.FF.MPFD

Task schedule result must satisfy the four constraints above (SC1-SC4), otherwise the project execution will be affected by schedule conflicts.

Definition2. T.ISD: The later date of T.Pre-Tasks.SS.MPSD and T.Pre-Tasks.FS.MPFD is called **T.ISD** (ideal start date).

Definition3. T.IFD: The later date of T.Pre-Tasks. SF.MPSD and T.Pre-Tasks.FF.MPFD is called **T. IFD** (ideal finish date).

Definition4. T.SD: The number of days between T.ISD and T.PSD is called **T.SD** (schedule delay). When T.SD > 0 we say that T is delayed.

3.3. Resource constraints of task

Project schedule should satisfy resource constraints besides the four schedule constraints. When assigning human resource to tasks, three RC (Resource constraint) should be considered.

RC1: T.R ∈ HR.RS
RC2: ∀ HR ∈ { HR | HR.WC.Day.Date ∈ [T.PSD, T.PFD]} → HR.WC. Day.Task = null
RC3: T.APR =T.NHRA

RC1 means that the assigned human resource must have the ability of the desired role. RC2 means that the assigned human resource must have enough spare time in the given duration of the task. Humans who satisfy RC1 and RC2 can be assigned to the task. When the human resources of the task satisfy all the three constraints, the schedule and resource of the task can be decided.

Definition5. HR.NET (Number of Executable Tasks): The number of un-assigned tasks which satisfy RC1 and RC2 with HR is called HR.NET.

4. Project schedule method based on resource availability

4.1. Method of resource allocation and project schedule

The main framework of the method is shown in figure 1.

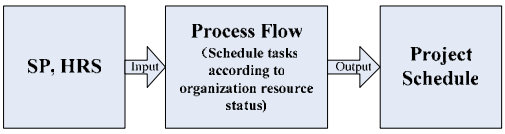

Figure 1. Main framework of the method

The detailed process flow is shown in figure 2. When scheduling tasks, we try to let the tasks start as early as possible, and we have an assumption below considering the characteristic of human resource.

Assumption2: We assume that it is a strong assurance for high productivity that the human does the same job continuously. Too much alternation among different tasks will lead to low work efficiency.

Inputs: Task set (SP), Human resource set (HRS)
Process flow:
Step1: Get task set (ts) = {T | T ∈SP ∧ T.Pre-Tasks = Φ};
Step2: Call Allocation (ts);
Step3: Get task set (ts) = {T | T ∈SP ∧ T.Pre-Tasks ≠Φ∧ {M|M∈T.Pre-Tasks ∧ M.HRA = null} = Φ∧ T.NHRA=null};
Step4: Call Allocation (ts);
Step5: if {T | T ∈ SP∧T.HRA = null}≠Φ, go to step 3; else go to step 6;
Step 6: Allocation finish.
The detailed process flow of some core functions are described in pseudo codes as following:

Function Allocation (ts)

```
{
        get all tq of ts (tq is a permutation of ts );
        for each tq
        {
                copy HRS to tq.HRS;
                for each task T  in tq
                {
                        Call Process(T, tq.HRS);
                }
                Re-calculate ISD and IFD of the tasks whose HRA is null in SP;
                get the plan finish date of project which is recorded as PFDP;
        }
        Choose the tq which has the earliest PFDP;
        Update SP and HRS according to the chosen tq and tq.HRS;
        }
}
```

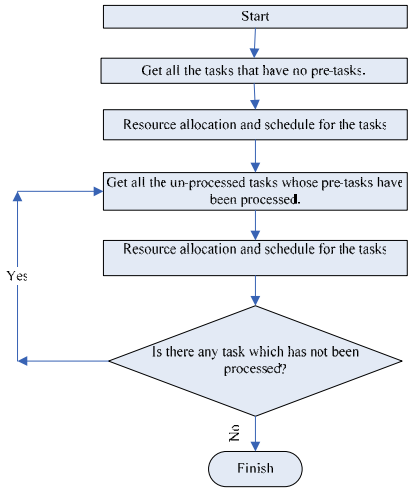

Figure 2. The detailed process flow

Function Process (T, HRS)

```
{
Get the number N of humans who have the role which T requires;
Set the smaller one of N and T.APR as the target resource amount Y;
Update HR.NET for all humans in HRS;
Ordered all the HR in HRS by ascending HR.NET;
T.PSD = T.ISD;
Do
{
        T.PFD = getPFD(T);
        Search the human combination which can satisfy RC1, RC2;
        If the size of human combination = Y
        {
                Break;
        }
        T.PSD = T.PSD +1;
} while (true);
T.SD = T.PSD – T.ISD;
Update T.HRA;
Update the work calendar of the human in HRS;
}
```

Function getPFD (T)

```
{
If (T.PSD+T.ED>=T,IFD) return T.PSD+T.ED;
If (T.PSD+T.ED<T.IFD) return T.IFD;
}
```

After all the tasks have been processed, we can get a practical project schedule which accords with schedule constraints and organizational resource availability.

4.2. Indicators for result evaluation

In order to evaluate and analyze the results, we define three indicators as following:

Indicator 1: **RUT** (Resource Utilization rate of the Task) = ED / (PFD – PSD + 1).

RUT>1 indicates that human resources of the task are overloaded. RUT<1 indicates that the human resource may have much more spare time during executing the task.

Indicator 2: **RST** (Resource Satisfaction rate of the Task) = NHRA / APR.

RST<1 indicates that the resource is not enough for the task.

Indicator 3: **DTP** (Delayed Task rate of the Project) = Number of tasks whose SD > 0/ Number of tasks in the project.

DTP > 0 means that there are tasks which can not start in time because of resource limitation.

These indicators can help project manager evaluate the result and find the root cause of abnormity. For example, if RUT<1, the project manager could assign additional work to the human resources to raise the resource utilization rate. If RUT>1, the project manager has to modify ED and APR of the task to avoid schedule risk. If RST<1 or DTP>0, new employees might be employed, or let the relative human resource delay less important tasks.

5. Example

5.1. Case design

Take a typical small software project for example. The plan start date of the project is assumed as 2008-4-1. The project manager wants to know the probable

finish date of the project when considering resource status. The software is divided into two modules (A and B). The role set is defined as RS = {D (Designer), P (Programmer), T (Tester)}. The tasks are listed in Table 2. The schedule constraints among tasks are shown in Table 3. The human resource status is shown in Table 4. Holidays are not considered for simplification.

Table 2. Tasks in the project

ID	Name	R	ED	APR
T1	System design	D	14	3
T2	A detailed design	D	10	2
T3	A development	P	6	2
T4	A test	T	4	2
T5	B detailed design	D	10	2
T6	B development	P	7	2
T7	B test	T	4	2
T8	Integration test	T	10	3

Table 3. Schedule constraints among tasks

ID	Pre-Tasks and SC	ID	Pre-Tasks and SC
T1	Null	T5	T1-FS
T2	T1-FS	T6	T5-FS
T3	T2-FS	T7	T6-SS, T6-FF
T4	T3-SS, T3-FF	T8	T4-FS, T7-FS

Table 4. Human resource availability

ID	RS	WC (Days occupied by other projects)
P1	D P	2008-05-05---2008-05-14
P2	D P	2008-04-10---2008-04-20
P3	D P T	2008-05-04---2008-05-10
P4	D P T	2008-04-25---2008-04-26
P5	T	2008-04-15---2008-04-23
P6	T	2008-05-15---2008-05-25

5.2. Resource allocation and task scheduling

At first, we schedule tasks considering only the schedule constraints. After implementing the method in section 4.2, we get the scheduling result show in Figure 3.

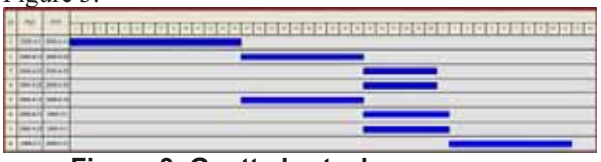

Figure 3. Gantt chart when resource constraints are not considered

The project duration is 41 days which is perfect because all tasks can start as early as possible. The project will finish on 2008-5-11, but it is impractical because resource constraints were not considered.

Now we implement our method to this case. First we will process tasks which have no Pre-Tasks. T1.ISD=2008-4-1, T1.IFD=2008-4-14. The satisfying resource combination is {P1,P3,P4}. T1.PSD=2008-4-1, T1.IFD=2008-4-14. Then we will process other tasks which have no unscheduled Pre-Task. {T2, T5} is our next target. We find that {T2, T5} can't start synchronously because there is not enough resource available. We will decide to delay which task using the method in section v4.1. The task set has two permutations: tq1={T2, T5} and tq2={T5, T2}. The schedule results of the two different permutations are shown in Table 5.

Table 5. Two optional schemes

	T	PSD	PFD	Human
{T2,T5}	T2	2008-4-15	2008-4-24	P1 P3
	T5	2008-4-25	2008-5-5	P1 P2
{T5, T2}	T2	2008-4-25	2008-5-5	P1 P2
	T5	2008-4-15	2008-4-24	P1 P3

We will calculate the ISD and IFD of the other tasks based on the two results. The finish date of the project is 2008-5-21 for tq1, and 2008-5-20 for tq2. We will choose tq2 to continue our approach.

{T3, T6} is the next target. Schedule the tasks in the same way until all the tasks have been processed. Finally the project schedule result is shown in Figure 4, and the task attributes are shown in Table 6.

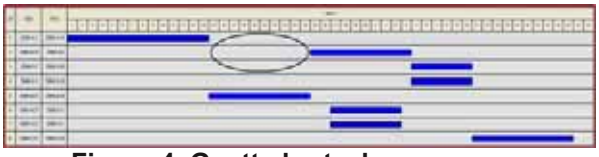

Figure 4. Gantt chart when resource constraints are considered.

Table 6. Task attributes after resource allocation

ID	PSD	PFD	HR	SD
T1	2008-04-01	2008-04-14	P1 P3 P4	0
T2	2008-04-25	2008-05-04	P1 P2	10
T3	2008-05-05	2008-05-10	P2 P4	0
T4	2008-05-05	2008-05-10	P5 P6	0
T5	2008-04-15	2008-04-24	P1 P3	0
T6	2008-04-27	2008-05-03	P3 P4	2
T7	2008-04-27	2008-05-03	P5 P6	0
T8	2008-05-11	2008-05-20	P3 P4 P5	0

Different from the schedule in Figure 3, the final duration of the project has been extended to 50 days. The overall schedule is longer but more practical because it can guarantee that all the tasks can be executed with enough resource. The black cycle in Figure 4 indicates the root cause of schedule delay. T2 will be delayed for 10 days because of limited human resource. Also, both T6 and T7 can not start as early as we expected in Figure 3.

5.3. Result analysis

We can use the three indictors in section 4.2 to analysis the schedule result. Indictors for tasks are shown in Table 7. The DTP is 2/8=0.25. From the value of the indictors two problems are discovered.

Table 7. RUT and RST of each task

ID	RUT	RST	ID	RUT	RST
T1	1	1	T5	1	1
T2	1	1	T6	1	1
T3	1	1	T7	0.57	1
T4	0.67	1	T8	1	1

(1) RUT < 1: The RUT of T4 and T7 is below 1. Project manager could assign additional tasks to P5 and P6 during the execution of task T4 and T7.

(2) DTP > 0: The causes of this abnormity are task T2 and T6 (T2.SD=10, T6.SD=2). That P2 does not have enough time during 2008-4-15 and 2008-4-20 causes T2 could not start in time. We will not discuss T6 because it is not on the critical path now.

Project manager may wonder whether hiring a new designer is necessary. Supposing a new designer P7 is added to the HRS, after implementing our method, we could get the schedule result shown in Figure 5, and the task attributes are shown in Table 8.

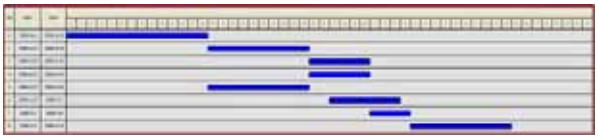

Figure 5. Gantt chart with a new designer

Table 8. Task attributes with a new designer

ID	PSD	PFD	HR	SD
T1	2008-04-01	2008-04-14	P1 P3 P7	0
T2	2008-04-15	2008-04-24	P1 P3	0
T3	2008-04-25	2008-04-30	P1 P2	0
T4	2008-04-25	2008-04-30	P5 P6	0
T5	2008-04-15	2008-04-24	P4 P7	0
T6	2008-04-27	2008-05-03	P3 P4	2
T7	2008-05-01	2008-05-04	P5 P6	4
T8	2008-05-05	2008-05-14	P4 P5 P6	0

The project duration would be 44 days after hiring a new designer. The different result will help the project manger to make decisions. After considering all the other factors the project manager can decide whether hiring a new man or delaying some assigned tasks of the key human resources, or that even 50 days is acceptable.

The case is simple but the usage of our method is illustrates clearly. It is proved that our method can provide decision support for project managers in many aspects, such as making practical project schedule, reaching high resource utilization rate, optimizing project plan and generating human resource plan.

6. Conclusion and future work

In this paper, we propose a method for project scheduling and resource allocation with consideration of both schedule constraints and resource constraints. Our method can offer decision support for project managers when making practical project plan. It can help software companies to achieve higher resource utilization rate.

Future work will focus on assistant tools development. The method will be integrated with Process-Agent technique. Optimized human resource allocation method using simulation technique will be further researched.

Abstract

The ability to generate sufficiently accurate effort estimates can be seen as a key success factor for multi-organizational projects focusing on the development of large and critical software systems. This is caused, for instance, by the need for synchronizing multiple development and verification and validation processes. Paradoxically, effort predictions in the critical software systems domain are still relying on human judgment. This requires much overhead and its reliability depends largely on the expertise and individual preferences of the involved experts. In particular, verification and validation by independent entity (IV&V) needs an estimation method that supports negotiating and managing IV&V costs in the context of sparse measurement data and low availability of domain experts. In order to address these problems, in this paper we propose applying a hybrid effort estimation method called CoBRA® for estimating effort for IV&V of mission-critical software systems. When applied in an industrial context, CoBRA® improved estimation accuracy and precision by about 40%, on average, compared to experts estimates and OLS regression.

1. Introduction

The average company spends about 4 to 5 percent of its revenue on information technology, with those that are highly IT-dependent - such as financial and telecommunications companies - spending more than 10 percent on it [5]. Now, a great part of those investments is wasted because software organizations are still proposing unrealistic software costs, work within tight schedules, and, in consequence, finish their projects behind schedule and budget (about 50% of projects), or do not complete them at all (more than 25% of projects). Moreover, even though projects are completed within a target plan, the functionality and quality of products delivered are usually cut to fit this plan [11]. This indicates that software project planning is a critical success factor of a software project.

Project planning in the safety-critical domain is particularly important and difficult at the same time. Large functional constraint, high quality requirements, and involvement of several independent parties make it much more challenging to plan mission-critical projects than to plan ordinary, non-critical software development projects. In that context, effective synchronizing activities of all involved parties are a key factor for project success. One example activity requiring such synchronization is verification and validation done by an independent organization, or independent verification and validation (IV&V). A mismatch between the IV&V plan and the overall project plan may lead to significant delays or (in extreme cases) to the skipping of certain IV&V activities. In consequence, the whole mission might be exposed to the high risk of a significant loss of money, and, in the worst case, injury or death of people. Yet, comprehensive support for planning and managing IV&V is missing.

Effort estimation approaches proposed by the research community have traditionally focused on planning and tracking classical, in-house software development. Effort estimation methods that grew upon those objectives focus on providing exact estimates. They do not, however, support an easily understandable, systematic and reliable analysis of the most relevant causal effort dependencies. Even though an accurate prediction is provided, software practitioners have hardly any support to prevent potential project overruns. In the short-term perspective, this would mean a lack of a solid basis for effectively mitigating project risks, and in the long-term perspective, a limited ability to identify process improvement areas and to learn. Moreover, estimation methods promoted by the research community require large data sets, whereas methods commonly employed by industry extensively involve domain experts.

All those aspects significantly reduce the applicability of existing estimation methods in the IV&V context, where reliable and comprehensive project management has to be provided despite the minimal availability of quantitative data and human expertise.

In this paper, we propose applying the Cost Estimation, Benchmarking, and Risk Analysis method (CoBRA®) [12][17] to estimate the effort of the IV&V of mission-critical software systems. CoBRA® is a hybrid method that combines analytical and expert-based estimation. It provides a systematic way to transform various sources of organizational knowledge (minimal set of measurement data and expert judgment) into a transparent and reusable effort model that supports achievement of a variety of project management objectives, such as risk management or nego-

tiating of project costs.

The remainder of the paper is organized as follows: Section 2 briefly characterizes the IV&V context. Section 3 gives an overview of existing software effort estimation methods, followed by a more detailed description of the CoBRA® method in Section 4. Section 5 presents the empirical results of an industrial application of CoBRA® for planning the effort of IV&V, followed by lessons learned (Section 6) in the study. The paper ends up with a brief summary and conclusions given in Section 7.

2. Independent Verification and Validation

2.1. Characteristics of IV&V

Independent verification and validation (IV&V) can be defined as a process where software work products generated by a development team are verified and validated by a completely independent organizational entity. Independence is considered here [7] in terms of technical, managerial, and financial independence. IV&V is typically applied in the context of safety- or mission-critical software systems, such as space and nuclear plant systems.

The typical constraint of IV&V, as compared to classical in-house V&V, is limited information on processed artifacts. On the one hand, there is limited knowledge about the software development environment; on the other hand, IV&V has to handle various types of mission-critical systems. This variety does not allow for collecting many historical project data. Moreover, involvement of three sites (customer-, development-, and IV&V-entity) in the software development process contributes to frequent and unpredictable requirements change.

In that context, managing an IV&V project's resources is critical and difficult at the same time.

2.2. Objectives of Effort Estimation

Besides traditional estimation objectives such as precise planning and tracking software resources, project needs decision-making support. In particular, explicit identification of factors having the greatest impact on IV&V cost and their quantitative impact should be supported. Identification of customer-specific factors (e.g., level of customer support) may be used to justify and negotiate IV&V costs that cannot be influenced by the IV&V supplier. On the other hand, identification of the IV&V supplier's characteristics (process and human capabilities) that have the greatest impact on increased IV&V costs will allow targeting improvement actions to specific process areas and improving the efficiency of IV&V. In consequence, project risks can be mitigated timely and critical organizational processes can be improved.

2.3. Current Effort Estimation Practices

A survey about current estimation practices at Japan Manned Space Systems Corporation (JAMSS) revealed that measurement data from around 10 already completed projects have been collected within the past 10 years. However, the data suffered from significant incompleteness (around 20% of missing data) and large variability – due to the high uniqueness of the considered projects. Since hardly any data-driven estimation method that would meet the estimation objectives (Section 2.2) can be applied reasonably, estimates are typically based on the judgment of one or more domain experts. Although sparse project data are available, experts based their estimates solely on personal experiences. One of the reasons is that the available simple size measures, such as pages of software requirements document, are believed not to reflect the amount of IV&V effort reliably. Yet, expert-based estimation did not provide satisfactory support for project management. First, the reliability of the estimates depends largely on individual expertise and preferences of involved domain expert. In consequence effort estimates are not accurate and vary widely across projects (see Table 4 and Table 5 in Section 5.5). Moreover, estimation costs much effort each time it is performed, and since it does not provide any explicit effort model, it hardly supports decision making in a project.

3. Related Work

Numerous types of estimation methods have been developed over the last decades. In this section we provide a brief overview of existing estimation methods from the viewpoint of their applicability in the context of IV&V. For a comprehensive review and comparative evaluation of existing methods, please refer to [16].

Existing effort estimation methods differ basically with respect to the type of inputs they require and the form of the estimation model they do provide. With respect to input data, we differentiate between three major groups: data-intensive, expert-based, and hybrid methods (combining available data and expert knowledge in order to come up with estimates). Among the data-intensive methods, some require past project data for building customized models (*define-your-own-model* approaches), others provide an already defined model, where factors and their relationships are fixed based on a set of multi-organizational project data (*fixed-model* approaches). The major advantage of fixed-model approaches is that they, theoretically, do not require any historical data to be applied. Those methods might be especially attractive in the IV&V context, where very sparse (if any) data are typically available. Yet, in practice, fixed models, such as COCOMO [2][1], are developed for a specific context (typically different from IV&V) and are, by definition, only suited for estimating the types of projects for which the fixed model was built. The applicability of such models for the IV&V context is, in practice, very limited. In order to improve their performance, a significant amount of organization-specific project data would be required for calibrating the generic model. In that case, the

little usefulness of the fixed-model approaches for IV&V effort estimation would not differ much from the define-your-own-model approaches, which require a significant amount of context-specific data to build customized effort models [15]. Application of the define-your-own-model methods in the context of IV&V is further limited by the additional requirements of specific methods. Parametric approaches, such as regression [14], for instance, make several assumptions about underlying project data (completeness, normal distribution, etc.) that are rarely met in the software domain. Non-parametric methods originating from the machine learning domain, such as artificial neural networks (ANN) [3] or Decision Trees/rules [15], make practically no assumptions about the data but are quite sensitive to their parameter configuration and there is usually little universal guidance regarding how to set those parameters. Thus, finding appropriate parameter values requires some preliminary experimentation.

In contrast to data-intensive methods, *expert-based estimation* does not require any project measurement data because estimates are based on the judgment of one or more human experts [2]. Expert estimation is, in fact, commonly used in the software industry (including IV&V). It does, however, have several significant limitations. First, much effort is required each time estimation is performed, and the reliability of the outputs it provides largely depend on the expertise and individual preferences of the human experts involved. Moreover, since the rationale underlying final estimates is not modeled explicitly, there is hardly any support for effective decision making in a project (risk management, process improvement, project scope negotiations, etc.). Recently, a few hybrid methods have been proposed to cope with deficits of data-intensive and expert-based estimation. They combine a reduced amount of both measurement data and human expertise to provide more reliable estimates with limited estimation overhead. Empirical applications [17][10] report on their higher estimation accuracy and stability when compared to data- or expert-based methods. Moreover, methods that employ explicit causal effort modeling (e.g., CoBRA® [17]) have proven to greatly contribute to the achievement of a variety of organizational objectives, such as risk management or process/productivity improvement.

4. The CoBRA® Method

CoBRA® [12][15] is a hybrid method combining data- and expert-based effort estimation approaches. CoBRA® the method is based on the idea that project effort consists of two basic components: nominal project effort and an effort overhead portion as presented below.

Nominal effort is the effort spent only on developing a software product of a certain size in the context of a hypothetical "ideal" project that runs under optimal conditions; i.e., all project characteristics are the best possible ones ("perfect") at the start of the project. *Effort overhead* is the additional effort spent on overcoming the imperfections of a real project environment, such as insufficient skills of the project team. In this case, a certain effort is required to compensate for such a situation, e.g., team training has to be conducted. In CoBRA®, effort overhead is modeled by a causal effort model that consists of factors affecting project effort within a certain context. The causal model is obtained through expert knowledge acquisition (e.g., involving experienced project managers).

$$\text{Effort} = \underbrace{\text{Nominal Productivity} \cdot \text{Size}}_{\text{Nominal Effort}} + \text{Effort Overhead} \quad (1)$$

$$\text{Effort Overhead} = \sum_i \text{Multiplier}_i(\text{Effort Factor}_i) + \sum_i \sum_j \textit{Multiplier}_{ij}(\text{Effort Factor}_i, \text{Indirect Effort Factor}_j) \quad (2)$$

An example is presented in Figure 1. The solid and dashed arrows indicate direct and indirect relationships, respectively. For instance, *Requirements volatility* has a direct impact on development effort. The strength of this negative influence on effort may, however, be modified (compensated) by *Disciplined requirement management* (indirect influence). The effort overhead portion resulting from indirect influences is represented by the second component of the sum shown in (2).

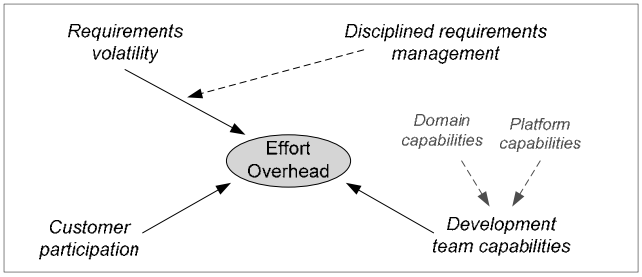

Figure 1: Example of a Causal Effort Model

The influence on effort and between different factors is quantified for each factor using experts' evaluation. The influence is measured by means of effort overhead, i.e., a relative percentage increase of the effort above the nominal project. In order to capture the uncertainty of evaluations, experts are asked to give three values: the maximal, minimal, and most likely cost overhead for each factor (triangular distribution).

The second component of CoBRA®, the nominal project effort, is based on data from past projects that are similar with respect to certain characteristics (e.g., development type, life cycle type) that are not part of the causal model. These characteristics define the context of the project. Past project data is used to determine the relationship between cost overhead and costs (see equation #1). Since it is a simple bivariate dependency, it does not require much measurement data. In principle, merely project size and effort are required, whereby both can be measures using any valid metric representing project size and effort.

Based on the quantified causal model, past project data, and current project characteristics, an effort overhead model is generated using a simulation algorithm (e.g., Monte Carlo). The probability distribution obtained could be used further to support various project management activities, such as effort estimation, evaluation of effort-related project risks, or benchmarking. More details regarding the CoBRA® method can be found in [12][15].

5. Case Study

5.1. Context of the Study

The study was performed in the context of JAMSS, a company that performs IV&V of space software systems (embedded software domain). JAMSS has been, for instance, supporting IV&V for critical space software systems created by the Japan Aerospace Exploration Agency (JAXA) for more than 10 years.

In this study, we focused on IV&V of the software requirements specification documents using the *document review* technique. The document review process starts with a risk analysis to identify a software system's operational risks. Software requirements are then reviewed in more detail based on their operational risks with respect to one or more review objectives. In principle, there were six review objectives [8] (Table 2): (O1) risk analysis, (O2) state transition completeness and consistency, (O3) design completeness for exceptional behavior, (O4) timing correctness and consistency, (O5) interface correctness and consistency, and (O6) traceability.

There were three ***domain experts*** involved in the study (Table 1) who provided their knowledge to build the effort overhead model. The main fields of expertise covered by involved experts included: software product quality & safety assurance (SPQSA), software safety reviews (SR), and safety assurance in operation (SAO).

Table 1. Involved domain experts

Expert	Expertise	Domain experience [#years]	Estimation experience [#projects]
1	SR	7	8
2	SPQSA	8	9
3	SAO	4	6

As project measurement data, the number of document pages was selected as the size of a software requirement because even if the complexity of a requirement complexity is related to the effort for reviewing a document, the document itself has to be read by the IV&V team in order to find out what this complexity is.

IV&V effort data from five projects were collected for each project. In practice, because some IV&V objectives were not addressed, effort data were not collected for each IV&V objective except for one project. Therefore, weekly working statuses of IV&V were used to abstract the effort for each IV&V objective. ***Measurement data*** available for the estimation included size and effort. Size was measured in pages of software requirements for objectives O1 to O5 and system specification (software and hardware) for objective O6 additionally. The effort was measured in person-days (PD).

Table 2. Review objectives considered in the study

Id	Objective	#projects
O1	Risk analysis	5
O2	State transition completeness/consistency	5
O3	Design completeness	5
O4	Interface completeness/consistency	4
O5	Timing consistency/correctness	3
O6	Traceability with correctness	5

5.2. Study Objectives

The objective of the study was to validate accuracy and precision of CoBRA in the context of JAMSS IV&V (compared to expert judgment and Ordinary Least Squares method) and its contribution to the achievement of defined organizational objectives (Section 2.2).

5.3. Study Design

5.3.1. Effort Estimation Procedure

Motivated by its numerous benefits, the CoBRA® Method was proposed as best fitting the effort estimation capabilities and objectives of JAMSS. First of all, CoBRA® proposes a systematic way to build an explicit and reusable effort model based on both implicit knowledge of domain experts and sparse measurement data. Moreover, it provides on the output a transparent and intuitive model of causal effort dependencies specific for the context where it was applied. The first step of the effort estimation procedure included development of the CoBRA® model using the knowledge of the involved domain experts and measurement data (size and effort) from already completed (historical) projects. For each of the six IV&V objectives specified in the study (Table 2), a separate CoBRA® model was developed. After the CoBRA® models had been created, each was validated on the historical data in a leave-one-out cross-validation experiment.

5.3.2. Study Hypotheses

In order to effectively support achievement of the estimation objectives, the outputs of CoBRA® need to be reliable. In our study, we evaluate reliability byvalidating the predictive performance of the estimation outputs, measured in terms of predictive accuracy and precision. We expect that CoBRA® will outperform the currently employed expert-based estimation as well as the Ordinary Least Squares method (OLS), one of a few data-driven methods that are applicable in the study context (due to very sparse measurement data). This leads us to two study hypotheses:

H1. *CoBRA® provides more accurate and more precise estimates than estimation based on expert judgment.*

H2. *CoBRA® provides more accurate and more precise estimates than estimation based on OLS.*

5.3.3. Evaluation of Estimation Performance

The effort models created in the study effort models were evaluated with respect to their predictive performance. We define *predictive performance* as the ability of the effort model to provide accurate and precise estimates. *Estimation accuracy* refers to the nearness of an estimate ($\hat{E}$) to the true value (E). In order to remain comparable to other estimation studies, we use common estimation error measures and accuracy measures [4], such as *relative error* (*RE* in equation #3) and *mean magnitude of relative error* (*MMRE*).

$$RE_i = \left(\hat{E}_i - E_i\right) / E_i \quad (3)$$

The Conte's RE and MRE measures are the subject of common criticism in the software research community [6]. One of the alternative measures of estimation error proposed is the so-called *z* measure (equation #4) [6]. It quantifies the ratio of the estimate to the actual value

$$z_i = E_i / \hat{E}_i \quad (4)$$

Estimation precision refers to the degree to which several estimates are very close to each other (i.e., the scatter in the data). For the purpose of comparability to other studies, we adopt the *Pred.m* measure. The *Pred.m* measures the percentage of estimates that are within *m%* of MRE [4]. In our study, we use *m = 25%* as typically employed in software estimation studies. Moreover, we adopt *relative standard deviation* (*RSD*) (5) proposed by [6] for software effort estimation as uncorrelated with size (S_i) (which is a weakness of classical standard deviation measures).

$$RSD = \sqrt{\frac{\sum_{i=1}^{n}\left[\left(E_i - \hat{E}_i\right)/ S_i\right]^2}{n-1}} \quad (5)$$

5.4. Study Execution

During the study execution, six CoBRA® models were created for each of the IV&V objectives.For each model, domain experts identified several factors (Table 3) that are responsible for the variance of IV&V efficiency for a certain objective (Figure 2).

5.5. Results and Interpretation

This section presents the results of the empirical study. Table 4 and Table 5 present the aggregated measures of the predictive performance. In order to test the significance of the observed effects, appropriate statistical test were performed [13] (at $\alpha = 0.05$). The results of a *Shapiro-Wilk W* test indicated that the MRE and z results come from normal population; in that case, a parametric *Paired T-test* for homogeneity of means was used. Since the RSD data violated the normality assumption, a non-parametric *Wilcoxon Matched-Pairs Signed Rank* test was used. Note that expert estimates were available for a subset of the past projects considered (indicated as *n* in Table 4 and Table 5). Finally, as we were afraid that for such a small data sample, statistical tests would not have enough power ($\beta\text{-}1 \geq 80\%$), we performed a power analysis.

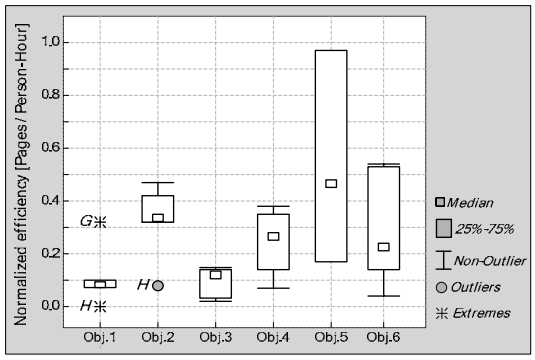

Figure 2. Overall efficiency of IV&V

Table 3. Effort factors considered in the study

Factors influencing IV&V efficiency	Objectives
Domain experience of the IV&V team	O1-O3
Requirements volatility allowed within an initial contract	O2-O4, O6
Novelty of applied IV&V technique	O3
Number of system's interfaces to other (sub)systems	O4, O6
Time pressure in the last IV&V phase	O5
Level of risk assessment done by a supplier or customer	O1
Fault Tree Analysis done by IV&V company	O1
Timing consistency objective included in IV&V	O5
Field Programmable Gate Array (FPGA) review performed	O5
New (inexperienced) personnel involved in IV&V	O1

5.5.1. Hypothesis H1

The results of the empirical investigation (Table 4) suggest that, in principle, CoBRA® provides noticeably more accurate estimates than either expert judgment or OLS for all considered IV&V review objectives (a few exceptions are marked in gray). For example, it improves MMRE by 70% and 40%, on average, compared to OLS and domain experts, respectively. Only few of the obtained results are statistically significant at the chosen α level (marked in bold). As expected, in most of the cases, statistical significance testing did not provide meaningful results ($\beta\text{-}1 << 80\%$). The only powerful results are marked in italics. Summarizing, we conclude that hypothesis ***H1 is valid***.

Table 4. Effort estimation accuracy

	CoBRA		OLS		Expert		
Obj.	***MMRE***	***Mean z***	***MMRE***	***Mean z***	***MMRE***	***Mean z***	***n***
O1	18.2%	97.9%	60.0%	44.1%	42.7%	57.3%	2
O2	25.4%	96.6%	34.0%	66.0%	37.1%	116.5%	4
O3	22.4%	101.%	32.1%	73.0%	36.0%	64.0%	3
O4	***24.1%***	98.6%	33.2%	66.8%	***44.4%***	55.6%	3
O5	39.6%	105.8%	46.3%	63.0%	72.2%	94.4%	3
O6	24.5%	93.1%	44.5%	55.5%	13.8%	88.8%	2

5.5.2. Hypothesis H2

The analysis of estimation precision (Table 5) suggests that, in principal, CoBRA® noticeably outperforms both expert judgment and OLS for all considered IV&V review objectives (a few exceptions are marked in gray). For example, it reduces RSD by 54% and 40%, on average compared to OLS and domain experts, respectively. Similar to accuracy, in most of the cases, statistical significance test-

ing did not provide meaningful results (β-1 << 80%). Summarizing, we conclude that hypothesis ***H2 is valid***.

Table 5. Effort estimation precision

5.6. Threats to Validity

Several threats to the validity of the presented case study were identified. First, the very sparse project measurement data available prevented us from achieving sufficient power of performed statistical tests. Moreover, expert estimates used to compare CoBRA®'s performance were available only for some of the past projects considered in the study. Finally, the conclusions drawn in the study are limited to the specific context of IV&V reviews at JAMSS. Generalization of the study findings requires further replications.

6. Lessons Learned

The following practical lessons were learned while applying the CoBRA® method for estimation effort of IV&V:

(**LL1**) *Effort estimation scope*: Since IV&V activities differ depending on the objective of IV&V, the scope of effort estimation (the context for which an effort model is built) should be limited to a single IV&V objective. Total effort is the sum of effort over all objectives.

(**LL2**) *Size and complexity of review*: The complexity of a document under review should be considered as an effort driver beyond simple size measures, such as number of document pages.

(**LL3**) *Effort drivers*: Considering effort drivers other than size is a very important aspect of effort modeling. We experienced that a single factor may multiply effort by as much as 10 times (e.g., a complete lack of risk assessment already done by a software supplier may increase the effort of independent risk analysis by up to 20 times). Such an effect is impossible to investigate based only on historical size and effort data.

7. Summary

In this paper, we proposed adapting the CoBRA® software estimation method to predict the effort of independent verification and validation (IV&V). The method provides a potential solution to estimation problems in the context of IV&V. By integrating data- and expert-based estimation, CoBRA® requires minimal amounts of project measurement data and reduces the involvement of domain experts. As a result, it provides a reusable model that supports strategic project/process objectives, such as risk management for effort overrun for each IV&V objectives. At the same time, as reported by several empirical studies, it provides accurate and precise estimates.

When applied in the context of an example IV&V organization, CoBRA® proved to provide more reliable estimates than both the expert-based estimation currently applied and ordinary regression (OLS) - one of few data-intensive methods applicable in the IV&V context. It improved the accuracy and precision of estimates by 40%, on average. At the same time the method provided a transparent, context-specific effort model that supported IV&V practitioners in achieving project and process management objectives (e.g., negotiating project scope or improving the effectiveness of IV&V activities).

Abstract
This article introduces a set of unified basic concepts for Process Capability Models for the unification, generalization and modeling of views of the structure and elements of relevant models, with more similar granularity of its leaf elements. This set is part of an ongoing research effort to evolve the current Software (and Systems) Process Improvement area towards a Model Driven Process Capability Engineering for Knowledge Working Intensive Organizations. The set is implemented in Eclipse Ecore. Its evaluation includes the modeling of a unified view of CMMI-DEV and ISO/IEC 15504-5 models as relevant examples.

Keywords
Software Process Improvement (SPI), Model-Driven Engineering (MDE), and Knowledge Working

1. INTRODUCTION

In a panel on Research Directions in Software Process Improvement (SPI), David Card pointed out that SPI "has become a driving force in the global software industry. … [however the majors SPI] approaches today are considered competitors. In reality they are all based on very similar concepts and techniques. The packaging obscures the underlying principles. Eliciting and refining underlying principles is the role of science" [1].

This article introduces a set of unified basic concepts as a proposal for the underlying principles of Process Capability Models that are a relevant part of SPI (now redefined as Software and System Process Improvement). SPI was established as a "driving force in the global software industry" around the development and successful usage of the Capability Maturity Model for Software (SW-CMM) [2]. Nowadays, the Capability Maturity Model Integration for Development (CMMI-DEV) [3], the successor of SW-CMM, and the ISO/IEC 15504-5 Exemplar Process Assessment Model for Software Engineering (ISO/IEC 15504-5) [4] are the dominant reference models for SPI. A more generic term – Process Capability Model – is proposed to mean all good practices reference models organized with the concept of Process Capability. Three more generic terms are also introduced: Process Capability Area, Process Capability Level and Process Capability Profile.

Process Capability Area is a set of related specific "what to do" good practices. Process Capability Level is a set of related generic "how good to do" good practices. Process Capability Profile is a model of a process, under the aspect of process capability, composed of pairs of a process capability area at a process capability level.

The article is organized as follows. This first section is an introduction to the article. The second section presents the research context and methodology. The third section defines goals. The fourth section introduces a class diagram for the unified basic concepts. The fifth section describes CMMI-DEV and ISO/IEC 15504-5 views. The sixth section provides evaluation against the goals. The seventh section presents related and future work. Finally the eighth section presents conclusions.

2. RESEARCH CONTEXT

The set of unified basic concepts introduced in this article is part of an ongoing research effort [5, 6, 7, 8] proposing a Model-Driven Process Capability Engineering for Knowledge Working Intensive Organizations (MDPEK) for the evolution of the current SPI area.

MDPEK is a Model Driven Engineering (MDE) [9, 10] for improving knowledge working (including software and system working) intensive organization, identifying and acting in relevant processes based on the concept of process capability, integrated with the organization strategy to better business results, driven by a Process Capability Profile defined with elements from one or more Process Capability Models [8]. The models are, for example, CMMI-DEV, ISO/IEC 15504-5, iCMM, eSCM-SP, OPM3, COBIT, ITIL, COMPETISOFT and MR-MPS and/or process capability views of different types of good practices models, such as ISO 9001, PMBOK, EFQM, SWEBOK and Agile Methodologies[1].

MDPEK focus on knowledge working processes, as defined first by Drucker [11]. In this sense, Process Capability Models not related with software or systems may also be used, as for example, the Process Capability Model for University Research Laboratories [12].

This research effort uses an industry-as-laboratory approach as proposed by Potts [13]. Potts argues that the traditional research-then-transfer approach is inadequate because it treats research and its application by industry as separate, sequential activities.

Following the industry-as-laboratory approach, a MDPEK exemplar methodology (named as PRO2PI for

[1] These fourteen models are well known. References for them are available elsewhere, for example, in Salviano [6, 8].

Process Capability Profile to Process Improvement) has been developed and applied in the industry together with the development and utilization of MDPEK and the set of unified basic concepts [5, 6, 7, 8].

The set of basic concepts introduced in this article is the result of the second phase of a project in this research effort. Phase 1 is a proposal and initial specification as described by Salviano [6]. Phase 2 is the development and implementation of a revised version and the modeling of CMMI-DEV and ISO/IEC 15504-5 models as examples.

3. RESEARCH GOALS AND METHODOLOGY

To guide the activities of the second phase, a main goal and five unfolded objective goals are defined. The main goal is that the unified basic concepts represent a useful proposal for the underling basic concepts of Process Capability Models. The first unfolded objective goal (Goal 1) is that the set of unified concepts generalize and unify the structure of CMMI-DEV and ISO/IEC 15504-5 models. The Goal G2 is that it has fewer, more generic and more flexible key basic concepts than the CMMI-DEV and ISO/IEC 15504-5 models.

The Goal G3 is that it supports the mapping and unification of the elements of CMMI-DEV and ISO/IEC 15504-5 models. The Goal G4 is that it supports a hierarchy of elements and represents the leaf elements with more similar granularity, than the correspondent elements of CMMI-DEV and ISO/IEC 15504-5 models.

Finally, the Goal G5 is that it supports the definition of process capability profiles with any combination among the elements of available models, reusing elements, preserving the original models and without the need to create new models.

4. *Geraes* CLASS DIAGRAM FOR THE UNIFIED BASIC CONCEPTS

The set of unified basic concepts for Process Capability Models is represented as the *Geraes* Class Diagram as illustrated in Figure 1 defined with TopCased [15], an Eclipse Modeling Framework [14] plugin to the definition of metamodels based on Ecore.

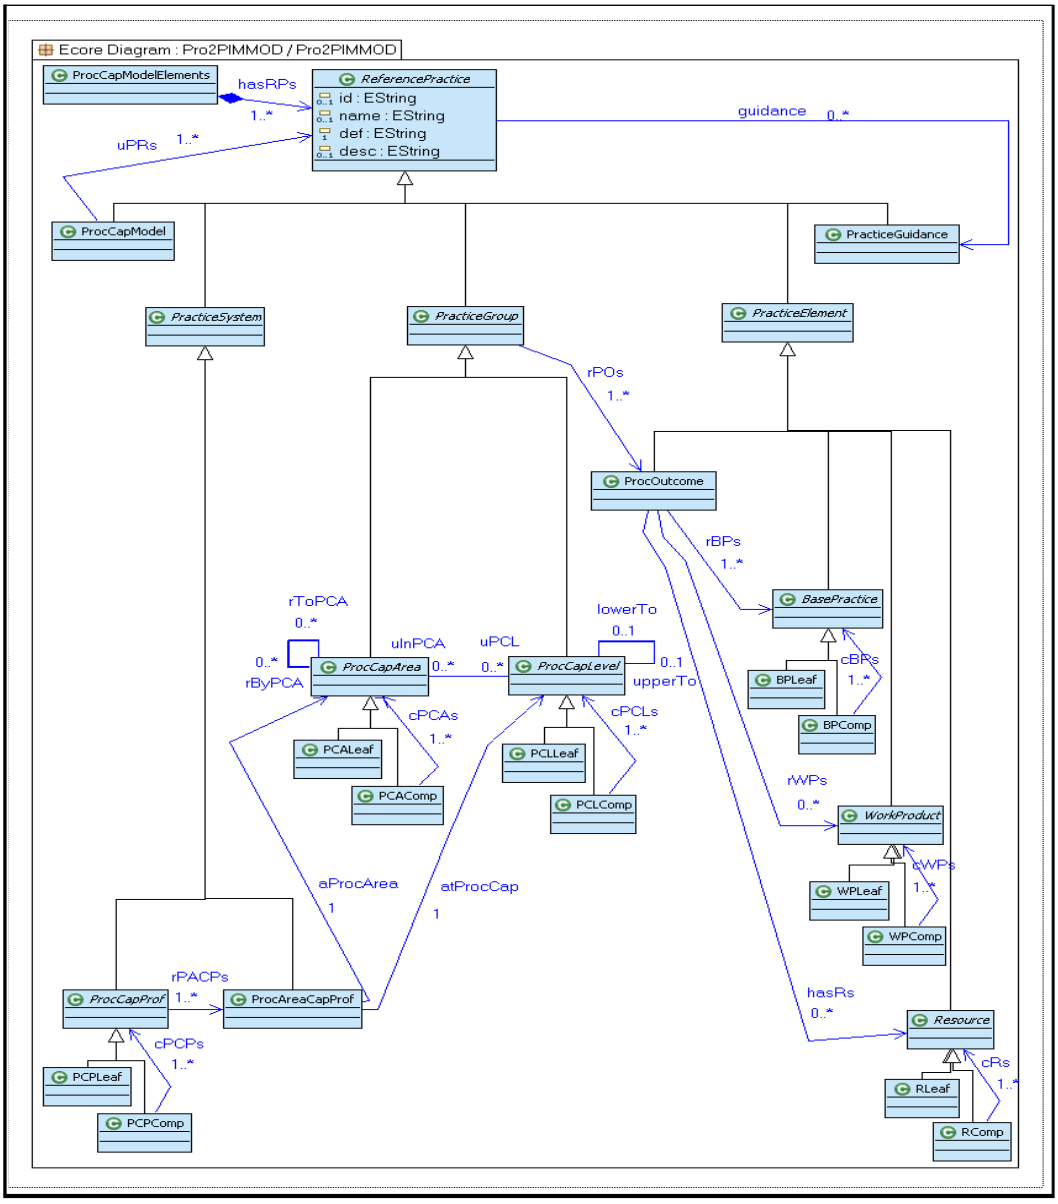

Figure 1 – *Geraes* Class Diagram in Eclipse Ecore

In Figure 1, for legibility's sake, the words Process, Capability and Profile are replaced by Proc, Cap and Prof.

An organization defines and uses a *ProcessCapabilityProfile* as a model of its current or future process. A *ProcessCapabilityProfile* is composed of one or more *ProcessAreaCapabilityProfiles*. Each *ProcessAreaCapabilityProfile* is a *ProcessCapabilityArea* at a *ProcessCapabilityLevel*. Each *ProcessCapabilityArea* and each *ProcessCapabilityLevel* is composed of one or more *ProcessOutcomes*. Each *ProcessOutcome* is composed of one or more *PracticeElements*.

A *ProcessCapabilityModel* is a collection of one or more *ReferencePractices*. *ReferencePractice* is an abstract super class for (with the exception of *ProcessCapabilityModelElements*) all Process Capability Model elements, including the *ProcessCapabilityModel* itself. There are four attributes for *ReferencePractice*: id (identification), name, def (definition) and desc (description). *ProcessCapabilityModelElements* is a collection of all *ReferencePractices*. A *ReferencePractice* may refer to one or more *PracticeGuidances*. *ProcessCapabilityModel* and *PracticeGuidance* are two concrete subclasses of *ReferencePractice*. There are also three more subclasses of *ReferencePractice*: the abstract classes *PracticeElement*, *PracticeGroup* and *PracticeSystem*.

PracticeElement has four subclasses: *ProcessOutcome*, *BasePractice*, *WorkProduct* and *Resource*. *PracticeGroup* has two subclasses: *ProcessCapabilityArea* and *ProcessCapabilityLevel*. *PracticeSystem* has two subclasses: *ProcessCapabilityProfile* and *ProcessAreaCapabilityProfile*.

ProcessAreaCapabilityProfile represents a *ProcessCapabilityArea* at a *ProcessCapabilityLevel*. *ProcessCapabilityProfile* is a collection of one or more *ProcessAreaCapabilityProfiles*. A *ProcessCapabilityProfile* is a collection of one or more *ProcessAreaCapabilityProfile*.

Each *ProcessCapabilityArea* and *ProcessCapabilityLevel* is a collection of one or more *PracticeElements*. A *PracticeElement* is a collection of one or more *ProcessOutcomes*. A *ProcessOutcome* is a collection of one or more *BasePractices*, zero or more *WorkProducts* and zero or more *Resources*. *ProcessOutcome*, *BasePractice*, *WorkProduct* and *Resource* are subclasses of *ProcessElement*.

The concrete class *ProcessAreaCapabilityProfile* is a connection between *PracticeSystem* and *PracticeGroup*. The concrete class *ProcessOutcome* is a connection between *PracticeGroup* and *PracticeElement*.

ProcessCapabilityArea, ProcessCapabilityLevel, ProcessOutcome, BasePractice and *ProcessCapabilityProfile* are modeled with two more subclasses each, using the Composer Design Pattern [16]. This design pattern addresses the need to compose objects into tree structures to represent part-whole hierarchies. Composite lets clients treat individual objects and compositions of objects uniformly. Each one of these classes is modeled as an abstract class with two concrete subclasses each: the first one models the composition relation (with the Comp suffix) and the second one models the leaf element (with the suffix Leaf). The composition and the leaf element use as a name the aggregation of the initials of the root element name (PCA, PCL, PO, PP, PCP and PCM) followed by the suffix Elem or Comp.

The class diagram in Figure 1 is named ***Geraes*** because its shape resembles the drawing in the cover of Milton Nascimento´s album named Geraes [17][2].

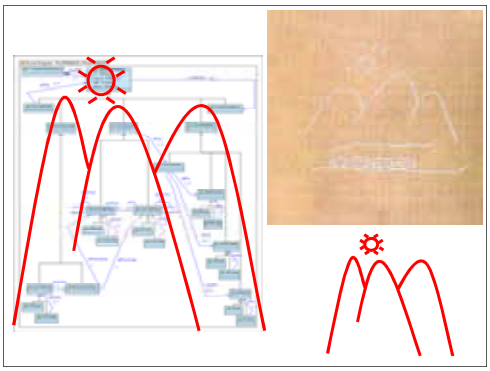

Figure 2 – *Geraes* Diagram and Geraes Album Cover

5. CMMI-DEV AND ISO/IEC 15504-5 VIEWS

This section is a partial unified view of the complete modeling of CMMI-DEV and ISO/IEC 15504-5 models that is described in a technical report [18].

A CMMI-DEV´s Process Area is modeled as a *ProcessCapabilityArea* composed of one, two or three lower level *ProcessCapabilityAreas*. Those lower levels *ProcessCapabilityAreas* correspond to the CMMI-DEV´s Specific Goals. There are twenty-two process areas and forty-eight specific goals in CMMI-DEV. The process areas are organized into four process area categories. Each process area category is modeled as a higher level *ProcessCapabilityArea*. Therefore these three CMMI-DEV concepts (process area category, process area and specific goal) are modeled as *ProcessCapabilityAreas* in three levels of composition.

The CMMI-DEV Project management process area category, for example, is modeled as a *ProcessCapabilityArea* composed of six lower levels *ProcessCapabilityAreas* (with ids "PP", "PMC", "SAM", "IPM", "RSKM" and "QPM"). The PP *ProcessCapabilityArea,* for example, is composed of three lower levels *ProcessCapabilityAreas* (with names "Establish Estimates", "Develop a Project Plan" and "Obtain Commitment to the Plan". Each one of these three lower levels *ProcessCapabilityAreas* is a *ProcessCapabilityAreaLeaf*, while each one of the two higher levels *ProcessCapabilityAreas* ("Project Management" and "Project Planning") is a *ProcessCapabilityAreaComp*.

[2] The idea of an icon is inspired in Favre on the S Mega-Pattern: "The shape of the S pattern has been chosen to directly mimic the layout of the piece of art *One and Three Chairs* from Kosuth" [9, p. 6].

The four original CMMI-DEV process area categories, twenty-two process areas and forty-eight specific goals are modeled as forty-eight *ProcessCapabilityAreaLeaf*s and twenty-two *ProcessCapabilityAreaComps* concrete classes. These twenty-two *ProcessCapabilityAreaComps* are the four process area category and the eighteen process areas with two or three specific goals. The four process areas with only one specific goal are modeled as *ProcessCapabilityAreaLeaf* because there is no difference between the original process area and its one specific goal.

A CMMI-DEV specific goal is a *ProcessCapabilityAreaLeaf* composed of *ProcessOutcomes*. There is no concept of outcome in CMMI-DEV. A specific goal is composed of specific practices. In order to model an outcome, each specific practice is modeled as an outcome and as a practice. The outcome is the practice rewritten with the passive voice. The specific practice "SP 1.1 Elicit Needs", for example, is modeled as a *BasePractice* (id "SP 1.1", name "Elicit Needs", and def "Elicit stakeholder needs, expectations, constraints, and interfaces for all phases of the product lifecycle") and as a *ProcessOutcome* (id "Out 1.1", name "Needs are elicited", and def "stakeholder needs, expectations, constraints, and interfaces for all phases of the product lifecycle are elicited").

An ISO/IEC 15504-5´s process is modeled as a *ProcessCapabilityArea*. There are forty-eight processes in ISO/IEC 15504-5 model that are organized in nine process groups. Each ISO/IEC 15504-5 process groups is modeled as a higher level *ProcessCapabilityArea*. The ISO/IEC 15504-5 process groups are further organized in three process categories. Each ISO/IEC 15504-5 process category is a higher level *ProcessCapabilityArea*. Therefore, these three ISO/IEC 15504-5 concepts (process category, process group and process) are modeled as *ProcessCapabilityAreas* in three levels of composition.

The ISO/IEC 15504-5 organizational life cycle process category, for example, is modeled as a *ProcessCapabilityArea* (name "Organizational"). This *ProcessCapabilityArea* is composed of four lower levels *ProcessCapabilityArea*s (with names "Management", "Process Improvement", "Resource and Infrastructure" and "Reuse"). The Management *ProcessCapabilityArea,* for example, is composed of six lower levels *ProcessCapabilityAreaLeafs*.

An ISO/IEC 15504-5 outcome and its correspondent base practices are a *ProcessOutcome* with *BasePractices*. Each base practice corresponds to one or more outcomes. When a base practice corresponds to more than one outcome, it is decomposed in a way that each element corresponds to only one outcome. The ISO/IEC 15504-5 Risk management process, for example, is a *ProcessCapabilityArea* with six *ProcessOutcomes*. The first *ProcessOutcome* is modeled with desc equal to "the scope of the risk management to be performed is determined". This first *ProcessOutcome* has only one *BasePractice* (id "MAN1.BP1", name "Establish risk management scope", and desc "Determine the scope of risk management to be performed").

A CMMI-DEV process capability level is a *ProcessCapabilityLevel* composed of one, two or ten lower level *ProcessCapabilityLevel*. Those lower levels *ProcessCapabilityLevel* are named Generic Goals in CMMI-DEV. There are six process capability levels in CMMI-DEV and seventeen Generic Goals.

An ISO/IEC 15504-5 process capability level is a *ProcessCapabilityLevel*, composed of zero, one or two lower level *ProcessCapabilityLevel*. Those lower levels *ProcessCapabilityLevel* are named Process Attribute in ISO/IEC 15504-5. There are six process capability levels and nine process attributes in ISO/IEC 15504-5.

The six original CMMI-DEV process capability levels and the six original ISO/IEC 15504-5 process capability levels are modeled as six *ProcessCapabilityLevels* composed of zero, one, two or three lower level *ProcessCapabilityLevels*. As both sets are based in the measurement framework of ISO/IEC 15504, they are similar. But they are not equivalent. Therefore, each set is modeled separated, but using a similar structure in order to facilitate further composition among them.

The ISO/IEC 15504-5 "Managed process" capability level and the CMMI-DEV "Managed process" capability level are modeled as *ProcessCapabilityLevel* (id "2" and name "Managed process"). This capability level is defined in ISO/IEC 15504-5 as composed of two process attributes (PA2.1 and PA2.2). The corresponded capability level in CMMI-DEV is defined as composed of ten Generic Practices (GP2.1 to GP2.10). The correspondent *ProcessCapabilityLevel* is modeled as composed of three lower levels *ProcessCapabilityLevels*. Table 1 describes these three lower levels *ProcessCapabilityLevels*, identified in column "Unified Leaf PCL". Some of the original Generic Practices and Outcomes are divided into two parts, identified as (p1) and (p2), in order to allow a correspondence to the other model.

Using the contents of Table 1 as a guide, the capability levels of the original CMMI-DEV, the original ISO/IEC 15504-5 and a unified view, can be modeled. They use a subset of the same fourteen *ProcessCapabilityLevelLeafs*. Unified 2.1.1, 2.1.6 and 2.3.4 exist in CMMI-DEV but not in ISO/IEC 15504-5. Unified 2.1.2, 2.2.1 and 2.2.2 exist in ISO/IEC 15504-5 but not in CMMI-DEV. A similar table is produced for capability level 3 (with also three *ProcessCapabilityLevelLeafs*), for capability level 4 and 5 (each one with two *ProcessCapabilityLevelLeafs*).

A CMMI-DEV staged representation is modeled with four *ProcessCapabilityProfiles*, each one representing a maturity level.

Table 1 - Example of Unified View

Generic Practices for CMMI-DEV Generic Goal 2		Unified Leaf PCL	Outcomes for ISO/IEC 15504-5 Process Attributes 2.1 and 2.2	
Id	**Name**	**Id**	**Id**	**Name**
GP 2.1	Establish Organizational Policy	2.1.1		
		2.1.2	PA 2.1 a)	Objectives for the performance are identified;
GP 2.2	Plan the Process	2.1.3	PA 2.1 b) (p1)	Performance of the process is planned;
GP 2.3	Provide Resources	2.1.4	PA 2.1 e)	Resources and information necessary are identified, (…);
GP 2.4	Assign Responsibility	2.1.5	PA 2.1 d)	Responsibilities and authorities are defined, (…);
GP 2.5	Train People	2.1.6		
		2.2.1	PA 2.2 a)	Requirements for the work products are defined;
		2.2.2	PA 2.2 b)	Requirements for documentation and control are defined;
GP 2.6	Manage Configurations	2.2.3	PA 2.2 c)	Work products are appropriately identified, (…)
GP 2.9	Objectively Evaluate Adherence	2.2.4	PA 2.2 d)	Work products are reviewed and adjusted as necessary ;
GP 2.8 (p1)	Monitor and Control the Process	2.3.1	PA 2.1 b) (p2)	Performance of the process is monitored;
GP 2.8 (p2)	Monitor and Control the Process	2.3.2	PA 2.1 c)	Performance of the process is adjusted to meet plans;
GP 2.7	Identify and Involve Relevant Stakeholders	2.3.3	PA 2.1 f)	Interfaces between the involved parties are managed.
GP 2.10	Review Status	2.3.4		

The abstract class *PracticeElement* and its concrete subclasses *ProcessOutcome*, *BasePractice*, *WorkProduct* and *Resources* represent the elements of the original specific and generic goals of CMMI-DEV, composed of specific and generic practices and sub-practices and typical work products, and the original outcomes, base practices, work products and resources from ISO/IEC 15504-5.

6. EVALUATION

As an evaluation, the achievements of the five objectives goals are commented. The achievement of Goal G1 is evidenced by the modeling of CMMI-DEV and ISO/IEC 15504-5 models. The achievement of Goal G2 is evidenced by the number of key concepts. Seven explicit key CMMI-DEV concepts (process area, specific goal, process area category, process capability level, generic goal, maturity level, capability profile) and one key implicit concept (process area capability profile) are modeled with four key concepts of the class diagram (*ProcessCapabilityArea*, *ProcessCapabilityLevel*, *ProcessAreaCapabilityProfile* and *ProcessCapabilityArea*). Four explicit key ISO/IEC 15504-5 concepts (process, process capability level, process capability profile and process attribute) and one key implicit concept (individual process capability profile) are modeled with the same four key concepts of the class diagram. For *PracticeElement*, four explicit key CMMI-DEV concepts (specific practice, generic practice, typical work product and sub practice) are modeled with four key concepts of the class diagram (*BasePractice* and *WorkProduct*). Six explicit key ISO/IEC 15504-5 concepts (outcome, base practice, work product, generic practice, generic resource and generic work product) are modeled with the four key concepts of the class diagram (*ProcessOutcome*, *BasePractice*, *WorkProduct* and *Resource*). As the same eight key concepts cover twelve CMMI-DEV concepts and eleven ISO/IEC 15504-5 concepts, this goal is considered satisfied.

The achievement of Goal G3 also is evidenced by the description of how the key elements of both models are modeled. The achievement of Goal G4 is evidenced by an analysis of what elements from CMMI-DEV and ISO/IEC 15504-5 are modeled as *ProcessCapabilityAreaLeaf* and *ProcessCapabilityLevelLeaf*. There are differences in terms of granularity among the original twenty-two process areas from CMMI-DEV, among the original forty-eight processes from ISO/IEC 15504-5, and between the two models as well. The Project Management process from ISO/IEC 15504-5 is similar to the set composed of two CMMI-DEV process areas: Project Management and Project Monitoring and Control. These two process areas have five specific goals. In order to make feasible the relationship among these two models, both, the ISO/IEC 15504-5 process and the pair of CMMI-DEV process area, are modeled as five *ProcessCapabilityAreaLeafs*. The forty-eight original ISO/IEC 15504-5 processes are covered by seventy-two *ProcessCapabilityArea*, and, the original twenty-two process areas of CMMI-DEV are covered by forty-eight *ProcessCapabilityArea*, with almost all of them already included in the seventy-two from ISO/IEC 15504-5.

The achievement of Goal G5 is evidenced by the class *ProcessCapabilityModelElements* as a collection of all elements. The reference to the elements is the only self-contained reference and allows the reuse of each element in any model.

7. RELATED AND FUTURE WORK

Mappings, comparisons and harmonization among concepts and elements from Process Capability Models in general, and from a CMMI-DEV model and ISO/IEC 15504-5 model in particular, have been done elsewhere, as for example, by Lepasaar et al. [19], Alexandre and

Habra [20] and Rout and Tuffley [21]. The iCMM and MR-MPS models combine elements from a CMMI model and ISO/IEC 15504-5 model. All of these related works address the goals G1 and G3, but they do not address the goals G2, G4 and G5.

Siviy and Kirwan [22] present an initial reasoning framework for harmonizing process improvement efforts when multiple improvement technologies and models are in use. *Geraes* is a specific proposal, based in process capability, for that reasoning framework.

As a future work, a phase 3 of the project is under way in which *Geraes* is under another revision in order to support the concepts of the other models listed in section 2. A preliminary analysis pointed out that most of these concepts are already supported. This revision is also a consolidation of the unified basic concepts as a complete formal specification and implementation Process Capability Profile Metamodel in order to define a consensual agreement on how elements of a process should be selected to produce a given Process Capability Profile. The concept of metamodel is used as proposed by Favre [9] and Bézivin [10].

8. CONCLUSION

This article proposes *Geraes* class diagram as a set of unified basic concepts for Process Capability Models, addressing the issue identified by Card [1]. The class diagram is evaluated against five defined goals, including the modeling of CMMI-DEV and ISO/IEC 15504-5 models. This proposal is part of an ongoing research effort to evolve the current SPI area towards MDPEK and PRO2PI. The class diagram helps the understanding the concepts of Process Capability Models independent of how a particular model implemented these concepts. This proposal is a relevant step towards a process capability profile metamodel that will support MDPEK and PRO2PI and therefore the consistent utilization of elements from multiple models to process improvement.

ABSTRACT
In order to be effective in the generation of high quality products, a software process must suit the application domain, the organization's unique features, the development teams and the specific characteristics of the project. On the other hand, software projects involve development risks, depending on the complexity of the project, the team expertise, the technology deployed and many other factors. In this paper, a systematic approach is proposed to manage risks in software development projects through process tailoring. This approach aims at adapting a process to a specific project, with the objective of minimizing its exposure to its identified risks. Goal/Question/Metric plans are defined to monitor risks. Some developed case studies are presented.

1. INTRODUCTION
Tailored software processes are required so that projects can adopt development methods, techniques and practices according to their specific needs. The Software Engineering Institute (SEI), through Capability Maturity Model Integration (CMMI), proposes that organizations define a standard process, common to all the organizations' projects, and tailor this process according to the specific characteristics of each process [11]. However, process tailoring is not a simple task; it requires knowledge and experience in the software process. While a process is tailored, the characteristics of the project and of the environment must be taken into account. Dependable software development [15] for instance, requires particular environment features, tasks, and support tools to support the formalization of specifications, to demonstrate program correction and to create software replication, among others. Planned development process models [11] highlight detailed identification of processes activities and tasks and are suited to projects where a system quality improvement is required to make the projects more manageable, and to forecast dates and costs. These process models guide the team as they develop the work [11]. Agile models highlight flexibility, being suitable to development of software with unstable requisites, by small teams of highly skilled developers [11]. Both agile and planned approaches have context-dependent shortcomings that, if are not addressed, can lead to project failures. The challenge is to balance the two approaches to take advantage of their strengths in a given situation while compensating for their weakness [2].

Keeping the processes descriptions is important because they allow reusing the organizations' knowledge and processes to be assessed and improved [14]. Reusing processes is a way of reusing experience and knowledge, making possible to create a collection of reusable processes, which can be inter-connected to instantiate new and more complex processes. To produce high quality software in a competitive way, on schedule and within costs previously estimated, it is also necessary to manage the risks involved in the software development of a specific project [5].

This paper proposes a systematic approach - Project Risk Management Approach (PRiMA), which aims at tailoring the organization's process, to be used in a specific project, inserting in it preventive and corrective actions for the prioritized risks of the project. The preventive actions to risks are described as process and organizational patterns, since those catch successful practices in software management and can be used in the elaboration or improvement of the software processes [4]. The organization's standard process and the organizational and process patterns related to the risks that they intend to prevent are stored in a knowledge base that must evolve with time based on the developers experience. This makes it possible to reuse a usable set of software process assets that improve process performance across the projects and provide a basis for cumulative, long-term benefits to the organization [14].

A Project Risk Management Approach Tool - (PRiMA-Tool) was developed to support the use of the systematic approach proposed. This tool allows that the organization's standard process to be tailored to meet the specific needs of

a project, inserting in the project process, actions to prevent and monitor risks. As the tailoring result, a website is created with the description of the process for the project.

The paper is outlined as it follows: Section 2 shortly introduces organizational and process patterns; Section 3 explains the systematic approach proposed to manage risks in software projects, called PRiMA; Section 4 describes PRiMA-Tool. In Section 5 some case studies are presented. Section 6 mentions some related work, and in Section 7 conclusions and future works are suggested.

2. ORGANIZATIONAL AND PROCESS PATTERNS

According to Coplien [4], successful software organizations use the same organizational and process patterns in the software development. These patterns are not found in less productive or not so successful organizations [4]. A pattern describes the essential part of a solution for a recurrent problem in a specific context [8]. Organizational and process patterns catch successful practices in the management of software development [4] and can be used to model a new organization and a new development process for a project, or also to improve an existent process. When put into practice together in an organized way, process patterns can be used to create software processes for the organization. Process patterns are considered blocks of reusable processes that can be used to tailor the software process to find the specific needs of the organization [4].

In this work, the organizational knowledge to prevent risks is described through rules that associate one or more risks to one or more patterns to which they propose a solution, preventing or minimizing the risks. The rules are associated with project contexts, where they work better. [7]. Rules have an accuracy factor, which measures the efficiency of patterns associated in risk control. A factor of 0 (zero) means the patterns does not help at all, while a factor of 10 means the patterns can be applied to completely eliminate the associated risks. The accuracy factor can be adjusted, by users, from real experiences of the use of the rule. The project context is identified in terms of three criteria, using an approach similar to Cockburn [3] and Boehm [2]:

- Defects Criticality: The possibility of loss associated with the occurrence of a defect. It ranges from loss of comfort (1) to the loss of many human lives (5);
- Team Size: The number of people involved is also an important factor considered by Cockburn [3]. The larger the project team, more intermediate documents must be produced to coordinate the work;
- Team Skill: Boehm [2] extends Alistair Cockburn´s classification of people, and uses it as an important factor to balance between agile and plan-driven methodologies. The classification ranges from: *people who are unable or are unwilling to collaborate* (level -1) to *people who can revise a method, breaking its rules to fit an unprecedented new situation* (level 3). The team skill is calculated according to the percentage of people classified in the levels of understanding.

The association of patterns to risks was based on the existing knowledge in published books and articles as [2][11][14][1][12] and in catalogues of existing patterns [4][8]. Figure 1 shows examples of risk association rules, such as the risk *ambiguously or imprecisely written individual requirements* to patterns that intend to prevent it in different project contexts. Different rules are associated to the same risk in different contexts. For example, **Rule 1** has as goal to prevent risk in projects with planned characteristics – large teams with medium abilities and software of low criticality [4][12], while **Rule 2** will be used to select patterns in dependable projects – high skill, medium teams and high criticality [4][15], and **Rule 3** will be used in projects with agile characteristics – high skill, small teams and medium criticality [1][8]. The above associations of risks to patterns are examples; the organization has to adjust and tune them to its reality and to elaborate new rules according to its needs.

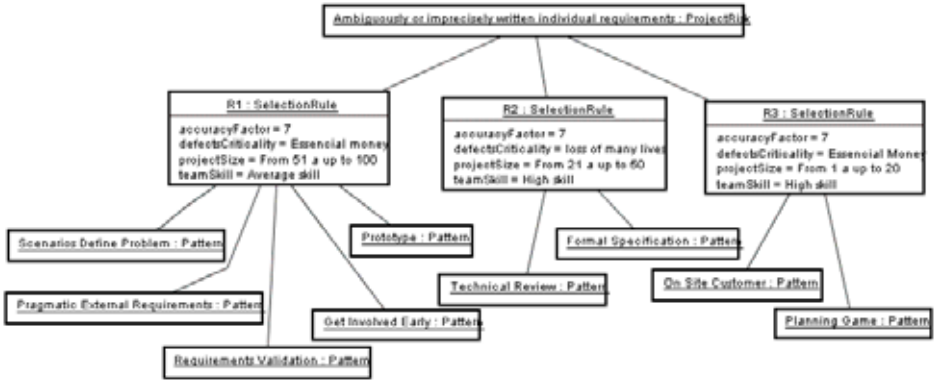

Figure 1 - Association of Patterns to Risks

An important characteristic of a process pattern is that it describes what must be done, but not exactly the details of how to do it [4]. It is necessary to identify the process elements required in the deployment of each pattern associated to the risks in a software process. Figure 2 shows process elements required to the deployment of the pattern *ScenariosDefineProblem*, as an example extracted from Coplien [4]. This association is based on the description of the pattern and on the practices described by models such as the CMMI [14], and by processes such as RUP [12], XP [1], PMBOK or by authors as Pressman [11], Sommerville [15], among others.

The activities, proposed by Rational Unified Process (RUP) [12], *Develop Vision*, *Find Actors and Use Case* and *Detail*

a Use Case are associated to the pattern *Scenarios Define Problem* (from Rule 1), as another example. Due to the readability of Figure 2 only the activity *Find Actors and Use Cases* was completely described, according to the description of RUP [12]. The process elements required to the insertion of this activity in a software process are highlighted in Figure 2. The activities, process elements associated to it, the patterns and the association rules are inserted in a knowledge basis.

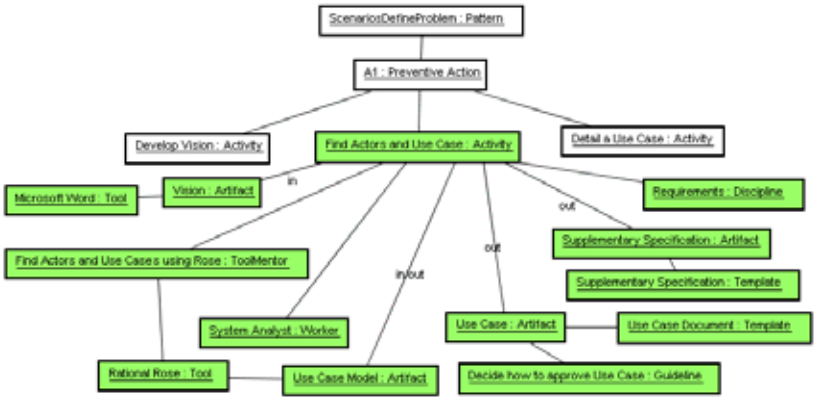

Figure 2 – Association of Pattern to Process Elements

3. PROJECT RISK MANAGEMENT APPROACH

The aim of the approach is to allow the elaboration of software development process for a specific project. This process has the objective of minimizing the project exposure to its identified and measured risks, according to the context of the project. Figure 3 shows the sequence of activities proposed by PRiMA.

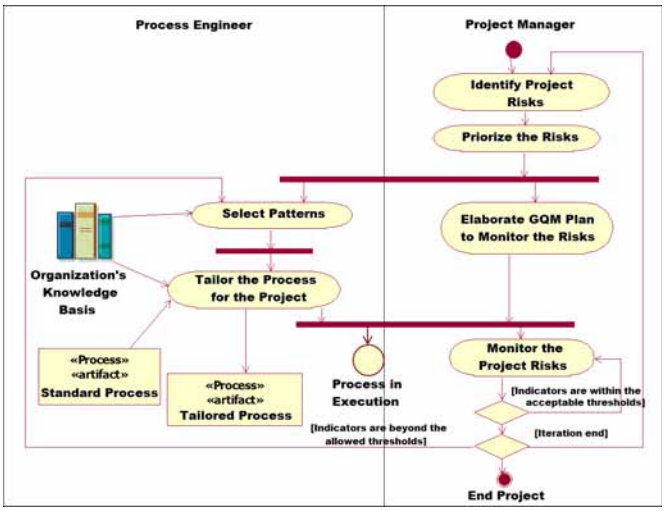

Figure 3 – Project Risk Management Approach

In the activity *Identify Project Risks,* the risks that may affect the project are identified. To help the project manager in this activity, the use of a common checklist of most frequently occurring risks is suggested [7].

To identify risks, the team members must be interviewed and group sessions must be organized with the team and with stakeholders involved in the project [5]. The process of identifying risks must not be limited to checklists proposed in the scientific literature. It is possible, for example, to create a list from the major problems that took place in the organizations past works, as suggested by DeMarco and Lister [5].

Considering that there can be a great number of identified risks for a project, each of a distinct nature and impact, in the activity *Priorize the Risks,* the risk exposure (RE) technique is employed to give priority to the risks that have more impact on the project and high or medium probability of taking place. Risk exposure, also called risk impact or risk factor, is the product of the probability of a non-satisfactory result to occur, and the loss associated to this non-satisfactory result. This work uses a 0 to 10 scale in order to measure the probability and the loss of each risk. Quantifying risks by risk exposure provides a relative priority order for all the identified risks. The project manager defines if all the risks identified will be handled, or just the ones with RE higher than a threshold. The cost to manage all the risks can be very high and risks with low probability of occurrence or low loss may not justify the cost to treat them [5].

The activity *Select Patterns* defines how to recover from the knowledge base, the patterns which aim to prevent the prioritized risks for a specific project [7]. In section 2 we described the proposed mechanism to select patterns from an organizational knowledge base.

The activity *Tailor the Process for the Project* describes how the process can be tailored to integrate the patterns selected to prevent the risks, resulting in the process defined for a project. The process tailoring is based on a process framework that integrates 1. the activities to be performed in all projects, 2. organizational patterns as preventive or corrective actions to risks, 3. GQM plans associated to risks. Each organization must define its own framework or tailor this to meet its specific needs. In the framework are described process tailoring guidelines and process configuration aiming to facilitate the tailoring task. The guidelines describe how to tailor process elements according to the size and formality of the project. Process configurations are pre-defined process models, aiming to meet typical projects or process improvement models, such as CMM. The framework structure is briefly described in section 3.1 of this paper.

During the project, it is necessary to monitor the risks to ensure that risks factors stay within the planned thresholds or to take some actions when they fall beyond the quantitative targets. In the activity *Elaborate the GQM Plan to Monitor the Risks,* the GQM Plan is defined. The GQM

Plan details the metrics that must be collected to answer the questions associated to the goals of the plan. The GQM goals must be formulated in the following way "Analyze the <*object of study*> aiming <*goal*> as regards to the <*focus*> in the point of view of <*point of view*> in the following context <*context*>". Table 1 shows, as an example, a GQM Plan to monitor the risk *ambiguously or imprecisely written individual requirements.*

Table 1. GQM Plan: Ambiguously or imprecisely written individual requirements risk

Risk: Ambiguously or imprecisely written individual requirements	
Goal: Analyze the project with the purpose of monitoring the requirements definition from the viewpoint of the development team.	
Question: Did the users validate the project requirements documents?	*Metric 1:* Percentage of Validated Requirements by the client RVRC = (amount of requirement documents validated/ total amount of requirement documents) *100

The risk monitoring is based on the metrics defined in the GQM Plan. The measures are stored in historical basis to be used in future estimates and in the project control. The metrics help the project manager to *Monitor the Project Risks*, providing visibility to their progress. The project manager must identify when corrective actions must be taken because the probability of occurrence of risk is growing. The probability of a risk to occur is defined by comparing the measurements done with pre-established thresholds. As results of the project risk monitoring, two situations may occur: 1. the measurements are within the acceptable thresholds, and a management action is not required; 2. the measurements are beyond the allowed thresholds, being necessary the execution of the activity *Select patterns* again to select other preventive actions to be inserted in the software project process.

At the end of any iteration, or periodically, the risks identified and prioritized for the project must be reviewed. In this review new risks may be identified, generating the need of tailoring the process again, and therefore new preventive actions can be included in the process to be used in the next iteration.

3.1 Framework

The basis of the tailoring task is a process framework, from which different processes can be instanced by the selection of process elements, previously defined by the organization. The framework is composed of a knowledge base, tailoring guidelines and process configuration.

The knowledge base comprises: software risks; instances of process elements (activities, roles, artifacts, disciplines, tools) used in the definition of software processes; activity diagrams describing the sequence of execution of activities by discipline; organizational and process patterns; rules of association patterns to risks; preventive actions describing the process elements needed to be deployed in patterns stored in the knowledge base; and goals, questions and metrics used to monitor risks.

Tailoring guidelines and process configurations are proposed to facilitate tailoring and definitions of the organization's process tasks. Process configurations are pre-defined process models, which include a set of process elements - they can be used as a starting point to define the organization's own process. These models were defined from well known processes or methodologies described in the literature. In the framework implemented with PRIMA-tool the following process configurations are suggested: simplified processes, as essential RUP [12], which describes a small set of elements to use the RUP in a project; complete, as RUP [12] and XP [1]; or extended to fulfill software improvement models, as RUP CMM Level 2 and RUP CMM Level 3. These process configurations are examples; every organization will define its process configurations according to its needs. SW-CMM and CMMI [14] consider that guidelines must be elaborated describing how to tailor the standard process of the organization to meet the specific needs of the project. These process tailoring guidelines are associated to the process elements and describe a list of alternatives to tailor a specific element. Process guidelines help the designer in tailoring processes, describing alternatives to tailor process elements according to the size and formality of the project. The guidelines are textual descriptions that describe details of how tailoring must be done to each process element [14].

4. PRIMA-TOOL

An experimental environment was developed composed of two tools: Pattern-Based Methodology Tailoring Tool (PMT-Tool) and Project Risk Management Approach Tool (PRiMA-Tool). PMT-Tool module was developed by Júlio Hartmann [7]. PMT-Tool is responsible for cataloguing the process patterns and associating them with the software risks by means of preventive rules, as well as selecting the pattern to prevent prioritized risks in a specific project. PRIMA-Tool module is responsible for the elaboration of the project software process, from organization's standard process tailoring, inserting in it the selected patterns to prevent the project risks and defining the Goal/Question/Metric Plans to manage the project risks. Having concluded the project process tailoring, Prima-Tool generates a website with the description of the defined process for the project to be consulted by developers, managers and process engineers. The tools are available for interested readers to play with at http://www.urisantiago.br:8080/prima/.

5. CASE STUDIES

Two case studies were carried out to validate the proposed framework. The case studies were made based on two software projects developed at a university, which will be called Y University. The projects show different characteristics, being one of the projects goal to develop a financial system in one of the Y University campuses (Fin$oft Project), while the other project goal is to develop

an academic system in a distributed way, by teams located at three different campuses of the same university (@cadSoft Project). Y University standard process is very simple, and it is based on a small subset of RUP activities, proposed by Essential RUP [12]. Table 2 shows in column 2, the activities that make the Y University standard process.

The team that will develop the Fin$oft software is composed of a project manager, two developers, two trainees and the Computing Center Coordinator, who is the Senior Manager of this project. The team is classified as a high-skilled team, as developers are experienced in the programming language employed and have already developed similar systems. The defined risks for the Fin$oft project are: *failure to manage end user expectations*, *misunderstanding the requirements*, *conflict between user departments*, *scope and goals are not clearly defined*, and *non-realistic schedule and budget*. Among the pattern list suggested by the PRiMA Approach, the patterns selected were: *EarlyAndRegularDeliverXP*, *PlanningGame*, *OnSiteCustomer*, *ConstantRefactoring*, *BuildPrototype*, *DocumentedSoftwareEstimate, SimpleDesign, SizeThe-Schedule and DocumentedConfigurationManagementPlan.*

Column 3 in table 2, shows the activities to be added to Y University's standard process (column 2) to form the specific process for the Fin$oft Project. The team that is developing Fin$oft financial software is small, with developers who are knowledgeable on the technology to be used in the project. The client is within the campus where the system will be developed, so the project configuration can use most of the agile methodologies. The main patterns suggested by PRiMA are those that aim to provide more agility to the organization standard process, based on RUP.

Another case study, @cadSoft academic software is being developed by three teams, totalizing 22 people: 3 project managers, 8 developers, 10 trainees and 1 senior manager, based on the Y University administrative area. The team is classified as average skilled, due to the large number of trainees and the fact that the team does not master the technology chosen for the system development. The defined risks for the @cadSoft project are: *lack of a methodology for the project*, *lack of required knowledge/skill in the project*, *misunderstanding the requirements*, *introduction of new technology*, *wrong development of functions of user interfaces*, *unfeasible design*, and *lack of top management commitment to the project*.

Table 2. Organization's standard process and Fin$oft's and @cadSoft's defined processes

Discipline	Organization's Standard Process	Fin$oft	@cadSoft
Requirements	Develop Requirements Management Plan	Write User Story Divide User Story Priorize User Story Develop a System Prototype Validate a System Prototype	Find Actors and Use Cases Structure the Use Case Model Detail a Use Case Review Requirements
Analysis and Design	Architectural Analysis Class Design Database Design	Write Tasks	Asses Viability of Arch. Proof-of-concept Construct Architectural Proof-of-concept Describe the Run-time Architecture Implement Innovative Idea Review the Architecture Review the Design Validate Innovative Idea
Implementation	Execute Developer Tests Implement Design Elements	Execute Unit Tests Implement Tasks Refactor Code	Execute Unit Tests Refactor Code Review Code
Test	Define Test Approach Define Test Details	Execute Acceptance Tests Write Acceptance Tests Write Unit Tests	Execute Acceptance Tests Write Acceptance Tests Write Unit Tests
Deployment	Create Deployment Unit Develop Support Materials		
Configuration and Change Management	Confirm Duplicate or Rejected CR Review Change Request Submit Change Request Update Change Request	Establish Change Control Process Write CM Plan	Establish Change Control Process Write CM Plan
Project Management	Compile Software Development Plan Develop Business Case Develop Iteration Plan Identify and Assess Risks Initiate Project Iteration Acceptance Review Lifecycle Milestone Review Prepare for Phase Close-out Prepare for Project Close-out Project Acceptance Review Report Status	Accept Task Classify by Risk Collect Metrics Define Iteration Scope Define Control Processes Define the Scheduler Define Velocity Develop Measurement Plan Elaborate Release Plan Estimate Task Estimate User Story Monitor Status Project Negotiate the Scheduler Team Negotiate with Customer	Assess Iteration Initiate Iteration Iteration Planning Review Plan Phases and Iterations Project Approval Review Project Planning Review Project Review Authority (PRA) Review
Environment	Select and Acquire Tools Set Up Tools Tailor the Process for the Project		Develop Development Case Review the Software Process for the Project
Training			Identify Training Execute Training

Among the suggested patterns listed to prevent risks, the following were selected: *ConstantRefactoring*, *SoftwareLifeCycleIsDefined*, *EarlyRegularDeliverRUP*, *ScenariosDefineProblem*, *ShunkWorks*, *ArchitectureTeam*, *ProjectProcessIsDefined*, *PeerReviews*, *ApprenticeShip*, *SeniorManagementReview* and *DocumentedConfiguration-ManagementPlan.* Column 4 shows the activities added to the Y University standard process (column 1) to form the specific process for the @cadSoft Project.

In the @cadSoft Academic System's process, the situation presented is opposed to that of the Fin$oft, because the team is distributed in different campuses, and the customer, in this case the University administrative area, is far from the development teams, the team is composed of many trainees, who usually stay in the team only for short periods. The most relevant patterns, suggested by PRiMA-Tool, are patterns which aim to provide more planning and documentation to the software process. Considering the difficulty in face to face communication in distributed teams, documents are generated so that the teams can communicate and keep informed.

PRiMA helps the process designer on performing the process tailoring. However, the process designer role is fundamental, and her careful empirical consideration and evaluation is necessary in order to tailor an adequate process for a given project. The tool is helpful because it suggests the most suitable patterns to the project, accordingly to the data which is recorded in its repository. It saves the time of the process designer to browse through dozens or even hundreds of patterns which are available.

6. RELATED WORKS

The proposed framework in this paper differs from other risk management approaches by proposing organizational and process patterns as risk preventive actions and for tailoring the organization's software process to prevent the risks identified for the project.

Gnatz et al [6] propose a framework to describe software processes. They do not consider quality standards or models during tailoring. Kiper and Feather [10] propose probabilistic models to manage risks, while this work uses risk exposition quantification. Probabilistic models are more complex and difficult to be used. Keshlaf and Hashim [9] propose a model for risk management and a tool, called SoftRisk, to support the process. It does not define how the risks are monitored and controlled during the software project. Roy [13] proposes a framework, called ProRisk, to manage risks in software projects. The framework requires a detailed analysis of the organization and the scope of the project to develop a group of risk factors and organize them in a way to reflect the different risk perspectives, making its use difficult.

7. CONCLUSIONS AND FUTURE WORKS

This article proposes a Project Risk Management Approach – PRiMA - which makes it possible to instantiate development processes tailored according to the identified and prioritized risks of the development project. The aim of tailoring is to elaborate a defined process to a project suitable to the project's context, taking advantages of agile methods, planned or hybrid, while preventing identified risks for the project. The approach presented in this paper is limited by the difficulties of validating the empirical knowledge of experienced process designers, software engineers and project managers, expressed as patterns and risk resolution rules. Nevertheless, it has a strong and original contribution to structure a systematic approach for capturing this knowledge and assisting process designers and project managers on leveraging it. The approach suggests that the use of risk analysis combined with organizational patterns is a promising way of overcoming the limitations of existing software process improvement frameworks. The information stored in the knowledge base can be updated and must improve with time and as the team gets more experience. Results of post-mortem analysis of projects can help in this task. Future works include the use of a workflow management system to create environments to support the execution of processes defined from PRiMA.

Abstract

Process tailoring consists on the manipulation of an existing software process to incorporate new elements or remove existing ones. However, it is essential to constrain tailoring activities to guarantee certain properties hold in the tailored process. Therefore it is necessary to define a properly mechanism for process tailoring capable to maintain the consistency and compliance of the resulting process. In this paper, we propose the use of a set of well-formedness rules required to ensure tailoring of standard software development process based on RUP process.

1 INTRODUCTION

The efforts to implement standard software development processes across large organizations have gradually increased in the last years. Because the product quality is associated to the process utilized in its construction [1] the goal is to adopt a well-defined process in software development.

The use of a standard software development process may allow the improvement of performance, predictability and reliability of the work processes; and the increase of productivity [2]. Furthermore, it also facilitates the implementation of the process capability maturity models such as ISO/IEC 15504 and Capability Maturity Model Integration (CMMI).

Nowadays, many "off-the-shelf" processes that facilitate the initial job of deciding the process elements have been suggested by the academy and industry. The most known one is the Rational Unified Process (RUP) [3] proposed by IBM Rational, which provides information regarding activities and tasks for software development and management.

However a "one process to fit all project needs" approach does not work in software development [4]. As each project is unique in terms of business domain, customer requirements and technology [2], there is a need to adapt the standard software development process to the requirements and the specific context of each project [5], [6].

The act of adjusting and/or particularizing the terms of a standard software development process to accommodate differences among projects is called tailoring [7]. It implies adding, deleting and/or modifying elements, and changing relationships. The result of tailoring activities is a bespoke software process, which is called project-specific software process.

Nevertheless, though recent studies have recognized the importance of process tailoring, it is important to stress the difficulties related to this task. Park et al. [5] and Xu [2] highlight as the lack of knowledge support may make tailoring a difficult task. Fitzgerald et al. [8] discuss some issues about how agile methods are used and tailored in practice, once there is not much knowledge about tailoring of agile methods. Yoon et al. [9] show the problems one might face in order to maintain the consistency between the tailored process and the standard software development process.

The main goal of this paper is to present a set of well-formedness rules based on a process metamodel to constrain tailoring activities as something that may contribute to some of the issues mentioned above. The well-formedness rules are based on the RUP metamodel [10]. We believe that these rules facilitate software development organizations to guarantee consistency on their tailored processes with their standard software development processes.

The paper is laid out as follows. Section 2 presents the relevant literature on process tailoring and describes how process tailoring is supported in the RUP. Section 3 shows the well-formedness rules. In Section 4, an example of usage is described followed by conclusions.

2 BACKGROUND

2.1 Process Tailoring

Nowadays, it is widely accepted that a standard software development process should be tailored to fit the needs of the projects context [11]. Important capability maturity models such as ISO/IEC 15504 and CMMI recommend

[1] *Study developed by the Research Group in Software Quality of the PDTI, financed by Dell Computers of Brazil Ltd. with resources of Law 8.248/91.*

tailoring standards before applying them to a specific project. For instance, CMMI, a current version of the SW-CMM, assumes that the best way to support the variation of the processes is to provide tailoring guidelines associated with the standard software development process to answer specific needs of the organization projects. These guidelines should specify which elements can be modified from standard software development process as well as in which circumstances this occurs. ISO/IEC 15504, on the other hand defines that organizations must have a strategy for tailoring projects assets. It implies the establishment and maintenance of a standard set of processes and strategies for tailoring project's needs. The processes should indicate applicability and expected performance, and identify detailed tasks, activities and associated artifacts.

Software development processes such as RUP, XP and OPEN also consider process tailoring. They provide some guidelines to orient the deletion of the non-applicable elements, addition of required elements, and modification of existing elements for a particular project.

Process tailoring is also not new in the literature [12] and it has recently become a target of attention to the software engineering community. Some researchers have been focusing their attention on project characteristics that influence tailoring decisions [13], [14]. The same issue has also been studied or understood as a "contingency factor" [15], [16]. Other authors have involved the knowledge management on process tailoring [2], [17].

The main interest of this paper is to guarantee the consistency between the tailored process and the standard software development process. A review of the literature though shows few studies addressed to this aspect. Yoon et al. [9] have proposed a systematic method to formalize a standard software development process, process tailoring and to verify the tailored process. The authors describe a set of tailoring operations to preserve the dependency relationships among the elements of the standard software development process. Although the authors have considered the conformity between the standard software development process and tailored process and suggested some operations for this purpose, their study have not considered several mandatory software process elements such as roles, tools, phases, etc.

Welzel et al. [18] have developed a method to process tailoring (ProcePT) based on a process model called GV-Model. The process model is formed by activities and artifacts that must be tailored in the project context. GV-Model provides a set of 90 conditions to hold the deletion of these activities and artifacts. The authors have also developed a tool to support the GV-Model in PROLOG. However, the limitations of this research are the same found in [9]. Additionally, the artifact deletion is the only tailoring operation considered.

Although some studies have tried to cover the standard compliance there is the need for additional research on the area, as it can be seen in a recent systematic review on process tailoring [6].

2.2 RUP and Process Tailoring

RUP is a software engineering process that can be adapted for a very large class of software systems, different apllication areas, different types of organizations and different project sizes. The act of "adapting the process" is what RUP calls by process tailoring. Bearing in mind that two projects within the same organization may also be different, RUP indicates the use of process tailoring for each software project. The result of this tailoring is part of what RUP calls a development case. A development case describes all activities, roles, artifacts, and templates that must be used in a software project.

To support process tailoring RUP provides a specific discipline called environment. The environment discipline focuses on the necessary activities to configure the process for a project. Besides, guidelines and white papers on tailoring RUP for different types of projects and domains are also available. The problem related to the guidelines and the environment discipline is their informallity, that is, no reference about RUP metamodel can be found on them. As a consequence it is not possible to verify the consistency of the tailored processes.

In this sense, we verify the need of a suitable specification of tailoring rules based on the process metamodel. Without these rules, it is impossible to guarantee the integrity of the relationships among the elements that compose the metamodel according to the standard software development process. Moreover, considering the complexity and the amount of elements that compose RUP, the process tailoring activities is impracticable without an automated support. In order to achieve that, it is necessary to specify a set of rules compliant to the process metamodel.

3 WELL-FORMEDNESS RULES TO RUP PROCESS TAILORING

The approach of this research to tailor RUP process is composed by a set of well-formedness rules to process tailoring. The rules lead to some tailoring operations that preserve dependency relationships among the elements that compose RUP process. These rules are based on an extension of original RUP metamodel presented in [19], which captures the elements and relationships required on tailoring activities. The extended metamodel is shown in Figure 1. The included classes in this metamodel from the original RUP metamodel are three: Task, Sub-artifact and Optional. And, the new relationships are: the self relationships of the Workflow Detail, Activity, Task and Sub-artifact classes and the relationship referred to as *modifies* created between the Activity and Sub-artifact classes.

The operations aimed by the well-formedness rules are to delete or add elements to RUP process. It has been developed rules for elements such as Disciplines, Workflow

Details, Activities, Artifacts and Sub-artifacts. It is important to note as mentioned above that sub-artifacts do not exist in the original RUP metamodel. So, it has been defined a new class in the proposed metamodel to this element, once it allows the representation of the parts of an artifact. The concept of sub-artifacts is required to the process tailoring since not all artifacts are generated by only one activity. Sometimes parts of an artifact can become from distinct activities. Thus, sub-artifacts are necessary in order to allow the deletion of an activity which is responsible for producing a sub-artifact no longer demanded for the software process. As a consequence, it is possible to select which parts of an artifact are necessary for a specific project during the process tailoring.

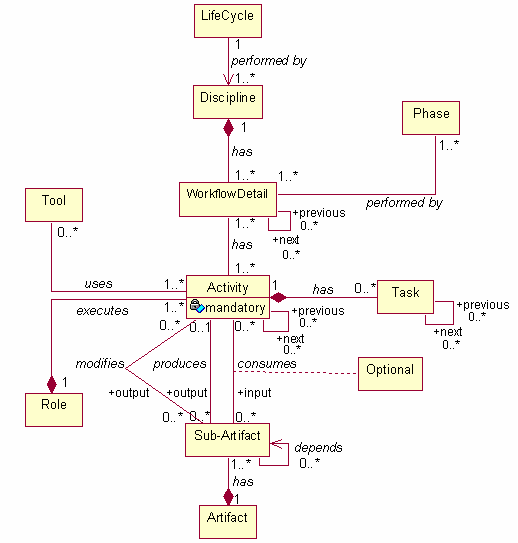

Figure 1 - The Extended RUP Metamodel

3.1 Tailoring Operation: Addition

As the UML multiplicity allows to refer to the number of objects in one class that can be related to one object in the related class and can be used on both sides of a relationship, it is considered that the well-formedness rules to addition operation are all expressed in the proposed metamodel. Thus, in order to add an element, the process engineer must respect the relationships of the added element only with other process elements. Details of the well-formedness rules to addition operations are provided bellow. Here, due to space constraints, we have decided not to illustrate the rules with tables as done in the following subsection.

Activity Addition: Adding activities instances implies in at least one relationship with the workflow detail element to indicate where the activity will be executed. Moreover, a responsible role for the activity execution and the related activities (precedent and subsequent ones) of the new activity must be defined. If necessary, the process engineer may associate tools to the new activity and create tasks to detail its execution. As activities have a clear purpose, usually expressed in terms of creating and/or updating artifacts, the process engineer may also associate the artifacts used by the new activity. Here, the process engineer uses the Sub-artifact class and the relationships referred to as *consumes*, *produces* and *modifies* to indicate which specific parts of an artifact will be consumed – in this case those mandatory or optional –, produced and/or updated by the new activity.

Workflow Detail Addition: When a workflow detail is added, at least one relationship with activity, discipline and phase instances must be created. In addition, related workflow details (precedent and subsequent ones) must be defined.

Sub-artifact Addition: When a process engineer wishes to produce additional information for a specific project he/she may add new sub-artifacts, which will be part of an artifact. In this tailoring operation, the process engineer must define at least one responsible role and optionally other roles that will update the new sub-artifact. The relationships referred to as *consumes*, *produces* and *modifies* may be used to associate the new sub-artifacts to different activities. Moreover, if the new sub-artifact has some kind of dependency relation to other sub-artifacts it must be created by the process engineer, who is also responsible for creating a relationship between the sub-artifact and an artifact.

Artifact Addition: Since we define an artifact as a set of sub-artifacts, the artifact addition operation implies in sub-artifacts addition. Thus, when an artifact is added at least one sub-artifact also must be included. However, it is known that when a process engineer applies the standard process to a small-size project or rapid application development, he/she may wish to manage process in higher-level to reduce workload and not to split an artifact. In this case, it is advisable to create for each artifact one sub-artifact with the same name of the artifact only. In ProTTo (our prototype cited in Section 4) it was implemented in the artifacts inclusion funcionality an option for process engineers to choose whether the included artifact need to be split or not. Thus, when an artifact is not split ProTTo automatically creates one sub-artifact with the same name of the included artifact.

Discipline Addition: Discipline addition is not supported since RUP disciplines cover all areas about software development.

3.2 Tailoring Operation: Deletion

Since RUP covers a large variety of development software, deletion operations are very common on process tailoring. For some of these operations, well-formedness rules are guaranteed in the present extended metamodel through UML relationships and its multiplicities. For instance, the composition relationships of the Discipline, Activity and Artifact classes, which define that the deletion of any of these elements implies in the deletion of its parts. However, many of the well-formedness rules can not be expressed using UML class model. So, we explain in a systematic way each deletion operation proposed in the present

approach. Bellow, all of them are illustrated with tables, since we may not express all well-formedness rules through the present extended metamodel as mentioned before. The tables show all affected elements by each tailoring operation and present a specific rule associated to each of them. Addiotionally, each rule contains a numeration to facilitate its identification.

Activity Deletion: Deleting activity istances of a standard software development process must be used only for optional activities (see the mandatory attribute of the Activity class in the Figure 1). In this operation, all activity tasks are deleted, since activities can be composed by tasks (see rule #9 of the Table 1). Moreover, related activities (precedent and subsequent ones) have to be connected in order to redefine the process workflow (see rule #1 of the Table 1). If a deleted activity produces sub-artifacts, it will be necessary to remove them from the activity (see rule #6 of the Table 1). In this case, if a removed sub-artifact has a dependency relationship with other sub-artifacts or it is mandatory consumed by other activities, other elements will have to be deleted (see rule #2 and #6 of the Table 1). Finally, all the associations of the deleted activity with the Role, Workflow Detail and Sub-artifact class have to be eliminated (see rule #3, #4, #5, #7 and #8 of the Table 1).

Workflow Detail Deletion: When a process engineer does not want to perform a group of related activities in a specific discipline he/she can delete workflow details. To do so, he/she must check whether the phases, activities and discipline related to the deleted workflow detail keep at least one relationship with another workflow detail. The phases, activities and disciplines that do not have other relationships also have to be deleted (see rule #1, #2 and #3 of the Table 2). It will also be needed to connect related workflow details (precedent and subsequent ones) (see rule #4 of the Table 2).

Table 1 - Well-Formedness Rules to Activity Deletion

Activity	#1	Related Activities (precedent and subsequent ones) must be connected.
	#2	Activities that consume the sub-artifacts (only the not optional ones) deleted by the activity must be eliminated.
Tool	#3	All the associations among the activity and tools must be eliminated.
Workflow Detail	#4	All the associations among the activity and workflow details must be eliminated.
Role	#5	All the associations among the activity and roles must be eliminated.
Sub-artifact	#6	Sub-artifacts produced by the activity and its dependent sub-artifacts must be deleted (this can imply in deletion of the other activities).
	#7	Sub-artifacts consumed by the activity must have its relationships eliminated.
	#8	Sub-artifacts modified by the activity must have its relationships eliminated.
Task	#9	All tasks of the activity must be deleted.

Table 2 - Well-Formedness Rules to Workflow Detail Deletion

Activity	#1	All relationships with activities must be deleted. If some activities no longer have relationship with other workflow details, they also must be deleted.
Discipline	#2	Workflow detail must be deleted from the discipline. If the discipline no longer has workflow details, it also must be deleted.
Phase	#3	All relationships with phases must be deleted. If some phases no longer have relationship with other workflow details they also must be deleted.
Workflow Detail	#4	Related workflow details (precedent and subsequent ones) must be connected.

Artifact Deletion: When an artifact is deleted its sub-artifacts must be deleted, too (see rule #1 of the Table 3). However, it will usually lead to other deletion operations (e.g. artifact deletion implies in executing deletion operation for all sub-artifacts of the deleted artifact).

Table 3 - Well-Formedness Rules to Artifact Deletion

Sub-artifact	#1	All sub-artifacts of the artifact must be deleted.

Sub Sub-artifact Deletion: Sub-artifact deletion is used to produce an artifact with different formats and levels of formality. Thus, when a process engineer wants to produce a less formal artifact he/she may delete pieces of this artifact, what can make it simpler. In order to delete a sub-artifact, a process engineer has to check if it is produced on software process or not. If so, he/she also has to delete its production activity (see rule #2 of the Table 4). Additionally, the process engineer must detele the sub-artifact of the artifact which it is associated and eliminate its associations with the Role class (see rule #1 and #4 of the Table 4).

Once the deleted sub-artifact is used by other activities, the process engineer must check whether it is mandatory or not. The activities where it is mandatory must be deleted (see rule #3 of the Table 4). Similarly, the process engineer has to check if the deleted sub-artifact has dependency relationships with other sub-artifacts, since these sub-artifacts also have to be deleted (see rule #5 of the Table 4).

Discipline Deletion: Deleting disciplines is implemented in the present approach following its use in RUP process, once some disciplines can be optionally performed (as Business Modeling, for example). In our approach, when disciplines are deleted the process engineer has to delete its workflow details (see rule #2 of the Table 5). Additionally, he/she has to eliminate the associations of the deleted discipline with the LifeCycle class (see rule #1 of the Table 5).

Table 4 - Well-Formedness Rules to Sub-Artifact Deletion

Artifact	#1	Sub-artifact must be deleted from the artifact. If the artifact no longer has sub-artifacts, it

		also must be deleted.
Activity	#2	The activity that produces the sub-artifact must be deleted.
	#3	The deleted sub-artifact must be disconnected of the activities. If some of these activities depend on the artifact to be performed they also must be deleted.
Role	#4	The association between the sub-artifact and roles must be deleted.
Sub-artifact	#5	The dependent sub-artifacts of the sub- artifact also must be deleted.

Table 5- Well-Formedness Rules to Discipline Deletion

LifeCycle	#1	The discipline must be deleted from the lifecycle. If the lifecycle no longer has disciplines, it also must be deleted.
Workflow Detail	#2	All workflow details of the discipline must be deleted.

4 EXAMPLE OF USAGE

We have applied the well-formedness rules to tailor RUP process in ProTTo – the tool prototype based on the proposed metamodel and on well-formedness rules to process tailoring [20]. We have considered the *Requirements* and *Analysis & Design* disciplines of RUP process as the standard software development process and we have tailored them by deleting some activities considered as optional on RUP process. Such activities are listed in Table 6.

Table 6 – Deleted Activities on Process Tailoring

Requirement Discipline Activities
Develop Requirements Management Plan (Deleted)
Find Requirement Attributes (Deleted)
Analysis and Project Discipline Activities
Perform Architectural Synthesis (Deleted)

In each deletion operation the side effects of the remained process elements were analysed, thanks to the impact analysis functionality available in ProTTo. This functionality allows any deletion operation, made in the process, to be propagated through out the various related elements. Thus, the affected elements are indicated by alert icones before the deletion is executed. Figure 2 illustrates the interface used in ProTTo to process tailoring. In this figure number 1 indicates the part of the interface used to perform the tailoring operations. **N**umber 2 and number 3 illustrate how a standard software development process is viewed in ProTTo. It is also possible to see an example of impact analysis in the figure in Number 2 and 3.

The first deleted activity in this example was the *Develop Requirements Management Plan*. This activity was performed in the standard software development process in a unique workflow detail called *Analyse the Problem*. Some partial results of the impact analysis can be found in Table 7. It shows tailoring operation led to the additional deletion of 2 artifacts, 8 sub-artifacts, 1 activity and 8 tasks. Moreover, the impact analysis shows that some relationships had also to be deleted, such as relationships among the deleted sub-artifacts and the activities that had consumed or modified them. Additionally, another impact caused by the tailoring operation, not shown in Table 7, is a process workflow change, that is, some deleted activities (*Develop Requirements Management Plan* and *Find Requirement Attributes*) were removed from the parallelism structures they had been configurated to work parallely with other activities in the workflow details in *Requirements* discipline.

We have also deleted the *Perform Architectural Synthesis* activity in the *Perform Architectural Synthesis* workflow detail. For this operation, the results of the impact analysis are shown in Table 8. Note that besides the exclusion of the *Perform Architectural Synthesis* activity other elements had also to be deleted. *In this case,* the tailoring operation led to the additional deletion of 1 artifact, 4 sub-artifacts and 5 tasks. Here, the process workflow had been changed for a second time in order to arrange the sequence of the activities execution in *Perform Architectural Synthesis* workflow detail.

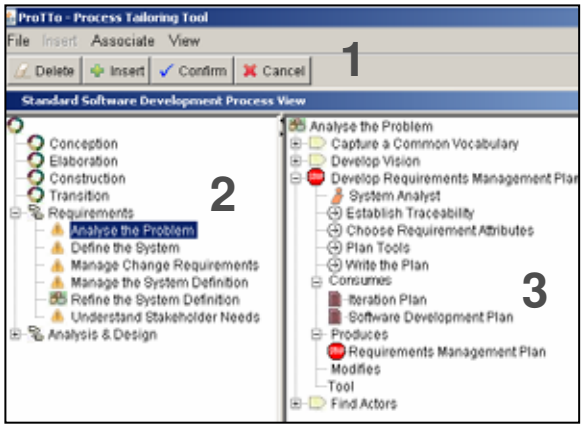

Figure 2 - Interface in ProTTo to Process Tailoring

5 CONCLUSIONS

In this paper, we have proposed capable well-formedness rules to lead the process tailoring. The main contribution of these rules is to guarantee the consistency between the tailored software process and the standard software development process in order to avoid tailoring unconformities. *In this paper, t*he focus has been on RUP process. However, we consider it possible to use this approach in other processes such as XP and OPEN, once these processes can also be tailored to specific projects. In this case, well-formedness rules must be adjusted considering the metamodel of each process.

Non-invasive software process data collection for expert identification

Andrea Janes, Alberto Sillitti, Giancarlo Succi
Free University of Bolzano/Bozen, Center for Applied Software Engineering
{ajanes, asillitti, gsucci}@unibz.it

Abstract

Software companies depend heavily on knowledgeable employees. Competence and skills management are essential instruments to understand how to employ the available skills in an optimal way.

Unfortunately, implementing knowledge management strategies like competence and skills management is challenging because resources, time and effort are required before benefits become visible.

This paper shows an approach to collect non-invasively (i.e., without requiring any effort by developers) data about "who" is working on "what" during software production.

We present two examples to show how to answer three questions: "who is the expert of a specific part of the code?", "who should do pair programming with whom?", and "what knowledge gap arises if a specific developer leaves?".

1. Introduction

Competence management and expert identification are activities within the field of knowledge management which aim to find out *who* knows *what* [1]. This information can serve various purposes, e.g., to find the right employees to staff new projects [2], to match positions with skills [3], or to support software maintenance [4].

In distributed environments or in larger development teams knowledge about *who* wrote a particular piece of code, *who* knows about a particular set of classes, *who* is responsible for a particular requirements document is essential. According to [5], software developers apply just as much effort and attention determining whom to contact in an organization as they do getting the job done.

To partly solve this problem, this paper proposes a measurement framework to extract knowledge about *who* knows *what* about software development artifacts (such as source code, documents, slides, spreadsheets, etc.) non-invasively, i.e., without the need by the developers to spend time on documenting their knowledge within a knowledge management system.

The information that is extracted builds on the idea that the programmer's activity, i.e. the adding, modifying, deleting, reading of code is an indicator of the knowledge that the programmer has about that part of the code [6].

Other approaches such as expertise recommenders, which suggest who has expertise in particular parts of the program also base their recommendations on this assumption. Tools such as Expertise Recommender [7], EEL [8], and Expertise Browser [9] make recommendations based on commits to source code repositories.

The objective of the expert identification measurement framework is twofold: the primary goal is to track the time spent editing the artifacts that are created during the software development process, such as documents, source code, spreadsheets, etc. to infer the user's knowledge on that artifact. Additionally, data that describes the artifact being accessed is also collected to allow the retrieval of an artifact using its properties as search criteria.

2. Related work

Examples of existing implementations can be categorized within two groups depending if the knowledge about *who* knows *what* has to be provided by the users of the system or if it is extracted from other sources.

Examples of tools of the first group are the StepStone Skills & Competency Management Module [10] or SAP ERP Human Capital Management [11] in which employees maintain their own or the skill profiles of their subordinates.

A common problem of knowledge engineering is how to generate knowledge with as less effort and resources as possible [12]. Asking employees to maintain their knowledge profile takes time which means that it will generate costs since if experts spend time sharing knowledge, they will be less productive [13].

To overcome this barrier to adopt knowledge management, tools that try to extract knowledge automatically from existing artifacts *who* knows *what* were developed. Two examples are AnswerGarden [14] which creates a knowledge repository storing the questions and answers exchanged between help desks and their clients and ActiveNet [15] which extracts knowledge

from the e-mail traffic, instant messaging, and digital workspaces that employees use in their every days' work.

Proposals like the "Knowledge Dust to Pearls Approach" [13] build on the AnswerGarden approach to refine the collected knowledge into "experience pearls" that are collected in form of an "experience base" for the purpose to be reused for the planning of future activities.

3. Measurement framework

To extract the desired knowledge from the ongoing software development process, we developed a measurement framework that is able to identify *on which artifact a user is currently working on*, to read *properties of the artifact currently accessed*, *how long* it is accessed, and to store this information in a central database. It was our focus during development that all steps can be done non-invasively, i.e. without the need for the developer to interact with the knowledge management system.

We use the period of time spent on a part of the system as an indicator of the knowledge of a developer. As a developer works on a system, he or she gains knowledge about the domain of the system, the development process used to build the system, and the design and implementation of the system [16]. Previous studies such as [6], or implementations such as [7] and [9] have shown that activity as a knowledge indicator can be used to build a model of what a programmer knows about a code base.

Currently our measurement framework can identify artifacts accessed using the Microsoft Office suite [1] (Word, Excel, PowerPoint, Visio, Frontpage, and Outlook), the OpenOffice.org office suite[2] (Writer, Calc, and Impress), and software development environments such as Microsoft Visual Studio[3], Eclipse[4], NetBeans[5], and IntelliJIDEA[6].

The mentioned applications allow to read the currently accessed artifact through a provided API. We developed a set of measurement probes (one per application) that constantly poll these applications about the current artifact accessed. As soon as the reported value changes, the amount of time passed since the last change is written to the local log file together with the current date, time, user name and name of the artifact accessed. In regular intervals the so collected log is transferred to a central server.

We assume that the API of the application to observe provides a function *getCurrentArtifact()* that we use to access the current artifact modified by the user (in most of the cases this is the artifact that is currently on focus). The following pseudo code describes how one measurement probe (i.e. an application of our measurement framework connected to the API of an application to observe) collects data.

```
initialize user with the current user
initialize app with the application name
initialize artifact using getCurrentArtifact()
initialize start with the current date and time

while application to observe is running
   // we want to collect data with the
   // granularity of one second so that
   // our application does not consume
   // too many resources on the machine
   // of the developer
  wait for 1 second
  if getCurrentArtifact() <> artifact then
    set now to the current system date and time
    set duration to now - start

    append user, app, artifact,
      start, duration  to the local log file

    set artifact = getCurrentArtifact()
    set start = now
  end if
end while
```

The pseudo code above shows how the probe constantly polls the observed application and generates an entry in the local log file if the current artifact changes. The so obtained activity log files are transferred to a central database where all data is stored. The three steps, artifact identification, local data caching, and data transfer are illustrated in figure 1.

What we consider as the concrete artifact depends on the application: within Microsoft Office and OpenOffice it is a file. This means that we track the accesses and modifications of the properties of files. Within programming environments we consider the method as the artifact, i.e., the time spent editing, adding, deleting a method is the highest granularity of the data that is collected. This data can be aggregated later e.g., at the class, namespace, or file level.

The measurement unit of time is *seconds*, which is then aggregated to hours or days on reports.

The result of the data collection step consists of artifacts, properties of artifacts, and the sequence of accesses on the artifacts (see figure 2). In this way, the described measurement framework collects *when, who* accesses *which artifact,* and – to allow the filtering of artifacts – logs properties that describe the artifacts accessed by the user.

Collecting data about the ongoing software production without the direct intervention of the developer has been proposed also in other contexts than Knowledge Management: e.g., the HackyStat tool [17], which can be used to collects metrics about produced artifacts to better control the software development process and to give

feedback to developers about the impact of their work on quality properties of the developed software.

4. Data analysis

To help users searching for experts within the system described above, we categorize the collected time spent editing artifacts according to different criteria.

For example, if the source code of a specific company is organized in such a way that the namespace indicates the component of the software system, it is reasonable to group the time spent per artifact by namespace. In this case, knowing the namespace, i.e. the component, helps to find who dedicated the most time accessing artifacts within that namespace, i.e. the employee with the most knowledge of this component, the expert [6].

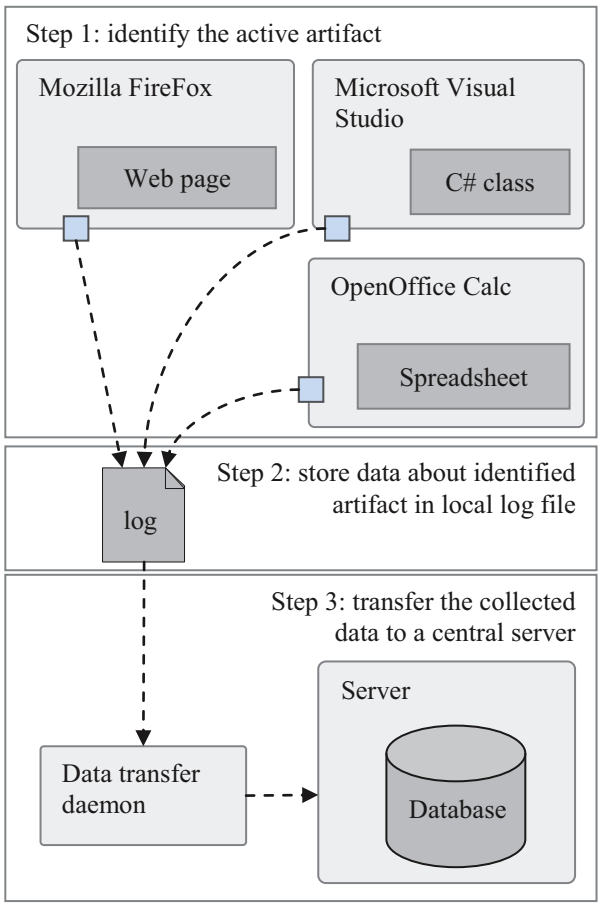

Figure 1. Overview of the framework

Other examples for classifying the access duration are the project name, prefixes of class names (e.g., "test" to find the testing experts), or types of documents.

To be able to change the rules easily, we use Prolog rules to define how the data should be classified (using Interprolog [18] as a bridge between Java and Prolog).

Within Prolog we define a set of predicates that correspond to the properties collected by the measurement framework which allow access to the table "properties" (see figure 2) within Prolog.

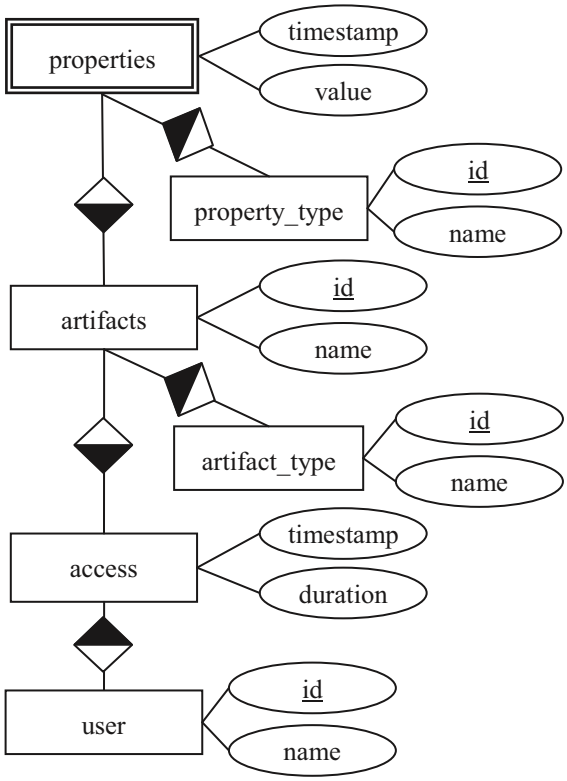

Figure 2. EER diagram of the measurement framework

Currently the following predicates are available for the use within Prolog rules:

a) *path(X, N)*: true, if the artifact with the id *X* is a file stored within the folder with the name *N* (*N* is specified as a Prolog array, i.e. ['c', 'a', 'b'] for the namespace "c:\a\b");
b) *file(X, N)*: true, if the artifact with the id *X* is a file with the name *N* (without path);
c) *class(X, N)*: true, if the artifact with the id *X* represents a class with the name *N*;
d) *method(X, N)*: true, if the artifact with the id *X* represents a method with the name *N*;
e) *namespace(X, N)*: true, if the artifact with the id *X* is contained within the namespace *N* (*N* is specified as a Prolog array, i.e. ['a', 'b'] for the namespace "a.b").
f) *access(Y, U, X, S)*: true, if the access with the id Y by the user *U* to the artifact *X* lasted *S* seconds.
g) *access_date(Y, D):* true, if the access with the id *Y* occurred on the date *D*.

To define a classification of the artifacts, we expect that the predicate *classification_artifact(T, X, C)* exists and that it returns true if an artifact with the id X is

contained in the class with the name C according to the classification criteria with the name T.

To classify the records stored within the table *access* (e.g. to classify certain accesses within a certain time range to a specific category) we expect that the predicate *classification_access(T, A, C)* exists and that it returns true if an access with the id A is contained in the class with the name C according to the classification criteria with the name T.

The resulting classifications are cached within the database so that they can be easily queried using SQL. Figure 3 shows the EER diagram of how the classifications of artifacts and accesses to these artifacts are stored within the database: classifications can be made according to different criteria. For example, it is possible to classify artifacts according to their importance and according to their size.

All criteria *T* that the classifying Prolog predicates *classification_artifact* and *classification_access* return are stored within the table *classification_criteria*. All classes *C* used within the two classification predicates are stored in the table *classification_classes*.

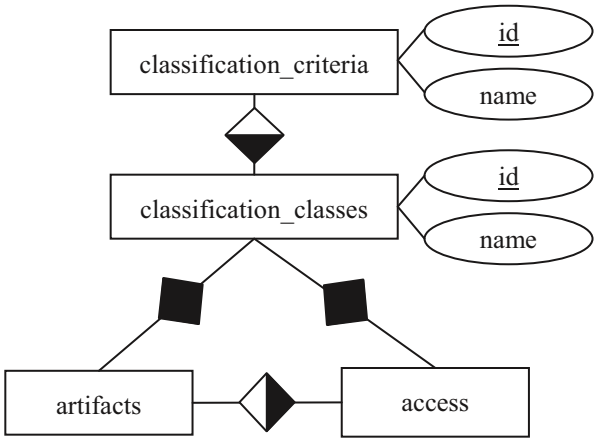

Figure 3. EER diagram of how the classifications of artifacts and accesses are stored in the database

5. Examples

In the following two examples we will show how the described measurement framework can be used to address expert identification and skill management issues.

5.1. Example 1

In the following example we describe the analysis of experts within a case study carried out for a company in the domain of industrial automation, which, for confidentiality, in the following we call "Acme".

Acme's IT department consists of about 50 employees, 23 of them are developing software for internal use.

We installed our measurement framework and collected the time spent per method, class, namespace, and file. Within Acme, the developers agreed that the development effort should be grouped on the namespace level, considering only the first two packages since the first package for them represents always the name of the project and the second package the name of a main component.

If, e.g. a class is contained within the namespace *a.b.c.d*, we attribute all the time spent editing in this class to the class *a.b*.

Therefore, as rules, we defined the predicate *first_two(X, H1, H2, R)* so that it is true if *H1* and *H2* are the first two elements of the array *X* and *R* is the remainder of the array:

```
first_two(X, H1, H2, R):-namespace(X, Y),
  [H1|T1] = Y, [H2|R] = T1.
```

Now, *classification_artifact(T, X, C)* can be defined as follows:

```
classification_artifact(T, X, C) :- T=expert,
  first_two(X, H1, H2, R),
  concat(H1, '.', P1), concat(P1, H2, C).
```

This means that for the type of classification *expert*, we consider an artifact with the id X part of the class C, if the first two packages of the namespace of the artifact X correspond to the name of C.

To visualize the data obtained using our measurement framework, every tool able to connect to a database using JDBC can be used, we used OpenOffice Calc[7] to query the database and to generate a pivot table of the format as shown in figure 4.

In this table, all classification items accessed within the analyzed period are shown as lines, the users accessing these classification items as columns. Within the pivot table the single values represent the sum of time spent by the specific user on a specific classification item.

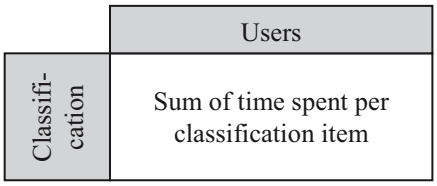

Figure 4. Schema of the pivot table to visualize the effort distribution

In this way, calculating the i^{th} largest value of time spent on each classification item, we obtain the i^{th} expert of that classification item. Within Acme, we used percentages (the time spent in relation to the time spent by the top expert) to ease the understanding of the resulting pivot table.

[7] OpenOffice.org Calc, http://www.openoffice.org/product/calc.html

In the example shown in table 1, user 2 has almost the same amount of experience as user 1 considering classes within namespaces starting with *project1.a*, but he is the only one that has experience with classes within *project2.c*.

Within our case study we formatted the table above to ease the understanding of the data for the user: we color the cells in dark green if the value is above 90% and in light green if it is above 50%.

The column "Experts" shows the number of users within the current line with values above 50%. If in this column the number of users is equal to 1, this means that there is only one user that knows about that part of the code. Within the case study we colored these cells in red.

		Users			
		User1	User2	User3	Experts
Classification	project1.a	100%	90%		2
	project1.b	10%		100%	1
	project2.c		100%		1
	project3.d	10%	100%		1

Table 1. Example of pivot table representing the knowledge of each user about the code within a classification item

To summarize, using the mentioned measurement framework and a tool to query the obtained data such as OpenOffice Calc, it is possible to:

a) determine the i^{th} expert of a specific part of the code, assuming that the time spent in adding, modifying, and updating reflects the knowledge of the code,
b) to show the experience of a specific user,
c) to evaluate the knowledge gap that will occur if a specific user will leave.

Point c) addresses the problem that when a person with critical knowledge leaves an organization, this creates severe knowledge gaps. It is crucial to understand *what knowledge* is lost to prevent valuable knowledge from disappearing. Additionally, knowing which knowledge disappeared can help to decide which skills are needed for the new employee and on which areas he or she should work on.

5.2. Example 2

Acme is using Extreme Programming [19] as software development methodology.

Within agile methodologies, the focus lies on "working software over comprehensive documentation" [20]. The produced source code is considered the most valuable asset, representing the knowledge of the development team. This knowledge has to be shared among team members using practices like "pair programming" (meaning that all code has to be programmed in two) or "common code ownership" (meaning that the entire team is responsible for the source code and that everybody has the right to modify everything) [19].

		Users		
		User1	User2	User3
Classification	project1.a	100%	90%	20%
	project1.b	80%	80%	100%
	project2.c	90%	100%	80%
	project3.d	70%	100%	80%

Table 2. Example of pivot table representing the knowledge of each user about the code within a classification item (considering only the last 6 months)

In such contexts it is important that *all* know *everything* about the produced code. A measurement framework as described here can be used to determine the knowledge of different developers about different subparts of the code and could be extended to recommend *who* should do pair programming with *whom* to optimally distribute the knowledge.

In the case of Acme, we decided to consider only the time spent in the last half year as an indicator of experience. If e.g., a programmer for more than half year did not dedicate time in the development of a specific component he or she had to do pair programming with one of the developers currently working on that part to be up to date with the last modifications.

For this we defined the predicate *classification_access(T, A, C)* as follows:

```
classification_access(T, A, C) :- T=expert,
  access_date(A, B), parse_time(B, C),
  get_time(D), E is D-C, E < 259200, C=pp.
```

This means that for the type of classification *expert*, we consider an access to an artifact with the id *X* part of the class *pp* (pair programming), if the access date (obtained as a string *B* and converted to the Prolog timestamp *C*) is not less than six months (259200 seconds) ago.

Within our SQL query we sum up all the accesses belonging to the class *pp*.

As in the example 1 we used OpenOffice Calc to visualize this data. The resulting table is formatted in the same way (see table 2 for an example), just that now the data shows *who worked on which classification item (i.e. the first to elements of the namespace) during the last 6 months.*

In the example in table 2 it is visible that user 3 should to pair programming either with user 1 or user 2 for the next requirement on the component *project1.a*.

Abstract

Web Services contribute to decrease costs and solve integration problems in web applications. On the other hand, they bring some complications to test activity and demand specific testing techniques and tools. In this context, the perturbation based approach has been successfully explored. Perturbation operators modify XML and SOAP messages that are then used as test data. However, the set of proposed operators are not complete. Considering this fact, in this paper, a new perturbation approach is introduced based on XML patterns associated to UML models. In this way, the approach considers semantic aspects related to other kind of faults. The implementation aspects and evaluation results of the introduced approach are also discussed.

Keywords: XML, fault-based testing, perturbation testing

1 Introduction

Web Services (WS) are software programs that operate independently to offer services over the Internet to other software programs, including web applications and other WS [16]. They are developed to allow interoperability among technologies, as well as, protocols, platforms and operating systems. WS are a well-known implementation of the Service Oriented Architecture (SOA), which conceptually defines a structured data exchanging model, providing the applications the ability to be loosely coupled with limited knowledge of each other implementations.

With the advent of Internet, the use of WS is crescent. They contribute to minimize costs and to solve integration problems in web applications. However, they demand specific testing techniques and tools and have been considered a challenge by many authors [7]. This fact is due to their specific characteristics. They are more widely distributed and heterogeneous. They involve multiple standards and protocols than traditional software, moreover, the absence of a user interface makes it harder to apply a test procedure, due to the loss of controllability. Moreover, WS admit changes of data flow among software components at execution time, what is called dynamic integration.

Bloomberg [2] presents several aspects involving Web Service testing. For example, WS make extensively use of XML technology [14] to exchange data among applications, thus, testing interactions based on XML messages is a very important aspect to be tested, contributing to Web Service quality assurance. The SOAP protocol [15] (basis of the Web Service technology) is an XML message that carries information and is responsible for invoking WS over the Internet.

Considering these different aspects, some works address Web Service testing [1, 3, 9, 10, 11, 13]. In [11] a framework that converts WSDL specifications into test scenarios is described. In [3] Finite State Machines are used to model and test the WS behavior. Heckel and Lohmann explore the use of contracts [9]. In [1, 10, 13] a method based on data perturbation of XML and SOAP messages is explored. XML messages are modified and used as test data for testing the interaction between pairs of WS. The method can be applied without knowledge about the implementa-

tion of the WS and has presented promising results in terms of revealed faults. However, the explored perturbation operators consider only syntactic aspects to generate the test data. Semantic aspects related to the data specification need to be considered because they can generate test data related to other kind of faults. With the objective of improving efficacy in terms of revealed faults, this paper introduces an XML pattern driven data perturbation approach.

The introduced approach makes use of UML-XML mapping techniques [5] and XML structural patterns [8]. To perturb an original XML message, the XML vocabulary, given by a schema and its correspondent UML model, is analysed. According to the pattern found in the schema, the original message is perturbed and used as test data. The idea is to consider the meaning of XML vocabularies to generate test data and to reveal specific faults related to the semantics of the XML messages. In this sense, the approach is adequate for applications that use XML vocabularies modeled with UML language and can be viewed as complementary to the existent perturbation testing approaches.

The remaining of this paper is organized as follows. Section 2 shows related works on WS testing. Section 3 overviews XML-UML mapping techniques and patterns used in the introduced perturbation approach. Section 4 describes and illustrates the XML pattern guided approach. Section 5 experimental results from an evaluation study and comparisons with traditional operators. Section 6 concludes the paper.

2 Web Service Testing

There are many issues involving Web Service testing [2], for example: testing SOAP messages; testing WSDL files; testing the publish, find and bind capabilities of a SOA; testing Web Service consumer and producer emulation; testing synchronous and asynchronous capabilities; etc. Some works address these issues. Tsai et al [11] describes a framework that converts WSDL specifications into test scenarios. In [12], a method for test data generation based on the topology of WS is proposed. Heckel and Lohmann [9] explore the use of contracts. Bultan et al [3] propose the use of Finite State Machine to model and test the behavior of composite WS. The model is composed by multiple peers that communicate with asynchronous messages. However, the test can also be conducted considering a peer-to-peer model. For this kind of model, the works [1, 10, 13] address the use of modified XML and SOAP messages to test WS.

In [10], Offutt and Xu have introduced an approach based on data perturbation for Web Service testing. The idea is to modify request messages by using some mutation operators. It is similar to mutation testing [6], however, the difference is that the mutants are actually the test cases to be used to test the Web Service. Similar works that have the same objective are [1, 13]. In [1] a tool, named SMAT-WS, is described and used in the test of nine WS.

Perturbation Based Testing of WS has been successfully applied. Experimental results show that this approach is fault-revealing. It can be considered a promising testing approach to test interactions of XML based components of SOA applications such as WS. It is independent on how the application (or service) is implemented. Another advantage is that test data generation can be easily automated. A disadvantage is that it is not possible to determine whether the set of operators is complete. The proposed operators, for example, only consider syntactic aspects of XML documents. Semantic aspects related to the data specification need to be considered. In the Section 4 we introduce a new kind of perturbation approach, guided by XML patterns.

3 XML Patterns Based on UML

The use of UML to define XML vocabularies presents some advantages: 1) UML allows the visualization and representation of XML structures through standardized diagrams; 2) ability to capture the semantics of the XML model; and 3) easy reading for humans. Some works address XML-UML mapping techniques. In our work we use the approach proposed by Carlson [5] and supported by the tool hyperModel [4]. The main concepts from the approach are illustrated in Figure 1. The UML classes are mapped to *complexType* definitions. In addition to, an element is declared, with the same type of the *complexType* of the class. The attributes and associations of the classes are mapped to XML elements. The used content model was <sequence>, which makes possible to list the class elements, with their multiplicity restrictions. The UML inheritance is mapped using XML Schema inheritance.

In [8], the idea of using UML models to establish XML patterns is introduced. The idea is to provide patterns to XML documents that are expressed with visual models. Two kinds of models are explored: design patterns related to Web applications and patterns more directly related to the structure of UML models used to model XML vocabularies.

Table 1 displays a summary of the main XML patterns. To illustrate the patterns, we will use the simplified XML vocabulary from OASIS Universal Busi-

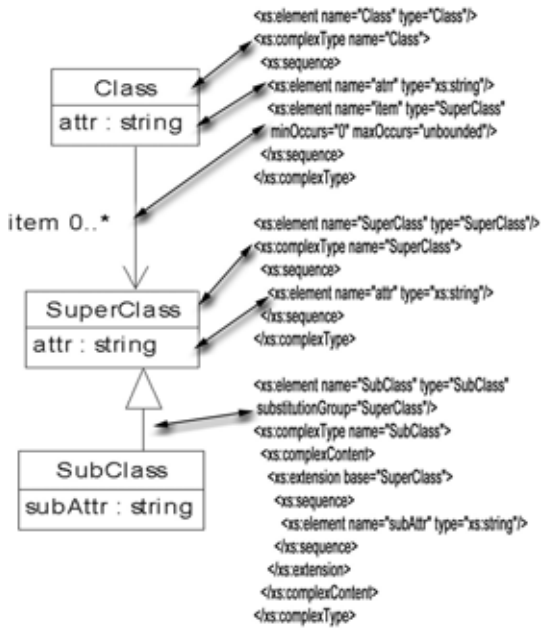

Figure 1. UML-XML mapping proposed by Carlson

Table 1. XML Structural Patterns

Pattern	Description
homologous association	expresses the association between two concepts in different contexts
recursive association	models a relationship among elements defined in a recursive way
multiple reference	models, as a singular class, an element that can be referenced by multiple classes
homologous derived	establishes a group of derived classes from a same basis class, which can present class relationships amongst themselves

ness Language (UBL) [4] shown in Figure 2. It models the transport of hazardous items, in which the temperature control is fundamental. In this fragment, we identify two groups of Homologous Associations. The first includes the associations *MaximumTemperature* and *MinimumTemperature*, the second one contains *EmergencyTemperature* and *FlashpointTemperature*. This vocabulary also presents the pattern Multiple Reference. Different classes refer to class *Temperature*.

4 Using XML Patterns for Test Data Generation

In this section, we explore the use of XML structural patterns for test data generation and introduce perturbation testing based on patterns. The idea is to consider the meaning of XML vocabularies to generate test data and to reveal specific faults related to the semantics of the XML messages. The approach can be applied in applications that use XML vocabularies modeled with UML.

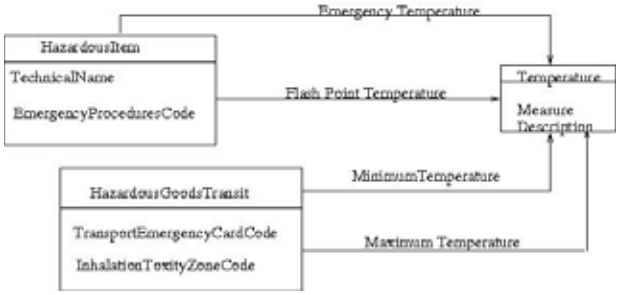

Figure 2. OASIS Universal Business Language Vocabulary Fragment

Initially, we introduced and implemented a set of four perturbation operators. The operators have the same name that the original pattern. To apply an operator, the correspondent pattern is identified in the XML vocabulary associated to the WS being tested, given by a schema and its respective UML model. In this way, we identify an element. According to a pattern, we decide the transformation to be applied and the element will be changed, removed, etc. Values in the message are changed by other possible ones present in a library of vocabulary instances. The perturbed message is then used as test data. The operators are:

a) HA (Homologous Associations): changes attribute values of a class related to an association A by the attribute values of the same class related to the homologous association B.

Consider again the vocabulary from Figure 2. The pattern Homologous Associations shows two different classes linked through two or more associations, which reveal the specific meaning of the relationships. The perturbation in the XML message, defined considering the pattern HA, consists of changing the data that corresponds to an association by the data related to other arbitrary homologous association. This way, the semantics of the message is altered to a different semantics, but possibly very close and coherent regarding the original meaning. For example, the application of HA can generate a test message that involves the *MaximumTemperature* and *MinimumTemperature* associations. A message relative to the hazardous items transport could present the following fragment to define the temperatures:

```
<HazardousItem>
```

```
  <TechnicalName> Plumbum Nitrate II
  </ TechnicalName>
        ...
  <HazardousGoodsTransit>
    <TransportEmergencyCardCode> 51
    </ TransportEmergencyCardCode>
        ...
    <MaximumTemperature>
      <Measure> 27 </ Measure>
        ...
    </ MaximumTemperature>
    <MinimumTemperature >
      <Measure > 10 </ Measure>
        ...
    </ MinimumTemperature>
  </ HazardousGoodsTransit >
</ HazardousItem >
```

Suppose that the chosen element to be perturbed is *MaximumTemperature* that has the measure value 27 for this instance. The developed perturbation algorithm will substitute this value by the content of a *MinimumTemperature* element, found in some instance of a given XML document. For example, consider that there is an instance with value -7 for *MinimumTemperature*, such as:

```
    ...
    <MinimumTemperature >
       Measure > -7 </ Measure>
        ...
    </ MinimumTemperature>
    ...
```

When perturbing the previous instance, the value of *MaximumTemperature* of the item being perturbed will be substituted by the value of *MinimumTemperature* of the second instance. The resulting instance is:

```
...
    <MaximumTemperature>
      <Measure> -7 </ Measure>
        ...
    </ MaximumTemperature>
    <MinimumTemperature >
       Measure > 10 </ Measure>
        ...
    </ MinimumTemperature>
       ...
```

In the perturbed instance the value for the maximum temperature is smaller than the value of the minimum temperature. This message can produce a failure, if such situation was not considered in the implementation of the web service being tested.

b) MR (Multiple References): changes attribute values of a class A related to a reference of class B by attribute values of A related to a reference of another class C.

Figure 3 presents a fragment extracted from UBL [4]. The class *Country* is referred by three other

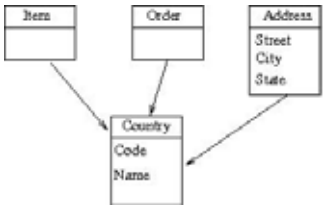

Figure 3. Multiple Reference Perturbation

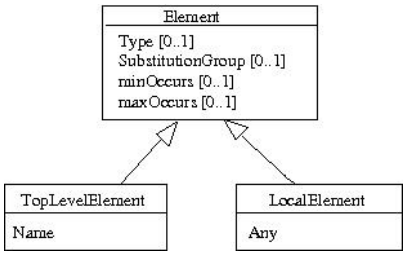

Figure 4. Homologous Derived Perturbation

classes. An example of perturbation is to change the value of attribute *Name* from class *Country* correspondent to the address of a client by other value correspondent to the source country of an item.

c) HD (Homologous Derived): changes attributes values of a derived class by common attribute values of the homologous derived class.

Consider the fragment of W3C XML Schema for Schemas vocabulary [4] of Figure 4. There are two derived classes for *Element*. The common attribute value of *minOccurs* (or *maxOccurs*) of *TopLevelElement* is changed by the attribute value of *LocalElement*.

d) RA (Recursive Association): in general, a document that follows this pattern corresponds to a tree hierarchy. The operator changes this hierarchy. Each element in the tree is changed by its predecessor (or successor) in the hierarchy. Consider the fragment of eBay XML API vocabulary [4] of Figure 5 and the following message:

```
<SOAP-ENV:Envelope ...>
 <SOAP-ENV:Body>
  <ns1:processCategory
      xmlns:ns1=''http://soapinterop.org/''>
   <name xsi:type=''xsc:string''>processors</name>
        ......
  </ns1:processCategory>
 </SOAP-ENV:Body>
</SOAP-ENV:Envelope ...>
```

The store is divided in categories and each derived category has its own subdivisions represented in a tree. A computer store has a division of components, which is divided into monitors and processors categories.

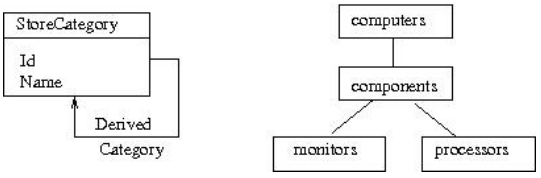

Figure 5. Recursive Association Pattern

An example of perturbation for the above message that uses RA operator is to change the value "processors" either by "monitors" or "computers", which are other categories in the hierarchy.

5 Case study

To make possible a better analysis of the proposed data perturbation guided by XML patterns, and to allow its practical application, a tool -called PDDP (Pattern Driven Data Perturbation Tool) - was developed. The fundamental artifacts for PDDP are: the SOAP message in which the perturbations are applied; the vocabulary definition used in the components communication; a library of vocabulary instances, used to derive the perturbed messages.

The initial SOAP message is used as a model to create the perturbed messages, where we have at least one modification of an element in the XML sub-tree that is encapsulated in the element *Body* of the SOAP protocol. The vocabulary definition is supported by tool hyperModel, driven to the Carlson mapping method. The XML Schema generated by hyperModel is used as an input for PDDP. The instances in the library that obeys the defined vocabulary are the source of elements used for the generation of perturbed messages.

A study was accomplished with PDDP to evaluate the applicability of the proposed perturbation approach and the efficacy of the operators in comparison with the traditional ones. To do this, we used the same system of WS used in the experiment reported in [1], as well as its results.

The system was tested during its development and the found faults are not seeded. It is composed by nine WS and integrates other systems that involve financial, administrative and structural government controls. Each Web Service was submitted individually to PDDD. During the execution of the tests we had free access to the database, so that results of the operations could be verified. Two input XML files were supplied: an XML Schema with the vocabulary definition, generated by hyperModel tool; and an XML file with instances of valid elements, according to the XML Schema. For each Web Service a valid initial message was given, from which the perturbed messages were derived.

Table 2. Test Cases and Faults

Web Service	Test Cases	Effective Test Cases	Found Faults
WS1	16	4	2
WS2	19	2	1
WS3	9	1	1
WS4	13	3	1
WS5	9	0	0
WS6	9	1	1
WS7	14	2	2
WS8	11	2	2
WS9	12	3	2
Total	112	18	12

Table 3. Operator Efficiency

Traditional Operators	ML	I	N	BE	IN
	14.81	29.63	38.89	6.61	4.65
	VI	S	B	U	
	25.56	35.19	16.67	29.63	
Semantic Operators	HA	RA	HD	MR	
	29.16%	27.77%	0%	20.14%	

Table 2 presents, for each Web Service, the number of test cases generated, the number of test cases that revealed faults and the total of faults found. From this result, we can analyse the contribution of each operator by analysing the total number of generated test cases and the number of revealed faults. MR operator presented the greatest contribution (72.2%). It is the most common pattern found in the model; the operators HA (8.3%) and RA (11.1%). On the other hand, the operator HD did not contribute to reveal faults. However this low contribution can be explained by the nature of the used WS. The parameters perturbed by the HD pattern correspond to a user login, which is related to a password. It is observed that the user validation mechanism is simple and did not present faults.

Table 3 presents results comparing the semantic and traditional operators.[1] The efficiency is defined as the quotient between the number of test cases that revealed faults for a specific operator and the total number of test cases generated by the same operator.

The semantic operators present similar efficiencies. This does not happen with the traditional ones. If we consider the general efficiency (the great average), the efficiency of the semantic operators (21.2%) is comparable to the efficiency of the traditional ones (19.2%).

Other point to be considered is the type of faults found by each group of operators. The operators have distinct characteristics and because of this, reveal dif-

[1]This table shows the following traditional operators (results extracted from [1]): Mod_ Len (ML), Incomplete (I), Null (N), Boundary Extension (BE), Inversion (IN), ValueInversion (VI), Space (S), Boundary (B) and Unauthorized (U).

ferent kind of faults. The traditional operators revealed faults related to validation of parameters. The semantic ones, generates valid messages, which are test cases with greater probability of revealing faults related to the application business logic. This can explain the reasons why the number of faults found by the semantic operators was smaller than that revealed by the traditional operators. To reveal faults related to the application businesses logic is something more ambitious and more difficult.

6 Conclusions

This paper explored the use of XML structural patterns in the test activity. Data perturbation techniques were extended and applied to test the communication of components that exchange XML messages. The result was the proposition of the pattern driven data perturbation approach.

The traditional perturbation operators only consider syntactic aspects: limit values, restrictions about data types and multiplicity definitions. The use of patterns to guide perturbation testing allows the generation of test data considering the meaning of the XML vocabulary. So the chance of generating significant test data is greater, as well as, the probability of revealing other kinds of faults.

We implemented a supporting tool that makes the use of the approach practical and shows its applicability. An evaluation experiment was conducted with a real system. The efficiencies of the introduced operators are very similar. However, the number of generated test cases and revealed faults are related to the characteristics of the vocabulary and found patterns.

When compared with traditional operators, the results point out that both groups of operators are complementary. The semantic operators contributes to reveal other kind of faults. They reveal faults related to the application businesses logic validation specially to the communication vocabulary. The traditional ones reveal faults more related to the parameter validation.

The pattern based perturbation testing is adequate for applications that use XML vocabularies modeled with UML language. In this work, the approach was explored for WS testing. However, it can be applied in other applications that not necessarily exchange message over the Internet or network. For example, to test the communication among modules of a system through XML messages defined according to some vocabulary. A possible extension for this approach is to explore the use of other models, such as ER.

Translating OWL Specified Domain Knowledge to Aspect Oriented Model

Juanzi Li, Xinyu You, Xiaoying Bai
Department of Computer Science and Technology, Tsinghua University
Beijing, 100084, China
{ljz,yxy}@keg.cs.tsinghua.edu.cn, baixy@tsinghua.edu.cn

Abstract- *OWL is a good candidate to establish the platform-independent machine-interpretable model of domain knowledge in an easy-to-understand, easy-to-use approach. It can also provide strong support for automatic model transformation and inconsistence checking by ontology reasoning mechanisms. Much research has been investigated to integrate ontology model with object-oriented models. However, current transformation methods suffer from the problems including code scattering, tightly coupling between classes and missing of structural and semantic information. To address the problems, the paper proposed an aspect-based approach to translate OWL ontology to AspectJ model. In this way, the knowledge can be separated from the code in the modelling phase and then integrated with the code automatically in the implementation phase. With the support of ontology technique, the OWL-specified domain model can be easily verified, reused and adaptive to changes. The proposed approach enables the externalization and automatic integration of the domain knowledge in the traditional object-oriented programming.*

1. Introduction

Inaccurate requirement understanding, complex software design and difficult code reuse are the important problems in software development. Various methods have been proposed to solve these problems, and model driven architecture (MDA) is an effective one. MDA aims at describing requirement using a platform-independent model and then translating the model to the implementation of the system [1]. The models in MDA include static structure model and event workflow, and static structure model is used more frequently in practical programming. How to describe the static structure model properly and how to adapt the change of static structure model in the implementation of the system are two problems in software development. We found that OWL ontology [2] is a good candidate to do this work. Thanks to its capacities of describing the domain knowledge preciously, OWL ontology is easy to understand and easy to use. At first, OWL ontology can bridge the gap between the requirement and design in software development. Secondly, OWL ontology can promote the software reusability because OWL itself is an open and platform independent mark-up language. At last, OWL can promote the automatic software development in model classification and inconsistence checking by using inference for OWL ontology.

At present, there exists a reasonable research to map OWL ontology to software programming languages such as Java. Most of the work focused on mapping OWL into object oriented (OO) model. Because of the differences between description logic and OO system, these methods have some problems such as meaning missing and structure inconsistent.

This paper provides a mechanism for mapping OWL ontology into aspect oriented model. By this mapping strategy, we can solve problems that existed in mapping OWL to OO model, and we have finished the translation tool based on it. The proposed approach enables the externalization and automatic integration of the domain knowledge in the traditional object-oriented programming.

2. Related Work

For the similar concept and relation, most research work was focused on mapping OWL ontology to OO model. In model translation, OWL ontology is translated some kinds of OO model language such as Java. Such good examples are Kazuki [3] proposed by David Rager, RDFReactor [4] proposed by Benjamin Heitmann, and Jastor [5] proposed by Ben Szekely.

Currently, all proposed methods focused on translating OWL ontology into OO model. As [6-7] stated: there exist fundamental differences in understanding OWL and OO system. For example, there is no class description in OO model. Especially, property in OWL ontology is independent of class, while the property in OO belongs to a part of class. Some problems of mapping OWL ontology into OO model are code scattering, tightly coupling between classes, and Code concentration.

A. Code Scattering.

As shown in Figure 1, in the OWL ontology, *Property1-3* are three resources independent of two classes *A* and *B*. When we map this ontology into OO model, the code of *Property2* will be scattered into *Class A* and *Class B*. This results in the problem of code maintenance. That is, if

Property2's description is changed, we need to change the code in both two classes synchronously.

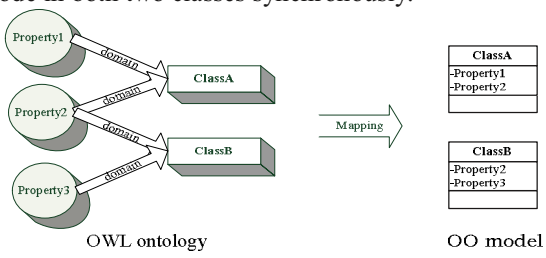

Fig. 1 Mapping OWL property to OO model

B. Tightly Coupling between Classes

In order to mapping the relationships between classes, translating model will obtain a lot of coupling relationships. As shown in Figure 2, to express the semantic of equivalent relationship between *ClassA*, *ClassB* and *ClassC*, six relationships in OO model are generated which make the coupling relationship are rather complex.

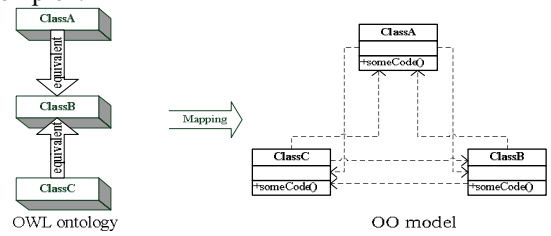

Fig. 2 Mapping equivalentClass to OO model

C. the Missing of Structure Information

Because OWL ontology and OO model have fundamental differences in structure description, translated OO model can not reflect the structure of OWL ontology. It makes the mapped model difficult to be understood. As shown in Figure 3, the property description and class description which are represented clearly in the OWL ontology are mixed together in OO model after translation as described in the right of Figure 3.

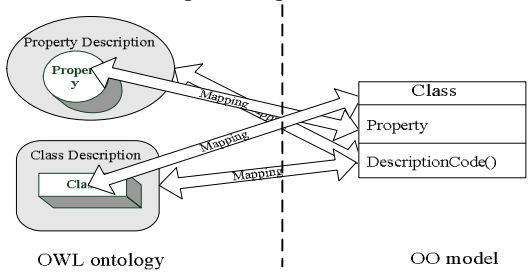

Fig. 3 Structure mapping between OWL ontology and OO model

As stated above, these addressed three challenges in model translation and also are the main concerns of this paper.

3. Mapping Principals from OWL Ontology to AO Model

As we know, there are two reasons which cause these problems. One is different structure between the OWL ontology and the OO model, and the other is the difference in description capacity of these two models language. To solve these problems, we try to find another programming model which is more flexible than OO model, and which is more suitable for the OWL ontology model.

In recent years, aspect oriented (AO) programming are becoming widely used to overcome the limitations of OO programming model [8]. AO programming introduces a new modular unit, called "aspect", for the specification of crosscutting concerns. It organizes the crosscutting relationships between objects by using weaving mechanism so that it can decoupling the relationship between objects and help to concentrate software's code. Aspect oriented model can express the syntactic and semantic features of the OWL ontology rather properly. By taking advantage of "aspect" module unit and its flexible crosscutting weaving mechanism, the problems addressed in translating the OWL ontology into OO model translation can be properly solved.

A. Code Concentration

AO model can encapsulate OWL elements including both class and property while keep their independence of each other. As shown in Figure 4, the properties in the OWL ontology can be mapped into AO model independently, and also these property aspects can be weaved into corresponding classes by inter-type declarations. It makes the codes be able to concentrate on the separate properties aspects.

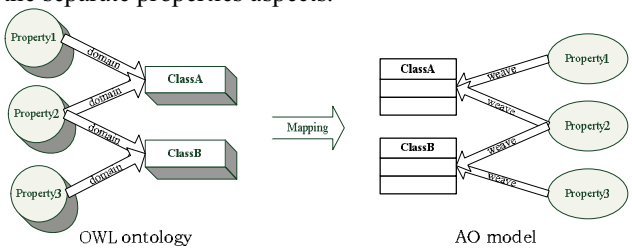

Fig. 4 Mapping OWL property to AO model

B. Decoupling Class Relationships

In AO model, we can generate an independent aspect for the relationships between multiple classes. As shown in Figure 5, *AspectEquivalent* is an aspect to show the equivalent relationship, the equivalent relationships between three classes *A, B* and *C* can be obtained by weaving *AspectEquivalent* into these classes respectively and only three relationships are needed.

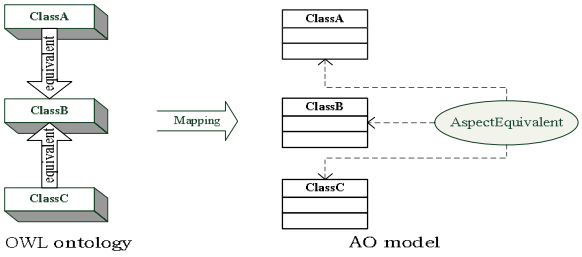

Fig.5 Mapping equivalentClass to AO model

C. Structure Consistency

The model generated by AOP is finer-grained and flexible, and it keeps the model structure consistency between the OWL ontology and the translated AO model. This makes the transformed model easily understandable, and also the transformed codes are easy to be maintained and reused. In our proposed method, three kinds of elements including class, class description and property in the OWL ontology are mapped to class, class description and property aspect respectively in the AO model. As shown in Figure 6, compared with mapping into OO model, mapping into AO model can keep the structure of the OWL ontology very well.

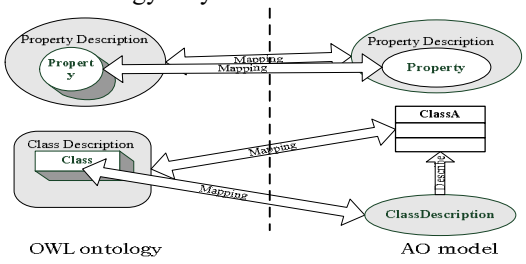

Fig. 6 Structure mapping between OWL ontology and OO model

In the following, we will propose a comprehensive translation method to map the OWL ontology into a general AO model using AspectJ [9]. Two principals are used throughout the translation. For the part of the OWL ontology, which is consistent with the OO model, we use the mapping method used in the mapping from the OWL ontology into the OO model. For the other part which are inconsistent with OO model in the OWL ontology such as class description, properties and restriction, we propose to aspects and weaving mechanism to perform the translation.

4. The Mapping from OWL Ontology into AO Model

In the translation, we first define interface IThing to be the ancestor of all mapped classes, it corresponds to class Thing in the OWL ontology. Each generated class has a unique id property which is set in the class constructor corresponding to the class name in OWL ontology. In the following, we will give the translation methods in detail.

A. OWL Class and Class Description

Referring to the class mapping method proposed by Aditya Kalyanpur [10], we make use of the well matching between the OWL class and the AspectJ code to perform the class mapping as follows. Each OWL class is mapped into an interface and an implementation class. The class description and class's restrictions on properties are mapped into a class description aspect in AspectJ.

1) Class

A class in the OWL ontology is mapped into an interface and implementation class in AspectJ. For example, class *A* in the OWL ontology will be mapped into interface *IA* and interface implementation class *CA* in AspectJ.

2) subClassOf

A subClassOf *B* in OWL is mapped into a inherit relationship between interfaces of two mapped classes *IA* and *IB* in AspectJ.

3) equivalentClass

Let OWL the equivalent class map into the interface with the same properties, and each equivalent relationship between classes is mapped into an equivalent relationship aspect. In this aspect, we declare these equivalent classes to implement all these equivalent interfaces. For example, *A* and *B* are two equivalent classes, in the equivalent relationship aspect, we create following AspectJ codes:

```
declare parents:(A||B) implements IA,IB;
```

Based on the interface programming, class *A* and class *B* can be used alternately so that the semantic of equivalent between class *A* and *B* can be expressed.

4) intersectionOf

In the OWL ontology, the *A* intersectionOf (*B*, *C*) represents that class *A* has the characteristic which both class *B* and class *C* has. We can translate it to this code in class description aspect:

```
declare parents : IA extends IB, IC;
```

In this way, *IA* will get the all characteristic of *IB* and *IC*.

5) unionOf

In the OWL ontology, unionOf has the opposite meaning with intersectionOf. We use this code to express it:

```
declare parents: (IB || IC) extends IA;
```

6) disjointWith

In the class description aspect, we can define a function with the same function name which returns a different type for all the member interfaces of this relationship. It can avoid these interfaces being extended or implemented by a same interface or class. So it can express the semantic of disjoint relationship in OWL ontology.

7) complementOf

A complementOf *B* in OWL represents two complement classes. In the class description aspect, let *IA* and *IB* are

two interfaces extend from the most top interface *IThing*. Then, we use the mapping method of disjointWith to make them be disjoint with each other, at last we can use class pattern expressions to let all interfaces which do not extend from *IB* extend from *IA*. So the mapping can be described as:

```
public IA IA.forDisjoint (){…}
public IB IB.forDisjoint (){…}
declare parents:(!IThing && IThing+ &&(!(IB
+))) extends IA;
```

8) oneOf

We check the value of object's id property in its constructor. If the id does not belong to the id set which is defined in the OWL oneOf statement, an exception would be thrown out.

9) Cardinality

We set a pointcut for the property setter in the class description aspect, and define an advice to check the number of items in the list of property values before this pointcut, if the number of items is not consistent with the cardinality, an exception is generated. In this way, we can separate the property restriction from the property definition and we can define different property restrictions for the same property in different classes. For example, in the OWL ontology, the cardinality of property *P* restricted on class *A* is 1, it will map into the AspectJ codes in class description aspect which is described as:

```
pointcut setP(List arg):set(List IA.P)&&
args(arg);
before (List arg):setP(arg){
     if(arg.size()!=1)
     throw new CardinalityException(…);}
```

10) hasValue

In the same way, we can use the similar mapping method with the cardinality mapping to check whether the list of the property values contains the object with correct object id.

11) someValuesFrom/allValuesFrom

We use the similar methods with the cardinality mapping to check if the objects in the list of the property values belong to right classes.

B. OWL Properties

OWL properties consist of the description of property constructs, the characteristics of properties and relations to other properties. Following gives the mapping from the property descriptions in the OWL ontology to AspectJ

1) domain

Domain describes the classes which have the properties. It defines which classes could have the properties. In the mapping into property aspect, the domain class points out a target classes set which the property to be weaved into. Firstly, we define a domain interface which represents all the domain classes. Secondly, we add the property to the domain interface by using inter-type declares. Finally, let the interfaces in the domain extend from the domain interface.

For example, person and publisher are two domain classes of property hasContact. In the property aspect, we define:

```
private List IhasContactDomain.hasContact;
declare parents:(IPerson||IPublisher) extends
IhasContactDomain;
```

If the classes in domain changed in the OWL ontology, we only need to modify the weaving target set (*IPerson*||*IPublisher*).

2) range

Range is used to describe the data type of property's value which a property can take. We use a list to represent all the property values in AspectJ, and check the type of all items in this list when setting the value of property.

For example, property hasContact has the range of class Contact, it can be mapped into:

```
public void IhasContactDomain.setHasContact
(List values){
…//check the values listed in the list, if the
value is not the types defined in the list, an
exception will be thrown out.
this.hasContact = values;}
```

3) Functional

Functional property is a property that can have only one (unique) value *y* for each instance *x*, i.e. there cannot be two distinct values *y1* and *y2* such that the pairs (*x*,*y1*) and (*x*,*y2*) are both instances of this property. In the mapping, when setting the property value, we can check the number of items in the list of property values. If the number is greater than 1, then an exception is thrown out.

4) InverseFunctional

InverseFunctional property means that this property value is unique in this system. In the property aspect, we maintain a property value list for all the Objects which have this property, and check the value when the property value is set. If the value has been existed, an exception is thrown out, else set the value and add it to the list.

5) Symmetric

A symmetric property is a property for which holds that if the pair (*x,y*) is an instance of P, then the pair (*y,x*) is also an instance of *P*. In the mapping, we use *P*(*a,b*) to indicate that object *a* has property *P* with value *b*. Symmetric property *P* (*a,b*) means *P*(*b,a*). In the property aspect, we add code to make *b.P=a* after *a.P* is set as *b*.

6) Transitive

The transitive property *P* means that *P(a,b)*, *P(b,c)=>P(a,c)*. To describe its semantic, we add a function to return all the transitive values. It means, for object *a*, the function will return *b* and *c*. For *b*, the function will return *c*.

From above description, for an OWL ontology described in OWL-DL, we can translate it into AspectJ codes which maintain the semantics of the ontology properly.

5. Implementation and Experiment

Based on the mapping principals and mapping rules described in section III and IV, we implemented a model translation tool which named OWL2AspectJ to translate the OWL ontology into AspectJ code. The input is a valid OWL document and the output is its corresponding AspectJ codes.

We use JDK1.5 as the running environment and use protégé OWL API as the OWL parser. For an OWL document input, the translation tool first parses the document using the parser and then maps it into AspectJ code automatically according to the mapping strategy proposed in the paper.

Using the OWL ontology presented in http://www.w3.org/TR/2004/REC-owl-guide-20040210/wine# as an example, after the translation, we can get the AspectJ code as shown in Figure 7:

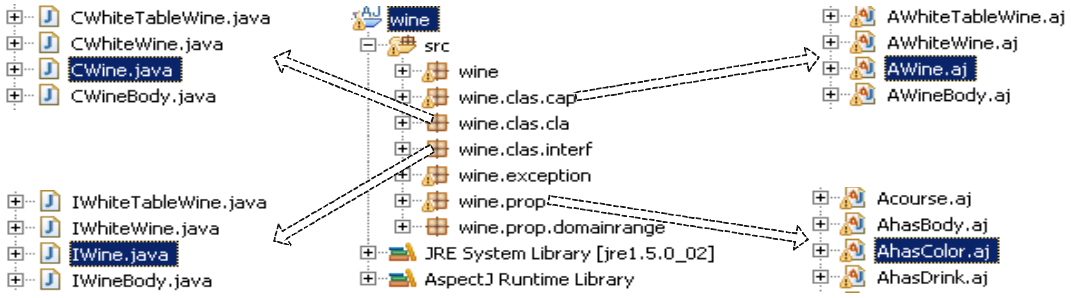

Fig. 7 Translated AspectJ codes structure

Where, *win.clas* contains all codes generated from classes and class descriptions in wine ontology. *clas.interf* contains the interfaces of the classes. *clas.cla* defines all the implementation classes. *clas.cap* contains the class description aspects. In the property mapping, *wine.prop* contains the codes generated from properties and their characteristics in OWL ontology. Where, *wine.prop* is the aspect of properties, and *wine.prop.domainrange* corresponds to the interfaces of domain and range. These codes are independent of each other, the aspects of classes and properties are interacted through the AspectJ weaving mechanism.

For the classes in ontology wine, after translation, three independent parts of codes are generated. They are the class interface *wine.clas.interf.IWine*, interface implementation class *wine.clas.cla.CWine* and class description aspect *wine.clas.cap.AWine*. The most important codes are defined in the part of *AWine*, it can operate on *IWine* by weaving mechanism to keep the semantic of the ontology. For the properties in Wine ontology such as *hasColor*, after translation, property aspect *wine.prop*, the interface of property *domain wine.prop.domainrange*, the interface of the property range *wine.prop.domainrange*, and *IhasColorRange* are generated respectively. The main codes are in *AhasColor*, and it can be weaved into corresponding classes.

6. Evaluation of the Mapping

In section IV, we have described the mapping method for the classes and properties in the OWL ontology in detail. Here, we use two examples to test whether the transformed codes can express the semantic presented in the OWL ontology.

Example 1: *ConsumableThing* and *NonConsumableThing* are two complement classes, we use following program to test the generated codes.

```
IWine w=new CWine();
if(w instanceof IConsumableThing)
System.out.println("w is ConsumableThing");
if(w instanceof INonConsumableThing)
System.out.println("w is NonConsumableThing");
IRegion r=new CRegion();
if(r instanceof IConsumableThing)
System.out.println("r is ConsumableThing");
if(r instanceof INonConsumableThing)
System.out.println("r is NonConsumableThing");
```

We could get the following result:

```
w is ConsumableThing
r is NonConsumableThing
```

This test indicates that the generated codes can classify wine and region into *ConsumableThing* and *NonConsumableThing* correctly.

Example 2: We also test the class description on oneOf for class *WineColor* by the following code:

```
IWineColor wc=new CWineColor("White");
```

It runs correctly. Then we run :

```
IWineColor wc=new CWineColor("blue");
```

The program throws an exception:

```
wine.exception.OneOfException: blue is not one
of {White Rose Red}
```

It indicates that generated codes can use the exception processing to constrain the semantic of oneOf.

7. Benefits from the Model Translation

The OWL ontology has high powerful expressive capacity and the AO model has high flexibility in programming. Using the translation from the OWL ontology into AO programming model may get following advantages.

A. Readability and Maintainability of Translated Code

How to keep the consistency between document and code has been a challenge in software development. The OWL ontology is build based on the concepts and relationships of a specific domain, and it can be easily understood by human and at the same time currently we have some OWL ontology editor tools with friendly user interface. On the other hand, the AO model is high consistent with OWL ontology in structure description. So we can use OWL ontology as the document of code and furthermore we can read, maintain and reuse the codes by using the OWL document. Once the OWL ontology is changed, software developers can quickly locate the code to be modified instead of calling translation again which can avoid overwriting the previous information.

B. New Programming Model Benefiting from the Code Structure of Property Independence

In the traditional OO programming model, property is treated as a class element and it is tightly coupled with one class. In fact, one property can exist in multiple classes. In this case, when a property changes, we have to modify the class codes with which each property is connected. It may result in the problem of code maintenance. Using the mapping method proposed in this paper, we can constrain the modification in the property itself. Also, if different classes have different requirements for this property, we can define the property restrictions in the classes.

As we know, in the translated AspectJ codes, each property has an interface to present its domain. In the development, we can deal with this property instead of considering the objects related to the property so that it provides a flexible programming model. For example, a cart is represented as a list of commodities object with different class. If we want to get the total price of all these commodities in the cart, by using traditional method, we need to know all items class before adding up their price. Now, we can only process the price's property independently and do not need to consider their real classes. What we should do is to cumulate the price by seeing all the items as the instances of *IPriceDomain*.

C. Rich Semantics of OWL Ontology would Bring New Characteristics to Programming

Translating the OWL ontology into the AspectJ code can maintain the semantics of the ontology and bring out some new characteristics for programming model. For example, in a marketing system, all classes are classified into two complement classes, *consumable* thing and inconsumable thing, and each has different characteristics. If we add a new inconsumable class *A* into the system and class *A* did not extends from any inconsumable class, class *A* will be seen as an inconsumable thing and get all characteristics of inconsumable thing automatically.

8. Conclusions

This paper proposed a new method to mapping OWL ontology to AspectJ. The methods can translate most elements in OWL DL into AspectJ code, and the translated codes can express the semantic of OWL ontology and is high consistent with the OWL ontology in both structural and semantic description. With the development of software and knowledge engineering, MDA based software development and ontology based knowledge management have been widely used. The convergence of these two fields shows a promising trend in software development. OWL ontology gives the well defined semantic model in the requirement domain, in the software development, developers can extract the OWL ontology they are concerned with. Then, the translation from the ontology to AspectJ can be performed to generate the corresponding aspect model to be the static structure of the system. At last, the further development can be made. In this way, we could speed up the software development and reduce the development investment.

MAPLE: a Maintenance Approach for Pattern-enabLed rEconfiguration of SOA-based enterprise application

Songlin Hu, Ying Liang, Jiuming Tian, Yicheng Song

***Abstract*--Service-Oriented Architecture (SOA) is widely adopted as a way to reach flexible integration of enterprise system, and Event Driven Architecture (EDA), which enables complex event processing as well as asynchronized communication among systems, is also attracting more attentions. The deployment of such an environment makes it possible for organization to improve interoperability and agility, and brings about new challenges to the maintenance and evaluation of the whole system at the same time. The paper first analyzes problems retrieved from a real engineering scenario, and proposes the MAPLE approach to implement two-level abstraction by reusing and reconfiguring of business and technical patterns. As showed by a legacy system integration experience in a Textile and clothing manufacture company, it provides a practical route to achieving maintenance and evolution of the EDSOA (Event Driven SOA)-based enterprise application.**

***Index Terms*--Maintenance and evolution; SOA based system; Event driven; Business pattern; Enterprise integration pattern; Textile and clothing manufacture.**

I. INTRODUCTION

As a popular paradigm, SOA is becoming a hot topic both in industry and academy. It shows some unachievable high level advantages when combined with event technologies, and is now treated as a fairly good choice for building large scale systems as well as reuse and integration of legacy systems.

Topics in early stage of the whole lifecycle of conducting a SOA based system have been the focuses of works in service computing area. The maintenance and evolution of such a system is becoming popular recently [1]-[2]-[3], but only a few current works have been presented to discuss it.

The objective of maintenance here is to modify the existing system while preserving its integrity. As a consequence, problems including expression of changes, impact analysis, change propagation, and revalidation should be tackled.

Even though the SOA based system, power by loose-coupled building block and flexible composition mechanism, has the potential ability to be adaptive to the changing requirements, it is still challengeable to have the complicate system reliably "reconfigured" according to new situations.

To achieving the goals mentioned above, the MAPLE is put forward here to describe and manage the relationships between technology and business models via two level abstractions, and enables maintenance by reuse and reconfiguration of the relationships. The objectives we are aiming at would be broken into two levels: the first one is BPEL reconfiguration in response to changes in business model, the second one is high level service reconfiguration in response to changes of usage of certain resources.

The paper is organized as below: the first section gives an overview of related work, engineering background, and presents the challenges generated from real application scenarios. The MAPLE approach is introduced in Section 2, including conceptual idea of pattern based two-level abstraction. Section 4 shows the whole framework along with roles for it. In Section 5, our application experience in a Textile and clothing manufacture company is illustrated. At last, conclusions and future works are presented.

II. RELATED WORKS, BACKGROUND & MOTIVATION

A. At Process Level

Whether it is named as abstraction or not, abstraction of process has been studied to improve the capability of process modeling and execution. Recently, semantic web service composition has been focus of famous SOA research groups, like Meteor-s [5] and SWARD [6], which can achieve semantic abstraction of services, and facilitate dynamic service selection at run time. While at the same time, model-driven BPEL management creates another way to process abstraction. IBM has put forward a product to map UML model to BPEL [7], allowing process modeler to create UML

This work was supported in part by the Chinese National High-Tech. R&D Programa under Grant 2006AA04Z158 and 2006AA01A106, and the National Basic Research Program, China, under Grant 2007CB310805 and 2005CB321807.

Ying Liang is with the Institute of Computing Technology, Chinese Academy of Sciences, Beijing 100190, China (e-mail: liangy@ict.ac.cn).

Jiuming Tian is with the Institute of Computing Technology, Chinese Academy of Sciences, Beijing 100910, China. He is also with Graduate University of Chinese Academy of Sciences, Beijing 100049, China (e-mail: tianjiuming@ict.ac.cn)

Yicheng, Song is with the Institute of Computing Technology, Chinese Academy of Sciences, Beijing 100910, China. He is also with Graduate University of Chinese Academy of Sciences, Beijing 100049, China. (e-mail: songyicheng@software.ict.ac.cn).

at first, and then map the UML models to corresponding BPEL. Similarly, Aalster proposes an approach and related algorithms to translate Petri-net to BPEL model [8]. The process modeler who is familiar with Petri-net-Like workflow can indirectly build BPEL without know the technical detail of BPEL languages.

In practice, the logic of BPEL is always much too complicated than the logic of business level processes, especially for the processes with asynchronized events as well as service invocations. With event driven features, the BPEL implementation of the business logic has to be fulfilled by using “receive”, “onMessage”, ”Correction” etc., which make the diagraph of the business process “stretched” or totally changed. The logic of BPEL is also affected by available services. Moreover, the users who want to use model driven BPEL approach should have to be familiar with technical models like UML, which is also hard for business user to grasp. Obviously, it is necessary to find a new way to enable the IT manager in the serving stage to adjust the processes to meet new requirements.

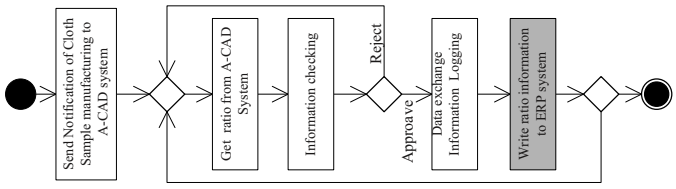

Fig. 1. Process model from business point of view

Fig 1 illustrates a real business level process. It describes the business logic for a data exchange procedure between legacy ERP and CAD systems. At the beginning, a notification is sent to a CAD workstation with initial data as soon as the ERP system receives a new order, and the design result will be exchanged back to the ERP system after the CAD designer finishing the task assigned. During the exchange procedure, a manager of the ERP system will verify the data, check to see whether to accept the data or not. If the data is rejected, the CAD designer will get the feedback, and executing the task again.

The process digraph looks sample from business point of view, while the corresponding BPEL model has to be designed as the one showed in Fig 2. It is obviously that it is far from practice to map the business level process like Fig 1 to an executable BPEL by using formalized specifications and automatic algorithms. It is essential to find another way to implement the abstraction.

In practice, due to the management standards or routines, organization structure and the functionalities assigned to the departments, there exist lots of similarities among business logics. The idea here is to take advantage of the patterns to construct the relationship between business view and technical view of the process, and to facilitate the design or modification of processes by reusing or reconfiguring the patterns. With the support of patterns, maintenance of BPEL can be achieved by reconfiguring high level process, while detecting dependency and impact of BPEL could be executed automatically, and the changing of BPEL could be implemented with automatic algorithm and sometimes with user interaction if needed.

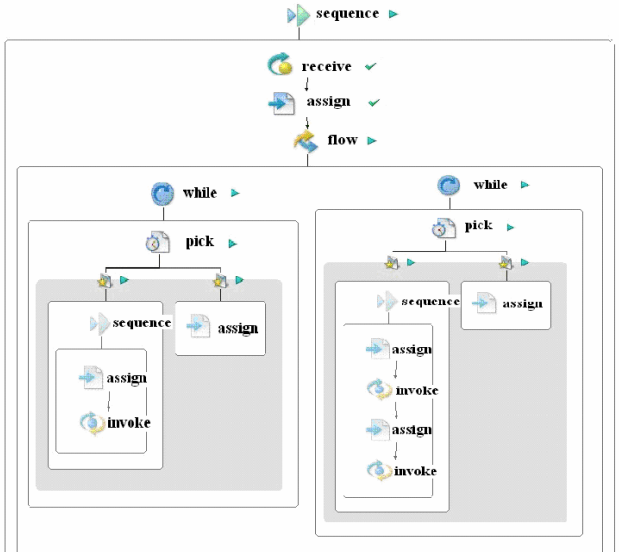

Fig. 2. BPEL model for Fig 1.

B. At Service Level

At service Level, wrapping of legacy system to web services can be treated as a kind of abstraction [9]. A service in one process can also be a set of abstract interfaces for another process. Abstraction can be semantic description of service interfaces using Meta-data or ontology as well. In this paper, we focus on high level abstraction of service by using Enterprise Integration Pattern (EIP) [10]-[11].

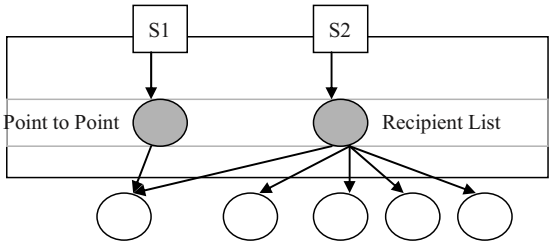

Fig. 3. Service Level Abstraction using EIP

Asset in an enterprise can be utilized in different way at different time. For example, in our engineering project, information A generated from ERP system is sent by process 1 to one CAD workstation. After a period of time, it is asked to be sent to a design group that contains a number of CAD workstations. Here, we can define one services S1, and generate S2 just by changing the integration pattern it uses.

The integration style for both of them is messaging. The Messaging System for S1 is message channel (point to point), while S2 should adopt message router (Recipient List).

Patterns like Translator and Message router can also be used to enable data transformation and complex message Routing. In this way, we can define services for different usage, which can enable service level abstraction.

III. MAPLE

Fig 4 gives a conceptual view for two-level abstraction. Process level abstraction is to build abstract business level process based on business pattern, while EIP based abstraction is a kind of service abstraction, which constructs abstract service using integration pattern.

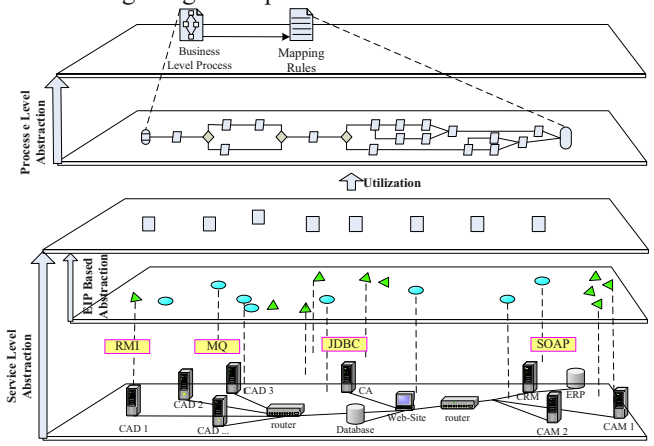

Fig. 4. Two-Level Abstraction

A. Business Template

In this approach, we use business template to describe business level process, BPEL, and the relationships between these two to represent a particular kind of business pattern. It is defined as following:

< business template >::= <ID>< business process >< BPEL Template >< Mapping Rules >
<business processes> ::= < service component >< logic node >
<service component> ::= < Messaging component >< RPC component >
<logic node>::= <sequence activity ><pick activity >< flow activity >< while activity >< start activity >< end activity >
*< BPEL Template > ::= < BPEL File >{< WSDL Files >}**
*< Mapping Rules >::= {< service component >< BPEL Object >}**

Mapping rules are the relationships between Service Components in business level process and Objects in BPEL, it only contain elements that users can modify without interfering with the whole process logic for a particular pattern. So far, 4 BPEL objects, namely: Invoke, receive, onMessage and reply activity, are involved in our approach. The validity of mapping rules should be guaranteed by template designers.

Service component mapping is mainly related to several elements in the BPEL and WSDL files, the specific relationship are listed as follows:

RPC component is related to “Invoke”, while the Message component could be “Receive”, “onMessage”, or “reply”. Any change to these two components will affect some other relevant elements besides themselves.

The operations allowed in a business pattern are:

Component changing: the operation is to change a component in business level process. It will result in change of related BPEL object. The system will synchronize reconfigure relevant elements, and will ask for user interaction to edit “Assign” objects if needed.

Component adding: the operation is to add a sequential or parallel component to the business level process. Corresponding object and relevant elements will be added to the BPEL.

Component deletion: the operation is to delete a component if it has no relationships with other components. Corresponding object and relevant elements will be deleted

Assign Modification: the operation is to modify the variables and their relations in “Assign” object. It is utilized to guarantee the validation of data flow.

The overall procedure for reuse of one pattern contains four steps: 1) Reconfigure the Pattern by an operation; 2) Automatically Detect impacts; 3) Read parameters and messages information from WSDL file for the service being change, and automatic change the partial structure of the BPEL, d; 4) Ask for user interaction to modify BEPL “Assign” object for data flow if needed.

TABLE I
RELATED ELEMENTS THAT WILL BE AFFECT BY CHANING OF PARTICULAR KIND OF COMPONENT

Component / Elements	RPC	Messag
WSDL file	Y	
import	Y	
partnerlink	Y	
partnerlinktype	Y	
variable	Y	Y
assign	Y	Y

B. Enterprise Integration Pattern

We propose abstract service based on Enterprise Integration Pattern. An abstract service shows high level view of one operation of service to users, from which the users can get the information of how the service works. It describes the EIP used by the services, corresponding end points and pattern dependent components it will use. The definition of Abstract Service is described as below:
<Abstract Service>::=<ID><Operation><WSDL><EIP pattern><End points><Pattern dependent Components>

Pattern dependent Components is the component related to particular pattern, like Message Router component or Message Translator component.

The abstract service can be directly mapped to the deployment files of the end points in the Enterprise Service Bus product like ServiceMix.

IV. FRAMEWORK AND ROLES

A. MAPLE Framework

The framework for MAPLE is illustrated in Figure 5. Besides tools that are already provided by current venders, like BPEL tools, ESB, Portal and IDE, four modules are added to facilitate the MAPLE approach, including:

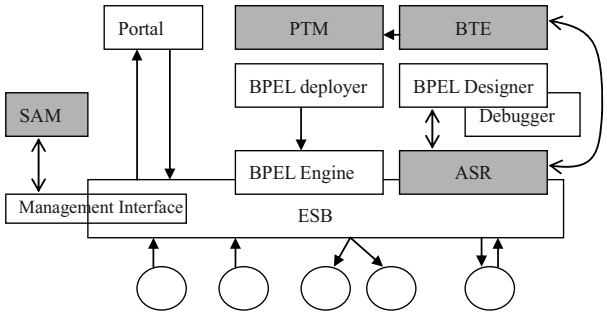

Fig 5. MAPLE Framework

Service Abstraction Manager (SAM): the SAM is the toolkit for designing abstract services using different enterprise Integration pattern. The configuration information of abstract services will be restored in Abstract Service Repository.

Abstract Services Repository (ASR): Repository for abstract services. BPEL designer and BTE will use it to get service and related WSDL file. It also maintains abstraction information that contains relationship among service and the endpoints related to it according to certain EIP. It can be used by BTE and BPEL designer.

Business Template Editor (BTE): It is utilized to model business level processes, and to edit mapping relationships between business level processes and BPEL. Changes of BPEL can be achieved by configuring the template, and the creation of new process can be done in the same way to generate new template with modified business level process and BPEL. The service components can be selected from ASR.

Business Template Mapper (BTM): Mapping changes of business level process to BPEL, detect impacts by rule and modify related objects in response to the changes.

The first two are used to manage service level abstraction, while the others are developed for process level abstraction.

B. Roles for the framework

Mattsson[12] has presented preliminary ideas on the roles required for developing, evolving and maintaining SOA-based systems. The roles are categorized into 7 groups, namely: SOA Front end support, Back end support, Traditional Back end support, SOA design, SOA management, Quality Assurance, Business Project Members[]. Here, we focus on roles for the maintenance & evolution system, especially the roles closely related to the Framework, while ignoring the others. The roles are:

Interface developer: The role belongs to *Traditional Back end support group*, and is responsible for developing and verifying interfaces based on legacy systems to meet the requirement of Service Abstraction Manager. It works in initial and evolution stages.

ESB Component developer: Responsible for designing, developing, testing of additional building blocks for integration and management, like logging service, auditing services, etc. The Service Components are plugged into Enterprise Service Bus as well. It works in initial and evolution stages.

Service Abstraction Manager: Responsible for managing original service end points and Service components, as well as data transformation rules deployed to ESB. The role creates abstract services by using suitable Enterprise Integration Pattern, and maintains the routing configuration in response to changing requirements of services. It can be treated as the combination of *Service Developer in SOA Back-End Support group* and *Service Designer in SOA Business Process Design group*. It works in initial, evolution and serving stages.

Business Process Orchestrator: The role develops BPEL based on the business process provided by Business Process Architect. It belongs to *SOA Business Process Design Group.* It works in initial and evolution stages.

Business Template designer: Designs business templates according to Business patterns. It has the responsibilities of both *Business Process Manager in SOA Back-End Support group* and SOA *process manager in SOA Management group.* It works in evolution and serving stages.

Process maintenance manager: The role utilizes the template defined by Business Template designer to construct new BPEL or to reconfigure the process, so as to implement small changes. It is similar as *Business Process Manager in SOA Back-End Support group.* It works in serving stage, and can also be used to rapidly create processes in evolution stage.

Interface developer and ESB component developer uses IDE like eclipse, Business Process Orchestrator uses BPEL designer, while the others will use the new modules in figure 5. SAM and SAR are tools for Service Abstraction n manager, Business Template designer and Process maintenance manager will use BTE and ASR.

V. CASE STUDY

The approach proposed in this paper has been applied in an ongoing integration project for a large textile and clothing Manufacture Company. The company owns 23 categories of IT systems like: D/CAM/CIM, PDM, ERP, etc. The integration project was launched to cope with the problem mentioned above in early 2007. After requirement analysis, a high level business process is draw to illustrate the overall collaboration process for order-driven manufacture.

By analyzing the business process, we find that the atomic process of the enterprise can be separated into several categories: The first category involves data exchange of fabric rate, fabric width, size scale, operation schedule, etc.; the second category involves management of the samples, files, production schedules etc.; the third category involves verification of cutting consumption, patch control etc. Each category contains large number of atomic service. Obviously, it will take great efforts to implement realization and

maintenance all of these processes. This paper proposes a new method which simplifies the creation and adjustment of processes by means of classifying the business processes with the similar logic, refining the business patterns, designing and generating business templates.

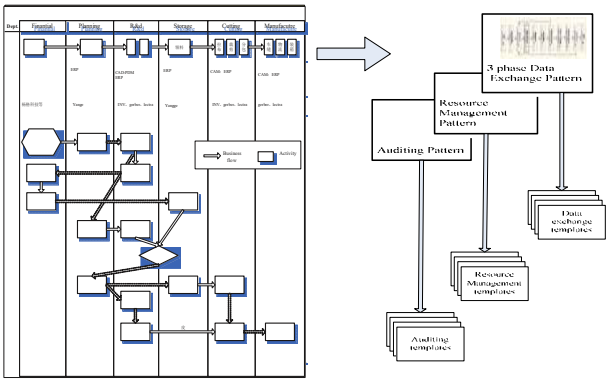

Fig. 6. Overall procedure and related business Patterns

Fig.7 shows an example of event-driven data exchange pattern, which includes 8 steps. The BPEL implementation related to this process has the same structure with the BPEL showed in figure 2.Figure 8 shows some parts of the BPEL framework in the basic template.

```

Fig. 9. A set of BPEL information for a specific invoke node. It is generated by change the empty invoke node to an existing service. The Business Mapper will retrieve information from related WSDL file, and automatically modify the BPEL files.

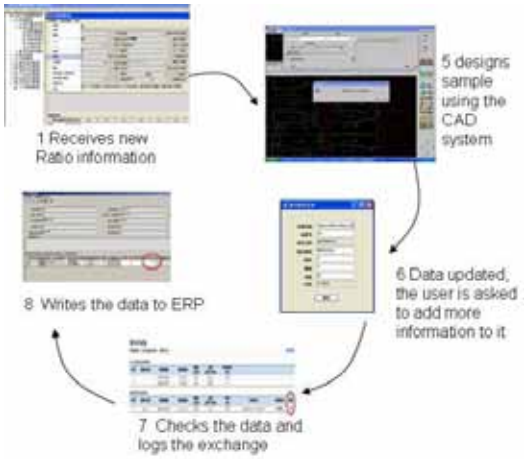

Fig. 10. The system user interfaces when run the BPEL to implement an event driven data exchange process between ERP and CAD systems.

The process showed in Fig 1. one can be generated from this template. Suppose ERP is treated as system A, and the user select a ERP write operation “*WriteSizeRatio*” in the service located in “*http://10.61.0.11/ERPWriter/?wsdl”* to take the place of the “*WriteDatatoA”* operation in the basic template. BTM will read information from the WSDL, and map the change to the BPEL. Figure 9 shows the generated template, with the operation replacement. In BPEL code, the words in italics are differences between basic template and generated template.

In this process, abstract services are configured using different pattern. For example, in step 2, event generated in the ERP system is wrapped to be a JMS message. Since the event should be used by another process, publish subscribe pattern is utilized, where the end point acts as publisher and the abstract service acts as subscriber.

After generating new BPEL for the ratio Data exchange between ERP and CAD systems, it can be deployed to the platform. Figure 10 illustrates some user interfaces.

VI. Conclusion

A maintenance approach for SOA based system is proposed based on two-level abstraction, which provides a practical way to facilitate reconfiguration of SOA processes and abstract services. Experiences accumulated in our first stage application in a real SOA based project prove that it can achieve easy-to-use reconfiguration without introducing unexpected effects to the whole system.

The future works includes improving the framework, implementing new functionalities for the new modules, formalized study on the descriptions of business template and abstract service, etc. Semi-automatic generating and validating of business pattern itself based on BPEL can be an interested topic as well.

Reliability Oriented QoS Driven Composite Service Selection Based on Performance Prediction

Lei Yang Yu Dai Bin Zhang
College of Information Science and Technology, Northeastern University
yanglei@mail.neu.edu.cn

Abstract

In order to improve the reliability of composite service, this paper proposes an approach of reliability oriented composite service selection. Firstly, a service reliability model which integrates request processing reliability and transmission reliability is proposed. In order to compute the transmission reliability, a semi-Markov model based performance prediction is used. Finally, we put the proposed reliability model into QoS driven service selection. Experimentations show that the proposed selection approach have better performance in preserving the reliability of composite service than traditional QoS driven selection approach.

1. Introduction

As web services operate autonomously within a highly variable environment (the Web), as a result of which their QoS may evolve relatively frequently, either because of internal changes or because of changes in their environment [1], such dynamic properties highlight the problem of QoS driven service selection.

Most previous works divides QoS and reliability into two different research fields and studies them separately. However, in reality, QoS and reliability are closely related and affect each other. Let us take one of QoS attributes, response time, as an example. The response time of composite service is a random variable affected by many factors. First, there are many services available on the Web with different request processing speeds. Thus, the response time can vary depending on which service is used for executing the task in the composite process. Second, some service can fail during its execution. So the response time is also affected by the processing reliability. Third, the communication links can fail during data transmission. Thus, the transmission reliability affects the response time as well. Then, when tasks are assigned to services with better response time and worse reliability, the failures of any service and any communication link will make the entire composite service incomplete. This will cause a re-selection to bind new services, which inversely increase the response time of composite service. Thus, this paper attempts to select composite service in order to maximize the QoS of composite service considering the effect of reliability as well.

In this paper, we propose an approach of reliability oriented composite service selection. Key to our approach is the proposed model of service reliability. Such reliability model integrates request processing reliability and transmission reliability, which can be used for evaluate the reliability of services. Meantime, a semi-Markov model is used to quantify the reliability of service. Then, reliability oriented QoS driven composite service selection is presented. Experimentations show that the proposed selection approach have better performance in preserving the reliability of composite service than traditional QoS driven selection approach.

2. Related Works

As web service is a kind of software on the Web, traditional reliability model for evaluating the software, such as Ref.[2], can be used to quantify the request processing reliability. However, as web service existing on the Web, the state of Network (such as load and throughput) will affect the reliability of service. Thus, when it is to model the reliability of service, traditional model for quantifying reliability of software cannot be directly used in the field of service composition.

In the researching field of service composition, researchers [3] use the successful execution rate of a service with the maximum expected time frame to quantify the reliability of a service. This approach is relatively simple. In Ref. [4], the researcher uses a Possion Distribution to quantify the reliability of grid service with the assumption that the data transmission

speed and failure rate of Network is a constant value. However, such assumption do not always hold true. Such reliability model cannot reflect the reliability of service in many situations.

Compared with the above works, we model the service reliability as an integration of request processing reliability and transmitting reliability.

3. Performance Prediction for Reliability Modeling

3.1 Preliminaries

In this section, we introduce some basic concepts that will be used in the remainder of the paper.

Definition 1. QoS of Atomic Service. For an atomic service s (which only contains one operation), the QoS of s can be defined as: QoS(s)=<$Q^t(s)$, $Q^p(s)$>, where:

- $Q^t(s)$ is the response time of s. $Q^t(s)=t_p+R/V_{transmission}$, where t_p is the request processing time; R is the amount of data needed to transmit between s and the execution engine and $V_{transmission}$ is the transmission speed.
- $Q^p(s)$ is the cost of invoking s.

From the definition, the change of request processing time, the transmission speed and the cost will influence the QoS of the service. The affected QoS of service will in turn influence the QoS of composite service. Cost for invoking a service is published by the service provider. The request processing time relies on the number of requests in the waiting list and the processing speed of the computer. The transmission speed is affected by the network. Compared with the changes caused by service providers, changes of the request processing time and transmission speed will be changed more frequently. Such change will affect the performance of service. The reliability of the service is to evaluate the degree to which the service can serve the request as announced QoS.

Thus, in this paper, we will based on the following assumption to model the service reliability:

(a) failure at different service and communication links is independent; (b) from the time of sending request to the service to the time of receiving the result from the service, data transmission speed is a constant value; (c) the failure rate of processing the request is a constant value; (d) the cost for invoking a service is never changed.

3.2 Model of Service Reliability in Context of Composition

QoS reflects how a service can implement the function with certain performance. In context of composition, service reliability represents the degree to which service can serve the request as estimated QoS. In the following, we will discuss how to model the service reliability.

In the context of composition, the earliest start time et_{ij} of component service j for task i in the composite process can be computed as Eq.(1).

$$et_{ij} = \begin{cases} \max_{k<i}\{et_{ku} + t_{ku}\}, k \neq 0 \\ 0, k = 0 \end{cases} \quad (1)$$

Where, task k (k<i) is the one that will be invoked before task i and t_{ku} is the response time of candidate service u for task k.

As web service existed in the complex Internet environment, the reliability of service should not only consider the processing reliability as most software, but also take into account of transmission reliability. In this paper, we model the service reliability as an integration of request processing reliability and transmitting reliability. To quantify request processing reliability, common software's reliability model [2] is used. To quantify transmitting reliability, as it relies on the current state of the Network, the holding time in current state and the predicted duration, we quantify the transmitting reliability based on a semi-Markov based performance prediction. In the following, we will give the definition of reliability of service.

Definition 2. Reliability of Service. Reliability of atomic service s in composite service CS is the probability that a request is correctly responded with the estimated time frame, which can be defined as follows: $R(s, CS)$=<$R_p(s, CS)$, $R_t(s, CS)$>, where

- $R_p(s, CS)$ is the request processing reliability, which can be defined as Eq.(2):

$$R_p(s, CS) = e^{-\lambda t} \quad (2)$$

Where, λ is the failure rate of service when processing a request; t is sum of response time of s and earliest start time of s in CS; Eq.(2) is a common in software's reliability, which has been justified in both theory and practice [2].

- $R_t(s, CS)$ is the transmitting reliability. We will show how to quantify it in section 3.3.
- The overall reliability of service s can be computed as Eq.(3)

$$R(s, CS) = R_p(s, CS) * R_t(s, CS) \quad (3)$$

Definition 3. Reliability of Composite Service. Reliability of composite service CS is the probability of that all the component service execute correctly, which can be defined as Eq.(4):

$$R(CS) = 1 - \prod_v (1 - R(s_v, CS)) \quad (4)$$

Where, s_v is a component service of CS.

3.3 Performance Prediction for Quantifying Transmission Reliability

We introduce discrete time semi-Markov model [5] for the prediction.

Definition 4. States of Data Transmission Speed. We use th_V_Q to signify the threshold of data transmission speeds in Qualified state.

- If $V(t)>= th\_V_Q$, then $ST(t)$ =Qualified state;
- If $0<V(t)<=th\_V_Q$, then $ST(t)$=Soft Damage state;
- If $V(t)=0$, then $ST(t)$=Hard Damage state.

Definition 5. Semi-Markov Model for Data Transmission Speed. Let Ω be the state space of data transmission speed Ω={1, 2, 3}. $Z=\{Z_t; t>=0\}$ is the random procedure on Ω. If the following conditions are true, we call that $Z=\{Z_t; t>=0\}$ is a semi-Markov process.

- If current state is i, the next state will be entered is j with probability P_{ij}. Especially, $P_{ii}=0$;
- Given that the next state entered will be j, the time it spends at state i until the transition occurs is a holding time t with distribution $F_{ij}(t)$.

Let $H_i(t)$ be the distribution of holding time in state i, $H_i(t)=\sum_j F_{ij}(t) * P_{ij}$. The average holding time in state i can be signified as μ_i. According to lemmas [5] of semi-Markov model, there exists stationary distribution $\pi=[\pi_1, \pi_2, \pi_3]$ and for each π_j, it can be computed as Eq.(5). Also, let P_i the steady-state occupancy probability of state i, it can be computed as Eq. (6).

$$\pi_j = \sum_{i=1}^{3} \pi_i P_{ij}; \sum_{i=1}^{3} \pi_i = 1 \quad (5)$$

$$P_i = \frac{\pi_i \mu_i}{\sum_j \pi_j \mu_j} \quad (6)$$

In order to predict the future state, it is required to get the context related to data transmission speed.

Definition 6. QoS-Related Context. The QoS-related context observed by observation o can be defined as $QC(o)=<t_{ob}, v, st_{ob}>$, where t_{ob} is observing time; v is the observed data transmission speed at t_{ob}; st_{ob} is state.

The aim of prediction can be described as: if the current state is i, current time is t and the holding time in current state is d, we need to predict the probability of the data transmission speed V_f at future time t_f above the expected speed V_e. Let j be the state V_e belongs to. To solve this problem, we will consider the following two situations:

- State j is same to i

In this situation, the probability can be a sum of the probabilities in the situations with no transition from t to t_f and situation with at least one transition. Then, the probability can be computed as Eq. (7).

$$\begin{aligned} & P((V > V_e) \wedge (D_i > d)) \\ & = P((V > V_e) \wedge (D_i > t_f - t + d | D_i > d)) \\ & + P((V > V_e) \wedge (Z_{t_f} = i) \wedge (d < D_i < d + t_f - t | D_i > d)) \\ & = (1 - F_i(V_e)) * \frac{1 - H_i(t_f - t + d)}{1 - H_i(d)} + (1 - F_i(V_e)) * P_i * \frac{H_i(t_f - t + d) - H_i(d)}{1 - H_i(d)} \end{aligned} \quad (7)$$

- State j is different from i.

If state j is different from i, it means that there exist at least one transition during the duration from t to t_f. Then, the probability can be computed as Eq. (8).

$$\begin{aligned} & P((V > V_e) \wedge (Z_{t_f} = j) \wedge (d < D_i < d + t_f - t | D_i > d)) \\ & = P(V > V_e) * P(Z_{t_f} = j) * P(d < D_i < d + t_f - t | D_i > d) \\ & = (1 - F(V_e)) * P_j * \frac{H_i(t_f - t + d) - H_i(d)}{1 - H_i(d)} \end{aligned} \quad (8)$$

According the prediction of transmission speed, the transmission reliability of service s in the context of composition, can be computed as Eq.(9):

$$R_t(s, CS) = P \quad (9)$$

Where, P can be either computed as (7), or (8), according to the current state of service.

4 Reliability Oriented QoS Driven Composite Service Selection

Reliability oriented QoS driven composite service selection is to maximize the QoS of composite service considering the effect of reliability as well. The problem of such selection can be described as (10).

$$\begin{aligned} & \max_v \ F(CS_v) \\ & s.t \ \ Q^t(CS_v) \le Q_c^t \\ & R(CS_v) \ge R_c \end{aligned} \quad (10)$$

Where, $CS_v=\{(t_1, s_{1,k1}),\ldots, (t_i, s_{i,ki}), \ldots, (t_n, s_{n,kn})\}$, here, t_v is the task in composite process and $s_{v,kv}$ is the service selected for tasl t_v; Q_c^t is the constraint of response time; R_c is the reliability constraint; F is the fitness function which considers both QoS and reliability of the composite service and can be computed as (11).

$$F(CS_v) = w_t * \left(\frac{Q^t(CS_v) - u_t}{\sigma_t} \right) + w_p * \left(\frac{Q^p(CS_v) - u_p}{\sigma_p} \right) + w_R * R(CS_v) \quad (11)$$

Where w_t, w_p and w_R are the weights ($0<=w_t, w_R, w_p<=1$, $w_t+w_p+w_R=1$). σ and μ are the standard deviation and average of the QoS values for all potential composite services.

Such problem can be mapped into a multi-constraints satisfying problem. Several approaches [6] can be used for solving such problem. As the limitation of this paper, we will not discuss how to use the algorithm to solve such a problem in detail.

5. Experimentations

Experimentation 1 is used to test the effectiveness of the proposed semi-Markov model based QoS predicting approach. Simulate test set of data transmission speed according to the Gaussian distribution. The threshold of failure probability is 0.9. The size of QoS-related contexts is 100000. Compare the relation among predicted result, predicting interval and the observation interval between two neighboring contexts. Table.1 gives the result (O_Q is the observation interval between two neighboring QoS-related contexts in *QCS*; *N* is the number of predictions; *R* is the average accurate rate of the predictions.

Table. 1. Semi-Markov Based Predicted Result

	O_Q=0.5s			O_Q=0.1s			O_Q=0.05s		
	I= 10	*I*= 60	*I*= 180	*I*= 10	*I*= 60	*I*= 180	*I*= 10	*I*= 60	*I*= 180
N	300	300	300	200	200	200	150	150	150
R%	95	86	80	97	93	83	98	95	92

Table.1 shows that if the observation interval between two neighboring contexts is smaller and the predicting interval is shorter, the prediction will be more accurate. When the observation interval is short enough, although predicting interval is a little bigger, the accurate of prediction will be better also. Thus, through minimizing observation interval, the accuracy of prediction result can be improved.

Experimentation 2 is used to test the reliability of composite service. Randomly generate 10 abstract composite processes. Select the composite service for each composite process. Simulate test sets of data transmission speed according to the Gaussian distribution and set I_Q=0.1s, the threshold of reliability is 0.95. Simulate change of data transmission speed according to Gaussian distribution from the beginning time of composite service execution to the completing time of composite service execution, after selection. Compare the response time of composite service. The result is shown in Fig 1.

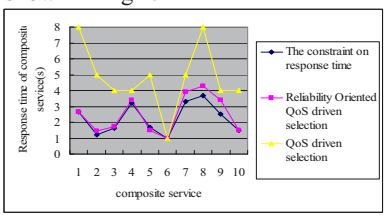

Fig. 1. Comparison of Re-Selection Numbers

Fig 1 shows that the composite service selected by the proposed reliability oriented QoS driven service selection approach always has better response time than the one selected by QoS driven approach. This is because that during the selection process, not only the QoS of composite service is considered, but also the reliability of composite service is respected in our approach. Thus, the more reliable composite service will always meet the constraint of response time.

The above experimentations show that the proposed approach is more effective in preserving the reliability of composite services.

6 Conclusions

In order to maximize the QoS of composite service considering the effect of reliability as well, we propose an approach of reliability oriented composite service selection. Model of service reliability is proposed. Then, we put such model into the problem of reliability oriented QoS driven composite service selection. Experimentations show that the proposed selection approach have better performance in preserving the reliability of composite service than traditional QoS driven selection approach.

Abstract*—RSS (Rich Site Summary, or Really Simple Syndication) is widely used for notifying readers of updated information on blogs and feeding news to readers quickly. RSS is very simple, and so is mostly used as a web service. However there is no satisfactory search engine which works for RSS. The reason is that RSS is continuously modified, and the structure of general search engines is ineffective to collect information from RSS sources.*

In this paper, we discuss a web crawling algorithm, and propose a structure for an RSS crawler which is geared toward collecting and updating RSS in the Web2.0 environment. The proposed method (1) uses visited domain name history to predict the location of the RSS of a new seed URL, and (2) updates RSS information adaptively, based on some update-checking heuristics. These approaches can serve as cornerstones for an efficient and effective RSS search engine.

Keywords*—Web2.0, RSS, Crawler, Adaptive Revisit manager*

1. Introduction

Web2.0 [1] is a next generation web service paradigm which is different from past technologies. In this paradigm, information providers and users are engaged in interactive communications about their demands and needs [2]. RSS (Rich Site Summary or Really Simple Syndication), a novel XML based technique in the Web2.0 environment, is used for transferring data easily, and notifying readers of updates to blogs via RSS reader applications or meta-blogs almost in real-time.

Historically, RSS has been used to refer to "Rich Site Summary," "RDF Site Summary" and "Really Simple Syndication." It is a data format based on XML, used to supply update information on websites with frequent content updates [3]. RSS is very simple, and so is mostly used as a web service especially on blogs. People can subscribe to an RSS "feed" with an RSS reader application. The feed lets people know that new information is available even though they do not visit the website, and people can use the reader application to categorize contents to their taste.

In response to the increasing use of RSS, sites have emerged which offer an RSS reader-like portal service, such as "allblog.net" and "naaroo.com" in Korea. These sites are called meta-blogs. People can add their RSS address to the meta-blogs by themselves. The meta-blogs check updates of registered blogs and categorize contents like news articles for portal sites. However the meta-blog is inconvenient because they involve passive registration of RSS by personal bloggers. Also people can only search for registered contents, and so the search results of portal contents are limited to narrow topics.

Development of a search engine specifically for RSS is needed to solve these problems. Generally speaking, a web search engine consists of three parts: a crawler, an indexer, and a searcher [4,5]. The crawler collects information from websites, and the indexer manages an index of gathered information to support fast retrieving. The searcher offers searching results based on the index. There are studies on RSS gathering, but the results have been less than satisfactory thus far. In this paper, we propose an RSS crawler that takes advantage of the features of RSS. This proposed RSS crawler makes use of gathered domain information to find the location of RSS from seed URLs. Furthermore it adaptively checks the updates from sites of collected RSS with an RSS manager. To do this, the RSS manager keeps information on the update time of each RSS feed.

The rest of the paper is organized as follows: Section 2 offers a brief overview and related work of the search engine and RSS. Section 3 describes the proposed RSS crawler with emphasis on the RSS crawling algorithm for effectively gathering RSS update information and on the structure of the RSS manager for adaptive updates of RSS feeds. Section 4 gives a comparison between our proposed approach and some existing work. Finally, in Section 5, we conclude the paper with remarks on future works.

2. Related Work

2.1. Web Crawler and RSS Search Engine

One of the most important reasons for Google to become a tremendously successful company in the web

service field is that Google has developed a search engine that crawls the enormous web very effectively. Google uses a totally automatic crawler and a specialized page-rank algorithm [6]. The days to register and categorize website information manually by humans are long gone. Most of the web search engines nowadays use some sort of automatic crawling algorithms.

There are researches for developing RSS crawler by various researching group [7-10]. Among them, beta version of Feedshow.com was developed by French researchers in 2006. It gathers RSS with crawler and provides a search engine. Furthermore Bloglines.com and Blogpulse.com are developed with their own RSS aggregator. However most of these services cannot adequately satisfy people's demands and needs, because the searching results are too limiting to fine useful information. Also ranges of the results are limited to their locality, such as Europe or the States. It seems that the problem stems from the lack of some effective crawling algorithm for aggregating RSS and from the disconnection between the web service and the features of RSS which update frequently.

There is also interest in developing the RSS indexer. Brooks and Montanez introduced autotagging and hierarchical clustering into the blogosphere [11]. The automatically generated tags were useful to help users with their choices. However these tags could not be combined with each other in any meaningful relationships, so people had to connect them by hands. It is acknowledged in the paper that the autotagging algorithm needs to be improved.

2.2. Features of RSS

RSS is updated when new content is added on a website or blog. The period of the updates is determined by the preferences of the information provider or the character of the service type. RSS can be located in the same URL-subpath as the blog in some cases, such as WordPress (an installable type blog) and Blogger (a joinable type blog), which are the two most popular blogging tools in the world.

The period of update is important in the collection of information from RSS. The internet has been growing consistently over the past two decades, and a large number of web pages are newly created every day. Furthermore the bloom of blogs results in new contents every day, with frequent updates all over the world. These voluminous newly created web pages far exceed the ability of search engines to crawl and process, so the revisit period for a particular website to check its update may be far longer than the update period of the site itself. This causes deterioration in the quality of search results, because the results may not contain the most recently updated contents until the crawler revisits the websites that appear in the search results.

This situation gets worsened especially in blogs. Many people post their thoughts about life and social issues, and often discuss these issues with other people. However many events happen everyday, so information and issues that people need and are interested in change fast.

Precision and recall are the popular evaluation measures for search engines. Precision is the percentage of related documents with keywords in the results. Recall is the ratio of number of related documents with matching keywords returned by a search to the whole number of related documents. A search engine with a long revisit period often cannot show newly updated information. As a result, the recall quality of the search engine deteriorates. On the other hand, while frequent revisits can improve recall quality, they cause unnecessary network traffic and maintenance costs.

A main feature of RSS in both installable type of blogs and joinable type of blogs is that RSS is located in the same subpath as the blog, and so we can gather RSS easily based on the domain information without visiting all URL links. With the addition of a new module to use domain information, we can improve crawling speed.

3. Proposed RSS Crawler

3.1. Gathering RSS with Domain Information

The main use of RSS is for blogs and news feeds. Between these two types of web services, blogs use RSS mostly widely. Accordingly, we can design an RSS crawler which gathers RSS by considering the typical features of blogs. The most commonly used blogs belong to either the installable and joinable type, such as WordPress or Blogger. In installable type blogs, people install the blog application on a hosted site in their own domain, while people join and get sub level domain access in the joinable type.

People have their own domain and web server in the case of installable type blogs. For example, WordPress has to be installed on a web server, and so its RSS is located in the same sub-path, assuming the owner did not change when they installed it. This feature is also applied with other kinds of installable type blogs. Therefore when the crawler visits a blog, it can recognize which kind of installable blog application is used while reading any web pages on that domain. With proper storage and indexing of these kinds of information, the crawler can find the location of an RSS without visiting all links.

Blogger is a representative example of the joinable type of blogs. In this case, the blog creates a sub level domain with a user ID, so if a user joins with ID “tom” then, the address of the blog might be generated as “http://tom.blogspot.com/”. Joinable blogs which generate sub level domains have a feature that allows RSS to be found in the same sub path location as the blog.

In this paper, we propose a path manager that uses the domain and path information when it crawls. The path manager analyzes and stores information about current

pages, and predicts the location of RSS in the current domain. The structure of the proposed crawler is shown in Figure 1. The crawler in Figure 1 has two features which are different from normal search engine crawlers: (1) a part for comparing domain information, and (2) a part for checking whether the blog is an installable type or a joinable type.

In the first step, the path manager checks that there is a visited upper level domain based on the top-level domain and second-level domain. This helps the crawler find RSS quickly in the case of joinable type blog. Next, the crawler checks whether the blog is an installable type, if there is no matched domain. The crawler identifies an installable type blog based on the pattern of path links and text. These can be analyzed and maintained during the crawling process. If the seed URL is based on either an installable or joinable type of blog, the crawler may find the location of RSS, and it can reduce unnecessary visits to find RSS.

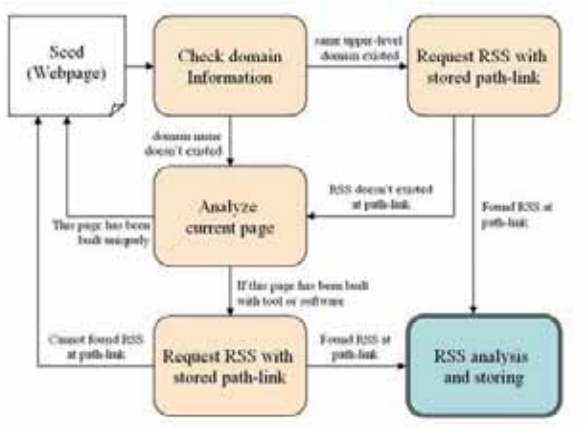

Figure 1. A structure of crawler for gathering RSS.

3.2. Adaptive Revisit Manager

In this subsection we describe an adaptive revisit method to check updates of RSS based on the update period of gathered RSS. Generally speaking, web crawlers revisit gathered websites occasionally to check updates and find errors in URL connections. RSS is more efficient on websites which are frequently updated than less visited websites. Furthermore information consumers are greatly satisfied when the RSS always includes recent information. Accordingly, the meta-blog and RSS reader applications have to provide recent information to satisfy people. The proposed crawler analyzes the <pubDate> element in gathered RSS, and uses it to predict the next update time. The <pubDate> element includes a date and time in the form: "<pubDate>Wed, 16 Jan 2008 01:51:44 +0900</pubDate>". With this information we can determine when the website is updated: daily or on specific day such as on Saturday. The crawler predicts next update time based on analyzed data, and revisits the RSS at that time. This adaptive revisit method is based on the posting pattern of the information provider.

The proposed crawler considers three pieces of information in the <pubDate> element: (1) The update time interval. The crawler finds the time interval of update, e.g., daily or weekly. This can be calculated from date information. (2) The day of the week. Posting a new article is the result of human work. People have their own life patterns, so the analysis of the day of the week can be an important clue. (3) The update time. A frequently updated time is also based on human patterns, and so we can expect that it is an effective indicator. Hence the crawler can revisit during frequently updated time to reduce the gap between posting time and revisit time. Based on the aforementioned heuristics we can expect an improvement in the recall quality of our search results.

Next we introduce an analysis method to be utilized by the adaptive revisit manager. This method analyzes gathered RSS files and applies a statistical method on the day of week and an adaptive method on time. Let P_u denote the probability of future day's update. Let U and $\bar{U}$ be the value of recent updated data (U is constantly 1) and the mean of past updated data respectively. The algorithm estimates the $\bar{U}$ using $\bar{U}=\delta_u/\delta_w$ where δ_w is a whole period for all data and δ_u is a number of days where there exist updated data. Table 1-(a) shows the presence or absence of updated data in a sample RSS. In this example, δ_w is 45 and δ_u is 25, so $\bar{U}$ is almost 0.556.

Table 1. Presence or absence of update in a sample RSS.

Sat.	*Sun.*	*Mon.*	*Tue.*	*Wed.*	*Thu.*	*Fri.*
1	*0*	*0*	*0*	*1*	*1*	*0*
1	*0*	*0*	*0*	*1*	*0*	*1*
1	*1*	*0*	*1*	*0*	*1*	*1*
1	*1*	*1*	*1*	*1*	*0*	*0*
1	*1*	*1*	*0*	*1*	*0*	*0*
0	*1*	*0*	*0*	*1*	*0*	*0*
1	*1*	*1*				

(a)

Sat.	*Sun.*	*Mon.*	*Tue.*	*Wed.*	*Thu.*	*Fri.*
6/7	*5/7*	*3/7*	*2/6*	*5/6*	*2/6*	*2/6*

(b)

The term α is a weight factor that controls the rate of convergence of the algorithm (always at 0.9), and β is a statistical weight factor that is calculated from the mean of update on the day of week. The β can be calculated according to Table 1-(b). The statistical weight factor of Tuesday which is a next day of the latest update is 0.333(2/6) in this example. Finally the probability is estimated using $P_u=\alpha\beta U+(1-\alpha)\bar{U}$. We determine 0.5 as the threshold. Here, the probability value is 0.355. It is smaller than the threshold, so we can predict that there may not exist an update on the next day. After that the algorithm recalculates an update probability of the day after tomorrow (Wednesday). In this case δ_w increases to 46. With the same method, $\bar{U}=25/46 \approx 0.543$ and β is 0.833(5/6), and so P_u is

0.804. We know that most likely there will be an update on Wednesday.

4. Comparison

In this section we compare our approach with some of the similar web services. Table 2 summarizes the comparative results. The similar web service providers include: Google, Feedshow, Bloglines, Blogpulse, and Allblog.

Table 2. A comparison with similar web services.

	Search Engine with Crawler					Meta-blog
	Our approach	Google	Feedshow	Bloglines	Blogpulse	Allblog
Method for collecting RSS	**RSS crawler**	web crawler	RSS crawler	RSS crawler	RSS crawler	register RSS by hands
Method for checking update	**adaptive**	static	static	static	static	adaptive
Times until Update reflection	**short**	long	long	short	normal	normal

As we mentioned in this paper, our approach consists of two major components. (1) The crawler that crawls RSS efficiently with gathered domain information. It reduces useless out-links so as to find RSS fast. (2) Revisit manager that is based on an adaptive and statistical method for checking updates. This helps to reduce the cost for checking the updates, and to promptly reflect the updates as soon as they occur. Google has absolutely nice performance but its method for checking updates takes too much time. Performance of Feedshow is very poor while Bloglines and blogpulse are in good performance range. However Bloglines checks updates once an hour and Blogpulse checks it once a day, thus creating unnecessary checking cost. Allblog is a different kind of service. It is a meta-blog, and people register their RSS to share with others. Its checking update strategy is adaptive according to frequency of RSS update. On balance, our approach can provide efficient performance with low update-checking cost.

5. Conclusion

RSS is the most widely used information distribution technique in the Web2.0 environment. It is an open standard for transferring data efficiently based on XML. RSS is widely used in many fields such as news and blog feeds, and data transferring on mash-up services. However, the state-of-the-practice in the field is that few existing RSS search engines is efficient and effective. As a result, development of better RSS search engines is critically needed.

In this paper, we described the design of an RSS crawler which gathers and updates RSS efficiently. The crawler, the main part of a search engine, is a tool to visit the vast World Wide Web and collect data. Commonly the crawler recursively analyzes out-links of web pages starting from a seed URL, but this method wastes too much time and network traffic to work efficiently for RSS. Furthermore we wanted to design a crawler just for gathering RSS effectively. The proposed RSS crawler in this paper has two main features: (1) It gathers RSS easily based on path and domain analysis of installable and joinable type blogs, which represent the majority of RSS use. (2) It revisits gathered RSS adaptively based on update pattern analysis of the period, day of the week, and time of updates on the target site.

The proposed RSS crawler appears to gather RSS more efficiently, and the adaptive revisit method can improve recall quality of the search results. The proposed method offers the possibility of reducing wasted time on crawling, and improving recall quality. For future work, we intend to implement the proposed RSS crawler and evaluate its performance.

QuickPay Online Payment Protocol

Jian Dai Mark Stamp
Department of Computer Science
San Jose State University

ABSTRACT In this article, we propose a new online payment protocol, QuickPay, which is built as a middleware framework for online payment and other online financial transactions. We provide the general design of the QuickPay system by describing its business and technical goals, system architecture, major players, and the relationships among the players. To show how QuickPay works, we discuss one specific application in some detail. We demonstrate that QuickPay can provide an effective and secure for online payments.

Keywords
Security, online payment, micropayment

INTRODUCTION

Online payment systems are designed to facilitate online purchases involving various amounts of money [3, 5, 8]. Online payments present several challenges, such as Trust between physically separated customer and vendor; anonymity of customer; instant payment; low processing cost; etc. [6, 9].

At present, many online payment systems have been developed. Based on their design principles and characteristics, we can roughly classify them into the following three categories: Token-based Systems [2 8, 7, 10, 12]; Account-based System [1]; and Protocol-based Systems [4].

Based on our analysis of existing online payment systems, we propose QuickPay as a generic online payment application which, in our estimation, provides an optimal tradeoff among the competing demands for security, effectiveness and cost. QuickPay has also been designed so that it can be used for the widest possible variety of commercial activities.

QUICKPAY REQUIREMENTS

We believe the following business requirements are the most critical to the success of a system such as QuickPay.

Openness - QuickPay can accommodate users who use other online payment systems.
High scalability - QuickPay is able to support additional customers and vendors without any impact on existing customers and vendors. This implies that there is no performance bottleneck in the system.
Independence and open plugin - Here, we mean that QuickPay supports different online financial transaction with different sets of protocols. Each set of protocol can plugin to the framework freely and independently.
Isolation - By isolation, we mean that QuickPay's users (vendor, broker, or customer, as discussed below), can have their own implementation for QuickPay's protocols. Their implementations are isolated from each other.
Security at low cost - This implies that QuickPay provides reasonable security (as compared to existing online payment systems), with a low overall cost.
Standard user interface - This means that QuickPay will have a standard user-friend interface for end users.

ARCHITECTURE

QuickPay is designed as a middleware application based on HTTP, Web Services, and other related open source protocols. In addition, we assume that in most cases, customers do online shopping from their own dedicated domains, such as home computers so that we can tie customer "identification" with specific machines. Secondly, we assume that a broker (who is responsible for settling accounts) has much less motivation to cheat as compared to vendors and customers, due to the broker's long-term interest in commissions.

QuickPay defines four main player roles for the system, as discussed below and illustrated in Figure 1.
System Host is the central controller and administrator for the whole QuickPay system. This is the only component that can be trusted by

all other players and it has the most authentication information on the other parts.
Vendor represents anybody (usually an ecommerce website) that is selling products (tangible or intangible) online and intending to use QuickPay to collect payments.
Financial Broker is an entity (typically, a financial institution) that serves to facilitate payments for online purchases on behalf of its customers (i.e., End Users in QuickPay). A Financial Broker is a trusted partner and is expected to have a long-term relationship with the System Host.
End User.is the final player role in QuickPay. In business term, an End User is generally regarded as a person who wants to use QuickPay to pay for his or her online purchase. In technical term, an End User represents an installation of QuickPay's client-side software, which is bonded to a machine (desktop, laptop, Palm, Internet Phone, or other).

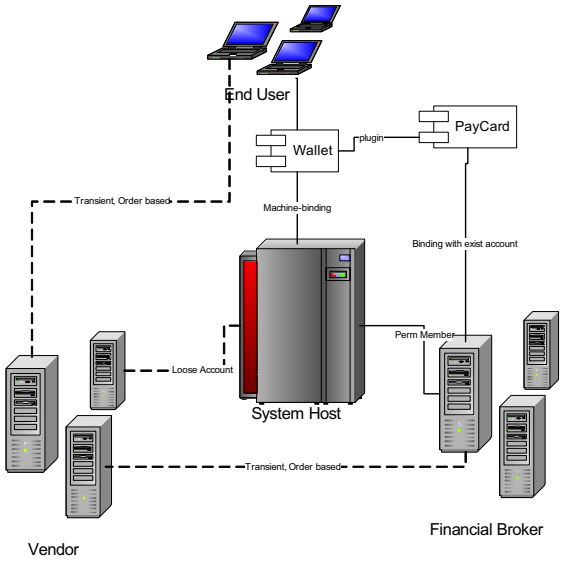

Figure 1

In addition to these player roles, the QuickPay system also defines two client-side software components. The **Wallet** is a browser plug-in software component provided by the System Host. It provides a standard QuickPay client side graphical user interface; maintains the necessary client-side data; and handles all of the online communication between End Users and other parts of the system. A **PayCard** is a Wallet plug-in software component provided by the Financial Broker.

Among these players, the System Host and a Financial Broker have the closest and most fully trusted relationship. Instead of serving End Users directly, QuickPay is designed to work with a Financial Broker, which in turn serves its End Users.

The System Host knows an End User based on the End User's Wallet, which contains a unique identifier assigned by the System Host and is bonded to a single physical machine. The Financial Broker deals with its End Users via PayCards. An End User obtains a PayCard if and only if he or she has an existing account with the host Financial Broker.

Anyone who wants to sell a product or service online can join QuickPay as a Vendor and use QuickPay to collect payments. Theoretically, all a Vendor needs is a unique Vendor ID from the System Host. Note that the Vendor only has an order-based one-time relationship with End Users and Financial Brokers.

QUICKPAY PROTOCOLS

As mentioned above, QuickPay is composed of a set of independent protocols. Considering the fact that it is not possible to cover all the protocols in this short article, we will briefly introduce the support protocols and then use the micropayment protocol as an example to describe some of the most common characteristics of the protocols. See [13] for complete details of the QuickPay protocol.

QuickPay Support Protocols QuickPay defines a set of support protocols. Their main purpose is to take most of the security burden from application protocols so that those application protocols can perform with relatively high security at low cost. For example, in QuickPay, an End User is designed to pay for an order to its Financial Broker indirectly. To support this feature, QuickPay employs an administration protocol, Add-PayCard, which serves to bond an End User (represented by its Wallet) to an existing account in an individual Financial Broker (represented by its PayCard).

Generally, administration protocols run much less frequently but are more critical for overall system security as compared to application protocols. Consequently, the implementation of these protocols can rely on high-security algorithms with relative high cost.

Example: Micropayment protocol. The Micropayment protocol must run at very low transaction cost in order to support mini-sized online orders. To achieve this goal, the QucikPay micropayment protocol is designed with the emphasis on performance over security. In addition, QuickPay shifts some security burden to administration protocols in order to improve the performance of this protocol.

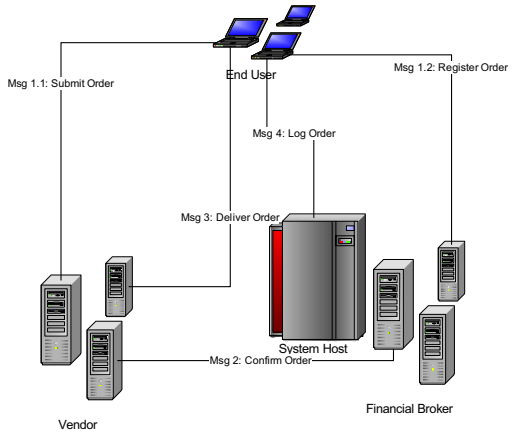

Figure 2

The QuickPay micropayment protocol consists of four steps and 5 messages as illustrated in Figure 2. The process starts when the End User submits an order to a Vendor, as represented by Message 1.1 in Figure 2. Note that this message contains information about the active Financial Broker. Simultaneously, the End User registers the order with the Financial Broker with Message 1.2, the integrity of which should be guaranteed by Financial Broker. After receiving the message, the Vendor will send a confirmation message (Message 2) to the Financial Broker. If the Financial Broker finds that the order has been registered by the End User, it commits to pay for this order on behalf of the End User; otherwise, it will deny the order. The Vendor will then deliver the order to the End User (Message 3) only if it obtains a commitment for payment from the Financial Broker; otherwise, it will deny the order. Once the order has been delivered to the End User, the End User will send a log message (Message 4) to the System Host so that System Host can track the order.

In this Micropayment protocol, all of the online transactions are public and in plaintext format. There is no direct security implementation applied to the transaction of these messages. The payment commitments of the Financial Broker made here are temporal, and will be finally settled in a batch settlement process. Note that the System Host is not directly involved in the payment transaction, but it does monitor the whole process indirectly by keeping track of orders.

DISCUSSION

As mentioned above, the central issue faced by online payment systems is how to achieve a reasonable tradeoff between transaction costs and payment security. Instead of focusing on trying to protect sensitive data at low costs with specialized algorithms, QuickPay is aimed at cutting the transaction cost (and, simultaneously, the value to the attacker) of the sensitive data that is transmitted. To accomplish this, QuickPay implements a set of unique strategies.

Unlike account-based payment system, QuickPay uses device-base (such as IP address) authentication. This greatly reduces the overhead of a transaction. As well known, spoof attack is the main security of such authentication. Besides taking advantage from built-in protection in standard protocol (such as TCP) and the fact that it is difficult for spook attackers to get response for their false request, QuickPay also designed additional protection for such attack. For example, the order-registration design can be used by Financial Broker to filter DoS attack and deny forgery orders from impersonate Vendor. The offline support of System Host can be used to reduce DoS attack against it.

QuickPay supports a finite set of Financial Brokers, whose information is public and static. Therefore, it is easy for a Vendor to identify a Financial Broker and it is difficult for an attacker to commit a false payment by impersonating a Financial Broker.

QuickPay requires a Financial Broker to guarantee the integrity of the transaction between its Payment Card and its host, and the Financial Broker only commits to a registered order. An attacker cannot make a forgery of the order unless he or she can register it, which would, in practice, be very difficult, if not impossible.

For most existing payment systems, the transaction process is linear. If any step in the payment chain is broken, the system is compromised. Suppose that such an application has two steps. If the security risk for each step is

5%, then the overall risk would be almost 10% since

$$10\% \approx 9.75\% = 1-(1-0.05)(1-0.05)$$

In contrast, QuickPay uses a collateral verification strategy. That is, for each payment request, the Financial Broker obtains information from both the End User and the Vendor. Under this approach, to obtain a 10% security risk for the overall process, each step in QuickPay can afford a security risk of about 33% to each component, since

$$10.9\% = 0.33*0.33$$

In other words, QuickPay can tolerate a much looser security implementation, which allows for much lower transaction costs, as compared to traditional payment systems.

.

Protection of passwords and other crucial user information is one of the most critical security issues (especially in account-based system), and it is costly to protect users' personal information during a payment transaction. In QuickPay, all of the players except for the Financial Broker do not have End User personal and/or Financial Information and there is no need to exchange such information during payment transactions. As a result, QuickPay itself bears no direct cost to protect such security-related information.

With many existing payment system, customers need to submit some credentials to vendors and those credentials potentially can be abused by malicious vendors to, for example, make fraudulent transaction. In QuickPay, the payment commitment is based solely on individual orders. Consequently, a commitment cannot be readily reused to collect any additional fraudulent payment.

CONCLUSION

In this article, we outlined QuickPay, an efficient online payment protocol designed for different types of online payment and other financial transactions. By identifying and focusing on the most common characteristics of different online payment situations, QuickPay can significantly outperform existing online payment applications. We believe that QuickPay satisfies the core requirements necessary to become a widespread financial solution for a variety of online business activities.

Sharing Application Logic across Programming Language Boundaries

Dennis S. Patrone Bina Ramamurthy
Department of Computer Science and Engineering, University at Buffalo
{dpatrone, bina}@cse.buffalo.edu

Abstract – As network-enabled devices and computerized services become ubiquitous in a breadth of applications, it is imperative that distributed system architectures enable components to communicate effectively and efficiently in heterogeneous environments. Standardized application-level network protocols are currently the most popular communication solution but a significant amount of flexibility is then lost at the network boundary. We propose an interaction model for distributed systems that will allow application knowledge in the form of programming logic to be shared across platform and programming language boundaries. We define an XML-based meta-language for describing application logic which is not targeted toward any one specific programming language, environment, or machine stack (real or virtual). Distributed applications can use this specification to exchange logic such as the details of application-level protocols in heterogeneous environments at runtime. This removes the distributed system's dependency on standardized and generalized application-level protocols. Distributed systems can also exchange algorithmic solutions to specific problems (knowledge dissemination), removing the need for any network-based communications to a centralized server. These freedoms will ultimately enable a distributed system that is more efficient, scalable, and adaptable than the current state of the art.

1. OVERVIEW

Distributed system components need to be able to communicate effectively and efficiently with each other regardless of their respective hardware platforms, operating systems, and programming languages (henceforth referred to in this paper simply as a system's "environment"). Current state-of-the-art in distributed system architectures provides only a partial solution. These systems generally achieve environment-independence by defining standardized, over-the-wire protocols that are targeted toward data sharing and request/response communications. Any environment can communicate with any other supported environment across network boundaries using the chosen standardized protocol. However, a significant amount of computational expressiveness is lost from the original programming language due to the inability of systems to share application logic across these language boundaries.

We propose an architecture which will allow distributed system participants to share not only data and method invocation requests, but actual application logic among heterogeneous components. We define an Extensible Markup Language (XML)-based meta-language, called the Application Logic Markup Language (ALML), which will allow distributed applications to share application knowledge in the form of data manipulation and flow control across language boundaries. The logic shared can include service-defined, client-side execution logic to create and modify application-level network protocols, allowing services to tune application-level protocols at runtime based on system-wide concerns such as usage patterns, network stability, and system loads. We hypothesize that a distributed system built on an ALML foundation will provide the basis for a more efficient, scalable, and adaptable distributed system than is possible using current state-of-the-art in platform- and language-independent distributed system technologies.

2. MOTIVATION

Current distributed technologies can be categorized into two broad architecture paradigms: message passing architectures and mobile code architectures.

2.1 Message passing architectures

Message passing architectures (e.g., CORBA [1], Web Services [2]) define system interfaces and network protocols to share data and remote procedure calls among heterogeneous components. Since the network traffic is defined as part of the standard, these architectures are often environment-independent and highly interoperable. They achieve this independence and interoperability at the cost of network flexibility. Their protocols defined independently of specific applications, and are therefore generally unable to exploit knowledge about a specific system's usage patterns, data flow, or other critical information which could help it potentially operate more effectively.

2.2 Mobile code architectures

Mobile code architectures (e.g., Java's Remote Method Invocation (RMI) [3]) on the other hand allow executable code to be shared from one distributed network node to

another. This code can contain implementation details on how the sender is going to modify the application-level protocol to improve performance for a given situation. The code could also contain algorithms that instruct the receiver how to perform a given function itself. These architectures are generally homogeneous in nature, at least at the communication level. This homogeneity is required for both ends of the communication pipe to be able to interpret the instructions that are communicated. While significantly more flexible with respect to controlling network bandwidth consumption and overall system performance (e.g., CPU utilization, remote request latency, etc) than message-passing architectures, expecting anything but prototypes and the smallest of real-world systems to be homogeneous is unrealistic.

2.3 A hybrid approach

Our goal is to create a distributed architecture that is a hybrid of these two approaches. This will be accomplished by combining the environment-independence of the message passing architectures with the protocol-independence of the mobile code architectures. As a first step, we are proposing the ALML specification as a "virtual language" to capture the application logic generally encoded in language-specific source code. An ALML-based distributed system is an environment-independent architecture with many of the benefits of a mobile-code architecture. These benefits include the ability to change network protocols at runtime and to inject new "knowledge" into clients at runtime. The significant distinction from other mobile-code architectures is that the information shared across the network in ALML is defined in a higher-level conceptual description of application logic rather than code compiled for a specific (virtual) machine stack. This logic description enables the system developer's intent to be interpreted and executed on the client side in any environment. Ultimately, this enables a mobile code architecture which also is environment-independent.

3. RELATED WORK

The Jini Network Technology architecture exhibits many of the dynamic benefits ALML is striving to reach [4]. However, Jini achieves these benefits in a "virtual platform-dependent" way, relying on a Java Virtual Machine (JVM) to interpret the compiled, shared application logic defined in Java's bytecode. Even though Java and .NET's Common Language Runtime (CLR) are technically platform independent by themselves, they are defined as different virtual machines and are not portable across their virtual boundaries. That is, Java bytecode will not execute on the CLR, and .NET's Common Intermediate Language (CIL) will not execute on a JVM. By specifying and sharing logic in portable XML, ALML allows the same logic representation to be interpreted in both, as well as any other existing and yet-to-be-defined, environments.

Reference [5] describes the general use of XML in distributed systems: a method to share data across the network. The XML specification allows application-specific tags to be defined. These tags are used to qualify data for storage and transfer in an environment-independent way. However, XML is simply a file-format specification and therefore details such as how to get XML files from one component to another in a distributed system are not included. Also, the meaning of the XML tags are not generally codified in XML but rather specified externally. So while XML may help applications understand distributed data it does not solve the data distribution problem. ALML adds the architecture-defined tags, their meanings, and bootstrapping protocols necessary to enable a distributed logic-sharing system.

Reference [6] proposes using XML to describe the behavioral specification (preconditions and postconditions) of using distributed resources. This is one step toward allowing distributed systems to better self-organize, but still requires compile-time knowledge about the application wire protocol in order to share this information. This approach only describes what will happen; it does not allow the service to describe how it will happen. XML has been proposed as its own programming language (e.g., [7], [8]). These languages have been targeted at their own unique runtime environments. Our language is not targeted at any one runtime environment but is a formal way to capture application logic that can be interpreted and executed in any number of environments. Turning that logic into an executable process is left to the end-consumer, maintaining the portability across environments. XML has also been used to define purpose-specific languages for modeling various processes in different applications (e.g., [9], [10]). ALML is an attempt to develop a general-purpose language which can be used by any application to describe the necessary flow of control and application logic in order to achieve some goal. Rather than defining purpose-specific XML tags, ALML defines generalized programming structures and flow-control statements allowing distributed systems to develop their own specialized capabilities.

4. APPLICATION LOGIC MARKUP LANGUAGE

The ALML architecture, shown in figure 1, is built on top of existing (and yet-to-be-defined) environments. The ALML specification and its corresponding XML schema definition (XSD) define the ALML logic grammar. A wire protocol for ALML-aware clients to "find and bind" with ALML-enabled services is included. A library (defined in ALML) provides generally useful utilities to ALML clients.

And an ALML engine can be included to process and interpret ALML logic definitions on the client-side.

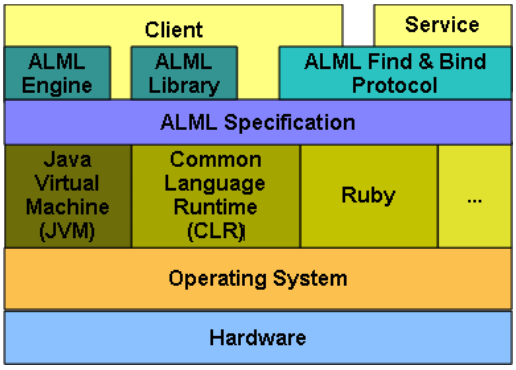

FIGURE 1: A HIGH-LEVEL VIEW OF THE ALML ARCHITECTURE.

While services can utilize ALML internally, this is not a requirement. Services need to provide an ALML-defined proxy via the find-and-bind protocol but need not execute the proxy logic at runtime themselves. The ALML proxy provided to the client will be interpreted in the client's environment, executing whatever application logic that service implementation defines.

4.1 The ALML specification

The ALML specification is an XML schema definition (XSD) which defines the ALML grammar and upon which the ALML system is built. The XSD includes standard object-oriented concepts including class definitions, packages or modules for grouping related classes, member variables, and methods. Standard flow-of-control constructs are also provided (e.g., looping, conditionals). The ALML specification is strongly typed, defining it own set of primitives. Standard visibility constructs are also provided.

4.2 The ALML find-and-bind protocol

The ALML distributed system will require a bootstrapping process which will allow clients to find desired services on the network and obtain the ALML-based proxy definitions at runtime without human intervention. While the specific details of this protocol have not yet been defined, it is expected that the specification will at a minimum provide multiple ways to locate a desired service such as the capabilities a client desires, definition of service attributes, and specific service addressing. The protocol should also operate over both UDP (broadcast for locating on a local network) and TCP ("well-known" locations for fixed installations and operation across routers and firewalls. Finally, the protocol will utilize widely accepted and supported application-level protocols (e.g., HTTP) and addressing mechanisms (e.g., URI) when appropriate.

4.3 The ALML library

The ALML library contains a set of classes that are guaranteed to be available to all ALML-compliant execution systems. This library provides useful capabilities that ALML services can make use of without implementing a significant amount of ALML code themselves and without requiring an extensive amount of XML to be downloaded to clients each time an ALML service is invoked. The library also provides hooks for ALML engines to provide certain capabilities which are tied to the specific client-side environments. The necessary library classes are still to be determined, but it is expected that standard mathematical operations (e.g., sin, cos, sqrt), networking objects (e.g., sockets), and standard input and output mechanisms will be a part of the toolset.

4.4 The ALML engine

An ALML engine is implemented for each supported environment. It is responsible for interpreting the XML-defined logic into environment-specific executable instructions at runtime.

5. LIZARD

A proof of concept system code-named Lizard is currently under development. The system implements core components of the ALML architecture in Java. It is being used to help identify required library classes and gaps in the ALML specification.

The proof-of-concept system is currently comprised of two parts. The first is the ALML XSD and a set of Java classes generated by JAX-B to operate over ALML XML files. The second is a specialized Java class loader that per request 1., converts a local ALML XML file into Java source file, 2., compiles the generated Java source file using the standard Java compiler javac, and 3., loads in the newly-generated class for client applications to use.

This particular implementation is not a requirement of an ALML engine; this is only a reference implementation. The extra step of generating source and compiling it using a Java compiler adds more overhead than having the ALML engine directly interpret or internally compile the ALML XML. However, this approach was chosen in the interest of saving development time. Presumably once the specification is well-defined, future implementations can focus more on runtime performance and less on ease-of-implementation.

As the system evolves, we plan to completely define the basic requirements for the ALML system and library. Currently only flow of control statements are supported. We also intend to define and implement a find-and-bind capability, including the ability to download ALML-related

files at runtime. Currently the system expects specific XML files in the local standard class path.

6. EFFICIENCY, SCALABILITY, AND ADAPTABILITY

We hypothesize that a distributed system architecture that supports sharing application logic will lead to systems that are more efficient, scalable, and adaptable than systems based on standardized network protocols. Distributed systems based on standardized network protocols by definition cannot modify network communications. These systems utilize compile-time bound client-side proxies—the code that communicates with the server over the network on the client's behalf. They are bound to the client at compile time since the proxy details are completely defined as part of the architecture's protocol standardization. Distributed systems that are capable of sharing application logic at runtime (mobile code) can exploit situational knowledge by deferring client-side proxy implementation details until runtime and changing them at any time. The details can then be tuned to any specific criteria which is important to the specific system (e.g., minimize network utilization, reduce latency, improve scalability).

6.1 Improving efficiency

Efficiency can be measured in a number of different ways: network throughput, CPU utilization, memory footprint, power consumption, etc. Every application will have its own criteria and thresholds for acceptable performance across scarce resources. Every protocol and usage pattern will affect different performance measurements uniquely. Selecting one generalized, standardized protocol will introduce a design bias and cannot possibly efficiently cover every situation. A system which allows services to provide mobile code to define smart proxies at runtime enables the system to react and adjust to changing situations.

For example, consider a simple banking distributed application with a Loan object that has three methods:

```
void makePayment(double amount);
double getBalance();
double getPayoffAmount();
```

Ignoring the complexities of exception handling and synchronization in distributed systems, we assume "makePayment" reduces the loan's principle by "amount" less any interest payments (also ignored here). The method "getBalance" return the loans current balance, or principle yet to be repaid. The method "getPayoffAmount()" returns the total amount to payoff the loan in one payment (assumed to be the principle possibly plus some interest and/or bank fees).

In defining an application-level network protocol, we must consider the expected usage of the Loan object. If we expect methods to be called individually and uniformly then a simple request-response messaging system per method may be appropriate. But if we expect the loan object to be utilized in a batch processing system where "makePayment" will be called n times (where $n > 1$) before a call to "getBalance" we may be able to significantly improve system performance by locally caching the total of all "makePayment" calls on the client side, and then making a single remote "makePayment" call to the service with the cached total as the first step in a "getBalance()" or "getPayoffAmount()" request. This level of batching will reduce network utilization by saving (n-1) "makePayment" requests being sent across the network. It will also reduce CPU utilization on the client by saving (n-1) marshalling and unmarshalling of remote requests. It further reduces the CPU service load by also distributing the logic for adding the payment (n-1) times to the client system. Finally, it reduces system latency by saving (n-1) network round-trips. And an even smart proxy could contain the logic for both proxy types, and chose the appropriate protocol based on usage patterns to even further improve overall system performance.

A mobile code-based architecture does not automatically solve the efficiency problem but rather provides a framework in which system designers and software engineers are able to solve distribution issues in a domain-specific and application-aware way.

There is extra cost associated with setting up a connection in a mobile code-based architecture, especially if that code is interpreted. There are additional up-front costs with respect to the network as the proxy code is downloaded. There are additional costs to CPU usage as the proxy code is compiled or interpreted on the first time it is used. There is also additional latency introduced in the initial call as the mobile definition is downloaded and interpreted. These costs, however, should be constant and therefore independent of n. Furthermore, in special circumstances system clients could also be seeded with initial proxies to further reduce initial connection costs when required.

6.2 Improving scalability

As discussed in section 6.1, tuning application-level protocols based on system usage can reduce demands placed on specific resources and/or distribute the processing of a distributed system, allowing the same software and hardware to provide greater capacity. Even so, if that capacity is reached, mobile code-based smart proxies can continue to help by providing the ability to redirect entire services, individual methods, and even specific requests across multiple servers helping systems achieve scalability.

These redirections can be based on past performance, current situations, or overall system goals—and all managed internally to the smart proxy on the client, but without tight client coupling. In some instances, the smart proxies can contain the entire logic to perform algorithmic-based services, further distributing the execution of a service across client machines, but maintaining the algorithm implementation definition at the service. If the algorithm needs to be updated in the future, the single service implementation is updated and the new algorithmic solution will be automatically pushed to all clients. This maintains the service distribution while helping with system maintenance.

6.3 Improving adaptability

As detailed in section 6.1, a mobile code-based architecture has the potential to enable smart proxies. These smart proxies, in turn, enable a distributed system to adjust runtime, application-level protocols to changing system demands. Section 6.2 describes how a mobile code-based architecture can also aid in adaptability when a service method or set of methods have algorithmic solutions. The algorithmic solution can be provided in the proxy, removing the need for any client-side communication back to the original service. The service is in effect "teaching" clients how to perform the service for themselves. This is very adaptable as clients can learn new "skills", and services can automatically update clients with improved algorithmic solutions, code the manage additional requirements or to handle emerging issues by changing the proxy implementation being provided.

7. CONCLUSIONS AND FUTURE WORK

We have proposed the Application Logic Markup Language (ALML) XML-based specification as a method for distributed applications to share application knowledge in the form of data manipulation and flow control across programming language boundaries. Our motivation for this work is to create a distributed system architecture which is capable of creating more efficient, scalable, and adaptable distributed systems than architectures based on standardized network-level protocols can. We have developed a proof-of-concept to show that describing application logic with an XML schema and executing that logic within a specific environment is possible. This is currently a work in progress. We need to completely specify the ALML language and determine if and how ALML can take advantage of environment-specific libraries and target platforms' native capabilities. A find-and-bind protocol to allow distributed systems to configure at runtime must also be defined. With mobile code comes great security concerns and these must also be addressed. Overall efficiency of the ALML specification must also be considered. For example a versioning mechanism for ALML documents may be appropriate in order to allow ALML engines to reduce redundancy when downloading and interpreting ALML files. Finally, we must provide ALML engine implementations in several diverse languages to show the portability and efficacy of ALML.

Synergizing Collaboration and Reuse in Software Engineering

Stefan Seedorf*) and Oliver Hummel†)

***Abstract*— Reuse is widely considered key to improving software productivity and quality. It appears in various forms – ranging from independent binary components to highly abstract knowledge codified as design patterns. Common to all these approaches is that they involve different people working together to construct reusable assets and adapt them to work in various contexts. In that sense, reuse is impossible to achieve without collaboration. In this paper, we therefore claim that collaboration should receive a higher profile in reuse. First, we investigate the collaborative aspects in two selected reuse approaches. We then show how they can benefit from collaborative tools, i.e. wikis and collaborative development environments, and propose a novel integration of the latter with recently developed component retrieval systems.**

I. Introduction

Software reuse has been assigned a pivotal role in substantially improving development cost, software quality and time-to-market [1]. With the vision of software reuse solving the "software crisis", many new development paradigms, methods and tools have been developed over the years. Nearly four decades after Software Engineering emerged as a discipline, reuse has retained most of its relevance in both academia and industry. Reuse approaches have been successfully adopted in a number of instances, e.g. Component-based Development (CBD) [2] and design patterns [3]. However, its interpretation has gradually shifted towards embracing any kind of knowledge that is reused during the development process [4, 5].

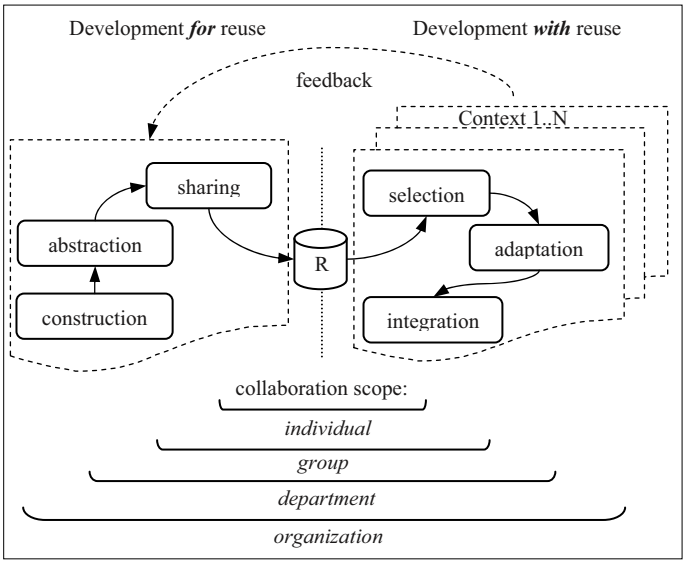
Although it has long been recognized that reuse is not only a technical but also a cognitive and social problem [6], the collaborative character of reuse has remained largely uncovered. Software development processes have recently become increasingly distributed since often geographically dispersed teams have to work together on large-scale development projects [7]. That is why issues arising with collaborative software development (CSD) have started to play a key role in software engineering research [8]. Collaboration is particularly relevant in the field of software reuse because it typically involves different stakeholders working together horizontally, by crossing organizational boundaries, and vertically, by cutting through different aspects of software engineering processes.

In this paper, we therefore investigate how software reuse approaches can be leveraged by taking a collaboration perspective. The paper is separated into two main parts: In section two, we study the fundamental relationship between collaboration and reuse. We analyze two cases in order to better understand the role of collaboration. In section three, we then show how collaborative technologies can be applied to improve recent component reuse technologies. Finally, we conclude by summarizing our findings and identifying directions for future work.

II. Relationship between Collaboration and Reuse

Systematic reuse is commonly split up into the two dimensions development *for* reuse and development *with* reuse [9]. Development for reuse deals with the creation of reusable artifacts, while development with reuse deals with their utilization in other contexts. The generic process steps included in these dimensions are depicted in Figure II.1. First, a software artifact is initially constructed with or without the intention of reusing it in other contexts. However, in order to actually make an artifact reusable there is always some kind of abstraction involved [10, 11]. Subsequently, the artifact is privately or publicly shared, e.g. by publishing it in a repository. This will enable other people to locate the artifact as a candidate for reuse. Development with reuse involves the selection of a suitable artifact, which is subsequently adapted to meet the requirements of a specific context and integrated into a software system [10].

Collaboration between individuals, groups, departments and organizations can be observed within the reuse phases as well as at the transitions between them. In most successful reuse scenarios, a dynamic interaction between development for and with reuse can be observed. In order to examine this relationship in more detail we take a closer look at collaboration in two particular cases: First, we analyze design patterns as a highly



II.1 Reuse process

successful example of knowledge reuse. Second, we investigate the collaborative aspects of product-line engineering.

A. Case 1: Design Pattern Reuse

Background. Inspired by work of Christopher Alexander in civil architecture [3], design patterns emerged in the early 1990s as a highly successful technique for reusing software design and architectural knowledge. A small group in the object-orientation community came up with the idea of composing a catalogue of recurring designs that would assist developers in writing object-oriented software. The first systematic collection of design patterns was published in the popular "Gang-of-four" book [3]. Today patterns are one of the most prominent examples for high-quality knowledge reuse. A pattern describes a solution to a common design problem [12]. Recurring experience about a domain is distilled and captured in a way that makes this knowledge easily acquirable by someone who does not have it [13]. A pattern description consists of several elements: a pattern name, a description of a problem, a solution, a context in which the solution works and discussion of the consequences. It is usually documented in text form, and optionally enhanced by diagrams and sample code. Hence, a pattern is not a software artifact that can be reused "as is", instead always needs to be located, assessed and interpreted by one or more developers before it can be applied to a specific context.

Reuse process. Although patterns should not be seen as "ready-to-use" recipes, they allow large scale reuse of development experience. A design pattern may capture the experience of just one developer; nevertheless it can be applied millions of times [14]. The conception process follows a typical scheme: Since designing software is a highly complex activity, developers use abstractions to decompose the problem into smaller, more manageable parts. The same or similar design decisions are made for recurring problems. Since some of the designs turn out to be better than others, learning processes are triggered. While a developer uses reflection-in-action and gains more experience, she is able to make tacit knowledge about "good designs" explicit.

Once this kind of knowledge is conceptualized and documented in the form of a pattern, it can be shared with other developers. This can be done by publishing pattern catalogues in books or - in a more participatory style – using Wiki systems such as [15]. If other developers encounter a design problem, they can search these media to investigate if a similar problem has been solved earlier and been described as a pattern solution. Usually, developers are able to narrow down a list of patterns to a few interesting candidates. After carefully weighing the costs and benefits of these candidates, one is selected and applied to the problem at hand.

More experienced developers will be able to recall suitable patterns and instantly decide about their suitability. Since they have embodied the necessary knowledge, they can effectively apply a wide range of patterns in various contexts. As part of a feedback loop, the experiences made by applying patterns can also be made explicit to create more specialized patterns or to guide fellow developers.

Role of collaboration. Pattern reuse is characterized by collaboration at different stages. First, a new pattern needs to be conceptualized by one or more developers. Despite the fact that a single developer may have the initial idea and knowledge required to express a solution in the form of a pattern, it is likely that it emerges when interacting with other developers who encounter similar problems. A pattern is typically the result of ongoing discussions about "good design solutions" to reoccurring problems. In that sense, patterns capture collective developer experience.

When a solution has repeatedly proven successful in several cases, it is worth describing and publishing as a pattern. Patterns can be shared by work teams and departments, but also by larger communities. An example for the latter is the first Web-based wiki, also known as Portland Pattern Repository, which was constructed by Ward Cunningham in 1995 to allow patterns to be collaboratively edited by an online community [15]. Unlike choosing books or online repositories to publish patterns, wiki systems provide a highly interactive approach to knowledge exchange. Not only are developers with the same interests invited to contribute patterns, it is also much easier to enrich the knowledge base. Other developers can discuss the pros and cons, provide links to related patterns or add examples in other programming languages. Such interactive ways of collaboration across organizational boundaries during the construction and abstraction phase provide a powerful example for a Community-of-Practice [16].

However, sharing a pattern is only one side of the reuse story, because it needs to be identified and interpreted before it can be successfully applied. Developers need background knowledge to understand a pattern, e.g. in object-orientation and modeling notations such as the UML, and they have to understand the problem space to decide about its suitability. Just as design is seen as a collaborative effort, so is the decision process of selecting and applying patterns. To this end, patterns become a focal point for both individual and collective learning. This leads us towards a key role of collaboration in pattern reuse: "Not only do patterns teach useful techniques, they help people communicate better and reason about what they do and why" [14].

To summarize, we can distinguish two major forms of collaboration in pattern reuse: on the one hand, they provide a scalable collaborative approach to transferring their know-how across projects, departments and organizations. On the other hand, using a common language during design supports developers in communicating architectural and design knowledge. This allows developers to collaborate more effectively in critical stages of the development process.

B. Case 2: Product Line Engineering

Background. Many software developing organizations create "a family of similar, but slightly different, systems rather than a single system" [17]. There is a potential to reuse the overlapping functionality of these systems, which cannot not be tapped when developing system by system individually. Software product lines (or system families) were thus introduced to plan software reuse right from the start. A software product line is a set of similar software systems which are developed and maintained together [18]. It typically consists of a product line architecture, a set of software components and a set of products [19].

On the one hand, developing a product line can only be useful when the systems have at least some features in common. This is typically the case when choosing systems from the same

application domain. The commonalities of systems therefore constitute the skeleton of a product line. On the other hand, there are also variabilities that need to be taken into account. Variable features are incorporated into the software assets to make them customizable for individual systems. In Product Line Engineering (PLE) it is therefore crucial to set the correct scope of a system family and to plan the commonalities and variabilities ahead so that the necessity of subsequent changes is diminished. Hence, PLE has a deep impact on all phases of Software Engineering processes, starting with requirements management. A number of methodologies for PLE have been proposed, such as Foda [20], PuLSE [21], and KobrA [17].

Reuse process. PLE is separated into two independent phases: First, domain engineering deals with identifying the commonalities and variabilities of the scoped products. A domain-specific architecture with reusable components is developed. Second, application engineering is the process of developing individual products on the basis of a product line architecture. Domain engineering is development for reuse, while application engineering is development with reuse.

Unlike in individual systems development, the requirements of a product family have to be collectively identified and analyzed. Some of the products may already exist, others may be planned in future. This makes the definition of a product line's scope difficult [21]. It is thus recommended that everything included by a concrete product is part of the domain [22]. During domain analysis a reference model is built from the concepts and relationships in the scoped domain [23]. Together with the commonalities and variabilities it frames the overall product line architecture. The architecture is decomposed into reusable parts that will be integrated into the individual products. All reusable parts follow a generic design by capturing variability in the domain. All reusable artifacts and documentation are made available through a mutual component repository [23]. In application engineering, only requirements of the dedicated product are relevant. In the ideal case all artifacts have been constructed during the domain engineering phase and can be taken from the repository [23]. In order to meet the individual product requirements, the generic artifacts are customized according to the previously defined variation points. However, the reuse process is not as straightforward in reality, because product requirements are constantly evolving [24]. In an evolutionary approach, the ability to provide feedback from individual product development to product line development is thus crucial.

Role of collaboration. Developing a software product line is always a joint effort which involves stakeholders from different organizational entities as well as disciplines. The collaborative character of PLE, however, has only recently been stressed [25, 26]. In a systematic approach the product line scope and supported features have to be negotiated previous to constructing or reengineering reusable artifacts. Since the required business and technical knowledge is distributed among many participants, a mutual agreement has to be reached first. To this end, "a collaborative approach can facilitate understanding the different stakeholder concerns and converging on mutually acceptable solutions" [26]. EasyWinWin [27] is proposed as an interactive negotiation technique for reaching satisfactory agreement among the stakeholders. Features and domains are prioritized according to the expected costs and benefits. It is then decided what becomes part of the reuse infrastructure.

Later, domain and application engineering activities have to be coordinated so that double work is avoided. On the technical side, the challenges are addressed by component-based approaches such as KobrA [17]. Precise specifications make it possible to develop components by independent providers and reassemble them during application engineering. Splitting the software lifecycle into domain and application engineering requires feedback between the two phases – changes in the latter have to be communicated to the domain layer. If these aspects of PLE are not carefully considered, it is possible that the initiative fails to bring the promised benefits.

C. Discussion

In the previous subsections, we analyzed the role of collaboration in two reuse approaches that appear very different at first glance. Design patterns are a leading example of reusing highly distilled knowledge in the development process. PLE, on the other hand, deals with systematically planning the reuse of software artifacts in a family of similar products. In the first case, software development is primarily seen as a creative, agile process. The collaboration between producers and consumers can be characterized as loosely coupled, because it is not necessary for consumers to provide feedback. Nevertheless advancements in design patterns are mainly driven by open communities who contribute to the overall knowledge base and help to guide other developers.

In contrast, the second case highlights the engineering perspective on software development. Here, collaboration between domain engineering and application engineering occurs not only during the inception phase. Since the requirements are continuously evolving, changes in individual applications have to be propagated back to the domain level, driving the evolution of the product line and thus naturally require a tight integration of collaboration techniques.

At second glance, however, both approaches expose similarities in terms of the underlying knowledge processes. Reuse can be interpreted as a collaborative knowledge construction process where knowledge is not seen as a commodity to be consumed, e.g. by retrieving artifacts from a reuse repository, but something that is collaboratively designed, constructed [28] and consumed. Knowledge about the application domain, architecture or design does not reside in one person's head but is distributed across disciplines, work teams or organizational entities. Therefore, the reuse process has to be viewed as a process of knowledge formation, where a shared mental model is created and transformed to match an artifact's varying contexts. The challenge lies in creating an environment in which the underlying knowledge processes such as externalization and combination are effectively supported (cf. [29, 30]). To this end, communities-of-Practice [16] provide flexible and informal ways of collaboration in both design pattern reuse and PLE. They encourage people with the same interest to engage and interact in a group, which facilitates knowledge-sharing and social learning.

After characterizing software reuse as a collaborative process, we will now look at how collaborative technologies can be enhanced to improve current reuse practices.

III. Enhancing Collaborative Technologies to Support Reuse

In section two we argued that reuse is an inherently collaborative process. While this insight may appear apparent to many reuse researchers and practitioners, it nevertheless has a profound impact for the emergence of new reuse methods and tools. We therefore introduce two key collaborative technologies in software engineering and describe by example how they can be enhanced to support core reuse tasks.

A. Wikis

In recent years, wikis have emerged as one of the most successful collaborative technologies [31]. Wikis enable Web content to be simultaneously edited by multiple users. One of the core principles is to encourage every reader of a wiki page to become an author as well – simply by editing the page content using a wiki language. Because of the low entry barriers communities have now got the opportunity to asynchronously work on a common subject of interest. Nowadays the most successful example of wikis is the Wikipedia. Wikis have also been widely adopted for the documentation of software projects by both open-source communities and enterprises.

Hence, wikis are an interesting candidate for addressing collaborative issues in software reuse. Interestingly, the very first wiki engine was developed for the shared development of design patterns (see Sec.2.1). In most cases, however, wikis are solely employed as a project documentation tool supporting the accessibility of unstructured knowledge. For example, wikis often serve as a simple problem/solution database. Only recently, has the wiki paradigm been extended to realize more sophisticated applications. These extensions already address specific reuse problems or could easily be easily customized to do so. Advanced usage scenarios of wikis in software and knowledge reuse include:

1. Requirements engineering in PLE
2. Semantic matching of software components
3. Reusing knowledge models across software projects

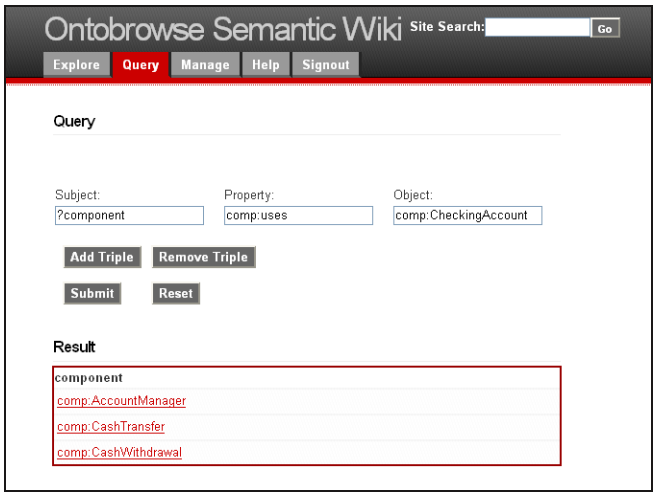
We will now discuss these advanced applications of wikis in more detail.

Requirements Engineering in PLE. Wikis have already been proposed as a lightweight approach for requirements elicitation, analysis, specification and management. The DisIRE (Distributed Internet Based Requirements Engineering) method employs Wikis for the distributed management of requirements [32]. The wiki pages are structured in a way that a requirement specification can be processed by external tools, e.g. to carry out a cost-benefit analysis. DisIRE can be applied to support the PLE scenario where the requirements of several products have to be managed as one (see Sec. 2.2). This is due to the fact that PLE is always a distributed process where the requirements need to be negotiated by multiple stakeholders. Wikis are also an appropriate tool for managing ongoing requirement changes, which is indispensable for long-term projects such as PLE.

Semantic component matching. Component matching is not an obvious feature of wikis. Nevertheless, recent semantic extensions have made it possible to utilize wikis as collaborative databases with machine-interpretable knowledge. Instead of purely processing text information as in traditional wikis, page content can now be decorated with semantic metadata. In this case, a knowledge model can be automatically extracted. This new generation of "semantic wikis" enables new applications in software engineering.

Ontobrowse semantic wiki has been specifically developed to support the sharing of architectural knowledge [33]. Pages are interpreted as entities, i.e. concepts, relations and objects. The wiki is thus no longer a "small web of formatted text pages" but a knowledge base that can be automatically processed. In Ontobrowse, a knowledge base is clearly separated into two parts: a knowledge structure defined by one or more ontologies (concepts and relations in a domain of interest) and instance knowledge defined by individual objects with their property descriptions. It is furthermore possible to add and modify text descriptions for every page as in traditional wikis.

In order to apply Ontobrowse to component matching, one has to set up the wiki in two steps. First, an ontology for software components has to be specified. It defines a terminology for describing software components, e.g. "component", "interface", "method", "input", "output" and "business object". Second, a plugin is created which maps component descriptions in a specific format (e.g. Java enterprise beans) to the ontology. The wiki can then be configured to automatically crawl for component descriptions in this format, extract the content and fill the wiki's knowledge base. Once the knowledge base has been initialized it is possible to formulate a specification-based query, e.g. for all components that use the business object "CheckingAccount" (see Figure III.1).



III.1 A semantic component query in Ontobrowse

The wiki provides a user-friendly frontend for specifying component queries and navigating component descriptions. Once a suitable component has been identified it can be easily retrieved if its location was inserted into the knowledge base.

Reusing knowledge models. In semantic wikis such as Ontobrowse it is not only possible but also encouraged to reuse the knowledge structure. Software projects setting up another wiki instance are able to reuse existing knowledge models (ontologies). Thus, reuse at the knowledge level is achieved.

Moreover, other knowledge models covering additional aspects of a software project – such as requirements and project management – can be added and refined as soon as they are required for a specific task.

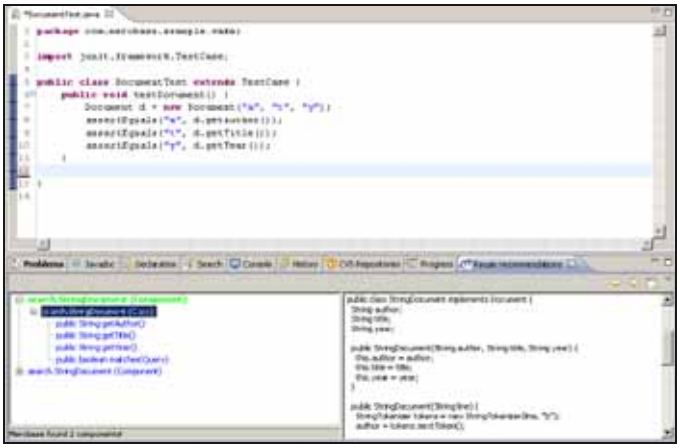
B. Collaborative Development Environments

In recent years, Collaborative Development Environments (CDEs) have appeared as a new category of development tools focusing not on individual productivity but supporting collaborative activities appropriately [34]. Typical features of a CDE are a versioned code repository for multi-side development, an issue tracker, project management and analysis tools, requirement management and documentation tools (e.g. wiki engine). Most platforms provide a Web interface as well as plugins for Integrated Development Environements (IDEs). Prominent examples of CDEs include CollabNet/Sourceforge[1], Codebeamer[2] and GForge[3].

Although a CDE allows many software projects to be managed in parallel, the potential for reuse across projects has yet to be recognized. So far CDEs provide little support for collaborative reuse of software components and code since common configuration management software such as CVS or SVN does not include support for targeted retrieval of reusable assets. In other words, search possibilities are limited and do not go beyond simple keyword matching even if a CDE includes source code in its searching capabilities. An additional problem is often the lack of awareness about potentially reusable software in large and distributed organizations. Thus, the challenge is to enhance CDEs with more sophisticated retrieval techniques for reusable material, i.e. source or binary components.

Although [35] provided a good overview on component retrieval techniques, the authors realized that none of them was actually usable in practice. To date, it is also not clear what the best approach for reusing components might be. Component-based development approaches such as KobrA [17] propose component selection based on a specification taken from the design of a system. This, however, requires retrieval techniques for components that go far beyond simple keyword matching. Another aspect related to this is certainly the problem of filling a repository with more than just a few hundred reusable components [36] since historically companies were normally not willing to open their intellectual property to researchers working on this challenge. Thus, the retrieval techniques for older prototypes were mostly too imprecise and not able to deal with the large numbers of software (typically many thousands if not millions of files) contained in the repositories of distributed companies [37] today. Up until now it is also not clear whether labor intensive approaches such as the previously mentioned semantic wikis or semantic web services will scale for that large number of reusable software.

In order to increase awareness of reusable components it is furthermore desirable that developers in one project are informed about similar software components in other projects without actively searching for them. This leads us to the idea of so-called proactive reuse recommendation tools that have first been popularized by Ye's CodeBroker [38] in the late 1990s. The basic idea is that a developer does not need to invest extra effort into querying the component repository – which can quickly lead to developers not reusing anymore if a few attempts have failed, according to [39] – since the reuse tool proactively searches for reusable material in the background and is supposed to present only those results that are likely to fit into the context a developer is working on. Thus, we believe a high relevance of the reuse results is crucial in this context. In an agile context the so-called Extreme Harvesting approach [40] utilizing test-driven reuse is able to deliver very precise reuse recommendations [37] based on queries that can be automatically derived from test cases as they are commonly used in agile development processes. Recently, the main effort was to develop a test-driven reuse tool tightly integrated into the Eclipse IDE in order to achieve fully proactive reuse recommendations for developers. Its test-driven mode requires a developer to apply an agile test-first development approach where our tool is able to recommend reusable candidates based on (JUnit) test cases a developer has just created. These test cases contain enough syntactical and semantical information to facilitate very precise recommendations, especially if a potential candidate could have been automatically tested in a secured (server-side) environment as shown in the following figure.



III.2 Screenshot of test-driven reuse in Eclipse

Alternatively, the developer is designing or coding as normal in his Eclipse environment. Meanwhile the recommendation tool is automatically analyzing the structure of the class under development and derives queries for the underlying component repository. Potential candidates (based on a syntax analysis) are immediately returned and proposed to the developer.

These features have been implemented in the Merobase search engine[4]. Its Eclipse plugin for providing proactive recommendations is called Code Conjurer[5]. The integration with CDEs is simple because Merobase is able to automatically build a unified index from a potentially large number of software configuration management repositories such as CVS or SVN from various company sites or even beyond company borders. The recently finished version can thus be used within the scope of collaborative development platforms. However, since it is not yet clear, how metadata such as UML diagram etc. from a wiki can

[3] http://gforge.org

[4] http://merobase.com
[5] http://merobase.com/plugin-manual.do

be integrated with the component retrieval server, we plan to present a more detailed discussion on this at another occasion.

IV. Conclusion

In this paper, we have taken a collaborative perspective on software and knowledge reuse. So far there has been very little emphasis on its collaborative character. In order to clarify the role of collaboration we have therefore analyzed two distinct reuse approaches, namely design patterns and PLE. Design patterns are a case of knowledge reuse, emphasizing the agile and community-based perspective towards software development. They enable design experience to be more easily transferred to other developers. PLE, on the other hand, reflects the systematic, engineering perspective. However, we have discovered that collaboration plays a vital role in PLE as well. Especially, community-based approaches are highly suited to support the continuous evolution of a software product line.

In the second part, we then investigated collaborative technologies that already receive a high profile in software development organizations and open source communities. In particular, software development wikis should receive an even higher attention. We have learned earlier that design pattern reuse inspired the development of wikis in the first place. In turn, one should also consider using wikis in other scenarios, e.g. to support requirements analysis for product families or matching reusable software components. In order to tap the full potential of software and knowledge reuse we call for a novel integration of recent reuse recommendation systems into collaborative environments. However, although the technical premises for semantic and pro-active component retrieval are already fulfilled, they still need to be integrated into CDEs. This will become our main focus in future work.

Abstract

Component containers play a key role as the infrastructure of component-based distributed applications. Nowadays, various kinds of components are emerging to satisfy requirements of developing applications on Internet. Hence, it's becoming more and more important to improve development process of component containers with software reuse methods. Product line engineering has proven successful as systematical reuse method, and is the best choice for component container family comparing to other software reuse methods. However, diverse understandings of CBSD concepts and big difference among architecture of existing component containers issue great challenges to yield component container product line. In this paper, we first standardize basic concepts of CBSD, including component model and component container, along with their relations. Feature model of component containers is extracted based on these concepts. Then we present architectural design, including modules, interfaces and invocations, as well as commonality and variability analysis, which followed by product derivation process to produce component container with product line through several kinds of intuitive actions. Product line architecture and product derivation process comprise a component container product line, named PLACE. A case illustrating development process of a J2EE servlet container with PLACE shows enhancement of reusability and effectivity of the product line architecture.

1. Introduction

Component containers are cornerstone of development of component-based distributed applications, since they provide deployment and run-time infrastructure following given component models [2]. Container is responsible for creating and managing component instances, allocating system resources automatically, acting as interaction agent among components and interpreting remote requests. Functionalities provided to components are encapsulated as infrastructure services, such as transaction monitoring and logging, which are transparent to client users of components.

Along with increasing component types, even more (because of different versions of component specifications) component containers are required. However, most of them are not new, but variants of previous built systems, which makes it essential to reuse both design knowledge and existing code systematically among component containers.

Software reuse refers to the use of previously developed software resources in new applications. Because less development effort to be made and reusable software resources are rigorously tested, software reuse can increase productivity and software quality.

Most of current software reuse methods are inappropriate as principal guideline for systematical reuse of component container. Design pattern (including architectural pattern) and reuse libraries are excluded because of incomplete reusing scope, while containers are too complex and diverse for domain-specific reference architecture, framework and generative methods. Product line engineering has proven successful as systematical reuse method [3], and is the best choice.

Product line engineering has become an important and widely used approach for efficiently developing portfolios of software products. This approach

produces order-of-magnitude economic improvements compared to one-at-a-time software system development [3]. In product line engineering, software development process consists of two major processes or life cycles: software product line engineering and application engineering [12]. During software product line engineering process, the commonality and variability in the product line are analyzed in light of the overall requirements of the product line. During application engineering process, an individual application that is a member of the software product line is developed. Instead of starting from scratch, as is usually done with single systems, the application developers make full use of all the artifacts developed during the software product line engineering life cycle.

In next section, challenges to apply product line engineering to component container domain are analyzed. And in Section 3, a product line of component container, named PLACE, is presented by giving its two major parts: product line architecture and product derivation process. A case is given in Section 4, in which a J2EE servlet container is developed with PLACE, and shows improvement of reusability and effectivity of the product line architecture. After related works are compared in Section 5, Section 6 concludes this article and gives future works.

2. Challenges to Apply Product Line Engineering to Component Container Domain

The first challenge we are facing is requirement modeling. Sources of requirements of component container include component specifications and existing component containers, and all of them internally follow component-based software development (CBSD) theory. However, different explanations are adopted among component specifications [1][2][10]. In order to build a product line of component container, understanding of concepts from CBSD must be unified.

Heineman and Councill define component, component model and component model implementation (a.k.a. component container) and their relations in [2] as following, and as shown in Fig.1:

> **Definition 1** A *component* is a software element that conforms to a component model and can be independently deployed and composed without modification according to a composition standard. A *component model* defines specific interaction and composition standards, while a *component model implementation* supports the execution of components and their assemblies that conform to the model.

We will use Definition 1 as common understandings of these concepts in this paper, according to which component model will be used instead of component specification, standard or other terminology without confusing.

According to Definition 1, component model acts as behavior and development guidelines of components and component based software systems, which is also requirement source of component container. We then will use component model as base of feature modeling of component container, as shown in Section 3.1.

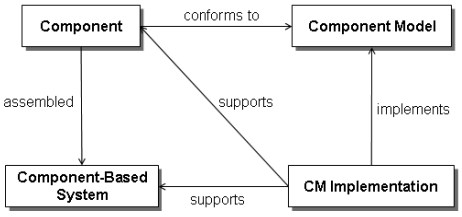

Fig.1 **Relationship among several concepts of CBSD**

The second challenge is abstraction of architectural design. Every component model has its own applicable area, for example EJB is middle-sized business component and web service is coarse-grained inter-organization component, because of what EJB using RMI/IIOP and JMS, supporting transaction and persistence while web service using SOAP along with WS-* specifications. Therefore, architectural design difference between component containers is critical for building product line.

Fortunately, basing on common understanding to CBSD concepts what we talked in the first challenge, component containers have common workflow (server/client paradigm and remote request handling), similar use cases (request handling, component deploying, system monitoring etc.), so that can be implemented by same set of architectural patterns and variability realizing techniques [4], which is of great help for handling design alternatives.

3. Product Line Architecture Design

3.1. Feature Modeling of Component Container

According to existing domain modeling methods, features are abstraction of services provided by and

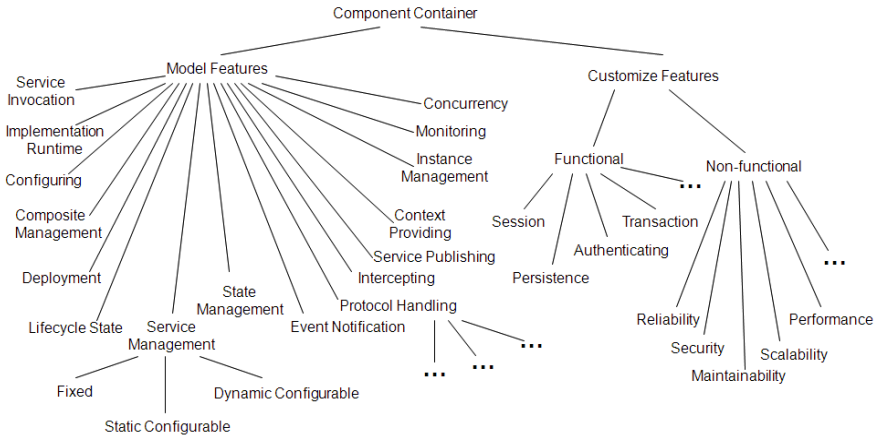

Fig.2 **Component Container Feature Graph**

techniques used in applications, and they are used by domain experts to communicate their idea, needs and problems. Feature-oriented modeling technique was first presented by Kang etc.[5]

Requirements of component container can be divided into two categories: those from component models and from container vendors. We call them model requirements and customized requirements respectively. Model requirements are explicitly regulated through component specifications, interface definition languages or protocol standards. Customized requirements are those except model requirement, which is proposed by container vendors basing on marketing strategy, user desire, development cost or state of practice. Features of product line are extracted from common requirements of most products in it. Therefore, features of component container consist of model features and customized features respectively. Layered relationships among features are shown in Fig.2, in which higher layer in the tree indicates more abstractive feature and lower layer means more concrete feature.

3.2. Architectural Design of Container Product Line – PLACE

In this section, we propose an architectural design of container product line, named PLACE (Product Line Architecture of component Container Environment), which is based on analysis in former sections as well as state-of-practice of architectural design of component containers. Modules and their relationship in PLACE are shown in Fig.3.

There are three kinds of architectural elements present in Fig.3. *Modules* are depicted by boxes, while *interfaces* are represented by black triangles on the edge of module boxes. Inner or outer directions of triangles show required interfaces or provided interfaces respectively. And *invocations* are by lines connecting pairs of interfaces. Modules, interfaces and invocations with dotted lines mean *optional elements*, while solid lines mean *mandatory elements*. Mandatory elements exist in architectures of all products derived from PLACE, comparing to optional elements which are only in architectures of some products within the product line.

We will introduce modules and their interrelations briefly.

Protocol processor is responsible for parsing and composing messages used to communicate with clients through network protocols. It converts request messages into in-memory objects, which are passed on to *service manager*; meanwhile it also composes response messages with results received from *service manager*, and sends them back to clients. Sometimes, p*rotocol processor* will invoke *concurrency controller* to handle requests concurrently.

Service manager is in charge of request dispatching as well as lifecycle managing of container services, which includes loading, starting and stopping. After *protocol processor* converts requests messages into objects, *service manager* processes them with intercepting container services, and then passes them on to *component manager*. Sometimes s*ervice manager* also invokes *concurrency controller* to provide container services with concurrency support, or send run-time status to *monitor*.

Component manager integrates many functionalities such as component invoking, configuring, lifecycle managing, lifecycle events notifying. *Deployer* invokes *component manager* when

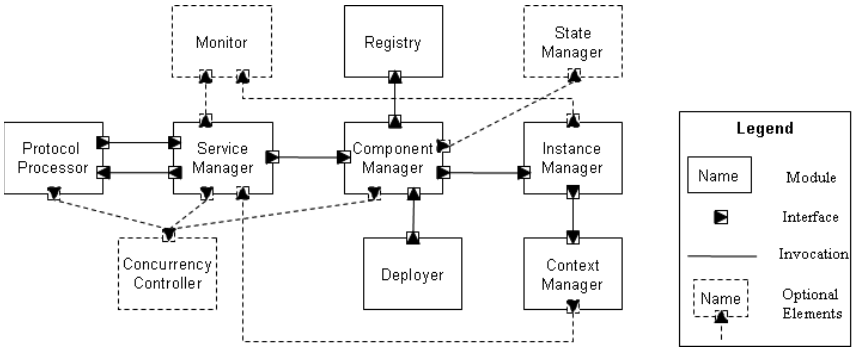

Fig.3 **Architectural Design of PLACE**

deploying components or component applications. When handling requests, *component manager* invokes *registry*, *state manager* and *instance manager* respectively, to look up, manage component states and component instances. *Component manager* also probably invoke *concurrent controller* to provide concurrency support to its submodules.

Besides providing component instances with environmental information, c*ontext manager* also receives and deals with invocations of run-time container services, which are perform by invoking *service manager*.

Monitor collects run-time information of container, whose possible sources are *component manager* and *instance manager* based on categories of information in current containers.

3.3. Commonalities and Variabilities in PLACE

Commonalities in PLACE include architectural modules' separation, relationships among them which defined by abstract interfaces and data structure of messages transformed among modules.

As shown in Section 3.2, these commonalities are based on common requirements of all component containers within PLACE according to feature graph in Section 3.1. For example, Deployer module is corresponding to 'deployment' feature in Fig.2, and its interface provided to Component Manger defines abstract methods as following. It accords to general actions of deployment functionality.

```
interface Deployer {
  boolean deploy(ComponentIdentifier compId)
            throws DeploymentException;
  boolean undeploy(ComponentIdentifier compId)
            throws DeploymentException;
}
```

Variabilities in PLACE can be classified into functional variability and non-functional variability. Functional variability includes adding or removing functionalities, adjusting behaviors of or relationships between modules, while non-functional variability includes extensibility etc.

Developer will realize variability by choosing one from design alternatives in product derivation process, which is explained in next section.

3.4. Product Derivation Process

Designing containers with PLACE has two steps: 1) product requirements analysis, during which architect compares concrete component model against common features in PLACE; 2) deriving concrete container architecture from PLACE, including three kinds of actions: *specialization, removal* and *augmentation*.

Specialization means to replace abstract modules supporting generic features with concrete modules supporting specific features. *Removal* means to remove modules or invocations not needed by concrete container, since requirements of every single container are only subset of that of PLACE. *Augmentation* is to add modules, interfaces or invocations implementing requirements that are not covered by PLACE.

4. Case Study

ONCE platform [5] consists of a series of software infrastructure products developed by Institute of Software, Chinese Academy of Sciences. Several representative component containers are included in ONCE, such as Servlet, EJB, web service, Portlet and BPEL containers.

Containers in ONCE have these following characteristics: a) Component models of all these containers are distributed component. b) For development of reusable assets, all products should use same programming language. Our choice is Java, since

most of them (EJB, Servlet, Portlet) belong to J2EE1 by Sun Microsystems, Inc., and the other two component models are also compatible with it.

We have applied PLACE in design practice of component containers in ONCE. Next, we will take design process of a Servlet container as a example.

Servlet technology2 resides in representative layer of three-layer architecture of J2EE applications, which is responsible for generating user interface code and handling interaction with clients. During development of ONCE products, we proposed following requirements to Servlet container to enhance usability:

a) Hot deployment, which means to deploy or undeploy Servlet applications (in WAR files) at run-time.

b) Web Administrative Console (WAC). User can monitor and manage components and component instances in Servlet container remotely through web user interface, and also can monitor components and instances by viewing various statistics information provided by WAC, start or stop deployed Servlet components. WAC should also support remote deploying, which allow client-side user to upload and deploy WAR files through web browser.

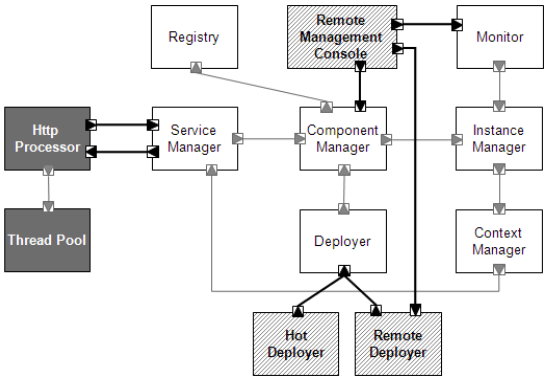

Fig.4 **Architecture of Servlet container derived from PLACE**

Comparing to PLACE architecture in Fig.3, Servlet container's architecture in Fig.4 shows the following variabilities:

Specialization. Protocol Processor and Concurrency Controller in PLACE are specialized to Http Processor and Thread Pool respectively, depicted by boxes with dark gray background. Protocol Processor follows monolithic design since this Servlet container only supports HTTP protocol, so it's specialized into Http Processor, and invocation parameters between Http Processor and Service Manager are OnceHttpRequest and OnceHttpResponse.

Removal. State Manager and related invocations are removed, so are invocations from Service Manager/Component Manager to Thread Pool, and from Monitor to Service Manager. Removed architectural elements are not in Fig.5 anymore.

Augmentation. Added parts include Remote Management Console, Hot Deployer, Remote Deployer and corresponding interfaces and invocations, which are shown as boxes with shadow background and bold lines

4.1. Discussion

In this case, only 3 of 12 modules are built from scratch, while 7 of 12 modules' definitions keep unchanged comparing to those in PLACE. Although development cost of different modules are very different and some implementing code may be written to complete modules' functionalities, total development time and cost is deduced remarkably.

While most of top-level modules being reused, reusability of source code is increased too. For example, thread pool which is originally developed for EJB container can be reused without rewritten except changing several parameters, such as size of thread pool.

5. Related Work

One research area related to our work is domain analysis [7] [8] [9]. Moon et al. [7] introduces a process for developing domain requirements where commonality and variability in a domain are explicitly considered. Within their metamodel for domain requirement, variation points are categorized into four types: computation, external computation, control, and data, which is similar to our classification of variations in component models. They also identify computation, external computation, and control variations in BehaviorPRelements (a perspective along a timeline), and data variations in StaticPRelements (a perspective along static structure). Chastek et al. [8] and Mei et al. [9] also propose interesting approaches to elicit and model domain requirement, but they all focus on requirement level of product lines, do not think about design and implementation levels as we do in PLACE.

Our work is also inspired by publications on component-based software engineering and component models [1] [2] [10]. Lau et al. [1] classify component

[1] Which also known as Java EE now. Java EE at a Glance, http://java.sun.com/javaee/

[2] Java Servlet Technology, http://java.sun.com/products/servlet/

models into a taxonomy based on commonly accepted desiderata for CBD (Component-Based Development) and evaluate categories with respect to these desiderata. Lau et al. regard software component model as a definition of semantics, syntax and composition of components. As we already quoted in Section 1, Heineman and Councill [2] define these concepts, component, component model and component model implementation, with each other. Szyperski et al. [10] define component without component model, and tend to look into component models and platforms from technical and strategic perspective. The main differences of our work are more detailed analysis and narrowed scope, based on container product line point of view. Their definitions of component models are too coarse-grained to guide domain analysis and architectural design.

6. Conclusion and Future Work

Software reuse can improve quality and productivity of component containers, which is crucial for fulfilling requirements of emerging component models. Product line engineering is a promising technique for systematical reuse of portfolios of software products. However, applying product line engineering is facing challenges including different understandings of basic concepts from CBSD and serious diversity among architectural designs of existing component containers.

In this paper, we analyzed these challenges and proposed PLACE: a product line of component containers, which consists of two major parts: product line architecture and product derivation process. Based on common understanding of basic concepts and feature modeling of component container, architectural design reflects general modules' separation, interfaces' definition and interacting relationships among them, while product derivation process shows practical procedure to design a component container product with PLACE with three kinds of intuitive actions. In the end, a case shows effectiveness of PLACE by illustrating development process of a Servlet container.

As future work, we are analyzing component models with variability modeling techniques, such as COVAMOF [11], to further reveal their interrelationship, and making effort to generalize this approach to apply to other product lines.

zawar.qayyum@univ-ubs.fr, flavio.oquendo@univ-ubs.fr

Abstract – **The π-Architecture Description Language (π-ADL) is a high level software architecture specification language, formally founded on the π-Calculus. π-ADL.NET is a software implementation developed for the purpose of integrating π-ADL in the Microsoft .NET platform, with the view of expanding the usage horizon and application possibilities of π-ADL as an executable formal language for prototyping and rapid architecture-centric development.**

Since .NET is a multilingual development platform, the ability of a .NET language to access software components written in other .NET languages opens up new possibilities for multilingual software development using π-ADL.

This paper proposes extensions to π-ADL to be implemented in the π-ADL.NET compiler, in order to allow it to use existing .NET APIs written in other .NET languages. The proposed extensions cover all the features of the .NET language foundation: namespaces, classes, constructors, methods, fields, properties, events, enumerations, exceptions, null-ness, method delegation, different aspects of casting, generics and inner classes.

Index Terms – **π-Architecture Description Language; .NET; Compiler; Platform Specific Extensions**

I. INTRODUCTION

An Architecture Description Language (ADL) is a language especially conceived to address the modelling needs of software architectures. Various ADLs have been designed with different approaches to software architecture modelling [1]. π-ADL, a relatively recent ADL [2] adopts a formal approach towards software architecture specification, based on the π-calculus. The main advantage of this approach is the reliability of the resulting system, a very important area of focus for large and complex software. However, the software architecture description should also be easy to understand and manipulate. For this π-ADL operates on the principle of first class citizenship for all language elements. In light of this approach, there are specific syntactic features of the language that enable the manipulation and use of program elements with a minimal amount of code, with a syntax that is easy to understand.

The π-ADL.NET project is a compiler and runtime system development effort with the goal of compiling π-ADL to the .NET platform and running architecture specifications on that platform. The motivation for this project is to provide a large experimental space for testing and evaluating the process oriented, formally founded π-ADL in the context of a widely used software development and execution platform. At the same time there is a need to specialize the π-ADL language in order to leverage the functionality available in the reusable .NET software libraries.

This paper proposes language extensions to π-ADL in order for it to interface with .NET software libraries. The .NET platform is fundamentally object-oriented, and the need to represent .NET semantics while remaining within the confines of the process-oriented paradigm of π-ADL poses a modelling problem. Section II presents some general details of π-ADL in order to put the language extensions in context. Section III provides syntactic details of the proposed language extensions. Section IV presents related work with a comparison to the .NET API access features in other .NET languages based on formal methods. Section V concludes the paper.

II. π-ADL

π-ADL is an Architecture Description Language presented in [2] [4]. The purpose of Architecture Description Languages is to model software architectures, and according to [5] they focus on the high-level structure of the overall application rather than the implementation details of any specific source module. However π-ADL also provides programmatic constructs that allow it to model implementation details, so it can be seen as both a modelling and an implementation language.

π-ADL can be considered as a benchmark for second generation ADLs in the sense that it is formally founded and allows the customization of run-time architectural concepts. These two features were not present in earlier formal ADLs.

```
behaviour {
  x : Connection [Boolean];
  compose {
    via a1 send Void where {x renames b};
  and
    via a2 send Void where {x renames b};
  and
    via a3 send Void where {x renames b};
  }
}

value a1 is abstraction() {
       b : Connection [Boolean];
       via out send "Hello";
       via b send true;
}
```

```
value a2 is abstraction() {
       bb : Boolean;
       b : Connection [Boolean];
       via b receive bb;
       via out send " World";
       via b send false;
}

value a3 is abstraction() {
       bb : Boolean;
       b : Connection [Boolean];
       via b receive bb;
       if (bb == true) do {
              via b send bb;
              via b receive bb;
       }
       via out send "!\n";
}
```

Listing 1. A Simple Multi-Agent System in π-ADL

The second feature implies that the semantic definition of high level architectural elements can be customized, allowing a large amount of flexibility when defining architectural styles [6].

π-ADL is formally founded on the higher-order typed π-calculus (hence the name), which encompasses a formal transition and type system. It conforms to the language design principles of correspondence, abstraction and data type completeness [2]. Type completeness assures first class citizenship to all types i.e. they can be declared, assigned, can have equality defined over them, and can be persisted. The structural operational semantics of π-ADL represent behaviour (and thereby computation) by means of a deductive system, expressed by a formal transition system in line with the language type system. Type soundness asserts that well-typed terms do not give rise to runtime errors under the transition system.

π-ADL has a layered syntactic structure, with a core language layer forming the foundation of higher layers that build upon one another. For example high level architectural concepts such as components and connectors are expressed in terms of behaviours and abstractions, which are fundamental units of execution. A behaviour is an independent unit of execution launched when a process starts executing. Abstractions are abstractions over behaviours as functions are abstractions over data. Abstractions need to be called from behaviours or other abstractions in order to issuing behaviours. In order to enable communication between different parts of a unit of execution, or amongst different units of executions, connections are employed. Send and receive statements allow synchronous communication through connections. π-ADL provides concurrency constructs in line with those of π-calculus, in the form of *compose*, *choose* and *replicate*. Sub-blocks inside a compose block will execute in parallel with each other, while from those inside a choose block, only one will execute. The replicate construct connotes the infinite replication of an execution block.

Arithmetic and assignment syntax in π-ADL is based on the familiar style of Java and C#. π-ADL supports a set of basic data types in the form of *Integer*, *Boolean*, *String* and *Float*; and a diverse set of constructed data types: *any*, *view*, *tuple*, *union*, *quote*, *variant*, *set*, *bag*, and *sequence* types. Listing 1 presents a sample π-ADL code highlighting the main syntactic features of the language. It demonstrates the modelling of a simple synchronized multi-agent system in π-ADL. Three parallel pseudo-applications of the abstractions a1, a2 and a3 are performed in the behaviour. The three abstractions then synchronize with one another to print the string "Hello World!" in the right order.

III. .NET EXTENSIONS TO π-ADL

We now present the proposed syntax extensions to π-ADL to provide support for accessing the .NET API. All details are presented from the π-ADL perspective, using elements defined in π-ADL to model the extensions. An understanding of the .NET language framework is assumed.

The focus of this current set of extensions is to allow the use of existing .NET libraries in π-ADL.NET, and not develop reusable components in π-ADL.NET for access through other .NET languages. The latter could form the focus of later work on π-ADL syntax extensions.

A. Declaring and Instantiating Classes

Let NET be the .NET governor behaviour, in terms of the π-ADL formalism. We declare that NET has connections type_in and type_out, and they both process values of type *Any* (i.e. values of any type). NET supports a typing system expressed by the .NET namespace value attached to each type it receives or sends e.g. "System.String". The π-

ADL type system is therefore extended to be able to evaluate the .NET namespace notation and hence recognize the .NET types. All .NET objects are treated as abstractions in π-ADL.

The instantiation of a .NET class would be as follows:

```
x:System::Text::StringBuilder; //declaration
via NET::type_in send
"System::Text::StringBuilder";
via NET::type_out receive x;
```

Here the type_in connection receives a string value indicating the type of object it will process. The NET behaviour then internally creates the object and sends it out via the type_out connection. A shorthand notation forming the language syntax for this would be an overload of the '=' sign connoting instantiation, with the restriction of using parenthesis after the class name:

```
x:System::Text::StringBuilder; //declaration
//instantiation:
x = System::Text::StringBuilder();
```

x would now contain a reference to an abstraction of type System::Text::StringBuilder.

B. Namespaces

In order to recognize the .NET namespaces and incorporate them for usage in π-ADL programs, we specify the namespaces being used in a π-ADL program using the *use* directive. It is used at the program level, outside behaviour or abstraction definitions. Therefore:

```
//... declaration(s)
x = System::Text::StringBuilder();
```

can be rewritten as:

```
use System::Text;
//...behaviour header
//... declaration(s)
x = StringBuilder();
```

Note that the namespace System is implicitly used and need not be declared using the use keyword.

C. Constructors

The statement

```
x = System::Text::StringBuilder();
```

would result in NET internally calling the default constructor of StringBuilder. In case a constructor with arguments needs to be called, we can employee NET::type_in as follows:

```
//invoking the StringBuilder constructor
// with an Integer argument defining
//initial length
//... declaration(s)
via NET::type_in send
      "System::Text::StringBuilder";
via NET:: type_in send 42;
via NET:: type_out receive x;
```

Generally, the arguments to the constructor will be sent via type_in to the NET behaviour, right after sending the string that contains the type of object that needs to be created. The shorthand notation to this syntax would be:

```
x = System::Text::StringBuilder(42);
```

Multiple arguments will be sent as a comma separated list e.g.

```
y = MyObject("arg1", true, 0.5);
```

D. Methods, Fields and Properties

In order to incorporate the use of methods in π-ADL, we develop an internal model of a .NET class that is recognizable in the π-ADL syntactic domain, and covers interaction with both static and non-static fields and methods. Each .NET class is represented by a corresponding behaviour, and serves to provide access to static fields and methods. Conforming with π-ADL syntax this behaviour contains publicly accessible variables (for representing static fields).

Static methods are treated as connections. Each connection receives an argument of type any. It also makes a return value available via an input prefix (for methods that have non-void return values). In order to model non-static fields and methods, a similar approach is used with the difference that abstractions and not behaviours represent objects.

Listing 2 shows a .NET class and Listing 3 shows how it would look like in π-ADL. Notice that a .NET class is fully expressed by a behaviour and an abstraction, to model the static and non-static aspects of the class respectively. The following example shows how fields and methods for .NET objects are accessed in π-ADL:

```
x : PiADL::Vector; y : Float;
x = PiADL::Vector(3,4);
compose {
      via x::Resultant send Void;
and
      via x::Resultant receive y;
}
```

The shorthand equivalent of the above code would be

```
x : PiADL::Vector; y : Float;

x = PiADL::Vector(3,4);
//shorthand for the method call compose
y = x::Resultant();
```

```
public class PiADL.Vector {
  private double _x, _y;
  public double X {
    get { return _x; }
    set { _x = value; }
  }
  public double Y {
    get { return _y; }
    set { _y = value; }
  }
  public Vector(int x, int y) {
    _x = x;  _y = y;
  }

  public static string Name()
  {
    return "Vector";
  }
```

```
public static string Space()
  {
    return "PiADL";
  }

  public double Resultant()
  {
    return Math.Sqrt(_x*_y);
  }

  public double Angle()
  {
    return Math.ATan(_y/_x);
  }
} //end class
```

Listing 2. .NET class (using C# code)

```
Vector names behaviour
{
  Name : Connection[any];
  Space : Connection[any];

  compose
  {
    replicate {
      via Name receive;
      via Name send "Vector";
    }
  and
    replicate {
      via Space receive;
      via Space send "PiADL";
    }
  }
} //end behaviour

value VectorInstance is abstraction {
  X : Float; Y : Float;
```

```
Resultant : Connection[any];
Angle : Connection[any];
dVal : Float;

compose
{
    replicate {
      via Resultant receive;
      dVal = X * Y;
      dVal = Math.Sqrt(dVal);
      via Resultant send dVal;
    }
  and
    replicate {
      via Angle receive;
      dVal = Y / X;
      dVal = Math.ATan(dVal);
      via Angle send dVal;
    }
} //end abstraction
```

Listing 3. π-ADL model for the .NET class

Fields and properties are treated as shorthand projections e.g.

```
x::Length = 42;
```

There is also a case of indexed properties, which are treated from the programmer's perspective as an array. Both arrays and indexed properties are accessed using square brackets enclosing the index value, such as:

```
a : System::Collections::ArrayList;
o : System::Object;
//initialize and populate a
o = a::Item[4];
```

E. Events

Abstractions handle events generated by .NET objects. The handles keyword will allow the assignment of an abstraction to handle a certain event type. The proposed syntax is:

```
use System::Windows::Forms;
behaviour {
       t : TextBox;
       t = TextBox();
       t::Click = a;
}
value a is abstraction (x : Integer)
       handles TextBox::Click {
//....
}
```

F. Enumerations

A .NET enumeration is modelled as a π-ADL view type, with all elements of type Integer.

G. Exceptions

Since exceptions are full-fledged classes in .NET, they can be treated using the same behaviour-abstraction model described in III.A. above. Examining the exception properties and variables, and calling its methods is the same as described in III.A. The exception handling syntax is the try-catch-finally approach seen in C#, as shown below:

```
s : String;
i : Integer;
e1 : FormatException;
e2 : OverflowException;
try {
       via out send "Enter an integer: ";
       via in receive s;
       i = Convert::ToInt64(s);
       i = i * i;
       via out send i;
}
catch (e1, e2)
{ via out send "Invalid input value."; }
finally {
  via out send
    "\n\n End of try-catch-finally demo.\n";
}
```

H. Null Values

.NET objects initialized as Null values can be recognized and compared using the null keyword. All .NET objects are assumed null at the time of declaration.

I. Delegates

.NET delegates are represented using the connection renaming syntax in π-ADL. For example we apply this proposed syntax for delegates to the class definition in Listing 3:

```
m : Connection[Any];
m renames Vector::Name;
```

J. Casting to and from System::Object

System::Object is the canonical root class from which all .NET classes are derived. Consequently, .NET collection types often cast into System::Object the elements they are collecting. In the π-ADL.NET compiler, each of the basic types corresponds to one of the primitive types of the .NET platform. The .NET platform provides the ability to box primitive types into representative objects e.g. the System::Int64 structure exists for 64-bit integers and so on. In π-ADL.NET the constructed types are implemented as .NET classes and hence are directly cast-able to and from System::Object. Therefore the following proposed syntax for casting π-ADL types to and from objects is easy to implement:

```
c : System::Collections::ArrayList;
v : view[a : String, b : Boolean];
o : System::Object;
i : Integer;

c =  System::Collections::ArrayList();
i = 5;
v = view(a : "Cast test", b : true);

c::Add(i); //implicit cast to System::Object
o = (System::Object)v; //explicit cast
c::Add(o);
v = (view)c[1]; //explicit cast
```

K. Upcasts and Downcasts

Following the syntactic convention in III.J, .NET objects can be cast to any one of their inherited types and back. As such casts are dynamically checked in .NET, any runtime errors resulting from incorrect casts will have to be handled using the exception handling mechanism discussed in III.G. The following example illustrates the syntax:

```
use System::Windows::Forms;
behaviour {
       b : Button; c : Control; o : Object;
       b = Button();
       c = (Control)b; //upcast
       o = (Object)c; //upcast
       c = (Control)o; //downcast
       b = (Button)c; //downcast
}
```

L. Generics

Since our current focus in .NET extensions for π-ADL.NET is to provide the ability to use existing class libraries only, and not to be able to create new ones, we need not go into a detailed syntax mapping for .NET generics. It is sufficient to be able to declare and instantiate a .NET generic class as follows:

```
c : GenericClass<Integer>; //declaration
c = GenericClass<Integer>(); //instantiation
```

For generic class with multiple generic parameters, the parameters can be comma-separated. From the π-ADL perspective, the class GenericClass<T> represents a family of behaviour-abstraction pairs, each one of which processes a certain data type. Note that this model is compatible with constrained generic classes as well [12]. π-ADL.NET will also be able to use its own basic and constructed types as type parameters when instantiating a generic.

M. Inner classes

Just as a regular .NET class is fully defined by its name and namespace, an inner class can be defined by its name, container class and namespace. From the π-ADL.NET perspective a public inner class is treated in the same manner as an ordinary class. For example if a class Container contains the class Inner, and is declared in the namespace MyNameSpace then the following π-ADL.NET code will be valid:

```
i : MyNameSpace::Container::Inner;
i =  MyNameSpace::Container::Inner();
```

The π-ADL.NET code then can access the members of Inner like for any other class or object.

IV. RELATED WORK

The work presented here merits a comparison with a similar work performed for other formally founded languages. One such language is F# [7], a .NET language based on ML [8]. Both languages are based on formal methods, although F# is a functional language while π-ADL is a process oriented language. But in each case, the foundations of these languages differ greatly from that of .NET, which is principally object oriented. Furthermore F# provides syntax level interoperability for all the .NET features discussed in section 3 except for generics, thus providing an almost equivalent level of access to the .NET API, when compared to the π-ADL .NET extensions. However F# has been designed as a .NET language right from the start, whereas π-ADL as a language is neutral to any platform technologies.

Another ML based language for the .NET platform is SML.NET [11] based on Standard ML '97. It supports most of the features discussed in section III, but does not provide support for events or generics.

L Sharp.NET [9] is an implementation of the Lisp functional programming language for the .NET platform. It provides support for namespaces, object instantiation, and access to static and non-static methods, fields and properties. Advanced features such as casting, event handling, exceptions and generics are however not supported. DotLisp [10] is a lisp like interpreted .NET language with limited support for .NET types and delegates, as well as exception handling. It does not allow the instantiation of objects or the use of namespaces.

In short when it comes to compilers and extensions to formally founded languages for .NET, the current body of related work restricts itself to functional languages. Plus as seen in this section, none of these languages provide support for generics, an important feature of .NET version 2.0 [3]. Seeing this reported work from another angle, there is no Architecture Description Language compiler for .NET besides π-ADL.NET. This work is thus a significant overture in that it provides the possibility of examining a process-oriented, formally founded Architecture Description Language in the context of the .NET universe.

V. CONCLUSION

The purpose of the .NET extensions to π-ADL is to provide syntactic basis for the π-ADL.NET compiler to interact with .NET libraries. At the same time, these extensions form a reference for interfacing π-ADL with other software technologies. The development of these extensions is particularly important in that the architecture oriented focus of π-ADL lends naturally to the notion of employing ready-made software components to put together a software system, or perhaps roll out a software development project in which both architecture and components evolve through interaction with each other.

One goal of the π-ADL.NET project is to allow software architectural modelling on a mainstream software development platform. The implementation of these proposed extensions will enable the development of software using multiple paradigms and languages simultaneously. This helps meet the universal goals of reliable and low-cost software development through the following advantages: effort put in defining the software architecture is employed directly in the resulting software system; the privilege of an architectural view of the system that can be analyzed through compilation and execution; and bringing the benefits of the architectural paradigm to the rich technological foundations of .NET.

Abstract

Software projects often require many software engineers to coordinate their efforts to build large software systems. How to support collaborative development among the stakeholders in a project, even if separated by time or space, to produce software artifacts efficiently becomes a very important problem. Software architectures are considered important because they are the blueprints for target software products and determine system-wide qualities, and they can be used to organize various software artifacts in software development process from a high level perspective. Based on such an important role of software architectures, this paper puts forward an approach to collaborative software development based on software architecture, to support the collaboration spanning the whole software lifecycle. Moreover, the paper provides the detail on how this method works efficiently by a case study.

1. Introduction

Software engineering projects are inherently cooperative, requiring many software engineers to coordinate their efforts to produce a large software system [1]. How to support collaborative development among the stakeholders in a project to produce software artifacts efficiently becomes a very important problem.

Typical software development methods provide collaboration support from two sides: one is to provide various communication mechanisms between software developers; the other is to provide collaborative support based software artifacts for software developers. For the first category, there are many kinds of communication mechanisms such as email, instant message, video meeting, etc. However, these communication mechanisms are based on natural language and quite short of standardization, which is easy to lead to ambiguous understanding for developers. On the other side, collaborative development method based on software artifacts can solve this problem if software artifacts have good structure, clear syntax and explicit semantics.

For the collaboration based on software artifacts, the version control systems are often used to manage the software artifacts, for instance, CVS, SVN, etc. These tools are very important for collaborative development among software engineers, but the artifacts stored in these tools are almost code-level programs, and lack a reasonable organization from the viewpoint of software development process. As a result, these tools are short of support for collaborative design and maintenance of software, which usually require the designers or maintainers to have a big picture about the system.

To support the collaborative development in the whole software lifecycle, it is necessary to provide software developers with an appropriate model to organize various software artifacts in software development process from a high level perspective. Then, software engineers can collaboratively develop software based on this model.

With software becoming large and complex, software architecture (SA) becomes a blueprint to guide the development and maintenance of software systems, and it plays an extremely important role in the whole software lifecycle. Now, some SA-centered development methods have been put forward. Richard Taylor and David Garland present their own Architecture Description language (ADL) and propose the SA-centered development method based on the ADL [2,3]. Siemens's Hofmeister etc. describe a set of architecture views and put forward a corresponding software development method from requirement to implementation [4]. IBM's tool "RSA" (Rational Software Architecture) also focuses on SA-centered development [20]. In a conclusion, SA has become the core of software artifacts in software development process and an ideal base for collaborative development. Now many SA-centered software development methods and tools (e.g., ArchStudio[5] and MolhadoArch[6]) have partly supported the collaboration among developers. But these tools do not use the semantics of SA adequately, and they just support simple collaboration for several authors based on the management of authority.

In this paper, we put forward a collaborative development approach based on SA. First, based on version control tool and semantic information of SA, we abstract

the information of fine-grained modification into SA in order to support designers to collaboratively design SA model. Then we can enlarge this collaboration mechanism from collaborative design to the whole lifecycle because SA is a core artifact in the whole software lifecycle. Via introducing bi-transformation technologies [7], we can use architectural knowledge based on version control tool to capture the transformation relationship between SA and other artifact to transform the modification manipulation of other artifacts to the modification manipulation of SA model, so as to support the collaborative development among different developers.

The rest of this paper is organized as follows. Section 2 presents some related work. In Section 3, we put forward an approach to collaborative development based on software architecture. Section 4 illustrates the approach with a case study. Section 5 concludes the contribution of the paper and gives the future work.

2. Related work

To the best of our knowledge, the researches on collaborative development based on SA cover several aspects. We organize the review of the related work from five main aspects as follows.

(1) The collaboration support for different development phase. Many SA development tools support collaborative authoring by versioning architecture description files, e.g., ArchStudio and ACMEStudio [8], but this kind of support for collaboration is fine-grained without the semantic information of SA. Thus, the support is just limited in the phase of SA design rather than the entire software lifecycle.

(2) **The support for communication mechanism of collaboration.** Our work is different from some researches which just use the mechanism of communication to support collaboration [9]. Our work supports the collaboration based on models, and it can eliminate the ambiguity induced by the communication in natural languages. On the other hand, these mechanisms of communication are also a supplement to our work and easy to be integrated to our framework.

(3) **The synchronization of artifacts in collaboration.** Our collaborative mechanism inherently supports the synchronization of artifacts, in other words, the synchronization among several replications of an artifact. Compared with the research on optimistic replication [11], our work can support large-granularity synchronization and even the synchronization of heterogeneous replications.

(4) **The visualization of collaboration.** One key issue in collaboration is how to assist the collaborative developers to know other person's work status (i.e., awareness) [10]. There are some related researches, in which the mechanism of these researches is similar to that of our work. That is, based on version control tool, to get the low-level information of modification and display the information in a direct way [12,13]. But their work is to show different detailed information from several views, and we organize the detailed information of modification in multi-view of software architecture. Another difference is that this visualized view is the threshold of collaborative development, and not just a static visualized display.

(5) **Integrated collaborative development tool**. There are some researches focusing on the integration of several communication tools [14,15,16]. IBM and Microsoft both have their commercial products to support collaboration. The core of these products is to abstract the common mechanisms from typical collaboration and communication, and integrate them together. However, our work is from the view of the development method based on SA, and discusses potential issues for collaboration. Moreover, most of these tools support collaborative communication based on fine-grained code, but we try to organize the collaborative development from a high level at SA.

(6) **Web based collaborative development environments.** Eclipse is an open source community. Its project focuses on providing a set of development platform and framework to facilitate the construction of software. Every eclipse project has an independent page as the entry to all tools based on the Internet, which includes identity authentication, CVS, mailing list, newsgroup, WiKi [17], and Bugzilla [18]. Now, our work focuses the integration surrounding IDE, and how to extend it to the Internet environment will be our future research work**.**

3. Our Approach

The core of our approach is maintaining the different versions of an architecture model, and revealing the change in the proper views of an architecture model, on the basis of the semantics of this architecture model. An overview of our approach is illustrated as Figure 1.

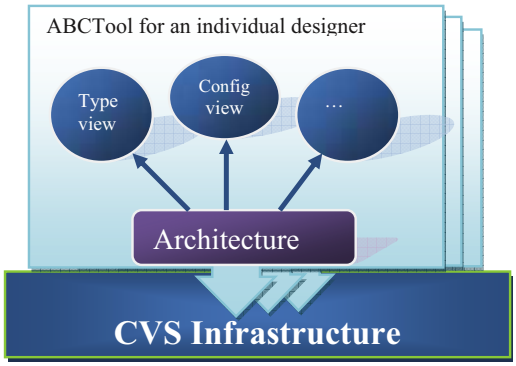

Figure 1. Approach Overview

In the rest of this section, we present several key aspects of our approach supporting collaborative development.

3.1. Software Architecture Model

By referencing the typical architecture description language (ADL) [19], we define the meta-model(described as Figure 2) of software architecture by using Eclipse Ecore. The core concept of this meta-model is *Component*. We partition and organize the software into components, each with a relatively individual concern. Components are associated with connections which link the provided and required interfaces together.

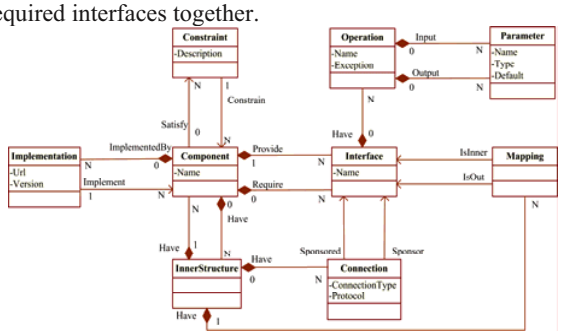

Figure 2. Software Architecture Model in Our Approach

We also introduce the concept of *InnerStructure,* which helps organizing the whole system as a hierarchical structure to support the stepwise refinement during architecture design. Based on the meta-model, we construct a software architecture modeling environment by using Eclipse GMF, named ABCTool, in order that we could assist designers to record their design decisions by recording their manipulations such as additions and deletions of elements and modifications of properties and relationships of elements.

The entire architecture model is recorded in the form of XMI in several files. Among the files, one set of files record the model information of the core elements, and another set of files record every view's diagram information, including diagram color, font and the layout of elements.

3.2. Version Control in Low level

Designers can modify the SA model via the graphic interfaces, including core model, elements and layout. When the designers finish and save the modification, some related XMI files will be changed. As pure context files, these XMI files can be managed by a version control tool. We select CVS to achieve this because ABCTool is based on Eclipse platform which provides fully support for CVS.

By using CVS, we can record who makes the modifications and what modifications have been made to SA model in the collaborative development process. We use Eclipse Plug-in to encapsulate the record file of these modifications and visualize them in ABCTool.

3.3. Visualization of the SA Model Modifications

By CVS interface, we can obtain the information about the modifications from the XMI files. By analyzing the modifications information, we can elicit which elements in SA model have been modified and what kind of modifications has been made. Moreover, we can display the modifications explicitly in ABCTool, for example, using different color to distinguish added components, deleted components and unchanged components.

3.4. Model Maintenance by Collaborative Developers

For changed model, collaborative developers can select accepting the modification, rejecting the modification or adding new modification to the modification. The maintenance activities for the modification can be mapped to the operations in CVS. During the maintenance, collaborative developers can use the modification information offered by CVS to identify the intention of the modification. Sometimes, they may need to contact the modificator directly to discuss the goal of the modification. We provide a support mechanism for peer-to-peer communication in ABCTool.

3.5. The Collaborations among the Developers in Different Phases

As a core artifact in the entire software development process, SA model is a suitable medium for various developers from different phases to communicate. In different phases, developers will deliver different artifacts, but most of these artifacts record some core information of SA. In other words, some transformation relationships exist between these artifacts and SA model. Thus, by transforming the core information in SA and adding special information in a given phase, the artifact in the given phase can be constructed. Using those research fruits in the bi-transformation field [7], we can use a set of transformation rules to reflect the modification of SA model to other model, and also reflect the modification of SA level information in other model to SA model. Thus, we can utilize the approach above to assist the collaborations among the developers participating in different phases.

4. Case study

The following case illustrates how ABCTool assists different developers to collaboratively design a large software system. In the entire software development process, there are various artifacts, and these artifacts have different versions. Eclipse has integrated CVS to support collaborative development, but CVS just manages artifacts as context. For example, in Eclipse, we can see the history page of every file, including the version number, modification time, and author etc. According to different version, we can use command "Compare" to view the difference between two versions. In design phase, as core artifact, SA model is often composed of Component Type View and Component Configuration View etc. Thus, the management mechanism based on context in CVS is not enough. To solve this problem, our modeling tool "ABCTool" provides the visualized version management for the elements in Component Type View and Component Configuration View etc.

Furthermore, the current version control tools do not support synchronized update of artifacts, and developers have to initiatively update the artifacts to get the new version. So it is quite short of support for a group of people to collaborate their development, which often leads to low efficient collaboration. Aiming at this problem, ABCTool notifies the update to other collaborative developers when a developer updates an artifact. ABCTool will also display different updates for collaborative developers, for example, red color represents the update of "delete", green color represents the update of "add", and yellow color represents the update of "modify".

We will illustrate our approach described in section 3 by the following case. The scenario is as follows. Two developers collaboratively design software system "Example". One's user name is "cvsuer", and the other's user name is "wangxh". Configuration View "My.adl_cofig" (Shown as Figure 3) is one of main design artifacts of SA. It is stored in the server of CVS. We use file "My.adl.cofig" to describe how ABCTool assists the collaborative design among developers. Suppose that both developers are collaboratively developing the software based on version 1.2 in the design phase.

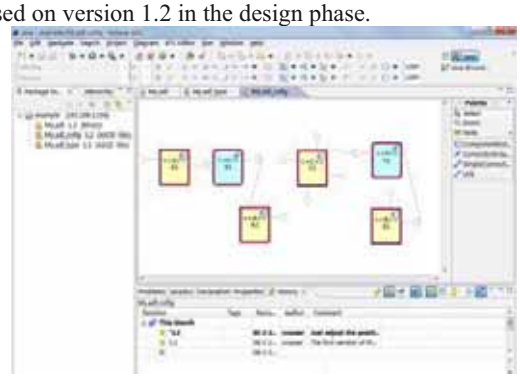

Figure 3. Component Configuration View "My.adl_cofig"

(1) User "wangxh" is editing file "My.adl.cofig" in the client. From the Page "History", we can see that there are two versions of this file, Version 1.1 and Version 1.2. In the server of CVS, newest version is 1.2. When user "wangxh" adds connector "Z1" and saves the file, we can see that the newest version in the client of User "wangxh" is still version 1.2 from the Page of "History" (described as Figure 4). Now the newest version is version 1.2 in the server. In the left navigator column, label ">" represents that the version of this file in the client is not consistent with the version in the server of CVS.

(2) After user ""wangxh" delivers the new version to the server of CVS, wangxh's client interface will be changed to Figure 5. We can see that the page of "History" shows the newest version in the client is version 1.3. We also see that file "My.adl_cofig" in the client is consistent with the file in the server from the left navigator column.

(3) When user "wangxh" submits new version, the page of "History" of another user "cvsuser" will display the version update of this file. At the same time, the tool will pop up a dialog box to remind user "cvsuser" that there is a new version has been submitted (described as Figure 6).

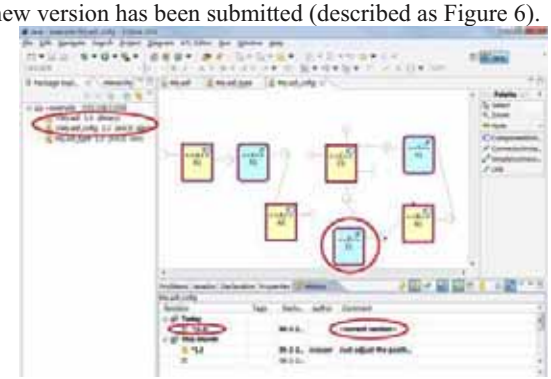

Figure 4. Wangxh' Client Interface before Version Update

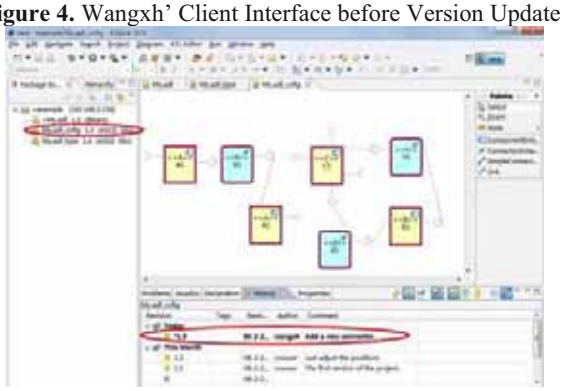

Figure 5. Wangxh' Client Interface after Version Update

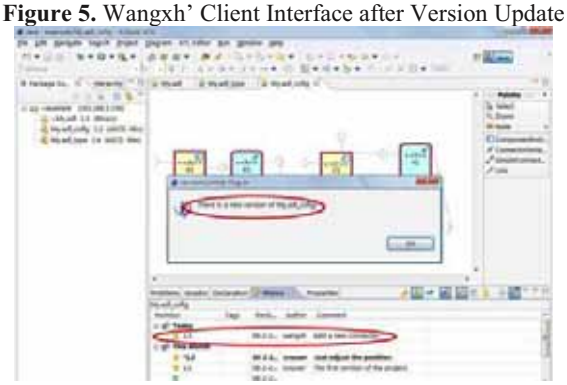

Figure 6. The Dialog Box to Remind the New Version

(4) When user "cvsuser" knows that the newest version of editing file "My.adl_cofig" is version 1.3, and its current version is 1.2, he can compare the difference between these two versions by the operation of "compare in ABCTool" (described as Figure 7). ABCTool can distinguish the classification of updates from their color. So, the new added connector will be highlighted green to represent its update is "add". Similarly, the element is yellow or red to represent the update is "modify" or "delete" respectively. The comparison based on the elements in diagram includes some kind of semantic comparison between these elements. So, it totally differs from the comparison based on text file.

We can see that the collaborative development supported by ABCTool is based on SA, and intuitionistic.

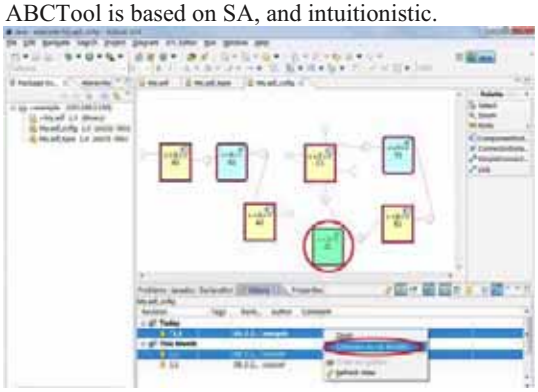

Figure 7. Compare the Difference between Two Versions

5. Conclusions

This paper puts forward an approach to support collaborative development in different phases based on software architecture. By using CVS, we can use software architecture model to distill the semantics of context changes recorded in CVS, and then use visualized SA modeling tool to display the change of SA model to assist different designers to collaborate their design. By using bi-transformation technologies, we can use the transformation relationships between SA and other artifacts to transform the modification manipulation of other artifacts from/to the modification manipulation of SA model and then use SA modeling tool "ABCTool" to support the collaborative development for different developers.

In the future, we will make further research on two key issues. One is how to provide more detailed controls on changes, including providing more semantics of change, introducing various developer roles, and managing authority. Another is how to introduce more architectural knowledge (e.g., design rationale) to facilitate the collaborative development.

Choosing a Software Architecture: An Approach and a Case Study

Abstract

The design of complex software systems requires careful analysis of alternative architectures, which may affect different qualities of an application. This paper reports on a case study in network management. Network management systems are traditionally designed according to a client-server paradigm. This work extends previous research that explored alternative solutions based on mobile code. Competing solutions are evaluated through analytical modeling. We also built a prototype design workbench, which supports more detailed comparisons of competing architectures by rapidly developing mockup implementations.

1. Introduction

Software architects are often confronted with the choice among different architectural paradigms in the design and implementation of complex software applications. Selecting the most appropriate style for the specific problem to be solved is not an easy task, and many factors influence the choice. Each choice, in fact, can have different effects on different properties that the resulting system should ensure. For example, one solution might be more robust, but might have a higher response time for certain functions. In general, no solutions can be found that work best in all possible practical situations, even for specific application domains and execution environments. It is therefore important to develop an approach that may support software architect in decision making.

In this paper we contextualize this general problem for an important class of critical software applications, namely network management (NM). NM is crucial for modern telecommunication networks, composed of thousands of interconnected nodes, which must be configured and monitored to guarantee a globally correct and efficient behavior. The network comprises many different kinds of devices: routers, switches, signal regenerators, repeaters. Because of distribution and accessibility problems, on site configuration and maintenance of individual nodes is often impossible. Rather, it must be performed by a remote NM system, which is responsible for collecting data from network apparatuses, monitoring them, and possibly reacting to the critical situations to guarantee the required quality of service.

NM is the discipline that studies the procedures and techniques used to monitor and configure the nodes of a telecommunication network. Besides conventional bookkeeping of on-line data and normal maintenance operations, NM is responsible for managing exceptional situations that can suddenly happen (e.g. broken links, traffic peaks). For example, to face a sudden overload of a particular network link, a performance management functionality might reconfigure a node by redirecting user traffic.

This paper is not strictly on NM. Rather, NM provides an interesting and realistic case study, which highlights how an architecture-driven software design process may provide a rational support to the reasoning and decision making of the software developer. We developed the case study in collaboration with industry[1], in the context of a feasibility study for the implementation of a new generation of NM services.

The currently adopted solutions to NM, such as SNMP [6] or RMON [14], adhere to a strict client-server paradigm, where the management station is in charge of querying nodes, collecting from them run-time monitoring data, and issuing appropriate response commands. The network management protocol specifies the format of messages and the semantics of operations. Because operations are described at a very fine-graine level, any NM functionality requires a large number of messages to be exchanged, and this *micro-management* causes serious efficiency drawbacks in terms of bandwidth consumption and computational burden at the management station. The links connecting the management station to the rest of the network easily become bottlenecks. Another source of congestion can arise when new software has to be delivered through the network. For example, to install, upgrade or modify the firmware code on a network

[1]We wish to thank Marco Mussini of Alcatel-Lucent, who challenged us to work on software architectures for NM, and Michele Panzeri who participated in the project.

element, a point-to-point connection must be activated with every node. The installation may become necessary as a response to detected congestion symptoms. Paradoxically, to react to congestion, the management station has to collect data from network nodes, thus further contributing to congestion. Access to the nodes involved in NM can thus become difficult or sometimes impossible. Network congestion generates response time degradation and hinders network scalability.

A software architecture based on mobile agents (MAs) [1, 4, 8, 9] appears to provide an appealing alternative paradigm for the design of NM systems. MAs can be defined as computational entities that act autonomously—proactively and reactively—and can relocate themselves on different nodes of a network. More precisely, we refer to MAs that fall under the so-called *weak mobility* paradigm. Weak mobility implies that an agent moves from one node and restarts its execution as a new process at the destination node. It can, however, carry state information as global data, as we will see later on in more detail[2].

Intuitively, an MA can be injected in the network and instructed to reach a set of controlled nodes to perform some NM functionality. At each node the agent may collect the necessary data locally, process them, and then eventually move back to a control station to report its findings. The ratio between the size of the data that must be collected locally and the data transported to the control station is called *semantic compression* performed by the agent. Intuitively agents look like an appealing solution whenever the network functionality that has to be performed fosters a high semantic compression. In fact, this would reduce network traffic over an equivalent solution based on the traditional CS paradigm. More generally, a NM architecture based on MAs looks appealing for the following reasons [4]:

- *Load balancing*: computation is distributed on many nodes.
- *Availability*: the control station may be temporarily down while the agents injected in the network locally monitor the nodes.
- *Asynchronous, autonomous, parallel interaction*. Mobile agents may work in parallel.
- *On-line extensibility*. On-the-fly installation (for versioning and patching) is easy to achieve.
- *Analysis precision*. The agent installed in a node can collect precise real-time measurements, independent of the network latencies that would be involved in a CS solution.
- *Network traffic reduction*. By migrating code near the data it processes, network traffic may be reduced ([11, 13]).

Main goal of our study was to precisely evaluate CS vs. MA architectures to try to minimize network traffic. The first approach we investigated was based on a simple mathematical model, which allows the designer to reason in a quantitative fashion about network traffic. This part of our contribution extends previous work [2]. Because of the limitations implicit in analytical reasoning, our next contribution has been directed to developing an environment that would support rapid prototyping. In this environment, it is possible to perform an empirical analysis of network traffic in the different cases.

Our experience confirms the need for the software engineer to be supported by a suitable methodology and tools while reasoning about different architectural alternatives. In fact, there is no winning solution in general, even in domain-specific cases, like NM. The architecture that performs better should be chosen depending on the specific functionality to provide. Also, the two approaches to reasoning—analytical modeling and prototyping—are complementary. In fact, the former may ignore some relevant phenomena that occur in reality and sometimes it requires input data that are difficult to anticipate. On the other hand, the latter may provide an estimate for such data to drive a more refined analytical modeling. Although our approaches to architectural reasoning are presented here to evaluate CS vs. MA, we argue that similar approaches can be followed in other cases of competing architectures, and can be extended to quality attributes other then network traffic.

This paper is organized as follows: Section 2 details the comparison of CS and MAs via analytical modeling. Section 3 describes the experimental workbench we developed for rapid prototyping. It also illustrates a simple case study adopted as proof of concept, which focuses on analysis of network traffic generated by a classification task performed by a neural network, implemented using both paradigms. Finally, Section 4 draws some conclusions, and discusses the general lessons learned from the case study.

2. Architectural Reasoning via Analytical Modeling

Previous work by Picco and Baldi [2] addressed this issue by comparing CS and MA on networks with uniform communication cost (e.g. a fully connected network). Their work describes a simple analytical model through which the alternative architectures are easily compared. Unfortunately, however, their work does not apply to several common practical cases. In particular, large telecommunication networks, for which NM is crucial, usually have a ring

[2] A taxonomy of mobile agents and the notion of weak mobility versus strong mobility have been introduced in [7].

topology. In this section we extend the approach of Picco and Baldi to networks with a ring topology, using the same formal notation. Let us introduce the following entities:

- η_{CS} = Protocol Overhead for Client Server
- η_{MA} = Protocol Overhead for Mobile Agents
- I = Request Size
- R = Reply Size

We assume the network to be composed of N nodes and, in a CS architecture, the management station performs Q requests of size I to each node, which replies with messages of size R. Instead in a MA architecture, an agent is injected in a node by the control station, with the purpose of letting it visit possibly all nodes of the network and performing some actions in each of them, consisting of issuing Q requests of size I and receiving replies of size R. After all nodes are visited, eventually the agent migrates from the last node back to the control station.

2.1. Total Network Traffic

The total traffic generated by a MA on a ring topology network can be modeled by the following formula:

$$T_{\text{MA}} = \sum_{n=1}^{N}(C_{\text{MA}} + S_{\text{MA,n}}) + \eta_{\text{MA}} \sum_{n=1}^{N}\sum_{q=1}^{Q} R_{q,n} \qquad (1)$$

The first term describes the traffic generated by an agent during its relocations: every agent has a size that is determined by a code fragment C_{MA} and a state $S_{\text{MA,n}}$. The second term describes the replies from the nodes, i.e., the data collected at each node, which must be communicated to the control as illustrated in Figure 1.

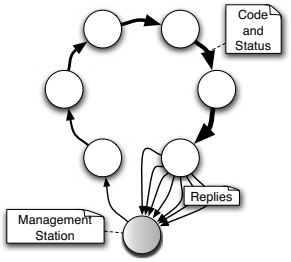

Figure 1. Mobile Agents communication flow

The state of the agent in each node is composed of the replies collected by the agent during its relocations. It is thus possible to write:

$$S_{\text{MA,n}} = \begin{cases} 0, & \text{if n=1} \\ \sum_{m=1}^{n-1}\sum_{q=1}^{Q} R_{q,m}, & \text{if n>1} \end{cases} \qquad (2)$$

Indeed for every node the status is the sum of the previous statuses (i.e. the information collected in the previous nodes). Assuming that the size of replies is a constant R we can write:

$$S_{\text{MA,n}} = \begin{cases} 0, & \text{if n=1} \\ \sum_{m=1}^{n-1} QR = (n-1)QR, & \text{if n>1} \end{cases} \qquad (3)$$

Consequently:

$$T_{\text{MA}} = \sum_{n=1}^{N} \eta_{\text{MA}}(C_{\text{MA}} + (n-1)QR) + \eta_{\text{MA}} NQR = \qquad (4)$$

$$= \eta_{\text{MA}}(NC_{\text{MA}} + \frac{N(N+1)}{2}QR)$$

Obviously, under the same assumptions made for MAs, for the CS paradigm the cost in a ring topology network is not uniform because the cost of communication depends on the distance in the ring between the management station and the node of interest.

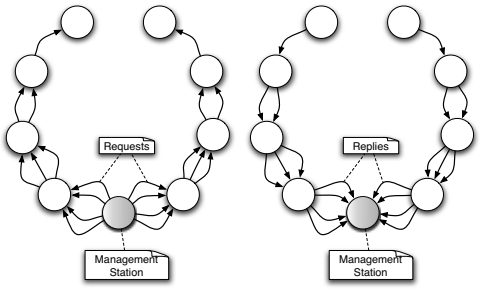

Figure 2. Client Server communication flow

Thus the total traffic can be modeled by the following weighted sum (see Figure 2):

$$T_{\text{CS}} = 2\sum_{m=1}^{\frac{N}{2}} mQ(\eta_{\text{CS}} I + \eta_{\text{CS}} R) \qquad (5)$$

where m represents a multiplicative factor (m = N/2 if we consider the traffic at the management station; m = (N/2)-1 at the adjacent nodes, and so on). The formula can be rewritten as:

$$T_{\text{CS}} = \frac{N}{2}\left(\frac{N}{2}+1\right) Q(\eta_{\text{CS}} I + \eta_{\text{CS}} R) \qquad (6)$$

At this stage, it is necessary to take into consideration the semantic compression. As we observed earlier, in fact, agents can compress the data collected. Thus the size of the reply computed by a MA at a given node can be a fraction of the size of the data that are transmitted back to the

management station in a CS setting. Assuming the size of the reply in the CS case to be a constant R and assuming the average reduction factor to be a constant θ, the size of the replies for a MA at each node is θR. T_{MA} then becomes:

$$T_{\text{MA}} = \eta_{\text{MA}}(NC_{\text{MA}} + \theta\frac{N(N+1)}{2}QR) \quad (7)$$

Moreover, assuming N to be large, and $\eta_{\text{MA}} \approx \eta_{\text{CS}}$, we obtain that $T_{\text{MA}}<T_{\text{CS}}$ if and only if:

$$C_{\text{MA}}<\frac{N}{4}Q(I+R) - \theta QR\frac{N}{2} \quad (8)$$

This inequality describes under which circumstances MAs are preferable to CS in terms of total traffic generated in a ring topology network. The MA code size is compared with a term that depends on number of nodes, number of queries, request and reply size and average semantic compression.

MAs can perform even better if *global semantic compression* can be achieved on replies. As an example, let us consider a scenario in which an agent travels through the entire network, computing at each node a compressed value, and delivering to the control station the maximum of such values. In this case the agent has to carry through the network only a single reply R containing the current maximum. Thus T_{MA} becomes:

$$T_{\text{MA}} = \eta_{\text{MA}}N(C_{\text{MA}} + R) \quad (9)$$

$T_{\text{MA}}<T_{\text{CS}}$ if and only if:

$$C_{\text{MA}}<\frac{N}{4}Q(I+R) - R \quad (10)$$

2.2. Network Traffic at the Control Station

Network management can generate intense traffic around the control station. Intuitively, this is especially true in CS cases. Thus, instead of analyzing the total network traffic, it may be interesting to evaluate the possible bottlenecks around the control station. The traffic generated by the CS paradigm is:

$$T_{\text{CS}} = \eta_{\text{CS}}NQ(I+R) \quad (11)$$

The formula represents the transmitted requests I and the received replies R between the control station and two adjacent nodes inside the ring (see Figure 2). On the other hand, for MAs we have:

$$T_{\text{MA}} = \eta_{\text{MA}}C_{\text{MA}} + \eta_{\text{MA}}NQR \quad (12)$$

Consequently $T_{\text{MA}}<T_{\text{CS}}$ if and only if:

$$C_{\text{MA}}<NQI \quad (13)$$

where NQI represents the total size of the requests. Moreover, considering semantic compression, we obtain:

$$C_{\text{MA}}<NQ(I+R) - \theta NQR \quad (14)$$

This inequality clearly states that MAs perform better if the agent's code is smaller with respect to the difference between the (semantically compressed) data collected by an agent and the size of the total requests and replies transmitted/received by the control station. Furthermore, if we analyze the traffic at the management station in case of global semantic compression we obtain:

$$C_{\text{MA}}<NQ(I+R) - R \quad (15)$$

We may conclude that the comparison of CS and MA architectures in terms of the generated traffic depends on several parameters of the application. Some of the data involved in the formulae may be difficult to anticipate, and might require some experiments to be performed in order to obtain them. We believe that in general this kind of analysis may benefit from a complementary kind of experimental analysis. The prototype workbench described in the next section has been developed to support this task.

3. Prototype Workbench

The workbench offers features that allow the designer to rapidly develop mockups of NM functionalities and run them to get comparative quantitative data (e.g., network traffic). Mockups comprise a set of sites, connected through a network. A middleware, called *playground*, supports communication and coordination of NM mockup components that run on top of it. Each site provides its own playground. To support rapid prototyping, we decided to use scripting languages to implement NM functionalities. Each functionality is implemented by what is called an *agent*. Agents should not be confused nor identified with MAs. They can be programmed to behave as MAs, but they can also support other paradigms, such as CS. Agents may be written in any scripting language. We developed support for Perl, Python, and Ruby, but others may be easily developed. A decoupling layer (i.e., the tool layer), provides an API that allows agents to transfer their execution from a playground to another and allows communication mapping the data provided by agents onto linear messages transferred by the middleware. Figure 3 shows a fragment of the architecture.

An agent defines an elementary functional unit. It is represented by a tuple <C, B, D>, where C is a code block that defines a computation, B is a dataset (called backpack) that stores useful information for the agent, and D is the agent's descriptor. D stores the static and dynamic description of an agent (interface, intention, version, author). If an agent implements an MA that collects data in each visited node, collected data are stored in the backpack. In such a case, the tuple that represents an agent is transferred from a playground to another as an XML file.

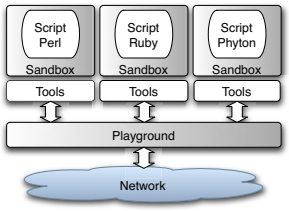

Figure 3. System Architecture

Agents may communicate via asynchronous messages. A message is defined by the pair <*E, Y*>, where E is the message envelope and Y is the body, which represents the information to transfer, and has variable length. E is also a pair <*S, R*>, where S identifies the sender and R identifies the receiver(s). S is defined by a pair <*IDsite, IDagent*>, which uniquely identifies an agent. Because the middleware supports both unicast and broadcast (at site level or at agent level), R can have one of the following structures:

- <*IDsite, IDagent*>: unicast.
- <*IDsite, **>: site unicast, agent broadcast.
- <*, *IDagent*>: site broadcast, agent unicast.
- <*, *>: site broadcast, agent broadcast.

An agent that wishes to send the message must provide information about the receiver(s) and the body. The communication tool automatically generates the rest of the message. Once sent, the message is passed to the middleware and then routed to destination. Once it arrives at destination, the message is queued, waiting that the receiver agent to read it.

The middleware provides two primitives that support agent mobility [3]: *Relocate* and *Visit*. First of all, when an agent wants to migrate across the network it creates the backpack containing the data to be carried to the destination. Afterwards, when a Relocate is invoked, an agent indicates to the middleware the destination site through its identifier IDsite. If the Visit primitive is invoked, the agent visits the whole network, site after site. It is not necessary to specify any destination but it still necessary to prepare the backpack containing the data. In this case, inside the backpack there is also additional information written by every playground visited by the agent during the Visit. At the implementation level, when a Relocate is invoked, an XML string representing the agent is sent to the destination playground, where a new process running the agent is started, with the backpack as a parameter.

[3] As we already mentioned, we support weak mobility, as defined in [5].

The playground offers to the agents a number of support tools, which allow new NM functionalities to be prototyped. The tools API provides the mechanisms (communication, migration and synchronization primitives) needed to implement different architectural styles; in particular, CS and MAs. Thus through the workbench it is possible to develop, test and monitor applications for NM designed in different paradigms. Different solutions may be tested in the form of mockups at design time by using this workbench, to support architectural reasoning, before implementing them as a new NM applications.

3.1. Experimenting with the Workbench

Hereafter we illustrate how the workbench can be used to support architectural reasoning. In our case study, we analyze the network traffic around the NM control station and we compare CS and MA solutions for a specific network management function that performs *alarm correlation*. Alarm correlation is a useful NM feature, which is often used for alarm filtering or diagnosis. An experiment we made is based on the approach described by [12], which uses neural networks for this task. Because a considerable amount of data must be collected from the network nodes to train the neural network algorithm, we decided to compare alternative solutions based on CS and MA paradigms, by evaluating the traffic generated around the NM control station. The neural network used in our case study needs about 10000 iterations to converge during the training phase. Using our prototype workbench, the solution of our case study can be designed with a CS architecture in which the neural network is implemented by an agent installed on the NM control station. The agent builds the dataset through requests to agents installed on the individual network nodes. Alternatively, it is possible to exploit MAs. Indeed, the neural network can be embodied inside an agent and the learning algorithm is executed on every node. For space reasons, we cannot report the details of the experimental results. However, they show that the CS solution generates much more traffic than the MA solution. Indeed, the latter does not need to transmit the entire dataset, because it exploits its capability to migrate the code near the data. Using MAs, the control station is only in charge of injecting the agent inside the network and receiving it at the end. Figure 4(a) summarizes the training time of the neural network depending on the number of iterations. Figure 4(b) summarizes the network traffic generated around the control station during the training phase. The MA paradigm becomes convenient with a relatively low number of iterations. In particular, it generates a constant traffic (corresponding to the agent implementing the neural network). Vice-versa, the network traffic generated by the CS paradigm grows linearly with the number of iterations.

(b) Traffic analysis

Figure 4. Experimental Analyses

4. Conclusions and Future Work

In this paper we addressed the issue of systematically supporting the choice of an architecture among a set of alternatives through rigorous, quantitative reasoning. We addressed the specific domain of NM, focusing on network traffic minimization. We developed two complementary approaches to architectural reasoning: one based on analytical modeling, and another based on execution of mockups. To support the latter, we developed a workbench environment. The workbench supports fast development of complex NM functionalities by exploiting the abstractions of agents, playgrounds, and tools. Mockup applications can be written in any scripting language and the system is designed with a plug-in support to add new languages and new tools. Finally, we have shown how the workbench can be used to perform experimental analyses. This work is part of our long-term research that aims at supporting software engineers in the design and early validation of software architectures. We are working on a variety of architectural paradigms and a variety of validation approaches covering both functional and non-functional requirements. In particular, we focus on validation techniques that include formal analysis via model checking [3, 10].

Abstract

Most formal software verification techniques are based on formal specifications of software behavior. Approaches to facilitate the creation of formal specifications include the Specification Pattern System (SPS) and Composite Propositions (CPs). Recent research into generating Linear Temporal Logic (LTL) formulas from SPS patterns resulted in a set of templates that support CPs, but are complex and difficult to verify. This paper describes PROTEF, a software framework to automatically generate and test formulas representing software specifications using model-checker-based testing. This method can be used to test templates in LTL and other formalisms. The framework was used to test LTL templates developed to support CPs.

1. Introduction

Software verification is a fundamental part of the software production process. Formal verification techniques, such as theorem proving [14], runtime-monitoring [4, 5], and model checking [1, 2, 8] are based on formal specifications of software behavior. Creating and validating formal specifications is a significant impediment to the adoption of formal verification techniques [6, 7].

There have been successful research efforts to minimize the challenges of creating formal specifications including the Specification Pattern System (SPS) [3], Composite Propositions (CPs) [10, 11], and the Property Specification Framework (Prospec) [10, 12]. These approaches assist a user in the creation of specifications based on commonly used patterns.

This work introduces the Property Testing Framework (PROTEF), a software framework to automatically generate and test formulas representing software specifications, in particular, specifications based on SPS and CPs. The framework consists of three main components: (1) Property Generator (PROGENE), (2) Property Test Generator (PROTÉGÉ), and (3) Property Tester (PROTEST). The purpose of each component in the framework is to complete each of the processes in the testing method's workflow. *Model checker-based testing* [15] is used here as a general method for testing software specifications based on SPS patterns and CPs. It can be used to test specifications generated in Linear Temporal Logic (LTL) and other formalisms such as Computational Tree Logic (CTL) [9]. PROTEF is described in details in Section 2.4, while PROGENE and (PROTÉGÉ) are described in sections 3 and 4 respectively.

2. Background

2.1. Linear Temporal Logic (LTL)

LTL is a highly-expressive formal language that is widely used in model checkers such as NuSMV [1] and SPIN [8], as well as for the runtime verification of Java programs [18]. The standard LTL operators are shown in Table 1. One problem with LTL is that it is hard to read. For example, it is not immediately obvious that the LTL specification $\square(a \rightarrow \diamond(p \wedge \diamond(\neg p \wedge \neg a)))$ represents the English requirement "If a train is approaching(a), then it will be passing(p), and later it will be done passing with no train approaching".

In this paper, an *execution trace* is represented by positions, read left to right, where each position indicates a state. The spaces are filled with the atomic propositions that are true in that state. A dash indicates no proposition is true. If more than one proposition is true, they are written between parentheses. Table 1 lists the usual LTL operators with example and counter example traces.

2.2. Specification Pattern System (SPS)

Dwyer [3] conducted a survey of software projects and identified a set of commonly occurring software properties. These properties were generalized, formally described, and categorized into *specification patterns*. SPS facilitates the specification of software properties by providing a set of general templates with natural language descriptions. After reading the English descriptions, practitioners identify

Table 1. Description of LTL Operators

Operator	Name	Example Trace	Counter Trace
$\neg$	Not a	$- - - - -$	$a - - - -$
$\wedge$	a And b	$(ab) - - - -$	$- - (ab) - -$
$\vee$	a Or b	$a - - - -$	$- - b - -$
U	a Until b	$a\,a\,a\,b-$	$a\,a\,a - b-$
X	Next a	$-a - --$	$a - - - -$
$\diamond$	Eventually a	$- - a - --$	$- - - - -$
$\Box$	Always a	$a\,a\,a\,a\,a\,a\,a\,a$	$a\,a\,a\,a - a\,a\,a$

Table 2. Description of CP Classes in LTL

CP Class	LTL Description (P^{LTL})
$AtLeastOne_C$	$p_1 \vee \ldots \vee p_n$
$AtLeastOne_E$	$(\neg p_1 \wedge \ldots \wedge \neg p_n) \wedge ((\neg p_1 \wedge \ldots \wedge \neg p_n)\, U\, (p_1 \vee \ldots \vee p_n))$
$Parallel_C$	$p_1 \wedge \ldots \wedge p_n$
$Parallel_E$	$(\neg p_1 \wedge \ldots \wedge \neg p_n) \wedge ((\neg p_1 \wedge \ldots \wedge \neg p_n)\, U\, (p_1 \wedge \ldots \wedge p_n))$
$Consecutive_C$	$(p_1 \wedge X(p_2 \wedge (\ldots (\wedge X p_n)) \ldots))$
$Consecutive_E$	$(\neg p_1 \wedge \ldots \wedge \neg p_n) \wedge ((\neg p_1 \wedge \ldots \wedge \neg p_n)\, U\, (p_1 \wedge \neg p_2 \wedge \ldots \wedge \neg p_n \wedge X(p_2 \wedge \neg p_3 \wedge \ldots \wedge \neg p_n \wedge X(\ldots \wedge X(p_{n-1} \wedge \neg p_n \wedge X p_n)) \ldots))$
$Eventual_C$	$(p_1 \wedge X(\neg p_2\, U\, (p_2 \wedge X(\ldots \wedge X(\neg p_{n-1}\, U\, (p_{n-1} \wedge X(\neg p_n\, U\, p_n)))) \ldots))))$
$Eventual_E$	$(\neg p_1 \wedge \ldots \wedge \neg p_n) \wedge ((\neg p_1 \wedge \ldots \wedge \neg p_n)\, U\, (p_1 \wedge \neg p_2 \wedge \ldots \wedge \neg p_n \wedge ((\neg p_2 \wedge \ldots \wedge \neg p_n)\, U\, (p_2 \wedge \neg p_3 \wedge \ldots \wedge \neg p_n \wedge (\ldots \wedge (p_{n-1} \wedge \neg p_n \wedge (\neg p_n\, U\, p_n)) \ldots)))))$

the template they need and substitute their propositions into the template. SPS introduces the concepts of *pattern* and *scope*. A pattern is the specification template describing the software behavior, and scope is the extent of program execution over which the behavior described by the pattern must hold.

2.3. Composite Propositions (CP)

Some applications require the specification of sequential and concurrent behavior, and it may be necessary to define groups of propositions and the relations between the propositions. Mondragon et al. [10, 11] created a set of abstractions that describe the relation between groups of propositions, referred to as CPs.

Mondragon defined eight CP classes that can be used to describe sequential and concurrent software behavior by identifying the relationships among the propositions in the properties. With CPs, propositions represent either conditions or events. Events are either the beginning or the end of a condition and are instantaneous, while conditions have duration. Conditions describe concurrent behavior, and events describe synchronization. Table 2 provides a description in LTL of the CP classes described by Mondragon. The subscript at the end of the CP class specifies whether the class refers to a set conditions (C) or events (E).

To motivate the use of CPs, consider the example requirement "Request (R) always triggers Acknowledgment (A) between Beginning of execution (B) and System shutdown (S)". Suppose R not only triggers A, but it also triggers Logging (L), and Validation (N). Questions that arise include Do they happen at the same time? Are they all required? Must they occur in a certain order? These concerns are addressed by CPs. In this case, assume that A, L, and N must all occur at the same time. Then we can use the $Parallel_E$ CP class. Using the LTL templates of the CP classes in Table 2 and applying direct substitution of the propositions in the property to the template yields: $Parallel_E$(A, L, N) $\equiv (\neg A \wedge \neg L \wedge \neg N) \wedge ((\neg A \wedge \neg L \wedge \neg N)\, U\, (A \wedge L \wedge N))$.

SPS uses direct substitution of single propositions into predefined templates to generate pattern-based specifications. Salamah [16] demonstrated that it is not possible to use direct substitution of composite propositions in SPS templates without losing the original intent of the pattern and scope.

To address the problem created by direct substitution, Salamah [16, 17] generated a new set of general pattern and scope templates like the templates generated by Dwyer. The correctness of a template is defined as the quality of maintaining its original pattern and scope semantics when substituting CPs while at the same time preserving the original intent of the CP classes. For the purposes of this work, we will call the pattern and scope templates created by Salamah *abstract templates*. Abstract templates (as opposed to SPS templates) have placeholders for CPs rather than single propositions. A template is instantiated by replacing the placeholder in the abstract template with a CP. An abstract template is correct if for all possible instantiations of the abstract template, the meaning of its pattern, scope and CP classes is preserved.

3. Property Testing Framework (PROTEF)

The goal of the work described in this paper is to gain confidence in Salamah's abstract pattern-based templates for LTL by testing them. Testing all the abstract templates is not an easy task given the total number of combinations of patterns, scopes and composite propositions classes. For example, restricting ourselves to CPs with three propositions, the abstract template from the $Absence$ pattern and the $After\ L$ scope, $\neg((\neg L)\, U\, (L \wedge \diamond P))$, would produces a total of 64 formulas, by substituting the 8 existing CP classes for L and the eight existing CP classes for P. Continuing in this fashion for all the abstract LTL templates and all the CP classes would produce over 30,000 formulas. In order to test all of the concrete formulas it is necessary to

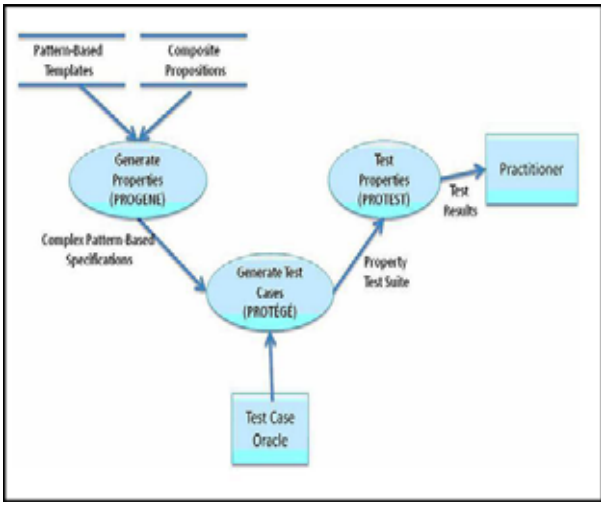

Figure 1. PROTEF Framework

develop a testing method that automates the generation and testing of the templates.

A framework for manipulating properties called Property Manipulation Framework (PROPMAN) was developed that includes the basic object-oriented modules required to manipulate pattern-based properties using Java. The Property Testing Framework (PROTEF) was implemented using PROPMAN. PROTEF is designed to use pattern-based properties for two particular purposes: (a) generating concrete specifications using abstract templates and (b) testing the generated concrete specifications. The effectiveness of PROTEF and the usefulness of our testing approach was demonstrated by testing the pattern-based specifications in LTL for all formulas in the $Absence$ pattern and the $Before\ R$ scope, limiting the choice of composite propositions to $Eventually_E$ and $AtLeastOne_C$.

PROTEF includes three subsystems: the Property Generator (PROGENE), the Property Test Generator (PROTÉGÉ) and the Property Tester (PROTEST). PROGENE is responsible for generating all the possible permutations of specifications that will be tested. PROTÉGÉ is the subsystem responsible for generating test cases for each pattern-based specification. Once we have the specifications and test cases, the job of PROTEST is to perform the actual testing of the formulas. This workflow, devised for testing a large set of pattern-based specifications, is depicted in Figure 1.

3.1. The Property Generator: PROGENE

PROGENE is the framework module that generates the pattern-based specifications that must be tested. Abstract templates are instantiated with CPs producing pattern-based specifications. By using all of the abstract templates for all patterns and scopes, and concrete CPs for all CP classes, we can generate combinations of pattern-based specifications. In the work described here, we have limited the abstract templates to a single pattern, a single scope, and two composite propositions classes.

The Property Generator module has several features required to make the framework general for further use. First, PROGENE works independently of the formal language. Second, it is extensible: In the event that new patterns and scopes are identified, they can be easily included in the list of supported patterns and scopes. Third, it extends to new CPs: Currently the work in composite propositions includes a total of eight composite propositions classes. If new composite propositions classes or new propositions types are identified, they too can be easily incorporated.

We use the abstract LTL templates presented in Salamah [16, 17]. We have chosen to work with only the abstract templates pertaining to the $Absence$ pattern and four CP classes. In the templates, each letter R, Q, L, and R with superscript LTL refers to a placeholder for a composite proposition in LTL, which is to be replaced by the practitioner's own CPs. Salamah's templates use the letters P and R with subscript H to indicate a special class of CPs that refer to the part of the CP where the proposition holds. Salamah also introduces special AND symbols: $\&_r$, $\&_l$ and $\&_{-l}$. These operations do not extend regular LTL, and they have special semantics that make specification easier. The semantics of these operators are out of the scope of this paper; however, PROGENE supports these operators.

PROGENE takes as input the templates similar to the ones shown in Table 3. Each CP placeholder in the templates needs to be identified. A notation for identifying placeholders in the templates was developed:

- $Proposition$: A proposition is a character identifier. The character is one of L, P, Q, or R.
- $NEGATED\_proposition\_type$: This placeholder will be substituted by the negated LTL formula for the CP in $proposition\_type$, where $proposition\_type$ is defined as in $CP(proposition\_type)$.
- $HOLD\_proposition\_type$: This is placeholder represents a special CP class, defined by Salamah. This special CP class is also depicted by an LTL formula and is dependent upon $proposition\_type$, where propositions are defined as in $CP(proposition\_type)$.

PROGENE provides the flexibility for the user to define new placeholders in addition or replacing the ones used to generate the formulas described here and included in the framework by default.

In the rest of this section, the listings, PC, RC, PE, and RE, refer to CPs named P or R, for conditions (C) or events (E) using the definition for $proposition\_type$ given above.

Table 3. LTL Templates for Absence of P Before R

Pattern/Scope	LTL Template
$Absence\,of\,P_C$ $Before\,R_C$	$\neg((\neg R)\,U\,((P\,\&_r\neg R)\,\&_l\,\diamond\,R))$
$Absence\,of\,P_C$ $Before\,R_E$	$(\diamond R \rightarrow \neg((\neg(NEGATED\_R$ $\wedge\,X\,HOLD\_R))\,U\,P\,\&_r\,\neg HOLD\_R)))$
$Absence\,of\,P_E$ $Before\,R_C$	$\neg((\neg R)\,U\,((P)\,\&_r\,\neg R)\,\&_l\,\diamond\,R)$
$Absence\,of\,P_E$ $Before\,R_E$	$(\diamond R \rightarrow \neg((\neg(NEGATED\_R\wedge$ $X\,HOLD\_R))\,U\,P\,\&_r\,\neg HOLD\_R)))$

The first template can be applied to cases where P is of type C. Similarly the second template can be applied to the cases where P is of type E.

The CP templates shown in Table 2 are instantiated using three simple propositions, and the resulting CPs will be directly substituted in the corresponding placeholders in the abstract templates in Table 3. Given the templates and CPs, PROGENE generates all the possible concrete pattern-based properties that can be generated by substituting the composite propositions into the corresponding placeholders in the abstract templates. In addition to the actual specification, PROGENE generates metadata regarding the origin of each concrete pattern-based property. The following listing is an example of the generation of one pattern-based property in our case study:

- Original Abstract Template: "Absence of PC Before RC"
  $\neg((\neg CP(RC))\,U\,((CP(PC)\&_r\neg CP(RC))\&_l\ \diamond\ CP(RC)))$
- Comprising propositions for the P and R CPs:
  - $AtLeastOne_C\ (P_1 \vee P_2 \vee P_3)$
  - $AtLeastOne_C\ (R_1 \vee R_2 \vee R_3)$
- Generated LTL Specification:
  $\neg((\neg(R_1 \vee R_2 \vee R_3))\,U\,(((P_1 \vee P_2 \vee P_3) \wedge \neg(R_1 \vee R_2 \vee R_3)) \wedge \diamond(R_1 \vee R_2 \vee R_3)))$
- Generated Metadata:
  - Base Property:
    - Label: Absence of P_C Before R_C
    - Pattern: Absence of P
    - Scope: Before R
    - Template: $\neg(((\neg R)\,U\,P\,\&_r\,\neg R)\,\&_l\,\diamond\,R)$
  - Generated Property: $\neg((\neg(R_1 \vee R_2 \vee R_3))\,U\,(((P_1 \vee P_2 \vee P_3)\,\&_r\,\neg(R_1 \vee R_2 \vee R_3))\,\&_l\,\diamond\,(R_1 \vee R_2 \vee R_3)))$
  - CP components:
    1. Label: $AtLeastOne_C$
       CP Class: At Least One Condition
       Formula: $(P_1 \vee P_2 \vee P_3)$
    2. Label: $AtLeastOne_C$
       CP Class: At Least One Condition
       Formula: $(R_1 \vee R_2 \vee R_3)$

The metadata will be used in the testing phase. It includes information such as the CP classes of each of the CPs that comprise the formula, as well as pattern and scope information of the pattern-based specification.

3.2. Property Test Generator (PROTÉGÉ)

A test case for a specification consists of an execution trace and an expected result. PROTÉGÉ is the subsystem that provides the functionality required to manage property tests. This subsystem prepares all the necessary elements for the Property Tester. Our testing method is based on the work of Salamah et al. [15].

Patterns, scopes, and CP classes have specific logical definitions and semantics that can be inferred from their English descriptions. For example, given a pattern-based property of type $AbsenceofPbeforeR$, where P and R are CPs of class $AtLeastOne_C$, we can infer that no CP P is TRUE before the CP R is TRUE. Since both P and R are of type $AtLeastOne_C$, we can further reason that we do not expect even a single proposition that belongs to P to become TRUE, before any of the propositions that belong to R becomes TRUE. This can be visualized using execution traces, for example, "$----R---P-------$". Since P and R are CPs of type $AtLeastOne_C$, if the proposition sets P and R are defined as P = $\{p_1,\ p_2,\ p_3\}$ and R = $\{r_1,\ r_2,\ r_3\}$, then, instantiating the CPs based on the LTL definitions gives $AtLeastOne_C$(P) = $p_1 \vee p_2 \vee p_3$ and $AtLeastOne_C$(R) = $r_1 \vee r_2 \vee r_3$. The original trace of execution may be replaced by "$- - - - r_1 - r_2 - r_3 - - - p_1 - p_2 - p_3 - - - - -$".

The trace of execution shown above satisfies the property, since there is an absence of all the propositions in P before the first proposition in R appears. Given a trace of execution and a pattern-based property as inputs, the expected output is whether the trace of execution satisfies the property. This constitutes a property test case: a trace of execution, a pattern-based property and TRUE or FALSE, depending on whether the trace of execution should satisfy the property.

Generating Test Cases PROTÉGÉ's main function is to generate property test cases. PROTÉGÉ is designed to automatically generate large sets of test cases. In order to gener-

Table 4. Traces of Computation of Absence P(Eventually$_E$) Before R(Eventually$_E$)

Trace of Computation	Expected Result(T/F)
$(R_1R_2R_3) - -P_1 - -P_2 - P_3 -$	TRUE
$(R_1R_2R_3P_1P_2P_3) - - - - - -$	TRUE
$- - - - - - - - - (R_1R_2R_3)$	TRUE
$- - - - (R_1R_2R_3P_1P_2P_3)$	TRUE
$- - R_1 - R_2 - R_3 - - P_1P_2P_3 -$	TRUE
$- - R_1R_2 - P_1P_2 - R_3 - P_3 - -$	TRUE
$- - R_1R_2R_3 - - P_1P_2P_3R_1R_2R_3 - -$	TRUE
$- - P_1 - P_2 - P_3 - - P_1P_2 - P_3 - -$	TRUE
$- - P_1P_2P_3 - - - R_1R_2R_3 - -$	FALSE
$- - - - - - P_1P_2P_3R_1R_2R_3$	FALSE
$- - - P_1P_2P_3R_1R_2R_3 - - -$	FALSE

ate tests for all properties resulting from the possible combinations of patterns, scopes, and CPs, it is necessary to use basic execution traces describing pattern-based properties of single propositions. These traces are defined in Salamah et al. [15, 16]. They define the basis for testing all the possible combinations of properties with CPs. In defining these basic traces, Salamah used boundary value analysis and equivalence class testing.

For the purposes of this case study, we generated a set of 68 cases to test the properties of type *Absence of P before R*, for the $Eventually_E$ and $AtLeastOne_C$ CP classes. [1] PROTÉGÉ reads traces and expected results from a file and stores these in the *property test oracle*, which provides tests for a specific pattern-based property. When a request is made to the oracle, it encapsulates the property, the execution trace, and the expected result into a structure that can be used by PROTEST. Table 4 shows example traces of computations used to test the template for $Absence$ of P_E. Before R_E, where both P and R are of type $Eventually_E$.

3.3. Property Tester (PROTEST)

PROTEST executes property tests created by PROGENE and PROTÉGÉ by using a model checker. In order to apply model checking to software three things are needed: a finite state machine model of software, a specification, and a model checker. The model checker exhaustively searches all possible states in the model verifying that it satisfies the specifications. In typical use, a model of a system is built, the system's specifications are created, and a model checker is run to verify that the model satisfies the specifications. Practitioners assume the correctness of the specifications and verify the software model.

[1] The automatic generation of test cases for the remaining pattern/scope combinations is left as a future work, and it is based on the same approach used for generating this set of 68 cases.

```

20.
```

Figure 2.
SMV Code Used in Testing

In our case, rather than verifying the model, we assume the correctness of the model and verify the specifications. This is the basis for what we call *model-checker-based testing* of properties. PROTEST includes an interface to the NuSMV model checker [1]. NuSMV was chosen for the simplicity of its modeling language, its graphical user interface, and its availability. By providing an interface to NSMV, PROTEST users are able to run the NSMV model checker using Java.

An execution trace can be transformed into a model in the following manner. Given an example execution trace: $- - - P_1P_2P_3 - - - R_1R_2R - - -$, number the states starting at 0. The example trace shows that P1 is true only in state 3, p2 is true only in state 4, and so on. We generate a model that has only one possible execution path. Figure 2 shows the SMV code created for this example.

The SMV code creates a Boolean variable for each of the propositions in the trace of execution and determines the value of the counter variable when the propositions will be true. The 'LTLSPEC' defines a property specification. The 'ASSIGN' section creates a counter from 0 to 14 matching exactly the trace of execution. A model is generated for each test case, the model checker is invoked, and the result is compared to the expected result.

4. Example Template Verification

To demonstrate the PROTEF framework, we generated and tested a subset of all the possible pattern-based properties based on SPS and CPs. The subset of properties included the *Absence of P* pattern and the *Before R* scope, limiting ourselves to two choices of composite propositions classes $AtLeastOne_C$ and $Eventually_E$.

The subset of the properties that we used included four pattern-based CPs. Table 5 shows the results of executing the model checker-based testing for the four generated prop-

Table 5. Test Results For Absence Before R

P	R	Test Cases	Tests Passed
$AtLeastOne_C$	$AtLeastOne_C$	16	16
$AtLeastOne_C$	$Eventually_E$	20	20
$Eventually_E$	$AtLeastOne_E$	18	18
$Eventually_E$	$Eventually_E$	14	14

erties: $Absence$ of P_C Before R_C, $Absence$ of P_E Before R_C, $Absence$ of P_C Before R_E, and $Absence$ of P_E Before R_E.

The initial execution of the test suite generated for the *Absence of P before R* pattern produced several failures. Expert reviews with the author of the templates, temporal logic experts, and practitioners revealed three primary causes: (1) There were errors in the expected values supplied to PROTÉGÉ. (2) The original templates were incorrect. (3) There were misinterpretations of the semantics of the $\&_r$ operation introduced in Salamah [16]. After the problems were corrected (i.e., the templates were updated and the $\&_r$ operator reimplemented), the test cases were re-executed successfully.

These three classes of errors demonstrate the importance of the testing effort. We independently discovered errors in the original templates, the same errors discovered during Salamah's attempts at formal correctness proofs. The miscalculation of the expected value of the test cases indicates how difficult it can be to create and read complex specifications. Tool support is essential. It is important to consider these original test failure causes in order to avoid repeating these potential failures in the future.

5. Conclusions and Future Work

One of the goals of this project is to be able to verify the correctness of all the pattern-based properties for any pattern, scope and CP class. In this work we built the software framework needed to achieve that goal and we demonstrated how to use the framework to verify a subset of the properties. The SPS authors state that they verify the correctness of their properties through formal peer reviews. PROTEF could help in the verification of their formulas in a more systematic and autonomous way and provide a higher degree of reliability.

The generation of execution traces is a fundamental part of testing the properties that is not automatic. It may be possible to create general tests from which concrete tests based on specific composite propositions classes can be generated, and further work is required in this area.

bmikolajczak@umassd.edu

Abstract

This paper presents a case study of integration of object-oriented design with Petri nets. Cooperating Objects are used for Petri net modeling of the object-oriented design. Firstly, all objects are represented by separate Petri nets. Secondly, a coordinating Petri net is designed to represent collaboration of objects involved. Benefits of both methodologies and of Object-Oriented Design and formalisms of Petri nets are used for verification and validation purposes. ATM case study has been used to illustrate the method presented. We used SYROCO tool in process of rapid prototyping of Object-Oriented systems by means of Petri nets.

1. Introduction

The purpose of this paper is to explore the integration of Object Oriented Design (OOD) using Petri nets (PN). OOD techniques are well established, but they lack a formalism and rigor. This becomes apparent when attempts are made to verify and validate a design prior to implementation. Extending the OO methodology to include parallelism makes the problem worse.

PNs provide a well understood formal method for modeling concurrent systems. PNs do not support the concepts of modularization, encapsulation, and information hiding. It is highly desirable to find a way to combine the best characteristics of these two differing design methods. In [4], a strategic amalgamation of the OOD with PNs has been presented. The approach preserves results of OOD and allows verification, and validation of the designed system using PN-based tools.

There are several approaches to integration of OOD and PNs. Among them are: Sibertin-Blanc [5], and Ceska et al. [3]. The goal of this paper is to explore the integration of OOD technique, PN's formalisms, and methodology of Cooperative Objects [5]. The case study chosen was that of a bank ATM machine. This OOD is adopted from [8] and it is not presented in the paper. We selected SYROCO that provides technology platform to define Cooperative Objects (COO). The COO language uses PNs to model internal operation of objects, and provides a mechanism to connect together the PNs of distinct objects.

The rest of the paper is organized as follows. In section 2 we present details of transformation from OOD to Collaborative Objects and to respective Petri nets. This section presents also execution of several scenarios for the ATM machine. The paper presents only small portion of a much larger project in technology transfer.

2. Petri Net Representation of the ATM Object-Oriented Design

We define first general algorithmic strategy of OOD specification with transformations into Petri nets that is expressed through the following macro-steps:

Step 1. For each class/object of the OOD define a corresponding Petri nets with its Object-Control Structure (OBCS). Classes/objects with inherent concurrency should have this feature explicitly expressed in the PN model.

Step 2. Using Collaboration Diagram of the OOD, create one PN that represents formalization of coordination of all classes/objects of the OOD by means of Petri net.

Step 3. Verify/Validate the OOD through simulation of the PN model; this will involve execution of the PN model with various positive and negative scenarios of interest.

We implemented *UserInterface* subsystem of the ATM, and a skeleton of the *Atm* class. The following objects were implemented as Cooperative objects: *Atm, BankCardReader, Form, Menu, SecureForm*, and *UserMessage*. Taking into account space limitation of the paper we present two PN models only. Fig. 1 represents a PN model of initialization of the *Atm* with a selection of ATM operations. Fig. 2.presents a PN model of the card validation process.

2.1. The Petri net model of the Atm class

The *Atm* class is the root class of the system. The *Atm* COO object is initialized when *Atm Init* operation executed. The *Atm Init()* operation creates the *BankCardReader* device object and initializes it. It also initializes the *Greeting* object. ATM system main menu is then initialized. The main menu is an instance of the *Menu* class. Finally, a single token is deposited into place *Initial* in the *Atm* OBCS.

A token in place *Initial* (Fig. 1) enables the firing of transition *InitializeAtm*. This transition invokes service *AtmInit*. Completion of service *AtmInit* deposits a token in place *Start*. A token in place *Start* enables transition *WaitForCustomer*. This transition invokes the *InsertValidCard()* service of the Greeting object, which is of class *UserMessage*. Upon completion of the service call, a Customer Identifier (cid) is returned, which becomes the token deposited in the *HaveCustomer* place. This token enables the *DisplayMenu* transition, which invokes the *GetChoice()* service of the *mainMenu* object, an instance of the Menu class. Upon completion of the *GetChoice()* service, a menu selection is returned which is deposited into place *HaveSelection* as a token. The menu selection token in place *HaveSelection* enables one of the five transitions connected to the place. Each transition handles one of the functions available on the main menu of the ATM system.

A valid menu selection of type QUERY enables the *BalanceInquiry* transition. This invokes a stub operation in the *Atm* class that reports activation of the Balance Inquiry transaction. Completion of this operation moves the menu selection token back into the *HaveCustomer* place, enabling the *DisplayMenu* transition as before. A valid menu selection token of type DEPOSIT in place *HaveSelection* enables the *Deposit* transition. This in turn invokes a stub operation in the *Atm* class that reports activation of the *Deposit* transaction. Completion of this operation moves the menu selection token back into the *HaveCustomer* place, enabling the *DisplayMenu* transition as before. A valid menu selection token of type TRANSFER in place *HaveSelection* enables the *Transfer* transition. This invokes a stub operation in the *Atm* class that reports activation of the Funds Transfer transaction. Completion of this operation moves the menu selection token back into the *HaveCustomer* place, enabling the *DisplayMenu* transition.

A valid menu selection token of type DONE, or an invalid menu selection representing activation of the *CancelKey*, in place *HaveSelection* enables the *Completed* transition. This in turn invokes a stub operation in the *Atm* class that reports completion of the customer session. Completion of this operation moves the menu selection token into the *Finish* place. The token in the *Finish* place enables the *RdyNextCustomer* transition. This transition invokes the *RemoveCard()* service of the Greeting object (from the *UserMessage* class). Upon completion of the *RemoveCard()* service, the return value is passed as a token to the *ResetATM* place. The token in the *ResetATM* place enables the *Restart* transition. This transition invokes the *LogUser()* operation, which is a stub simulating the activities performed to close out a customer session. Upon completion of the *LogUser()* operation, a token is deposited in the *Start* place, readying the *Atm* object for another customer session. The *AtmInit()* service makes a series of calls to the *AddItem()* service of the *MainMenu* object. These calls initialize the ATM main menu. Each call provides a text string used as the menu label, and a *menuChoice* item returned when that menu entry is selected.

2.2. The UserMessage Design

An arbitrary number of *UserMessage* objects can be instantiated at any time, each one represented by independent PN Object Control Structure (OBCS). The *Greeting* object is defined by the *Atm*. The object is initialized by *Init()* operation that appears in the *UserMessage*. Each *UserMessage* object requires access to single *BankCardReader* object and single *DisplayScreen* object of the ATM system Fig. 2).

The *Greeting* object *InsertValidCard()* service is invoked by transition *WaitForCustomer* of the *Atm* object. This invocation enables transition t1 of the *UserMessage* OBCS. Transition t1 deposits the service request token in place *SrvReq*, and it deposits a control flow token in place *GreetingMsg*. A token in place *GreetingMsg* enables transition t2. When t2 fires, it calls the *DisplayScreen* device, and then it invokes the *Input()* service of the *BankCardReader* device. Transition t2 does not complete until the *BankCardReader Input()* service completes, returning a *UsrResp* token (Rtn) which is deposited in place *CardStatus*. This token indicates whether or not a valid bankcard has been inserted into the ATM machine and validated by customer. A valid response token in the *CardStatus* place, along with a service request token in the *SrvReq* place, enables transition t3. This transition returns the response (Rtn) to the caller that invoked the *InsertValidCard* service. In the case of a valid response, the return value contains customer identification (cid). An invalid response token in the *CardStatus* place indicates an invalid card, or a cancel request by the customer. In this case transition t4 is enabled, which deposits a token into the *InsertWaiting* place. The *InsertWaiting* place will not enable transition t5 until the token has been in place for a time delay. After that, transition t5 can fire and will deposit the token into place *GreetingMsg*. This restarts the greeting cycle again, the original request remains pending and control does not pass back to the caller of the *InsertValidCard()* service.

The Greeting object service *RemoveCard()* is invoked by the ATM object OBCS transition *RdyNextCustomer*. This invocation enables transition t6 of the *UserMessage*

OBCS. Transition t6 deposits the service request token (*req*) into place *Srv2Req* and also deposits a control token into place *RemoveRdy*. The token in the *RemoveRdy* place enables transition t7. Transition t7 invokes the *Eject()* service of the *BankCardReader* device. Upon returning from the *Eject()* service, a token is deposited into place *Ejected* of the *Greeting* object. The presence of a token in place *Ejected*, as well as the presence of a service request token (*req*) in place *Srv2Req* enables the firing of transition t8. Transition t8 creates a return parameter (Rtn) and sets it to a valid response before returning it as a token to the caller of the *RemoveCard* service.

2.2. The *BankCardReader* Design

Startup of the *BankCardReader* Object OBCS (Fig. 2). Only one *BankCardReader* object is created in the ATM system. This occurs during initialization of the *Atm* object. A pointer to this object is saved and distributed to other classes that require access to the *BankCardReader*. The *BankCardReader* device is initialized by the *Atm* object invoking its *Init()* routine. The *BankCardReader Init()* operation first initializes the *Form* object called *pinForm*. This is a secure form used for entry of the customer PIN number. Then the prompt used to obtain the PIN is initialized. The *BankCardReader* object OBCS begins running as a result of the call to the *Init()* operation.

The *Input()* service of the *BankCardReader* is invoked by transition t2 of the *Greeting* object service *InsertValidCard*. This call enables transition t1 of the *BankCardReader* OBCS. The action of transition t1 calls operation *IsCardPresent()*. This operation is a stub. Transition t1 uses the boolean flag to fire one of two emission rules depending on the returned value. If there is no card present in the device, transition t1 deposits a token in place *NoCard*. If there is a card present in the device, then a token is deposited in place *CardPresent*. In either case, a token *req*, representing the service request, is also deposited in place *SrvcReqHolding*.

The token in place *CardPresent* enables transition t2. Transition t2 calls operation *IsCardValid()*. This operation is a stub that simulates a hardware/software function that determines whether or not the inserted card is a valid ATM bankcard. If the inserted card is not valid, transition t2 deposits a token in place *InvalidCard*. This token enables transition t3, which displays an appropriate message to the *DisplayScreen* device, and puts a token into place *RemoveCard*. Operations following place *RemoveCard* will be described later. If the inserted card is valid, transition t2 transfers a token to place *ValidCard*, which subsequently enables transition t6. Transition t6 calls operation *ReadCardPin(),* followed by a call to operation *ReadCardCid()*. Operation *ReadCardPin()* is a stub. The stub operates by asking the user to enter the PIN number associated with the card. The response is saved in attribute *cpin* of the *BankCardReader* object.

2.3 The *Menu* Design

An arbitrary number of *Menu* objects may be created at any time. Each object includes two basic functions, an *AddItem* service that builds the menu by adding selectable menu items to it, and a *GetChoice* service that displays the menu in its current state, allowing selection of an entry and returning a *UsrResp* item indicating the selection. The design of the Menu COO class contains by far the most complicated OBCS of any of the other COO classes. The implementation included one instance of a Menu object, the *mainMenu* object used by the *Atm* subsystem as its main menu for a customer to choose a transaction to be performed. The complexity of this class demands that an overview of the design be presented prior to describing the detailed functioning of the Petri Net composing the OBCS. The *AddItem* service is used to build the menu, adding entries to the *MenuData* place. This place is the central data store that holds the essence of the menu.

The design approach implemented was to map the current set of menu choices (it starts from the beginning of the menu) from place *MenuData* onto the available set of keypad keys stored in place *KeyData*, creating a set of menu display items for the current page of the menu, which are then stored in place *DisplayData*. This set of display items contains additional menu choices not present in place *MenuData* to specify selection of the next menu page, or a return to the top of the menu if we are at the last menu page. The current page of the menu is then displayed one item at a time, constructing a set of menu choice items, which are stored in place *ChoiceData*. A keypad entry is solicited from the customer and used to select a choice token from place *ChoiceData*. This item is either returned as a menu selection, or used to generate the next display page of the menu if it is a "next page" or a "top of menu" selection. The handling of boundary conditions adds to the complexity of the Menu object. Cases in which the menu has no entries (the *AddItem* service has not yet been called), there are more keys available than menu items to be displayed, or a key is pressed that does not correspond to a valid menu choice must be properly handled. The Menu class design selected allows for a menu to change (via the *AddItem* service) between invocations of the *GetChoice* service.

The *mainMenu* object is declared by the *Atm* object. The *mainMenu* object is initialized with a call to its *Init()* service. The Menu class *Init()* service begins by saving the pointers to the *DisplayScreen* and the *Keypad* objects passed to it. Then a number of attributes are initialized to denote an empty menu. The text labels used to display the "next page" and the "top of menu" entries are defined. The keys available for menu selection use are defined in

array *key_data*. The *KeyItem* class is defined as X. Tokens representing these key definitions are created and put into place *KeyData*. The initialized contents of place *KeyData* must be preserved throughout all of the menu processing. At this point the *mainMenu* object OBCS begins running, and control returns to the *Atm* object. The *AddItem()* service is used to add menu entry items to the menu object. Examples of *AddItem()* service calls for the *mainMenu* object can be found in transitions *InitT1* through *InitT5* of the *AtmInit* service. Parameters of the service call are the label, the text string used to label the menu entry, and the choice, a *menuChoice* type, used to denote the menu item selected. An invocation of the *AddItem()* service enables transition t1 of the Menu OBCS. The transition calls operation *SaveItem()*. This operation creates a *MenuItem* from the label and choice input parameters. A *MenuItem* consolidates the menu entry text label, the return choice, the index, or position of this menu entry within the menu, and the key that will be assigned to this entry. Transition t1 deposits this *MenuItem* as a token into place *MenuData* and returns control to the caller of service *AddItem()*. Place *MenuData* holds the essential data comprising the menu. The contents of this place must persist uncorrupted throughout the lifetime of the menu object.

2.4. Startup of the ATM

The *Atm* object is designated as the *root* object of the system. This part shows the ATM waiting for insertion of a card into the bank card reader device. The "no" answer given to the *BankCardReader* stub operation *IsCardPresent* simulates the hardware device sensing the absence of a card. After a short delay imposed by the *Greeting* object the main menu greeting prompt reappears on the display screen.

This part demonstrates the customer canceling during PIN entry. The ATM machine detects the presence of a valid, readable bankcard. The bankcard reader device then extracts the PIN number and the Customer Identification number from the bankcard. Next the customer is prompted to enter the PIN. The customer enters the correct PIN, but before pressing the ENTER key, decides to cancel by striking the CANCEL key. Note that the "x" key as described in the design of the *Keypad* class simulates the CANCEL key. As a result, the card is ejected and the ATM machine resets for the next customer. A valid card is inserted and the PIN and Customer ID are read from it. The customer is prompted to enter the PIN the first time, and it is entered incorrectly. Notice the secure version of the *Form* class echoes the PIN entry back so it is unreadable on the display screen. An appropriate response is displayed to the customer and he is given another opportunity to enter the PIN. This is repeated two more times until the ATM machine announces it is retaining the bankcard. At this point the bank card reader device would "swallow" the ATM card, the machine resets, and the initial greeting message is again presented. Successful validation of the customer makes available the customer ID for use by the rest of the system. The customer elects to terminate the session by selecting the completion item on the menu. The system announces completion of the transaction, termination of the customer session, ejection of the card and resets with display of the main greeting message. Notice that removal of the card in this scenario is different than in previous scenarios. In previous scenarios the card is never validated and so the *InsertValidCard* service of the *Greeting* object never returns control to the *Atm* object. In this scenario the *Greeting* object does complete and the *Atm* object executes the *mainMenu* object. The card removal is done by invocation of the *Greeting* object *RemoveCard* service [transaction *RdyNextCustomer* in the Atm OBCS.

3. Conclusion

The basic concept to combine OOD with Petri Nets to model causality and concurrency is sound. The concept is to embed the Petri net inside the object class, using it to model the current state of the object. It also ties together all of the objects Petri nets into a structure that can be run for simulation purposes. The paper demonstrates that effective and scalable application of this concept to a middle size OOD is practically possible.

Abstract

Numerous formal approaches to software assurance are available, including: runtime monitoring, model checking, and theorem proving. All of these approaches require formal specifications of behavioral properties to verify a software system. Creation of formal specifications is difficult, and previously, there has been inadequate tool support for this task. The Property Specification tool, Prospec, was developed to assist users in the creation of formal specifications. This paper describes Prospec 2.0, an improvement to the previous version, by addressing the results of a study conducted to assess the usability of the tool and by adding functionality that supports the validation process.

1. Introduction

Formal methods to support software assurance require the identification of behavioral properties of the software system, generation of formal specifications for the properties, validation of the specifications, and verification of the correctness of the system. The effectiveness of the assurance approach depends on the quality of the formal specifications, and a significant hurdle to the use of formal approaches is the development of correct formal specifications.

Typically, the person creating the formal specification must have a strong mathematical background and be aware of the subtleties of the specification language. For example, model checkers, such as SPIN [1] and NuSMV [2] use formal specifications written in Linear Temporal Logic (LTL) [3], which can be difficult to read, write, and validate. This problem is compounded if requirements must be specified in more than one formal language, which frequently is the case if more than one verification tool is used. The specifier must be aware of the differences in expressiveness of each of the target languages.

The Property Specification (Prospec) 1.0 tool was developed to address some of these challenges. Prospec uses the Specification Pattern System (SPS) [4] and Composite Propositions (CP) [5] to assist developers in the elicitation and specification of system properties.

Usability studies of Prospec have shown that it facilitates the elicitation, understanding, and specification of formal properties [6].

This paper describes Prospec 2.0. In particular, it describes the new features in Prospec that are aimed at improving the tool's support for generating and validating formal property specifications.

2. Background

The Specification Pattern System (SPS) [4] is a set of patterns used to assist in the formal specification of properties for finite-state verification tools. SPS patterns are high-level abstractions providing descriptions of common properties that hold on a sequence of conditions or events in a finite state model. SPS patterns characterize two behavioral aspects: the occurrence and the order of events or conditions.

Occurrence patterns are *universality*, *absence*, *existence*, and *bounded existence*. Order patterns are *precedence*, *response*, *chain of precedence* and *chain of response*. In SPS, a chain pattern defines a sequence of events or conditions. *Chain-precedence* and *chain-response* patterns permit specifying a sequence of events or conditions as a parameter of precedence or response patterns, respectively. SPS restricts the specification of sequences to precedence and response patterns.

In SPS, a pattern is bounded by the scope of computation over which the pattern applies. The beginning and end of the scope are specified by the conditions or events that define the left (L) and right (R) boundaries, respectively.

A study by Dwyer et. al. [4] identified the *response* pattern as the most commonly used pattern, followed by the *universality* and *absence* patterns. These three patterns accounted for 80% of the 580 properties sampled in the study. Because of the frequency with which response properties occur, it is important to provide abstractions that support multiple propositions when specifying sequence of events or concurrent behavior. Because multiple propositions may occur in the cause and effect part of response properties, CPs can be used to assist in their specification and validation. By using CPs in either part of the response pattern (the cause or effect), it is possible to represent common behavior associated with

concurrent systems, such as synchronized join and fork, concurrency, non-determinism, and sequences.

Mondragon et al. [5] introduced Composite Propositions (CPs) to handle pattern and scope parameters that represent multiple conditions or events. The introduction of CPs supports the specification of concurrency, sequences, and non-consecutive sequential behavior on patterns and scope. Mondragon proposes a taxonomy with twelve classes of CPs. In this taxonomy, each class defines a detailed structure for either concurrent or sequential behavior based on the types of relations that exist among a set of propositions.

The original version of Prospec is an automated tool that guides a user in the development of formal specifications. It includes patterns and scopes, and it uses decision trees to assist users in the selection of appropriate patterns and scopes for a given property. Prospec 1.0 extends the capability of SPS by supporting the specification of CP classes for each parameter of a pattern or scope that is comprised of multiple conditions or events. The use of CP classes allows practitioners using Prospec to specify ordered sequences, non-deterministic sequences, and concurrency. By using CPs, a practitioner is directed to clarify requirements, which leads to reduced ambiguity and incompleteness of property specifications.

Prospec uses guided questions to distinguish the types of scope or relations among multiple conditions or events. By answering a series of questions, the practitioner is lead to consider different aspects of the property. A type of scope or CP class is identified at the end of guidance. Prospec generates formal specifications in Future Interval Logic (FIL) [7] and the Meta-Event Definition Language (MEDL) [8].

3. PROSPEC 2.0

3.1 Prospec Revisions

A formal experiment evaluated the effects that the original Prospec and SPS have over the quality of the generated software property specifications with respect to completeness and correctness [17]. SPS supports the creation of specifications through a web site and manual substitution of propositions into templates. The following research hypothesis was supported: *users who specify software properties using Prospec, identify, on the average, more correct patterns and scopes than users who specify software properties using the SPS web site.* The subjects also provided comments for Prospec in the post-evaluation form. They suggested that Prospec:

- provide the capability to access all the properties defined in a given project;
- allow the capability to apply the negation operator to propositions;
- indicate the properties that contain a recorded assumption; and
- modify the physical position and labels for parameters *S* and *P* in the *response* and *precedence* patterns in the pattern screen.

These and other observations made when using Prospec motivated the creation of Prospec 2.0. The revised tool includes changes to the user interface and, more significantly, the tool is being revised to generate LTL specifications with support for validation of the specifications. To provide the ability to export properties into other software tools, Prospec 2.0 uses XML.

3.2 Linear Temporal Logic Generation

Salamah et. al. [9, 16] showed that direct substitution of one or more parameters for a pattern or scope that includes CPs may result in a specification that does not meet the intent of the user. Consider the following example: "The delete button is enabled in the main window only if the user is logged in as administrator and the main window is invoked by selecting it from the Admin menu." The property could be classified *Existence(P)* with *Before R* scope, and *P* is a classified as $Eventual_c(p_1,p_2)$[*1] where p_1 denotes "User logged in as an administrator," p_2 denotes "Main window is invoked," and *R* denotes "Delete Button is enabled. The SPS template for *Existence(P) Before R* is $(\Diamond R) \rightarrow (!R \; U \; (P \wedge !R))$ and the formula for $Eventual_C$ is $(p_1 \wedge X \; (!p_2 \; U \; p_2))$. Direct substitution would yield:

$$\Diamond R \rightarrow (!R \; U \; (!R \wedge (p_1 \wedge X \; (!p_2 \; U \; p_2)))).$$

This, however, would permit the delete button to be enabled between the time that the administrator logs in and the administrator invokes the main window.

To address this, Salamah [16] introduced general templates to support the generation of LTL formulas that use CPs. For example, consider the *Response (P, Q)* pattern with Global scope in which *P* and *Q* are $Consecutive_C(p_1, p_2)^*$, i.e., $(p_1 \wedge X \; (p_2))$ and $Parallel_C \; (q_1, q_2)^*$, i.e., $(q_1 \wedge q_2)$. The general template for the "Response- Global scope" is:

$$\Box \; (P^{LTL} \rightarrow (P^{LTL} \; \&_l \; \Diamond \; Q^{LTL})),$$

where P^{LTL} and Q^{LTL} represent LTL formulas for the CP class and $\&_l$ is a special operator that ensures that $\Diamond Q^{LTL}$ is "anded" only with the last element of the sequence represented by P^{LTL} [9, 16]. As a result the formula becomes:

$$\Box \; ((p_1 \wedge X \; (p_2)) \rightarrow (p_1 \wedge X \; (p_2 \; \wedge \; (\Diamond \; (q_1 \wedge q_2))))).$$

[*] The complete list of CP classes and their LTL descriptions is available in Mondragon et. al., [5].

In the previous example for enabling the delete button, the general template for the *Existence(P)* with *Before R* scope example described earlier is: $!((!(P^{LTL} \&_r\ !R^{LTL}))\ U\ R^{LTL})$, where $\&_r$ is a special operator that denotes that $!R^{LTL}$ holds at all the states within the sequence represented by P^{LTL} [9, 16]. As a result, the correct formula is:

$$!((!(((p_1 \ \&\ !R)\ \&\ X((!p_2\ \&\ !R)U\ (p_2\ \&\ !R))))\ U\ R)$$

To support validation of generated formulas, each general formula has associated traces of computations that represent behaviors that are accepted or not accepted by the LTL formula being tested. The traces of computation can be used to test the formulas using a model checker [16, 20]. In addition to supporting the process of testing the LTL formulas, these templates provide visual representations to aid the user in understanding the meaning of the complex LTL formulas that are generated, helping those users who are not immersed in formal representations.

Salamah [15] used multiple techniques to verify the correctness of the general formulas: formal proofs, testing, and reviews. In order to support the formal proofs, the work included formal definitions of patterns and scopes that use CPs. This supports the ability to define similar properties in other specification languages.

A secondary effort in Salamah's work involved modifying the original LTL formulas provided by Prospec for patterns and scopes whose parameters contained only single propositions and CP. The approach to simplify the formulas was to reduce the number of states in the Büchi automaton (BA) generated from an LTL formula. The size (number of states) of the automaton that results from the intersection of the BA generated by the LTL formula and that of the system model has as its upper bound the product of the number of states in each of the two. Work has been done by other researchers on the translation of LTL to BA to reduce the number of states in the resulting BA and to speed up the process of the BA generation [12, 13, 14]. It was possible to reduce the number of temporal operators, and as a result improve the efficiency of 17 out of 30 the formulas defined by Prospec [21].

3.3 Interface

Prospec 2.0 includes new features to support the specification of properties. The interface maintains the support and functionality of the original Prospec, i.e., the guiding screens for selecting scope and patterns remain the same. The main changes to the interface are related primarily to CP specifications and information presentation.

Figure 1. presents the main screen for Prospec 2.0. To the left in the main screen the *Property Browsing Tree* is shown. The larger frame on the right encloses screens (as opposed to the original implementation in which individual screens were distributed over the available screen space). The larger frame provides practitioners with a separate context for each property. The enclosing frame enables concurrent property specification as well as easy transition between these property specifications.

Since Prospec 2.0 supports concurrent property specifications, a *Property Browsing Tree* is available for accessing properties. The *Property Browsing Tree* allows practitioners to browse, traverse and quickly preview properties being specified. Also, the *Property Browsing Tree* allows editing of properties attributes such as scope, pattern, CPs, and propositions, as shown in Figure 1. Once a user selects a property attribute in the tree, the appropriate window will be opened allowing modification of the property attribute.

Another interface improvement is the *Visual Representation window*. This window will provide a visual representation of the specified property as a trace of computation that shows the scope and the specified property pattern. The visual representation in conjunction with the written description will be the base for the validation capabilities of Prospec 2.0.

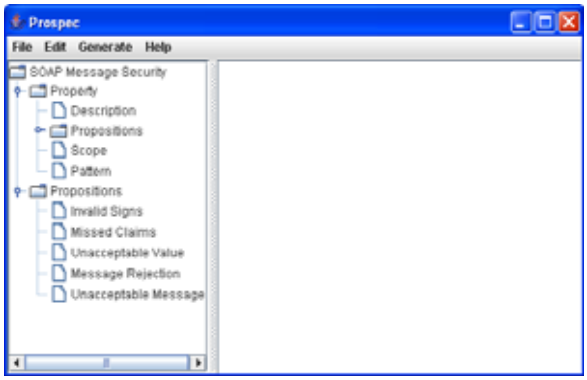

Figure 1. Prospec 2.0 Main Window

The *Property* window describes the basic property information such as the property name, the informal property description as provided by the client and any assumptions made about the property, as shown in Figure. 2 and Figure 3. Properties can be created by clicking on the *New* button, removed by clicking on the *Delete button* and stored into the viewing table by clicking on the *Save* button. Different Properties can be browsed and viewed by selecting them from the table of propositions. The *scope* section includes the *scope* type, assumptions made about the *scope*, and the left and right propositions. CP attributes include a *Type* to differentiate between events and conditions, a *CompositeProp* to identify the desired CP, and a *PropositionList* including the simple propositions to be used in the CPs. A proposition is described by a symbol and a description.

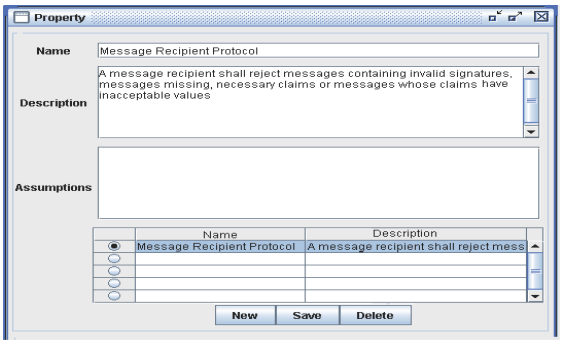

Figure 2. Prospec 2.0 Property Specification Window Upper Section

A new feature in Prospec 2.0 is a window that allows the user to view a summary of the property being specified. The window shows the current state of the specification and the formal specification if defined. This window is embedded into the *Property* window, as shown in Figure 3.

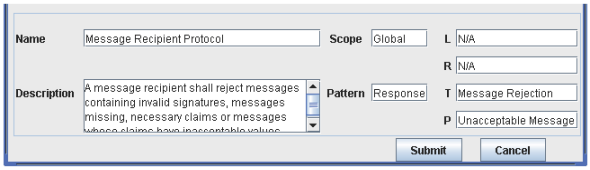

Figure 3. Prospec 2.0 Property Specification Window Lower Section

Prospec 2.0 allows users to create, save, and print reports of the specifications. The reports are created either directly from the Prospec 2.0 application or from the XML files containing the metadata of the property specifications. The reports include the informal specification as provided in the description section of Prospec 2.0, the formal specification as generated by Prospec 2.0, information to construct the visual representation matching the generated formal specification, and the corresponding metadata such as logic used or version number.

4. Scenario

The following scenario illustrates the use of Prospec. Jill is a software engineer working on security issues in web services. She recognizes that the system must support the following requirement: "A message recipient shall reject messages containing invalid signatures, messages missing necessary claims, or messages whose claims have unacceptable values [18]." Since the project team will use a model checker to verify the algorithms, she needs an LTL specification.

Jill starts Prospec and creates the new property project *SOAP Message Security* and selects *LTL* as the logic to be used for the formal specification. She accesses the property browsing tree and double-clicks the *property description* attribute to open the *property description* screen. Using this screen, she names the property *Message Recipient Protocol* and provides the informal description.

Now Jill must identify the scope, the region of the program over which the property must hold. She accesses the property browsing tree and double-clicks the scope attribute to open the scope specification screen, which displays English descriptions of the five available scopes. After using the decision tree in the Guided Selection screen, Jill selects Global as the property scope as shown in Figure 4. Properties with Global scope must hold over all states of execution.

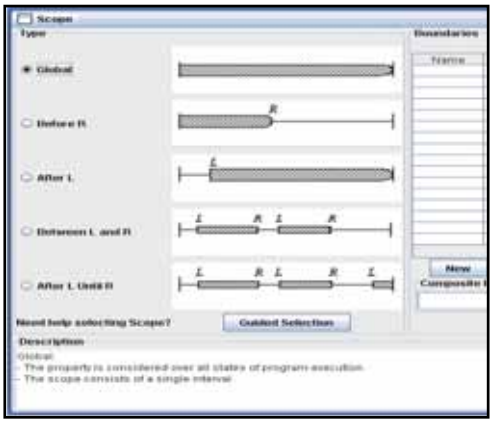

Figure 4. Section of Prospec 2.0 Scope Window

After identifying the scope, Jill selects a pattern. Selecting the *pattern* attribute of the property browsing tree opens the *pattern specification* screen. The five available patterns are described there, and Jill decides to use the *Response (T,P)* pattern as shown in Figure 5. In this pattern, the conditions or events described by *T* are a response to the conditions or events described by *P*. The letters *T* and *P* represent a proposition and a composite proposition (CPs), respectively. This choice is appropriate since Jill wants to ensure that there is a rejection whenever an unacceptable message is received. Prospec offers guided selection to assist a user in the selection of an appropriate pattern.

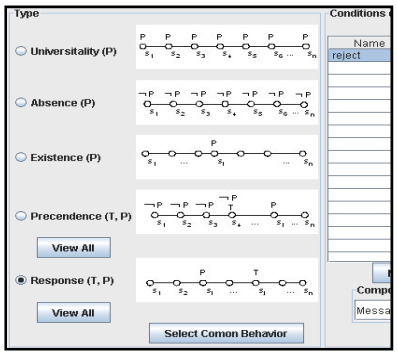

Figure 5. Section of Prospec 2.0 Pattern Window

Once the pattern has been selected, Jill defines *T* and *P*. To define *P*, Jill creates the simple propositions *invalid_sign* (*Message contains invalid signatures*), *miss_claims* (*Messages are missing necessary claims*), and *unacceptable_value* (*Messages have claims with unacceptable values*). Because *P* is defined by three propositions, Prospec displays a message indicating that a CP must be defined. Once the CP screen is accessed as shown in Figure 6, Jill determines that the three simple propositions are *conditions* (*propositions that hold in one or more consecutive states*) and should be combined using $AtLeastOne_C$ *(G)* to indicate that at least one of the propositions in the set *G* can trigger the condition. A decision tree in the *Guided Selection* screen for CPs can be used to determine which CP to use. To define the *T* parameter, Jill creates a new proposition *reject* (*Message is rejected*), indicating that the message recipient rejects the incoming message. This completes the pattern definition.

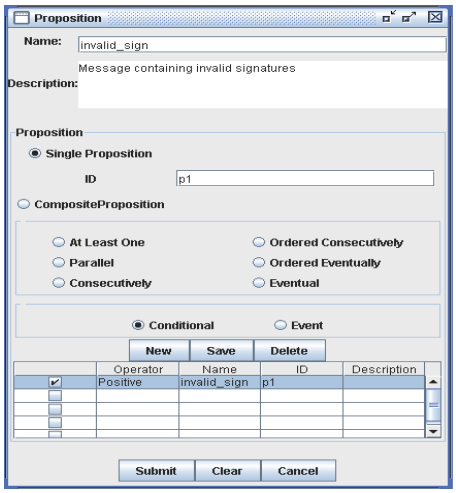

Figure 6. Prospec 2.0 Scope Window

To create the LTL formula from the scope and pattern, Jill selects the *view formula* button on Prospec's main screen. Prospec takes the scope, pattern, and CP and generates the LTL formula:

$$\square((invalid\_sign \mid miss\_claim \mid unacceptable\_value) \rightarrow \Diamond reject)$$

This formula specifies that during the execution of the program, whenever an unacceptable message is received by a message recipient, a rejection follows. In addition to the LTL formula, a set of sample execution traces is presented showing possible sequences of execution and the value of the formula for each sequence. Jill reviews these execution traces to ensure that the formula captures her intent.

An execution trace is a sequence of states read from left to right. Each space represents the propositions that are true in that state. If no proposition is true, a "-" is used. If more than one proposition is true, the propositions are enclosed in parentheses. Some of the execution traces for the *SOAP Message Security* property are shown in Table 1. For this example, symbol *I* stands for proposition *invalid_sign*, symbol *M* for proposition *miss_claim*, symbol *U* for proposition *unacceptable_value*, and symbol *R* for proposition *reject*.

Trace of Computation	Result
--I---R---	*Satisfied*
--RU------	*Unsatisfied*
U---M-----	*Unsatisfied*
(IM)--------R	*Satisfied*

Table 1. SOAP Message Security Property Execution Traces Examples

5. RELATED WORK

This section describes other tools used also for the elicitation and formal specification processes and how these efforts differ from Prospec 2.0.

5.1 Propel

The goal of Propel [10] is to help practitioners write and understand properties by providing templates that explicitly capture details as options for commonly-occurring property patterns based on SPS. The provided templates are represented using both disciplined natural language (DNL) and finite-state automata (FSA). The practitioner can view both representations simultaneously and select from which representation to elucidate the desired property.

The main difference between Prospec 2.0 and Propel is that Prospec 2.0 uses guided questions to distinguish the types of scope or relations among multiple conditions or events while Propel uses DNL. Also the pattern visual representations differ between the efforts, in Prospec 2.0 timelines are used while in Propel FSA are used.

5.2 Timeline Editor

Timeline Editor [11] allows the formalization of certain type of requirements. To formalize these requirements a series of events and required system responses are placed on a timeline. The tool converts the timeline specification automatically into a test automaton. The timeline specification can then be used directly by a logic model checker or a test-sequence generator.

As opposed to Prospec 2.0, Timeline Editor cannot capture group of events occurring in arbitrary order nor provide visual feedback for validation purposes. Prospec 2.0 allows practitioners to specify group of events

occurring in arbitrary order by using CPs and SPS. Also, the traces of computation generated by Prospec 2.0 allow practitioners to validate that the specified properties match the practitioner's intent.

5.3 SPIDER

SPIDER [19] generates specification properties using natural language representations. This process is based on a natural language grammar and specification pattern system to derive a natural language sentence. This sentence is then mapped to the temporal logic that can be analyzed formally by a tool such as SPIN. The structured language grammar supports translations of untimed and timed properties to multiple temporal logics.

There are three main differences between Prospec 2.0 and SPIDER. Prospec 2.0 offers support for composite propositions, guided selection in the specification process, and property validation using traces of computations.

6. CONCLUSIONS

In this paper, we describe Prospec 2.0, an improvement to the property specification tool Prospec 1.0. We discuss the new features of Prospec 2.0 and describe how these changes enable practitioners to use Prospec 2.0 as both as an automated formal property specification tool and as an automated formal property specification validation tool. The use of XML in Prospec 2.0 and its ability to be interoperable, it will be possible now to integrate the Prospec into the chain of tools that could provide the desired end-to-end automation for all aspects of software development.

***Abstract*—A large imbalance between proportions of the not-fault-prone and fault-prone program modules in a software measurement dataset has an adverse impact on the trained software quality model. This rarity of known fault-prone modules during software quality modeling is a common occurrence, especially in high assurance systems. Such disparity in proportions of the two classes is observed in other domains as well. We present an evolutionary computing-based data sampling approach to address class imbalance in binary classification problems. The approach, named Evolutionary Sampling, works by "naturally" selecting the good instances in the training data and removing those that are redundant, irrelevant, or impart no additional knowledge. We compare our majority undersampling technique with the other existing majority undersampling techniques, i.e. random undersampling, Wilson's editing, and one-sided selection. Our approach can also be combined with a genetic algorithm-based optimization of a classifier's modeling parameters. The multilayer perceptron neural network is used in this study as the underlying software quality model. Case studies of two real-world software measurement datasets are used for evaluating our genetic algorithm-based data sampling approach with the other majority undersampling techniques. It is shown that Evolutionary Sampling is significant in outperforming the other data sampling techniques, and shows a clear improvement over the software quality model built without any data sampling.**

I. Introduction

Knowledge-based software quality modeling often involves learning from a training dataset that consists of a very large number of high-quality (or not-fault-prone) program modules and a very small number of low-quality (or fault-prone) program modules. Often seen in high-assurance systems [1], [2], [3], this rarity of known fault-prone modules poses a unique class imbalance that impedes the training of a useful software quality estimation model. The class imbalance problem is also observed in other domains, such as diagnosis of rare medical conditions [4], detecting oil spills from satellite images [5] and detection of computer security breaches [6].

A software quality classification model is typically built using known software measurement and defect data from a prior system release or a similar software project developed previously. The given classification algorithm aims to extract and learn associations between the different software metrics and the defect data for the training dataset. The validated model is then ready to predict the unknown quality-based class for a program module with known software metrics.

Given a binary classification problem such as predicting program modules as either fault-prone (*fp*) or not-fault-prone (*nfp*), a training dataset that suffers from class imbalance can be divided into a majority class (not-fault-prone) and a minority class (fault-prone). A classifier trained on such a skewed dataset is more likely to predict a new instance as belonging to the majority class since it was over-represented during the training process. Such a model is clearly not useful, since the more important minority class (fault-prone modules) will go undetected more often. The definition of what is considered as a *fp* or *nfp* program module is dependent on the software project and its quality improvement objectives.

We present a novel and effective genetic algorithm-based approach for sampling a training dataset suffering from class imbalance such that instances from the majority class are intelligently removed. The resulting training dataset is relatively more balanced than the original since the minority class size remains unchanged. A data sampling technique that reduces the majority class size, while maintaining the minority class is termed majority undersampling. In contrast, a data sampling technique that increases the minority class size, while maintaining the majority class is termed minority oversampling. Developed as a research prototype, eIλANN implements the proposed Evolutionary Sampling (EVS) approach and also facilitates a GA-based optimization of the underlying learner's modeling parameters. eIλANN is extensible to almost any existing binary classifier.

This paper compares EVS with every other existing majority undersampling techniques that address class imbalance in machine learning problems. Those techniques include random undersampling [7], Wilson's editing [8], and one-sided selection [9]. The other category of data sampling techniques (i.e., minority oversampling) that address class imbalance are not considered for comparison in this paper due to space limitations; however, they are compared with EVS elsewhere [10].

The EVS data sampling approach is presented and evaluated with case studies of two real-world software measurement datasets. In the case of both case study datasets, the minority class instances (i.e., *nfp* modules) are less than 10% of the total number of instances in the given training dataset. The same software project data are also used in the comparison of EVS with the three other majority undersampling techniques. The Multilayer Perceptron, as implemented in WEKA [11], is the learner used to build software quality models in this study.

We empirically demonstrate that EVS improves classifier performance compared to software quality modeling without applying any data sampling technique. In addition, it is shown that EVS performs significantly better than all other majority undersampling techniques, i.e., EVS is better than random undersampling, Wilson's editing, and one-sided selection for the case studies presented.

The contributions of this paper include: (1) presenting Evolutionary Sampling, a novel GA-based data sampling technique for addressing class imbalance, (2) a computationally intensive empirical study that compares the proposed data sampling approach with other existing majority undersampling techniques, and (3) application of data sampling techniques for addressing rarity of fault-prone modules in knowledge-based software quality estimation modeling.

The remainder of the paper is structured as follows: Section II

summarizes the other three majority undersampling techniques that are compared with EVS; Section III discusses the default parameter settings for the Multilayer Perceptron learner and performance metrics used for evaluating the software quality classification models; Section IV details the proposed data sampling approach along with relevant GA background; Section V describes the case studies, and discusses the empirical results; Section VI concludes our paper with key research findings and suggestions for future work.

II. Other Majority Undersampling Techniques

The three other majority undersampling techniques we examine include random undersampling, Wilson's editing, and one-sided selection. Random undersampling (*RUS*) is an effective, yet simple, technique in which a portion of the majority class instances are removed at random from the training data. Weiss et al. [7] report an equal balance between the majority and minority classes is often desirable, but that the optimal ratio between the two groups will vary with different datasets and domains.

Wilson's editing (*WLE*) strives to remove noisy instances of the majority class based on a k-nearest-neighbor (k-NN, with k = 3) algorithm that classifies each instance in the training dataset using the remaining instances [8], [12]. The training dataset is reduced by removing instances that were incorrectly classified by the 3-NN algorithm. An alternate version of WLE incorporates a weight factor, based on the class distribution, that is taken into account when computing the distance between instances. This weighting results in some bias toward identification of the minority class instances.

One-sided selection (*OSS*) aims to remove both noisy and redundant instances of the majority class from the training dataset [9]. Initially the redundant instances are removed by creating a consistent subset of the original training dataset that will correctly classify all of the training data using a one-nearest-neighbor (1-NN) rule. Incorrectly classified instances and borderline instances which lie close to the boundary between the two classes in the feature space are removed using Tomek links [13]. A Tomek link exists between a positive (minority class) and a negative (majority class) instance if the two instances are nearest neighbors of each another.

III. Selected Learner and Performance Metrics

The learner we use in conjunction with the different data sampling techniques in this study is the Multilayer Perceptron (MLP). We use WEKA's [11] implementation of the MLP learner with (unless stated otherwise) the following default parameter settings: a learning rate of 0.3 with no decay; a momentum rate of 0.2; 500 training epochs/iterations, validation set at 10% of original dataset; an error threshold of 20 for the validation set; a random number generator seed of 0; and 3 nodes in one hidden layer.

In a two-group (positive and negative) classification problem, if the positive group represents the minority class and the negative group represents the majority class, then a false positive indicates an error in which a majority class instance is incorrectly classified as belonging to the minority class [7], [14]. A false negative indicates an error in which a minority class instance is incorrectly classified as belonging to the majority class. A true positive and true negative would respectively represent correct classification of a minority instance and a majority instance. Evaluating competing models with multiple metrics simultaneously may be difficult when there is no clear winner. We use singular metrics that are well-known performance metrics in data mining and machine learning – Area-Under the ROC Curve, Geometric Mean, and F-measure [11].

An ROC (Receiver Operating Characteristic) curve is a visual representation of a classifier's performance in which the model's true positive rate (y-axis) is plotted against its false positive rate (x-axis) [15]. A desirable ROC curve is one that maximizes the Area-Under the ROC Curve (AUC). Since an ROC curve does not show bias toward the majority class, the AUC value serves as a good singular performance metric when dealing with class imbalance. The AUC provides a rating for the classifier's general predictive ability regardless of class prior probabilities and misclassification costs [16].

The Geometric Mean (GMean) provides a singular measure for evaluating classifier performance compared to using multiple classification error rates or classification accuracies. The GMean is computed as $\sqrt{(true\ positive\ rate) \cdot (true\ negative\ rate)}$. Kubat et al. [9] suggest the geometric mean as a good performance metric for classification problems involving class imbalance. A higher GMean indicates that a classifier is balanced and shows good performance for both classes. We use the AUC and GMean performance measures in the fitness function for our Evolutionary Sampling process, as explained in Section IV-B. The AUC and GMean are also computed as model evaluation metrics.

The *F-Measure* (F-Meas) is based on two information retrieval metrics, Recall (or effectiveness) and Precision (or efficiency), where Recall is the true positive rate and Precision is the ratio of the true positive rate and the sum of the true positive rate and the false positive rate. When Recall and Precision are given equal importance, the F-measure is computed as $\frac{2 \times Recall \times Precision}{Recall + Precision}$. The fitness function of our Evolutionary Sampling approach does not include the F-measure, which is instead used as an independent performance metric to evaluate the classifiers.

IV. GA-Based Data Sampling

A. Genetic Algorithms

GAs perform optimization, simulating natural evolution by creating offspring as a result of mating of the fitter individuals [17]. Each individual is a solution to the problem being addressed. This evolutionary process continues until some stopping criterion (e.g., achieved fitness level or number of generations processed) is reached and the fittest individual is chosen and will hopefully have a near-optimal solution encoded in its genes [18]. The genes are the parameters of a solution, i.e. an individual. During the simulated evolution, various genetic operators (e.g., *crossover*, *mutation*, etc.) may be used to mimic the mating process among fitter individuals.

The crossover (or recombination) genetic operator simulates the process of natural mating by creating offspring that contain genetic material from both parents. To create the chromosomes in the children, we set a randomly determined *locus*, or crossover point in the parents' chromosomes. The first child receives a copy of the first parent's genes up to the crossover point and the second parent's genes after that point. The other child receives the second parent's genes to the left of the locus, and the first parent's genes to the right. The above crossover is a single-point crossover, and is used in our study. The other crossover types used in the literature, multi-point crossover and uniform crossover [19], are not used in our study.

The mutation genetic operator plays a key role in the exploration of the search space as it actually alters the gene alleles to new values instead of simply recombining the gene alleles which already exist in the population. When an individual's chromosome consists of a binary string, the mutation operator may invert the bit value for a randomly selected gene. In a more complex chromosome that encodes integer or real values, creep mutation can be used to add or subtract a random amount from the gene, but within specified bounds. We

use a method proposed by Tate [20] which creates mutated clones of individuals independently of the crossover genetic operator.

A natural selection process is needed to determine which individuals in the population have better fitness. The best chromosome selector orders the individuals in the population by fitness and selects the fittest to remain for the next generation. The best chromosome selector can lead to an early convergence which may represent a local-minimum and not the optimal solution [21]. We use the best chromosome selector as a preprocessing stage for the crossover and mutation operators with the aim of preventing a poor individual from being selected for crossover and mutation.

Ranking selection orders the individuals by fitness at the beginning of the selection process, and only considers an individual's goodness ranking relative to other individuals, regardless of their actual fitness magnitudes. Generally, tournament selection is preferred over roulette wheel selection [18]. In tournament selection, a set number of individuals (tournament size) are randomly selected to participate in the tournament. We select four individuals for tournament selection, as explained in the next section. Once the individuals are picked, the system ranks them according to their fitness and then plays out as a tiny roulette wheel. The fitter the individual in the tournament, the greater its chance of being selected. The winner of the tournament survives to become part of the next generation. The system conducts as many tournaments as needed to obtain the desired population size. We use tournament selection at the end of each generation to provide a way to return the population to its desired size for the next generation.

B. Evolutionary Sampling

elÀNN is a GA-based data mining application developed for our research on addressing class imbalance. Written in Java, this tool currently includes three machine learners, Multilayer Perceptrons, C4.5 and RIPPER, and is based on the WEKA framework [11]. While elÀNN can be extended to include Evolutionary Sampling (EVS) with other machine learners, in this study we focus on Multilayer Perceptrons (MLP). elÀNN also implements a GA-based solution for optimizing modeling parameters of the machine learner, i.e., the MLP architecture in our case. EVS is a majority undersampling technique that works to reduce the number of majority class instances used to train a classifier. This philosophy reflects the relatively very large proportion of the majority class (*nfp*) instances as compared to the minority class (*fp*) instances.

We utilize the basic gene types provided in the Java Genetic Algorithms Package (JGAP) library [22] which elÀNN uses as its GA engine. In JGAP, each of the genes (`BooleanGene`, `IntegerGene`, and `DoubleGene`) is an individual object and the set of genes for an individual is contained in a `Chromosome` object. The genes are considered basic units in the chromosome for purposes of crossover and mutation, and we can set maximum and minimum values for each gene. The chromosome of an individual in elÀNN contains information on how to sample the dataset and how to optimize the learner when building the classifier. We use GA to find an optimal sample of the majority classes used in the fold's training portion of the dataset – five-fold cross-validation is used in our study.

We define two basic chromosome parts (see Table I) for an individual in a GA-based experiment using elÀNN. Part A contains the genes needed to tune a machine learner's modeling parameters, and Part B contains the genes used to perform evolutionary data sampling. Both parts of the chromosome can be ignored during evolutionary computing based on whether each is required for a given experiment in our study.

TABLE I
CHROMOSOME DEFINITION FOR THE MLP LEARNER

Part	Gene Type	Values	Description
A	`DoubleGene`	0.0 to 1.0	Learning rate
	`DoubleGene`	0.0 to 1.0	Momentum rate
	`IntegerGene`	1 to $\hat{m}$	Number of nodes in first hidden layer
	`IntegerGene`	0 to 2	Number of additional hidden layers
	`IntegerGene`	1 to $\hat{m}$	Number of nodes in second hidden layer
	`IntegerGene`	1 to $\hat{m}$	Number of nodes in third hidden layer
	`BooleanGene`	true or false	Decay learning rate for back-propagation
B	`BooleanGene`	true or false	Sampling flag for N_0
	`BooleanGene`	true or false	⋮
	`BooleanGene`	true or false	Sampling flag for N_{n-1}

The genes in Part A differ according to the configuration parameters for a given learner. All the genes in Part B of a chromosome contain a Boolean allele. A chromosome's Part B has one gene for every majority instance in the dataset being tested. A gene value of true indicates that the corresponding data instance should remain in the training dataset, while a false value informs the system to remove that instance from the training data. Data sampling is only done from the training dataset, i.e., we never alter a fold's test dataset.

The chromosome definition for the GA-based experiments with MLP is shown in Table I. The numerical ranges shown in the table for the non-Boolean parameters are based on a combination of our prior machine learning experience and good coverage around the default parameter values as per WEKA [11]. If m represents the number of attributes in the given dataset, including the class attribute, then $\hat{m}$ is the lesser of m and 20. This is done from a computational efficiency consideration point of view.

The MLP chromosome allows for up to three hidden layers (`IntegerGene`). While two hidden layers are sufficient to approximate any continuous function [23], we allow elÀNN to consider up to three hidden layers with the aim of producing better results. However, given two MLP configurations with similar performances, elÀNN considers the less complex MLP as the better one. Part B of the chromosome has $N_0, N_1, \ldots, N_{n-1}$ genes, each representing a `BooleanGene` (true or false) for data sampling inclusion.

The fitness function of our GA system combines two effective performance factors, AUC and GMean. We opted to use both a threshold-independent factor (AUC) and a threshold-dependent factor (GMean) in an effort to evolve more generalized software quality classification models with less overfitting tendency [11]. The raw fitness, in its simplest form, of an individual X is given by the expression $f(X) = \alpha(AUC) + \beta(GMean)$, where α and β are constants which weigh the relative importance of the AUC and GMean factors, and add up to 1. We assigned a value of 0.5 to both α and β, making them equally important in the evolutionary process.

Given two individuals, we want to state that the better performer is fitter in every case. When two individuals perform similar we look at the sample size to decide which of the two is fitter – the one with a smaller sample size is better. The final fitness function for our data

sampling approach with MLP is given by,

$$f(X) = round\left(10^s\left[\alpha(AUC) + \beta(GMean)\right]\right) + \left(1 - \gamma\frac{k_H + k_O}{max(k_H + k_O)} - \delta\frac{I_N}{max(I_N)}\right) \quad (1)$$

In the above equation, s is the number of digits after the decimal place which we want to consider from the combined AUC-GMean raw fitness value – we opt for $s = 4$. The numbers of hidden and output nodes in the MLP network are given by k_H and k_O, respectively. We define complexity for the MLP model as the ratio of the actual number of hidden and output nodes to the maximum possible number of those nodes. We use ratios for both the network complexity and the sample size (I_N) so that they both respectively range between 0 and 1. γ and δ are weights used to adjust the importance of the MLP complexity and the sample size factors, where $\gamma + \delta = 1.0$. We consider both factors equally and assign a value of 0.5 to each.

The weighted sum of the network complexity and sample size factors will always range from (0,1]; hence, we subtract that sum from 1 because we want the function to minimize it as GA works to maximize the overall fitness. As we focus on binary classifiers, the MLP model will always have two output nodes ($k_O = 2$) as per WEKA [11]. k_H will vary according to the parameters encoded in Part A of an individual's chromosome when optimization of the MLP configuration is considered during evolution. When optimization of MLP configuration is not considered, we use a default value of three nodes in one hidden layer; hence, the complexity term equals one.

The following steps summarize the GA implemented in elNN and used for our empirical investigations. The goal of our GA system is to maximize the fitness function defined in Equation (1).

1) Create a population with the specified number of individuals (100 for the experiments in this research). Randomize the allele values for each individual's genes.
2) Create a sampling reference dataset with copies of the majority class instances. The order of the instances in this reference dataset matches the order of the genes used for evolutionary sampling in the individual.
3) Add a sampling index value to all the instance objects in the training data. The sampling index is simply the index of the instance in the reference dataset created in Step 2. It corresponds to the position of the evolutionary sampling gene in each individual's chromosome. elNN performs this step as a preprocessing measure to create a look-up system between the evolutionary sampling genes in the chromosome and the actual training data instances so that there will be no need to conduct searches for instances in the training data as the genetic algorithm progresses.
4) Create training and test pairs of datasets for each of the folds for five-fold cross-validation. Use the experiment number (1–20) to seed the random number generator for splitting the data. A five-fold cross-validation involves randomly dividing the software measurement dataset into five subsets, and training the classifier with four subsets while the remaining subset is used for testing (evaluating) the classifier. This process of training and testing is repeated five times, each time with a different evaluation dataset.
5) Loop for the desired number of generations:
    a) Run the "best chromosome" natural selector. Keep the fittest 75% of the population to take part in this generation and discard the remaining individuals.
    b) Apply the crossover operator. The number of crossovers to perform is equal to 50% of the current population size. For each mating in single-point crossover we randomly select two individuals from the population with replacement. The two new individuals are then added to the population to be processed by natural selection at the end of the generation.
    c) Apply the mutation operator. Each gene in all of the chromosomes in the population has a 25% chance of mutation. Mutation does not change the individual being mutated, but rather if an individual has one or more genes selected for mutation, the algorithm creates a copy of the individual and mutates the copy's genes. A mutation rate of 0.25 reflects the results of Tate [20] and Haupt [24], which suggest that for complex gene encodings (such as our GA system) a higher mutation value (instead of the traditional 0.1) would be more beneficial. Tate [20] also recommends increasing the mutation rate when one is unable to increase the population size, generally because of the computational overhead involved.
    d) Run the tournament natural selector to select individuals who will survive to the next generation. In each tournament of four randomly selected individuals, one is chosen for survival. The fittest individuals are more likely to be chosen, but it is not guaranteed that they will be.

In the algorithm above, an individual's fitness value is calculated on demand. When elNN calls for an individual's fitness for the first time, it performs the following steps:

1) Create five threads, one to handle each of the five folds for our cross-validation procedure. Each thread receives a copy of the fold training dataset and the fold test dataset created in Step 4 of the GA algorithm.
2) For each thread:
    a) For each instance in the fold training dataset, use the sampling index value stored with the instance in Step 3 of the GA algorithm to find the corresponding gene in the individual's chromosome. If the Boolean allele value for that gene is false, remove the instance from the thread's training dataset.
    b) Instantiate the selected WEKA classifier. This involves using the default parameters for the classifier if elNN is set for data sampling without classifier parameters' optimization.
    c) Build the classifier using the fold training dataset.
    d) Evaluate the classifier using the fold test dataset. Store the resulting performance metrics (AUC and GMean) for the individual.
3) Take an average of the performance metrics for the five folds to be used for calculating the individual's fitness. We use this average only to score the individual for the genetic algorithm. The GA considers the individual to be a composite of the five folds; however, we report all five scores for the cross-validation folds separately for the fittest individual at the end of the experiment. Thus, one experiment represents one model run on five (cross-validation) datasets and, therefore, gives us results for five runs.

We run each GA experiment 20 times, each time with a different seed for the pseudo-random number generator used for cross-validation as explained in Step 4 of the GA algorithm. At the end

of a set of experiments, we have results for 100 GA runs for one experiment. The average values of the respective performance metrics are reported.

V. Empirical Investigation

A. Case Study Datasets

The *CM1* project is a NASA mission software responsible for the monitoring and analysis of science instruments. Written in C, this project's data is made available through the Metrics Data Program at NASA. Each program module in the dataset provides the software metrics for a module or a function in the *CM1* project. The dataset includes 13 numeric and two nominal independent attributes and a nominal class attribute. The minority class consists of the software modules considered to be *fp*, while the majority class represents the modules which were *nfp*. There are a total of 505 modules, of which 48 (9.50%) are *fp* while 457 (90.50%) are *nfp*.

The *SP2* project contains software metrics and defect data for a release of a large-scale telecommunications system written in Protel, a language similar to Pascal [25]. Program modules in the dataset represent the source code modules in the software project. The 42 numeric independent attributes describe the program module's values for various software metrics. The dependent attribute is nominal and identifies the module as *fp* or *nfp*. The *fp* modules form the minority class, while the *nfp* modules form the majority class. There are a total of 3981 modules in *SP2*, of which 189 (4.75%) are *fp* while 3792 (95.25%) are *nfp*.

B. Experimental Settings, Results and Analysis

The evolutionary experiments were conducted with a population size of 100 individuals and for 100 generations. These specific values were based on considering a combination of computational practicality and obtaining relatively good results. However, it is likely that a larger population size and a longer evolution would yield better performances. An evolutionary experiment in our study involved 20 runs of stratified, five-fold cross-validations to train and test an MLP classifier with a given dataset.

We use the experiment run number (1-20) to seed the random number generator when creating the five cross-validation folds. A given run involves five instantiations of the classifier, where each involves one-fifth of the modules in the dataset being reserved for evaluating (testing) the classification model, while the remaining four-fifths are used to train the model. At the end, we have 100 values for our performance metrics, i.e., product of 20 runs and 5 folds. For a given GA experiment, this translates to 200 evolutionary computing models for the two datasets in our study. The two GA-based experiments (evolutionary sampling with, and without, MLP configuration optimization) develop a total of 400 evolutionary models. Considerable time and computing resources were involved to complete all the experiments in our study. This is a common observation in a typical evolutionary computing-based analysis.

The performance metrics for the MLP models trained both without any data sampling technique and with Evolutionary Sampling are shown in Table II. The *BAS* column represents MLP models trained without any data sampling technique and with default options for the MLP learner of WEKA. The *EVS-DF* column represents MLP models trained with default parameter configurations (of WEKA) and with Evolutionary Sampling. The *EVS-OT* column represents MLP models trained with both Evolutionary Sampling and with optimization/tuning of the MLP parameter configurations. The MLP models are evaluated on the F-Meas, AUC, and GMean performance metrics. Recall, F-Meas was not used in our fitness function as compared to the AUC and GMean.

TABLE II
Results of GA Experiments With MLP

F-Meas performance			
Dataset	*BAS*	*EVS-DF*	*EVS-OT*
CM1	0.053	0.431	0.415
SP2	0.129	0.327	0.342
AUC performance			
Dataset	*BAS*	*EVS-DF*	*EVS-OT*
CM1	0.812	0.840	0.838
SP2	0.829	0.841	0.845
GMean performance			
Dataset	*BAS*	*EVS-DF*	*EVS-OT*
CM1	0.094	0.759	0.754
SP2	0.260	0.608	0.639

TABLE III
Majority Undersampling Techniques' Results

F-Meas performance				
Dataset	*EVS-DF*	*RUS*	*WLE*	*OSS*
CM1	0.431	0.312	0.198	0.094
SP2	0.327	0.272	0.166	0.147
AUC performance				
Dataset	*EVS-DF*	*RUS*	*WLE*	*OSS*
CM1	0.840	0.807	0.805	0.809
SP2	0.841	0.834	0.832	0.830
GMean performance				
Dataset	*EVS-DF*	*RUS*	*WLE*	*OSS*
CM1	0.759	0.676	0.332	0.162
SP2	0.608	0.714	0.313	0.286

The *EVS-DF* and *EVS-OT* models clearly outperform the *BAS* models, making a clear case for addressing the rarity of fault-prone modules in software quality modeling. This is true for both software measurement datasets and for all three performance metrics. An ANOVA and Tukey's Honestly Significant Difference (HSD) statistical analysis indicated that the *EVS-DF* and *EVS-OT* models are significantly better than the *BAS* models at $\alpha = 0.05$ [10]. A comparison between the *EVS-DF* and *EVS-OT* models indicates that the two modeling approaches are relatively competitive with respect to all three performance metrics.

We compare our EVS approach with other existing majority undersampling techniques, and those results are summarized in Table III. The table reflects classifier performances of MLP learners trained using the default parameter configuration in WEKA. The table does not include the *EVS-OT* results because those software quality models were trained with optimization of modeling parameters for the MLP learner, as discussed earlier. The *RUS* results are the best performances among random undersampling rates of 5%, 10%, 25%, 50%, 75%, and 90% for a given dataset. The results for *WLE* represent the better value of the standard and the weighted versions [8].

In the case of the smaller software measurement dataset, *CM1*, the *EVS-DF* models are always better than all of the other majority undersampling techniques. This is true for all three performance metrics considered in our study. In the case of the larger software measurement dataset, *SP2*, the *EVS-DF* models have the best performances with respect to F-Meas and AUC. However, with GMean as the performance metric, the *RUS* technique gave the best results. An

ANOVA and Tukey's HSD statistical evaluation revealed that when combining all results from both datasets, the *EVS-DF* models were better than the other majority undersampling techniques [10].

VI. Conclusion

Evolutionary Sampling is presented as a viable data sampling technique for addressing rarity of the minority class instances in a machine learning dataset. This paper addresses the problem in the context of software quality classification modeling where the proportion of fault-prone modules is often a very small fraction of the software measurement training dataset.

Implemented as a research prototype, eLǸNN, the proposed majority undersampling technique can also be combined with a genetic algorithm-based optimization of the different modeling parameters of a machine learner. This paper focuses on using the multilayer perceptron neural network as the binary classifier of choice; however, the proposed approach and comparative study can be extended to most other binary classifiers. Currently eLǸNN implements the C4.5 decision tree, RIPPER, and Multilayer Perceptron learners, and is based on the WEKA data mining tool framework.

Software measurement datasets from two real-world software projects are used as case studies for evaluating the proposed Evolutionary Sampling approach. In addition to comparing the before and after Evolutionary Sampling software quality models, this study also compares EVS with three other majority undersampling techniques. They are random undersampling, Wilson's editing, and one-sided selection. A comparison with other data sampling techniques, i.e. minority oversampling, is not presented due to space limitations.

Empirical results of the case studies presented clearly indicate that EVS improves the software quality model's performance as compared to modeling without any data sampling technique. A classifier is evaluated based on three independent performance metrics, namely Area-Under the ROC Curve, Geometric Mean, and F-Measure. Compared to the other majority undersampling techniques, the proposed approach shows a significant improvement, especially when F-Meas and AUC are considered as performance metrics. Among the two software measurement datasets, random undersampling fares competitively for the larger dataset. This is likely due to the availability of good majority class instances even after randomly eliminating some majority class instances.

Some directions for future work include further validation with additional datasets and optimizing the different GA parameters such as population size, number of generations, mutation rate, and crossover rate. While GA parameters' optimization would likely improve the end results, such analysis comes at the expense of increased computational and time complexities. However, some of that concern can be alleviated since GA generally lends itself well to parallelism, and parallel systems can provide added benefits to using evolutionary techniques.

Abstract

Software engineering research and practice thus far are primarily conducted in a value-neutral setting where each artifact in software development such as requirement, use case, test case, and defect, is treated as equally important during a software system development process. There are a number of shortcomings of such value-neutral software engineering. Value-based software engineering is to integrate value considerations into the full range of existing and emerging software engineering principles and practices.

Machine learning has been playing an increasingly important role in helping develop and maintain large and complex software systems. However, machine learning applications to software engineering have been largely confined to the value-neutral software engineering setting. In this paper, the general message to be conveyed is to apply machine learning methods and algorithms to value-based software engineering. The training data or the background knowledge or domain theory or heuristics or bias used by machine learning methods in generating target models or functions should be aligned with stakeholders' value propositions. An initial research agenda is proposed for machine learning in value-based software engineering.

Keywords: *value-based software engineering, machine learning, stakeholder value propositions, Pareto modules*.

1. Introduction

Software engineering research and practice thus far are mainly conducted in a value-neutral setting where each artifact in software development such as a requirement, a use case, a test case, a defect, and so forth, is treated as equally important during a software system development process [2]. There are a number of shortcomings of such value-neutral software engineering [1]: (1) its exclusion of economics, management sciences, cognitive sciences, and humanities from the body of knowledge needed to develop successful software systems; (2) its delimitation of software development by mere technical activities; and (3) its failure to explicitly recognize the fact that software systems continue to satisfy and conform to evolving human and organizational needs is to create value. Value-based software engineering (VBSE) is to integrate value considerations into the full range of existing and emerging software engineering principles and practices so as to increase the return on investment (ROI = (benefits–costs)/costs) for the stakeholders and optimize other relevant value objectives of software projects [1, 2].

Machine learning (ML) has been playing an increasingly important role in helping develop and maintain large and complex software systems. However, machine learning applications to software engineering have been largely confined to the value-neutral software engineering setting [29-31,33]. In this paper, the general message we attempt to convey is to apply ML methods beyond the value-neutral software engineering setting and to VBSE. The training data or the background knowledge or domain theory or heuristics or bias used by ML methods in generating target models or functions for software development and maintenance should be aligned with stakeholders' value propositions (SVPs) and business objectives. Even though the transition to VBSE from the traditional value-neutral setting is necessarily evolutionary because not all the theories, infrastructures, methodologies and tools for VBSE have been fully developed yet, there are a number of agenda items for VBSE [2].

The goal of the road map in VBSE is to make software development and maintenance decisions that are better for value creation [2]. On the other hand, the hallmark of ML is that it results in an improved ability to make better decisions. VBSE offers a fertile ground where many software development and maintenance tasks can be formulated as ML problems and approached in terms of ML methods. The purpose of this paper is to describe an initial research agenda for ML applications to VBSE with regard to the identified areas in VBSE (value-based requirement engineering, architecting, design and development, verification and validation, planning and control, risk/quality/people managements, and a theory of VBSE [2]).

The rest of the paper is organized as follows. Section 2 offers an overview of the related work. Section 3 highlights some important concepts in VBSE. In Section 4, we describe an initial research agenda for ML applications in VBSE. Finally Section 5 concludes the paper with remark on future work.

2. Related Work

In addition to machine learning in (value-neutral) software engineering (MLSE), there are a number of related and emerging software development paradigms: search-based software engineering (SBSE), evidence-based software engineering (EBSE), model-based software engineering (MBSE), artificial intelligence in software engineering (AISE), and computational intelligence in software engineering (CISE). We provide a brief account for each of the paradigm. Figure 1 highlights their similarities and differences.

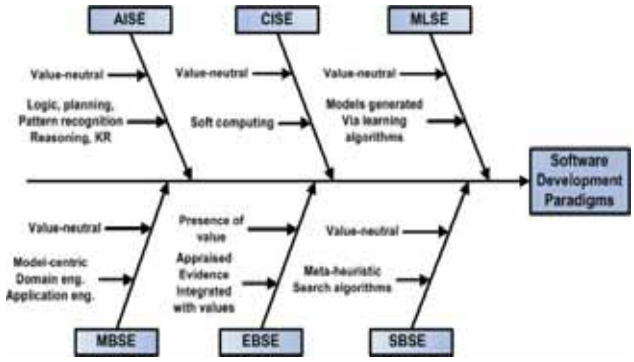

Figure 1. Emerging software development paradigms.

2.1. MLSE

ML falls into the following broad categories: *supervised* learning, *unsupervised* learning, *semi-supervised* learning, *analytical* learning, *reinforcement* learning, and *multi-agent* learning. Each of the categories in turn includes various learning methods. Supervised learning deals with learning a target function from labeled examples. Unsupervised learning attempts to learn patterns and associations from a set of objects that do not have attached class labels. Semi-supervised learning is learning from a combination of labeled and unlabeled examples. Analytical learning relies on domain theory or background knowledge to learn a target function. Reinforcement learning is concerned with learning a control policy through reinforcement from an environment. Multi-agent learning is an extension to single-agent leaning. There are many emerging learning methods such as argument based machine learning, interactive learning, transfer learning, and so forth.

In software development, there are processes, products and resources [9], which in turn have internal and external attributes. Internal attributes describe an entity itself, whereas external attributes characterize the behavior of an entity (how the entity relates to its environment).

A partial list of ML applications in value-neutral software engineering includes [29-31, 33]: (1) Predicting or estimating measurements for either internal or external attributes of software development processes, products, or resources. (2) Discovering either internal or external properties of the processes, products, or resources. (3) Transforming products to accomplish some desirable or improved external attributes. (4) Synthesizing or generating various products. (5) Reusing products or processes. (6) Enhancing processes. (7) Managing products.

There were many different ML methods utilized in the aforementioned applications [29-31, 33]. A common property in the existing ML applications is that the software engineering issues were tackled solely from technical or logical perspectives (involving mappings and transformations, for instance) without the value dimension being taken into consideration (e.g., how to increase ROI for the stakeholders and optimize other relevant value objectives of software projects). The training data or the background knowledge or domain theory or heuristics or bias used by the ML methods in generating target functions did not contain any value propositions.

2.2. SBSE

SBSE treats software development tasks as a search problem with regard to a set of constraints and a search space of possible solutions [6, 12]. It relies on evolutionary algorithms, gradient ascent/descent, particle swarm intelligence, simulated annealing, tabu search or colony optimization techniques to tackle the software development or maintenance tasks. So far its applications have included the following areas in software engineering: requirement engineering, project planning, cost estimation, maintenance, reverse engineering, refactoring, program comprehension, service oriented tasks, quality assessment, and testing (structural, functional, non-functional, state-based properties, robustness, stress, security, mutation, regression, interaction, integration, and exception). Value considerations are not explicitly incorporated into the search process.

2.3. EBSE

EBSE is geared toward improving the decision making process related to software development and maintenance by integrating current best evidence from research with practical experience and human values [7, 15]. There are five main steps in EBSE as delineated in [7, 15]: (1) Translate a relevant problem or need of information into an answerable question. (2) Glean the literature for the best available evidence that can be used to answer the question. (3) Assess the evidence for its validity, impact, and applicability. (4) Combine the appraised evidence with practical experience, and stakeholders' values and circumstances to make decisions. (5) Evaluate performance and find ways to improve it. An important strength of EBSE is that it does take into consideration SVPs.

2.4. MBSE

MBSE is centered on software models, modeling, and model transformation technologies. It is a disciplined approach to developing and extending a product family. The software models provide the necessary information to support, economically and effectively, future changes to a software product family. By focusing on models that capture and consolidate developers' understanding of a family of software products, reusable assets can be developed that satisfy a wide variety of uses and can be utilized to analyze existing software to quickly compose or synthesize new solutions for subsequent products in a product family [4, 21, 26]. The goal is to achieve the benefits of reuse, shorter time to market, product maintainability and higher quality. However, value considerations are not prominently factored into the paradigm.

MBSE consists of two parallel engineering processes: domain engineering and application engineering, and sanctions the concepts of product families, a production system, and software assets (the reusable resources needed in application engineering such as domain models, software architectures, design standards, communication protocols, code components and application generators).

Many organizations have model-based development paradigm in place: Microsoft's Software Factory [10], Lockheed Martin's Model Centric Software Development [28], and NASA JPL's Defect Detection and Prevention [8].

2.5. CISE

In CISE (or software engineering with computational intelligence), soft computing techniques such as fuzzy sets, neural networks, genetic algorithms, genetic programming and rough sets (or combinations of those individual technologies) are utilized to tackle software development issues recently [13, 14, 16, 17, 23]. The results have been largely confined to the value-neutral setting.

2.6. AISE

The application of some general artificial intelligence techniques to software engineering (AISE) has produced some encouraging results [19, 20, 22, 25, 27]. Some of the successful AI techniques include: knowledge-based approach, automated reasoning, expert systems, heuristic search strategies, temporal logic, planning, and pattern recognition. Again the results thus far have been obtained in the value-neutral setting.

3. VBSE

The essence in VBSE is that the approach aims at aligning software development and maintenance with customer requirements and strategic business objectives. It offers a framework where SVPs are incorporated into the technical and managerial decisions made during software development and maintenance [1, 11].

Value includes product, process and resource attributes. Value attributes include: profits (generated from products), strategic positioning in market share, utility, relative worth, reputation, customer loyalty, innovation technology, cost reduction, quality of life, improved productivity.

An emerging agenda of issues in VBSE has been proposed in [2], that includes the following areas:

- Value-based requirements engineering. The key objectives include recognition of success-critical stakeholders, elicitation of SVPs, and reconciliation of SVPs.
- Value-based architecturing. The goals are to iron out the discrepancy between a system's objectives and achievable architectural solutions.
- Value-based design and development. The goals are to ensure that a software system's objectives and its value considerations are embodied in the software's design and development practices.
- Value-based verification and validation. The objectives are to ascertain that a software solution meets its value objectives and that V&V tasks are sequenced and prioritized as investing activities.
- Value-based planning and control. The objectives in this area are to incorporate the value delivered to stakeholders into the product planning and control techniques.
- Value-based risk management. How to factor the value considerations into principles and practices for risk identification, analysis, prioritization, and mitigation is the main focus in this area.
- Value-based quality management. The goals are to prioritize desired software quality considerations with respect to SVPs.
- Value-based people management. The tasks involve building stakeholder team, manage expectations, and reconcile SVPs.

To facilitate ML applications in VBSE, a number of concepts need to be in place, one of which is about Pareto modules.

Figure 2 depicts a reported study in [5] where the dotted line reflects the value-neutral practice in which an automated test data generation tool assumes that all tests have the same value. The Pareto curve for the empirical data, on the other hand, displays the actual business value where one of the fifteen customer services accounted for 50% of all billing revenues.

We refer to module(s) that realizes a service of such a high positive impact on the system's ROI as *Pareto modules*. They are the most important modules of a software system with regard to its product value. How

modules contribute to a product's overall value hinges on reconciled SVPs.

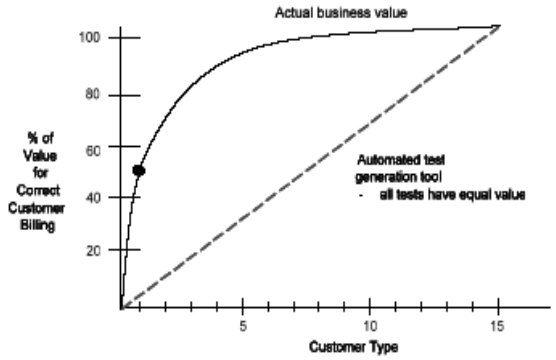

Figure 2. Pareto distribution for varying test case value.

For a given software system Ω, we can define a set $\mathbf{M}_\Omega$ of modules, a valuation function υ, and a value set $\boldsymbol{V}$ as follows:

$\mathbf{M}_\Omega = \{m_i \mid m_i \in \Omega\}$;
$\upsilon: \mathbf{M}_\Omega \rightarrow [0, 1]$;
$\boldsymbol{V} = \{\upsilon(m_i) \mid m_i \in \mathbf{M}_\Omega\}$

The valuation function υ can be defined by SVPs and has the following properties:

- $0 < \upsilon(m_i) \leq 1$, for all i;
- $\sum_{i=1}^{n} \upsilon(m_i) = 1$.

We define a partially ordered set $(\boldsymbol{V}, \leq)$ where $\leq$ is a binary order relation on $\boldsymbol{V}$ and satisfies reflexivity, anti-symmetry and transitivity for all elements in $\boldsymbol{V}$. We say that $\upsilon(m_p)$ is a *principal element* for $(\boldsymbol{V}, \leq)$ if we have the following:

$$\forall \upsilon(m_j) \in \boldsymbol{V}\ [\upsilon(m_j) \leq \upsilon(m_p)]^1$$

We use ρ to denote the *principal module* as specified by $\upsilon(m_p)$. We define a *principal-element-ordered subset* $\boldsymbol{V}_{[m_i, \rho]}$ of $\boldsymbol{V}$ and its cumulative value $\mu_{[m_i, \rho]}$ as follows:

$$\boldsymbol{V}_{[m_i, \rho]} = \boldsymbol{V} - \{\upsilon(m_k) \mid \upsilon(m_k) \leq \upsilon(m_i)\}$$
$$\mu_{[m_i, \rho]} = \sum \upsilon(m_j) \in \boldsymbol{V}_{[m_{i,} \rho]}$$

Now we are in a position to formally define the concept of Pareto modules.

Definition 1. Given a threshold value $\tau \in (0, 1]$, we identify a principal-element-ordered subset $\boldsymbol{V}_{[m_i, \rho]}$ such that $\tau = \mu_{[m_i, \rho]}$. Modules in $\boldsymbol{V}_{[m_i, \rho]}$ are referred to as Pareto modules with regard to τ.

If $\tau < \mu_{[m_i, \rho]}$ but removing any m_j from $\mu_{[m_i, \rho]}$ would result in $\tau > \mu_{[m_i, \rho]}$, then the condition of $\tau = \mu_{[m_i, \rho]}$ is relaxed to that of $\tau \leq \mu_{[m_i, \rho]}$.

[1] If there are several principal elements in $\boldsymbol{V}$, we can use other criteria to designate one for the discussion.

4. Research Agenda for ML in VBSE

In this section, we first discuss some general issues on how to calibrate ML methods for VBSE tasks. Using Boehm' VBSE agenda in [2] as a roadmap, we then describe some preliminary agenda items of how ML can help with the goals, objectives and tasks in VBSE.

4.1. How to calibrate ML methods

ML methods formulate various general hypotheses, models and target functions through either observed training data, or some background knowledge or domain theory, or a combination of both. The generalization process during leaning also hinges on certain adopted bias or heuristics.

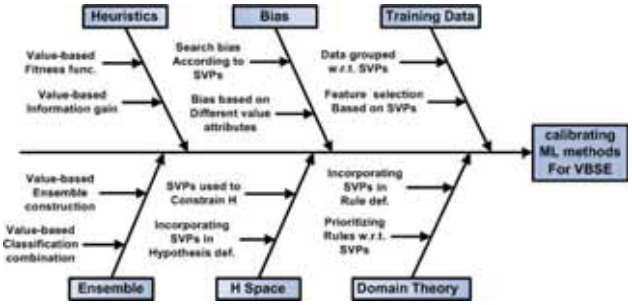

Figure 3. Calibrating ML methods for VBSE.

To calibrate ML methods for VBSE tasks, the fundamental issue is how to incorporate SVPs from the business value level into the technical level details of ML model generation process. Specifically, this translates into the following issues: how to use SVPs to select data features and to group training data, how to incorporate SVPs into domain knowledge representation, how to prioritize rules, based on SVPs, in domain knowledge during model generation, how to include SVPs in defining search bias, how to use different value attributes in defining domain-specific biases for the search process, how to utilize SVPs in defining hypotheses and constraining hypothesis space, how to factor SVPs into ensemble construction and classification combination process when ensemble learning is used to generate models, and how the value concept plays a role in defining ML method-specific heuristics (e.g., fitness function, information gain measure).

4.2. Value-based requirements engineering

For the objectives in value-based requirements engineering, techniques such as business case analysis, requirements prioritization and release prioritization have proven to be effective [2].

ML methods can be utilized to assist business case analysis, and requirements and release prioritization. Specifically, ML methods can be used to predict or estimate software cost, software size, software development efforts, and release prioritization and timing.

These prediction, estimation or cost models would help stakeholders gain insight on what capabilities are not feasible with regard to budget, schedule and technology constraints, which features of a system are most important and attainable, and which aggregate of capabilities will meet stakeholders' critical needs given the resource constraints. This in turn will assist stakeholders in prioritizing and reconciling potential conflicting value propositions. Possible ML methods for generating the models include: decision trees, Bayesian learning, neural networks, genetic algorithms, genetic programming, case-based reasoning, and inductive logic programming.

4.3. Value-based verification and validation

The key techniques in value-based V&V are value-based and risk-based testing techniques [2]. Central to those techniques is how to align SVPs with the technical level details in test construction and execution and how to sequence and prioritize testing activities as investing activities [24, 32].

Since we only have the Pareto module concept in place, we need to introduce defect-intensive and defect-prone modules, impact and non-impact defects before we can use an SVPs-based approach to identify modules of the aforementioned types and decompose the overall test data generation process for a given software system into a sequence of test data generation cycles with each focusing on some specific testing objective(s). From a value-based standpoint, to improve the return on investment, we want to make sure to first maximize the success rate of Pareto modules and to minimize the chance of having impact defects that devastate the value contribution. Afterwards, attention can be focused on non-impact defects and non-Pareto modules. Thus, a prioritization of cycles can be generated that is driven by the value consideration and allows the most critical modules with regard to SVPs to be thoroughly tested first.

For each cycle, a number of ML methods can be utilized to generate test cases for different classes of modules. Some possible ML methods include: genetic algorithms [18], genetic programming, inductive logic programming and rule-based active learning.

4.4. Value-based risk management

There are a number of techniques for value-based risk management: the risk-based "how-much-is-enough" techniques, the risk-based analysis for project predictability, the risk-based simulation, and the risk-based testing techniques [2].

A pivotal concept in risk management is the *risk exposure* (***RE***) involved in a prescribed course of actions. ***RE*** is defined as follows:

$$\boldsymbol{RE} = \boldsymbol{P}(\mathscr{L}) \times \boldsymbol{S}(\mathscr{L})$$

where $\boldsymbol{P}(\mathscr{L})$ is the probability of loss $\mathscr{L}$, and $\boldsymbol{S}(\mathscr{L})$ is the size of loss. $\mathscr{L}$ can be defined based on any value attribute as discussed in Section 3. In the risk exposure profile analysis [3], there is a dichotomy between planning and market share as the value attribute: inadequate planning results in little delay to capture market share but high ***RE*** due to oversights and rework; excessive planning reduces the chance of major problems but at the expense of high ***RE*** because of time-to-market delays.

ML methods can be used to help find the "sweet spot" for different risk profiles and different risk exposure profiles. Depending on the circumstances, either inductive learning, or analytical learning, or a combination of inductive and analytical learning can be deployed.

4.5. Value-based design and development

To ensure that a system's objectives and its value considerations are embodied in the software's design and development practices, the software traceability techniques play an important role [2]. During the software development process, many artifacts are produced and maintained: documents, requirements, design models, test scenarios, and so forth. Trace dependencies are to identify relationships among those artifacts and the quality of the trace dependencies should reflect the value of the artifacts they attempt to bridge. This is vital for a number of reasons, from documentation, program understanding, impact analysis, consistency checking, reuse, quality assurance, user acceptance, error reduction, cost estimation, to customer satisfaction.

ML methods can be used to establish value-based trace dependencies among different artifacts. Methods such as instance-based learning (case-based reasoning), inductive logic programming, rule-based learning would lend themselves to the task.

4.6. Value-based quality management

ML methods can be used to generate predictive models for identifying high risk or fault prone components as an integral part of the quality management. Because of the need to align desired quality properties with SVPs, value considerations should be, directly or indirectly, involved in defining or contributing to those quality properties. SVPs should also help prioritize the desired quality factors.

ML methods that are appropriate for the task include: decision trees, genetic programming, neural networks, case-based reasoning, inductive logic programming, and concept learning.

5. Conclusion

VBSE offers a new software development paradigm that recognizes the importance of business and customer value considerations. It tackles the decision making process in software development and maintenance from a value-based perspective. In this paper, we discuss the issue of ML applications to VBSE. Because ML applications to software engineering thus far have been

largely confined to the value-neutral setting, we reviewed the landscape in the field and took a closer look at the emerging agenda for VBSE to find out how ML can be positioned to play a larger role in VBSE. We propose some guideline on how to calibrate ML methods to accommodate the value considerations that are so critical in accomplishing VBSE agenda items. Using Boehm' VBSE roadmap as a guide, we describe some preliminary agenda items on how ML can help with the goals, objectives and tasks in VBSE.

The take-home message of this work is two-fold: VBSE offers a ROI-conscious approach to software development and maintenance, and ML has an active and important role to play in various agenda items in VBSE.

The viability of ML applications in VBSE hinges on the outcomes of empirical studies, which will be pursued as our future work. How to solidify SVPs into various ML methods is an open issue worth studying.

Abstract

This paper addresses the problem of clustering defect reports. Clustering defect reports can provide valuable information to software testers, e.g. it could help better plan and prioritize the testing effort as testers could focus on testing the features with most defects as indicated by the largest clusters identified. In this paper, we present results obtained with one clustering algorithm, K-means, and two models of defect reports. In one model we use the summary field of the reports and in another the description field. Our experiments on defect reports from Mozilla's Bugzilla, a database of defect reports related to the open source Mozilla project, showed that clustering defect reports based on their summary field (average accuracy=44.2240%) outperformed clustering based on the description field (average accuracy=29.3581%). Both methods outperform the baseline of randomly picking a cluster (accuracy=20.0000%). We evaluated the clustering algorithm with respect to clusters containing bug reports that refer to the same underlying problem.

1. Introduction

We address in this paper the challenging task of clustering defect reports. Defect reports are detailed descriptions in natural language of defects, i.e. problems in a software product. The quality and proper handling of defect reports throughout the testing process will have a great impact on the quality of the released software product. The defect reports are currently analyzed manually by testers, developers, and other stakeholders. Manual analysis is tedious, error-prone, and time consuming, leading to a less efficient testing process.

We propose here automatic methods to analyze defect reports. In particular, we propose automatic methods to clustering defect reports in order to discover patterns among reported defects. Clustering could reveal sets of related problems and this information could be further used to better plan the testing effort. For instance, a large cluster of related reports could indicate which feature(s) of the software product needs to be further tested. While a cluster of defect reports that look similar content-wise may not always describe the same underlying bug, i.e. root cause, they could highlight visible features of a product that need more attention from the testing team. However, in this paper we address the more challenging task of clustering defect reports based on their describing the same underlying bug. This is possible by evaluating the clustering using reports that were judged by developers as being duplicates, i.e. describing the same bug.

Defect reports are filed by testers (or users) who discover the defects through testing (or use). The reports are stored in a database called defect database. It is the developers' job to take open, i.e. not yet fixed, defects from the database, analyze the corresponding reports, and fix the defects. Defect reports include many details about the corresponding defects including an *id* that uniquely identifies the defect, the *status* of the defect (e.g. new, verified, resolved), a *sum-*

mary field, and a *description* field. The description field is the richest source of information about the defect. The field describes in plain natural language details about the defect, including symptoms and steps to reproduce the defect. The summary field is an one-sentence description of the problem.

We propose here advanced methods for analyzing defect reports that take advantage of the description and summary fields of the reports. Our approach is to use advanced natural language processing (NLP) and informational retrieval (IR) techniques for automatic analysis of the reports. We regard each defect report as a textual document and use a well-known technique in IR, called the *vectorial representation*[1], to represent documents.

In our experiments, the K-means clustering algorithm proved to be by far the most successful (we tried several other clustering algorithms, e.g. EM, FarthestFirst available in Weka, a machine learning toolkit[15]) to find clusters of similar defects and thus the paper focuses on reporting the results obtained with this algorithm. We used two models to represent defect reports, one based on the summary field and another based on the description field of reports. Our experimental data consisted of defect reports collected from the open source Mozilla project (www.mozilla.org) but the proposed methods are transferable to defect reports from other projects, e.g. Eclipse (www.eclipse.org). The clustering was evaluated based on reports describing the same underlying problem. That is, defect reports are in the same cluster if they describe the same underlying problem. As a preview of our results, we found that using the summary field of defect reports for clustering (average accuracy=44.2240% when compared to human judgment) is better than using the much longer description field (average accuracy=29.3581%). We could say that given a set of defect reports we could identify the subsets, i.e. clusters, referring to the same underlying bugs with an accuracy of 44.2240%.

The rest of the paper is organized as follows. In the next section, *Related Work*, we outline previous efforts that are relevant to our work. The *Defect Management* section offers details about how defect reports are handled in the open source Mozilla project and its associated defect tracking tool Bugzilla. In the following section, *Experiments and Results*, we present details about our experiments and the results obtained. A *Discussion and Future Work* section follows. The *Conclusions* section ends the paper.

2. Related Work

There are two major lines of previous research relevant to our work. First, there is work on defect clustering. Second, there is research on using NLP and IR to mine artifacts from software repositories and in particular to analyze defect reports for various purposes.

Clustering is the unsupervised classification of data points (usually represented as vectors in a multidimensional space) into groups (clusters) based on similarity. A cluster is therefore a collection of objects which are *similar* to each other in the same cluster and are *dissimilar* to objects belonging to other clusters. The clustering problem has been addressed in many contexts and by researchers in many disciplines. This reflects the broad appeal of clustering and its usefulness as one of the steps in exploratory data analysis. While we are not aware of any particular work on clustering defect reports, there is published research related to clustering defects in the manufacturing of semiconductors[4] and integrated-circuits (IC; [14]). Karnowski and colleagues [4] showed that fuzzy logic can help better cluster defects on semiconductor wafer maps. Singh and Krishna[14] have shown that using clustering information in optimization testing can significantly improve the shipped product contrary to the previous assumption that the probability of a test to detect a faulty circuit is independent of the number of faults in that circuit.

The usage of natural language processing applications to improve software development and testing has been around at least since 1990s [13, 6, 7, 2].

More recently, there has been renewed interest in applying natural language techniques to mine useful artifacts from the various repositories associated with software projects (see the yearly Workshop on Mining Software Repositories at http://msr.uwaterloo.ca). We discuss next a series of research efforts that are directly related to our work on clustering defect reports.

Linstead and his colleagues [5] described a framework to automatically mine developer contributions and competencies from a given code base. They also used the framework for extracting software function in the form of topics. Their findings indicate that it is feasible to extract the function (in the form of topics) of source code and developer expertise on these topics. This information could be used, for instance, to better plan defect fixes: the most qualified developer will be assigned to handle defects related to topics s/he is expert in. Linstead and colleagues [5] treated source code as text.

The use of the vectorial representation[1] to address defect report related issues has been explored by Runeson, Alexandersson, and Nyholm [11] for the task of identifying duplicate defects (see also the work of Rus and Shiva [12]). It is noted that identifying duplicate defect reports is not exactly the same with clustering defect reports. Runeson and colleagues adapted ReqSimile (a tool that links customer wishes to product requirements using statistical natural language processing [10]) to identify duplicate defects. ReqSimile uses the vector space model and cosine similarity [1] to decide how related two requirements documents are.

The vector space model represents documents in a collection as vectors of V dimensions, where V is the vocabulary, i.e. the set of distinct words, of the collection. There is one dimension for each word in the vocabulary. Entries in documents' vectors are weights which indicate how important the corresponding word/dimension is for distinguishing the content of the document from other documents. If a word does not occur in a document, the corresponding weight is zero. The similarity of two documents is given by the cosine of the corresponding vectors, which can be seen as the normalized dot product of the vectors. Runeson, Alexandersson, and Nyholm [11] used the term frequency (TF) of words in a document as the weighting scheme. In this paper, we use a more powerful weighting scheme, namely Term Frequency-Inverted Document Frequency (TF-IDF; see the *Experiments and Results* section). Their experiments were conducted on Incident Reports, i.e. defect descriptions, from software projects at Sony Ericsson Mobile Communications. For each set of duplicate descriptions they identify a master defect. Their evaluation focuses on how well their method can retrieve the master defect in the list of top N most similar defects to a given defect description. Here, we use the vectorial representation with TF-IDF weighting for the task of clustering defect reports.

3. Defect Management

During testing, defects within software are discovered through testing (and fixed) and new functionality is added, which must be tested. The testers report defects using a defect management tool, also called defect tracking tool, whose back-end is typically a relational database. The general process of handling defect reports includes the following steps: the defect is found and filed in the defect tracking tool, the report is evaluated by an analyst, the defect is assigned to a developer, the developer finds the defect and fixes it, and the defect report is closed. The tester, analyst, and developer could be same or different persons depending on the size of the project. In open source projects, users voluntarily report defects.

3.1 Defect Handling in Mozilla

It is important to understand the details of defect handling in the Mozilla open source project because our experimental data is collected primarily from Mozilla's Bugzilla. Bugzilla, a bug tracking tool, allows testers to report bugs and assign these bugs to developers. Developers can use Bugzilla to keep a to-do list as well as to prioritize, schedule, and track dependencies. Not all entries in Bugzilla are bugs. Some entries are Requests For Enhancement (RFE). An RFE is a report whose severity field is set to enhancement.

Ideally, before reporting a defect, the tester must reproduce the bug using a recent build of the software, to see whether it has already been fixed, and search Bugzilla to check whether the bug has already been reported. If the bug can be reproduced and no one has previously reported it, the tester can file a new defect report including: the component in which the defect exists, the operating system on which the defect was found, a quick summary of about 60 or less characters, a detailed description of the defect, and attachments, for instance screenshots. We focus next on the summary and description fields (as presented in Mozilla's Bug writing guidelines), the two information-rich fields of any defect report.

A good summary should quickly and uniquely identify the defect. It should explain the problem, not the suggested solution. Example of a good summary is *Canceling a File Copy dialog crashes File Manager*, while bad examples are *Software crashes* and *Browser should work with my web site*.

The description field is a detailed account of the problem. The description field of a defect report should contain the following major sections, although the breakdown of the field into these sections is not enforced in Bugzilla: *overview* (more detailed restatement of summary), *steps to reproduce* (minimized, easy-to-follow steps that will trigger the bug; including any special setup steps), *actual results* (what the application did after performing the above steps), *expected results* (what the application should have done, were the bug not present), *build date* & *platform* (date and platform of the build in which you first encountered the bug), *additional builds and platforms* (whether or not the bug takes place on other platforms or browsers, if applicable), and *additional information* (any other useful information).

Any deviation from the above guidelines leads to vague reports which in turn lead to a less efficient process of handling the defects. On the other hand, recording every detail about a defect can lead to overkill. The reality is that seldom defect reports include all the above suggested details. In this paper, we present experiments on defect reports as collected from Mozilla's Bugzilla. In general, the collected reports are of good quality but reports of lower quality can be found among the collected reports.

4. Experiments and Results

We present in this section details on applying the K-means clustering algorithm to cluster defect reports. The results of the experiments on data from Mozilla's Bugzilla are discussed.

Clustering is the unsupervised classification of patterns (usually represented as a vector of measurements, or a point in a multidimensional space) into groups (clusters) based on

similarity. In other words, it is *the process of organizing objects into groups whose members are similar in some way*. A cluster is therefore a collection of objects which are *similar* to each other in the same cluster and are *dissimilar* to the objects belonging to other clusters.

Typical clustering involves the following steps [3]: data representation (optionally including feature extraction and/or selection), definition of a similarity measure appropriate to the data domain, clustering or grouping, and assessment of output.

We will address in more detail these steps next, starting with the *Data representation*, as a great deal of effort has been spent on this step.

4.1 How to Represent Defect Reports?

A first basic issue we must address is the logical view of the reports (see [1] more information on logical view). We may want to model the reports in the simplest way possible, for complexity reasons, while capturing the gist of the defect. The description field of a report is the most informative piece of information about the defect. On the other hand, it may contain too much information. Using the shorter summary of a report may lead to a more efficient algorithm for clustering as fewer words need to be considered to capture the meaning of the report. We experimented with both models, description vs. summary, in this paper and report the winner.

Another important issue is the formalism used for the representation. We used the vector space model [1]. The vectorial representation of documents was briefly described earlier in the *Related Work* section. A key feature in the vector space model is the weighting scheme of the words. We used the TF-IDF scheme, a composed measure that is the product of the frequency of a term in a document (TF), and its inverted document frequency (IDF)[1]. The basic idea of the TF-IDF measure is that a word is important, has a large weight, if it occurs frequently in the document (high TF) and if it does not occur in too many other documents (low document frequency which means high inverted document frequency[IDF]).

4.2 Preprocessing

Each defect report must be preprocessed before it is mapped onto the vectorial representation. Preprocessing maps a report onto a list of tokens that have linguistic meaning, i.e. words. It is comprised of the following steps: tokenization, stop word removal, and lemmatization. Tokenization, a well defined step in natural language processing, separates punctuation from words. Another important preprocessing step is to remove stop words. We used a standard list of stop words, e.g. the SMART list (ftp://ftp.cs.cornell.edu/pub/smart/english.stop). Lemmatization is another preprocessing step coming after stop word removal. It maps each morphological variation of a word in a text fragment to its base form, e.g. *go, going, went, gone* are all lemmatized to *go*, their root or base form. We used the WordNet lemmatizer available in the WordNet library[9].

[1]The IDF of a word is the percentage of distinct documents the word appears in from a very large collection of documents. It is used to measure the specificity of the word. The fewer documents a word occurs in, i.e. the rarer, the more specific the word is.

4.3 Clustering Experiments

Clustering software defect reports can take different forms. For instance, the clustering can be based on either the severity of the bug, or based on the fact that the defect reports describe the same defect, i.e. they are duplicates, or based on other criteria such as component/feature-specific clustering, e.g. clustering printer-related defect reports.

In this paper, we chose to defect reports based on their describing the same underlying bug. We regard a defect report and its duplicates as a cluster. This modeling is adequate as the original defect report should be similar, content-wise, to its duplicates. The data used in our experiments comes from Mozilla's Bugzilla where duplicate information is available. The duplicates are marked as such by members of the Mozilla development team and thus we deem them highly reliable. We automatically collected our experimental data from Mozilla's Bugzilla database as described next.

To create our data set, we started collecting 20 Bugs from the *Hot Bugs List* of Mozilla's Bugzilla. The *Hot Bugs List* contains the most filed recently bugs. The list can be sorted based on the number of duplicates (see the *Dupes* field for each entry in the *Hot Bugs List*). A secondary criterion for selecting the reports was the severity of the reports because we wanted to have diversity among the clusters in terms of severity. Thus, we finally chose the top 20 defect reports from the *Hot Bugs List* in terms of largest number of duplicates and diversity of severity. We retrieved 50 duplicates for each of the 20 defect reports. Hence, the total number of bugs considered were 1020. Only the top 20 bugs from the *Hot Bugs List* were chosen because only these bugs had more than 50 duplicate each. Having fewer than 50 duplicates for each original bug would have led to too small clusters. The list of 1020 bugs served as input to the Data Collection module of our system that automatically collects over the Internet (from Mozilla's Bugzilla database) the *Description* and *Summary* of these 1020 bugs and stores them locally in text files. The final data set contained 1003 data points because we eliminated 17 reports which had no proper description fields. For these eliminated reports the description field was empty or was simply redirecting the

user to another bug, e.g. the field contained textual pointers such as "*see bug #123*".

The data set was further processed and analyzed with two data mining tools: RapidMiner[8] and Weka[15]. We used RapidMiner to generate the vectorial representations for defect reports. Weka was used to apply the K-means clustering algorithm to the data set. The two processing steps are explained in more details below.

The **TF-IDF Generation Module** computes the TF-IDF weights for each term in the vocabulary. For *Description* documents, i.e. reports represented using their *Description* field, the vocabulary size was 4569. The vocabulary size indicates the number of dimensions of the document vectors in the vectorial representation. For *Summary* documents, the vocabulary size was 991. From the vocabulary size of the two representations, description vs. summary, we notice the efficiency of the summary-based representation which has lower dimensionality.

In the next step, the defect reports in vectorial representation must be mapped to a format that WEKA requires in order to do clustering. The required format is the ARFF (Attribute Relation File Format) file format. This file can be generated using the RapidMiner's *ArffExampleSetWriter* operator.

Clustering. There are two major categories of clustering algorithms as listed below.

- *Hierarchical clustering* algorithms produce a nested series of partitions based on a criterion for merging or splitting clusters based on similarity.
- *Partition based clustering* algorithms identify the partition that optimizes (usually locally) a clustering criterion.

Example algorithms from each category are hierarchical agglomerative (HAC) and K-means, respectively [15]. HAC produces a hierarchical structure of clusters while K-means leads to a flat, direct clustering. In HAC, each data point is initially regarded as an individual cluster and then the task is to iteratively combine two smaller clusters into a larger one based on the distance between their data points. In the K-means algorithm, we specify a priori the number of clusters (K) we would like to have in the end. In testing, this could be useful when testers want to find out what are K, say K=20, clusters in the set of open defects. The algorithm usually starts with K seed data points which are considered as individual clusters. In subsequent iterations, the remaining data points are added to some cluster based on the distance to the centroid of each cluster. The centroid is an abstract data point of an existing cluster that is found by averaging over all the other points in the cluster. A distance metric must be defined for clustering algorithms. The advantage of using K-means is that it is very easy to implement and relatively efficient i.e. $O(t \times k \times n)$, where n is the number of objects, k is the number of clusters and t is the number of iterations. In many cases, the $k, t \ll n$ and hence can be ignored.

K-Means Clustering with Weka. We used the Simple K-Means algorithm in WEKA to obtain the clusters and automatically evaluate the performance of the clustering. Some implementations of K-means only allow numerical values for attributes. In case of categorical attributes they must be converted to numerical values. It may also be necessary to normalize the values of attributes that are measured on substantially different scales (e.g., *age* and *income*). WEKA's SimpleKMeans algorithm automatically handles a mixture of categorical and numerical attributes. Furthermore, the algorithm automatically normalizes numerical attributes when doing distance computations. The WEKA's SimpleKMeans algorithm uses Euclidean distance measure to compute distances between instances and clusters. To perform clustering, we needed to set a couple parameters: *number of clusters*, which informs the clustering algorithm how many clusters to generate, and *seed*. The seed value is used in generating a random number which is, in turn, used for making the initial assignment of instances to clusters. In general, K-means is quite sensitive to how clusters are initially assigned and thus it is often necessary to try different values and evaluate the results.

4.4 Results

The clustering *accuracy* is the number of documents correctly clustered divided by the total number of documents. WEKA includes an evaluation module that automatically compares the output of the clustering algorithm to the correct clustering, which in our case are the expert human judgments regarding whether one description is a duplicate of another as indicated in Mozilla's Bugzilla.

The performance of the K-means clustering algorithm depends on the number of seeds initially used to start the clustering. We experimented with various values for the *seed* parameter to find what is the best number of seeds to use. We varied the seed value from 0 to 1003 in increments of 1. For *Description*-based representation of reports, the maximum performance was found to be for the seed value 33, which is 47.7567%, and the minimum performance was found for the seed value 175, which is 7.2782%. The average performance obtained was about 29.3581%.

For *Summary*-based representations, the maximum performance was found for seed value 825, which is 59.8205%, and the minimum performance was for seed value 275, which is 34.2971% . The average performance obtained was about 44.2240%. Thus, our proposed method is able to identify clusters of reports describing the same underlying problem with an accuracy of 44.2240%. A baseline approach would be to always guess one of the twenty clusters

for an average accuracy of 20%. A statistical t-test (α=0.05) was used to compare the baseline to our approach and found our approach to be significantly (p¡0.0001) better than this baseline. The null hypothesis was that the average accuracy computed over 1004 seed points is equal to the average accuracy of the baseline approach.

5. Discussion and Future Work

Having a clustering feature integrated in a defect tracking tool such as Bugzilla could be extremely beneficial. For instance, in a large software development project this feature can be used periodically, e.g. once a week or once a month, to analyze the set of open defects by clustering them. The clusters can be used by the testing team in various ways, for instance to prioritize their work. We plan to continue our investigation of clustering defect reports by using other representations for defect reports, e.g. using only the *overview* section of the description field of a software report. One interesting research question to be explored in the future is the suitability of our proposed methods to cluster similar but not necessarily identical defect reports.

6. Conclusions

We addressed in this paper the challenging task of clustering defect reports. The evaluation was based on clusters containing defect reports describing the same underlying bug. Our experiments on defect reports from Mozilla's Bugzilla with the K-means clustering algorithms showed that using reports' summaries together with a TF-IDF vectorial representation leads to better clustering than using full descriptions of reports, which is also computationally more expensive.

7 Acknowledgments

Subjective Assessment of the Mutual Influence of ISO 9126 Software Qualities: An Empirical Study

Sandro Morasca

Università degli Studi dell'Insubria
Como, Italy
sandro.morasca@uninsubria.it

Abstract— **It is usually believed that software qualities may influence each other and that improving one software quality may cause some other qualities to worsen. Since no commonly used set of metrics exist for quantifying the software qualities of interest, the perception of the influence of one software quality on another is often used in practice when making decisions about software development. We describe the results of an empirical study on the beliefs of software practitioners in the mutual influence of the ISO 9126 software qualities. The study shows that the subjects believed, on average, that a number of influences exist between the ISO 9126 software qualities. However, the practitioners did not believe that trade-offs exist among several of these software qualities. In other words, they believed that improving one quality is often likely to improve other qualities as well.**

Keywords-ISO 9126;software quality

I. INTRODUCTION

During software development, decisions are made to obtain better software products in terms of several software qualities. Software qualities (or attributes) are usually divided into internal and external software ones:

- Internal software qualities (e.g., size, structural complexity, coupling) can be measured based on the knowledge of the software product alone;
- External software qualities (e.g., reliability, usability, maintainability, and readability) are related to both the software product and its environment. External software qualities are related to the many "users" of a software product, e.g., reliability and usability are related to the software's final user; maintainability and readability are related to the software developers.

External software qualities are usually the qualities of industrial interest, since they are related to the behavior of a software product towards its "users." On the other hand, the study, measurement, and "improvement" of an internal software quality is fully justified only if that internal software quality is believed to be linked to least one external software quality of industrial interest or to a process quality (e.g., cost, time-to-market). For instance, one of the goals of the introduction of object-oriented software development techniques was to obtain software systems divided into modules that were "better" in terms of their degree of internal cohesion and external coupling, i.e., with a higher degree of internal cohesion and a lower coupling with each other. However, higher cohesion and lower coupling were not the final objective of the introduction of object-oriented techniques: higher cohesion and lower coupling were supposed to improve the external qualities of software systems, e.g., in terms of maintainability, reusability, error-proneness, etc. Thus, even when they are based on some internal software quality, decisions on software development techniques and processes are actually often made to improve of some external software quality. Furthermore, even when the goal is to improve some process quality, decisions do affect external software qualities.

In this paper, we focus only on external software qualities, so the term "software quality" is used in this paper with the meaning "external software quality," unless otherwise explicitly stated.

It is commonly believed that there may be interactions among software qualities, and that improving one of the qualities of a software product may have a (possibly adverse) effect on other software qualities. It is argued that, if this was not the case, then it would be possible to improve all software qualities at the same time. This entails that practitioners must constantly make decisions as to how to proceed during all software development phases based on a balancing among the different software qualities that are affected by the decisions. For instance, a design decision may increase the level of one quality while decreasing the level of another. Therefore, the interactions among software qualities should always be taken into account during the software development process.

In principle, decision making should be based on quantitative information, if possible. This requires:

- the definition of adequate measures for the qualities of interest, and
- empirical studies that ascertain or at least provide convincing support on the existence and nature of the interactions among software qualities.

However, the state of the art of software measurement has not reached a point in which (1) adequate measures are often available for the qualities of interest, and (2) a sufficient number of studies are available on the interactions of software

qualities. As a consequence, software designers and developers often make decisions based on their own beliefs in the existence and nature of interactions among software qualities.

The goal of the study documented in this paper is to assess the degree of belief of software practitioners on the interactions among the ISO 9126 software qualities, and determine if there is some degree of consensus among the practitioners. This paper takes an empirical approach, in that its results are based on data collected from practitioners in a series of empirical studies carried out with practitioners from Italian and Swiss software companies. We wanted to obtain a characterization of software practitioners' beliefs about the mutual influences of software qualities, i.e., have a quantitative idea of the distributions of these beliefs and descriptive statistics such as mean, standard deviation, and median. In addition, we also explored the significance of these beliefs are from a statistical point of view. At any rate, this study provides initial evidence, but more studies are certainly needed to gather more evidence.

The remainder of the paper is organized as follows. Section 2 concisely describes the ISO 9126 standard. Section 3 describes the setting of the empirical study. The statistical hypotheses we tested are in Section 4. The empirical results are reported and discussed in Section 5. Section 6 concisely reports on the internal, external, and construct validity of the empirical study. Conclusions and outline of future work are in Section 7.

II. ISO 9126

A few quality models have been defined in the last few years, starting from [9]. Quality models are often defined in a hierarchical fashion (e.g., see Fig. 1). The overall quality of a software product is viewed as composed of a set of qualities. These qualities may be hierarchically refined by several layers of qualities (some of which may be internal software qualities). At each layer, the relative importance of each quality may be weighted depending on the measurement problem at hand. This hierarchical refinement process ends with the definition of a set of measures to quantify each quality. The weights provided to each quality may be used to combine the values of the measures into a single value for the overall software quality.

In some quality models, the qualities and measures associated with all the nodes of this hierarchical structure are fixed [9]. In other quality models, some parts are left tailorable/unspecified, for instance the set of measures [5]. There are also general, flexible framework that can be tailored to several different environments and measurement objectives, like the Goal/Question/Metric paradigm [1,2], which allows for the building of different quality models and measures. Depending on the measurement application at hand, different qualities may be chosen to be studied. Also, the same quality may be refined via different sets of qualities in different measurement applications. At the end of the hierarchical generation process, different measures may thus be generated for different measurement applications.

At any rate, like in many other engineering disciplines, efforts have been made in recent years to reach a standard view of software quality and of a quality model. This has led to the definition of the ISO 9126 quality model [5, 6, 7], in which software quality is viewed as composed of 6 qualities.

The ISO 9126 [5] standard was originally defined in 1991. Refinements and guidelines have been provided over the years. For instance, standard sets of external and internal measures have been provided in the new version [6, 7] of the ISO 9126 standard and a measurement process-oriented view has been introduced in the ISO 14528 standard. However, the basic structure of the ISO 9126 standard has not been substantially affected by the its evolution. Thus, we have used the original standard in this study.

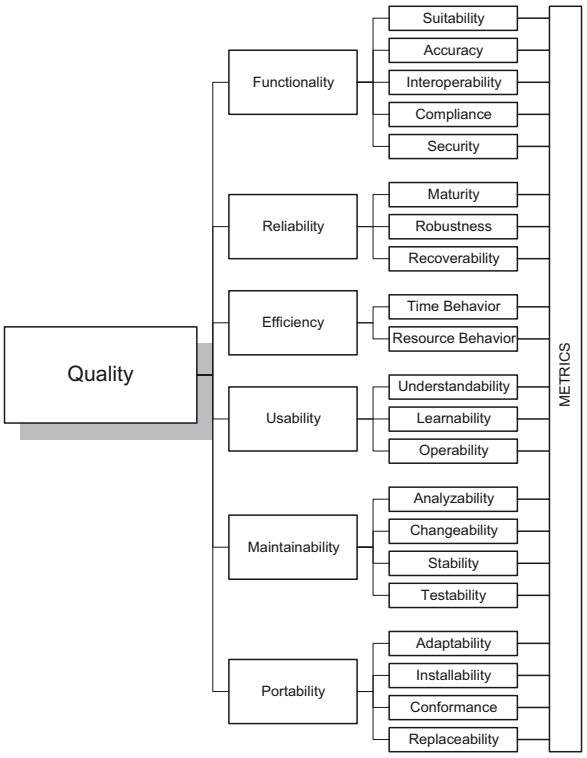

Figure 1. The layers of ISO9126.

The ISO 9126 standard is organized on four layers (see Fig. 1). The first layer is that of the overall software quality. On the second layer, the overall software quality is refined as being composed of six qualities. Each quality is refined in terms of a set of qualities on the third layer. The qualities defined on the third layer afford direct quantification via a set of measures, which are left unspecified in the original standard. For completeness, we now list the six qualities on the second layer along with their refining qualities on the third layer.

- Functionality is about meeting stated and implied needs when the software is used under specified conditions.
- Reliability is about maintaining the level of performance under specified conditions.
- Efficiency is about providing the required performance relative to the amount of resources used, under stated conditions.

- Usability is related to being able to understand, learn, and use the software under specified conditions.
- Maintainability is related to analyzing software products to find a fault, change the software products, making sure the change does not have side-effects, and testing the new version.
- Portability is related to being able to make a software product run in different environments.

The ISO 9126 standard also says that these qualities describe, with minimal overlap, software quality. Thus, they are somewhat orthogonal, even though this does not mean that there are no dependencies among them. However, some degree of independence should be there. If there was a very strong influence between two such qualities, one may wonder why they are both in the standard. This is what happens in other fields as well. When a strong statistical correlation is found between two variables, then the two variables basically contain the same information, since, once one of them is known, the other one is basically known too, i.e., it can be discarded from the core modeling of some phenomenon as being redundant.

ISO 9126 is therefore a general reference model that lists a number of qualities that software practitioners should have in mind when they build software. Practitioners should be aware that interactions among these qualities may exist, so they can make informed decisions during software development. Here, we focus on how aware practitioners are of these interactions.

III. Setting of the Empirical Study

The main goal of the empirical study was to evaluate the degree of consensus about the influence of each second-layer ISO 9126 quality on the others. The empirical study involved 145 software practitioners from Italian and Swiss software development companies, who were attending advanced classes on software quality. The subjects were involved in a variety of different application domains, from business software applications, to web applications, to automotive, etc. The data were collected during ten editions of the same course on software quality, over a period of 4 years, from 2000 to 2004.

The ISO 9126 standard was first explained to the subjects. Then, the subjects were asked to quantify their personal degree of belief about how strongly each ISO 9126 quality influences the other ISO 9126 qualities and data were collected. Data were collected by means of a very simple data collection form, organized in the shape of a matrix. Each cell of the matrix was related to a pair of qualities, one of which was the "influencing" quality, say *X*, while the other was the "influenced" quality, say *Y*. The idea was to check whether it was believed that pushing for quality *X* (the "influencing" quality) would also affect quality *Y* (the "influenced" quality), as both qualities depend on the same root cause, i.e., the way the software is written. We distinguished an influencing from an influenced quality because the influence of *X* on *Y* may not necessarily be of the same type (i.e., positive or negative) and strength as the influence of *Y* on *X*.

For each pair of qualities <*X*, *Y*>, the subjects were asked to provide a value on a –5 .. +5 scale, where the value –5 has the meaning "*X* strongly negatively influences *Y*" and the value +5 has the meaning "*X* strongly positively influences *Y*." Thus, value 0 has the meaning "*X* does not influence *Y*." The -5 .. +5 scale was chosen because (1) it would clearly represent both negative and positive influences and (2) a sufficient number of values were available to respondents to quantify their beliefs about the degrees of influence and provide different rankings for different degrees. It was made clear to the subjects that the single values of the scale were not important *per se*, but they were used to obtain a ranking of the beliefs of the various influences. For instance, the value '4' *per se* did not provide much information, but it indicated that the subject believed a higher degree of influence than a '2' value. The subjects were also allowed to leave blank the values associated with a pair <*X*, *Y*>, if they did not feel sufficiently confident about providing any value. This was done to reduce the number of unsubstantiated guesses. For completeness, it was explained to the subjects that "blank" and 0 had two different meaning, i.e., "blank" meant "don't know," while 0 actually meant "I believe there is no influence." It was made clear to the subjects that there was no "correct answer" for any of the pairs <*X*, *Y*>. The aim of the survey was only to capture the participants' beliefs in a quantitative form and no consequences of any kind would derive to them from their answers. In addition, the survey also had the pedagogical goal [3] of making the practitioners reflect about the ISO 9126 standard, the meaning of its qualities, their interactions, and the fact that software quality needs to be planned in advance and that development decisions may have an impact on several different qualities.

IV. Statistical Hypotheses Explored

The hypotheses we tested are of two kinds, as follows.

- Hypotheses related to single distributions. Since the data we collected were ordinal [10], we investigated hypotheses related to the median of each distribution, instead of the mean, which, strictly speaking, is not a meaningful indicator of central tendency for ordinal data [10]. The motivations for these hypotheses related to single distributions come from conventional wisdom that has it that qualities do influence one another. We wanted to test whether our respondents actually believed in this idea. Given two qualities *X* and *Y*, our null hypothesis was H_0: $M_X = M_Y$, and the alternative hypothesis was H_1: $M_X \neq M_Y$, where M_X and M_Y represent the medians of *X* and *Y*, respectively. As explained in Section III, these hypotheses have the meaning "if software is written in such a way as to push for quality *X*, I believe that quality *Y* is also affected." Since no assumptions on the direction (positive or negative) of influence could be safely made, our above statistical hypotheses were nondirectional, and we used two-tailed statistical tests to test them [8]. Note that two-tailed statistical tests are more conservative than one-tailed tests for a given level of statistical significance, so it is less likely to reject the null hypothesis with two-tailed tests. Thus, we wanted to be even more careful about investigating the existence of such beliefs.

- Hypotheses related to the associations of pairs of distributions. Given two qualities *X* and *Y*, we checked whether there was an association between the ranking provided by the subjects about the influence of *X* on *Y* and the influence of *Y* on *X*, i.e., the influence between *X* and *Y* works in both directions. For each association checked, the null hypothesis states that there is no association, while the alternative hypothesis states that there is a positive association, since one may expect that if it is believed that there is a positive (resp. negative) influence of *X* on *Y*, then there is a positive (resp. negative) influence of *Y* on *X*. Studying these associations is an additional way of checking whether the subjects believed that (1) there is a real trade-off between qualities (this is the case when a double negative association exists between the distributions, i.e., improving *X* makes *Y* worse, and improving *Y* makes *X* worse), or (2) the two qualities *X* and *Y* support each other (this is the case of a double positive association between the distributions, i.e., improving *X* also improves *Y*, and *vice versa*).

V. RESULTS

Here, we first provide the results on the hypotheses related to single distributions are in Section V.A. The results related to associations between distributions are in Section V.B.

A. Results Related to Single Distributions

Table I contains the summary statistics for the data collected for each of the possible pairwise interactions between ISO 9126 qualities. Each ISO 9126 quality is identified by its initial letter. The rows represent the influencing qualities, while the columns represent the influenced qualities. Each cell of the matrix in Table I contains the values of:

- *N*: the number of values collected
- *1Q*: the location of the first quartile
- *M*: the median of the data distribution (the value 0.5 in cell <*F*,*U*> is due to the midpoint approximation used when a distribution has two medians)
- *3Q*: the location of the third quartile
- *m*: the average value of the data distribution
- σ: the standard deviation of the data distribution
- *p*: the statistical significance of the Wilcoxon signed rank test [11], used to test the hypothesis about the believed influence between the two qualities. The Wilcoxon signed rank test is appropriate for assessing hypotheses about the medians of single data distributions of discrete, ordinal data.

We have also reported the values of *m* and σ to provide a more complete idea of the central tendency and spread of the data distributions, though the data were collected on an ordinal scale, for which *m* and σ are not appropriate, in principle.

As a first observation, Table I shows that the 145 subjects provided values for most of the cells. The cell with the highest number of values (135) corresponds to pair <*F*,*M*> and the cell with the lowest number of values (117) to pair <*U*,*R*>. This seems to indicate that most subjects had a sufficiently solid idea about most interactions among software qualities.

Second, the data distributions show a fairly large spread of values. As could be expected with 145 total respondents, all of the 30 data distributions actually have the maximum spread possible, i.e., -5 .. +5 (this piece of information is not reported in Table I, because it would be the same for all cells). As for the interquartile range, the average of the distance between *1Q* and *3Q* is 4.43 and the standard deviation is 1.07. In addition, all of the standard deviations of the distributions are between 2.31 and 3.06. These measures of spread show that the participants' consensus about the influences between ISO 9126 software qualities was limited and some of the participants believed that there was a really strong interaction between software qualities, but their beliefs were conflicting.

TABLE I. STATISTICS FOR THE DISTRIBUTIONS

Third, notwithstanding the spreads of values, a number of distributions show that it makes sense to hypothesize the existence of some degree of consensus about the influence of some software qualities on other software qualities. To this end, the statistical significance of the results is quite clear. We set a statistical threshold of 0.05, as is customary in empirical software engineering. Based on the number of responses we

had for each distribution we could safely use the normal approximation to the exact distribution of *W*, the statistic used in the Wilcoxon signed rank test. Since the test is two-tailed, p-values less than 0.025 provided us with evidence to reject the null hypothesis. We have obtained statistically significant results in 15 distributions out of 30, i.e., in half of the cases, our respondents believed that two qualities interact.

Fourth, it is somewhat surprising that the majority of influence relationships are believed to be nonnegative. This can be assessed in several different ways. Out of 30 medians, 2 turned out to be negative, 21 null, and 7 positive. The interquartile range turns out to be more biased towards negative values (e.g., -2..1, like in the case of <*F,P*>) in 8 cases, centered on 0 (e.g., -2..-2 like in the case of <*U,E*>) in 6 cases, and more biased towards positive values (e.g., -1..3, like in the case of <*F,M*>) in 16 cases. Out of 30 relationships, 20 have a value $m > 0$ and 10 have a value $m < 0$. So, all of these statistics provide the same kind of evidence. These results are somewhat unexpected, since it is commonly believed that there is a trade-off among software qualities, i.e., trying to improve one of them may result in worsening another.

In addition, 8 out of the 10 distributions with a negative value for *m* are actually related to Portability, so only 2 out of the 20 distributions that do not involve Portability actually have a negative *m*. Based on these results, one may conclude that the respondents in the sample viewed Portability as a sensitive quality that needs to be taken into account during development, since decisions about software products to improve other qualities may negatively affect Portability.

B. Results Related to Associations between Distributions

Table II contains the values of Spearman's *rho* and Kendall's tau_b [4] about the agreement of the rankings of the influences <*X,Y*> and <*Y,X*>. We used Spearman's *rho* and Kendall's tau_b because the variables we used are ordinal ones. Both statistics range between –1 (perfect negative association) and +1 (perfect positive association), so they quantify the degree of association. In addition, both statistics can be used to check whether the association is statistically significant. We found that there is a statistically significant association (at the 0.05 level) between the rankings of the influence of quality *X* on quality *Y* and the rankings of the influence of quality *Y* on quality *X* for all pairs of qualities <*X,Y*>.

For a pair of qualities <*X,Y*> where both the influence of *X* on *Y* and of *Y* on *X* are statistically significant (see Table I) and the influence is of the same direction, these results show that the respondents seem to believe, even though with various degrees of strength, that there is a bidirectional influence between qualities. Specifically, the association with the highest values for *rho* and tau_b involves Usability and Portability. The subjects seem to indicate that there is a real trade-off between these two qualities, since the values of m for both <*U,P*> and <*P,U*> in Table I are negative and also the interquartile ranges are biased towards negative values. The second highest values for *rho* and tau_b involve Functionality and Reliability. This result could actually be somewhat expected, as this indicates that the subjects believed that the two qualities support each other, i.e., improving one will also improve the other.

Let us now look at pairs of qualities for which there is no conclusive evidence on the fact that one influences the other, but the influences in Table I are of the same sign, e.g., Efficiency and Functionality, though there is evidence that Functionality influences Efficiency, as shown by the p-values in Table I. Table II shows that there is an association between the scores of <*F,E*> and <*E,F*> which seems to confirm that, even though the influence <*E,F*> is not statistically significant, the two qualities in general are believed to somewhat support each other, or at least they are not conflicting anyway, even though one influence is stronger than the other. Further investigations may be needed in this case, though.

TABLE II. SUMMARY STATISTICS BY INFLUENCING AND INFLUENCED QUALITY

<X,Y>	<Y,X>	rho	tau_b
<F,R>	<R,F>	0.68	0.60
<F,E>	<E,F>	0.59	0.46
<F,U>	<U,F>	0.60	0.50
<F,M>	<M,F>	0.35	0.31
<F,P>	<P,F>	0.58	0.52
<R,E>	<E,R>	0.61	0.49
<R,U>	<U,R>	0.54	0.42
<R,M>	<M,R>	0.31	0.26
<R,P>	<P,R>	0.35	0.29
<E,U>	<U,E>	0.55	0.45
<E,M>	<M,E>	0.51	0.44
<E,P>	<P,E>	0.65	0.56
<U,M>	<M,U>	0.50	0.43
<U,P>	<P,U>	0.71	0.61
<M,P>	<P,M>	0.61	0.54

As for those pairs of qualities for which there is no evidence that either quality influences the other (e.g., see the cells for <*E,U*> and <*U,E*> in Table I), the results on *rho* and tau_b provide further support for the lack of actual influence.

VI. VALIDITY OF THE EMPIRICAL STUDY

Like in any empirical study, we need to examine the factors that may have biased our results. We believe that the following factors may have influenced an empirical study like ours.

A. Internal Validity

These two factors could pose a threat to the internal validity of the empirical study.

- *Subjects*. The subjects were not selected beforehand, so, no self-selection occurred, and various different professional figures were involved. This may be acceptable for the internal validity of our study.
- *Knowledge on ISO 9126*. All the subjects were given the same information about ISO 9126. It would not make sense to "randomize" this factor, i.e., provide the subjects with different degrees of knowledge about ISO 9126.

B. External Validity

The question may arise as to how representative our empirical study is in the population of empirical studies on ISO 9126 qualities.

- *Subjects*. It would not be possible to claim that the subjects were representative of the population of software project leaders and developers. However, no pre-selection was carried out and the class was given 10 times to different people with different backgrounds, skills, and expertise in different application domains.
- *Knowledge on ISO 9126*. Not all project leaders and developers are in general knowledgeable on ISO 9126, and even those who are may have various degrees of knowledge. However, some knowledge on ISO 9126 was an obvious precondition of the study, if only to have a common terminology across all subjects.

C. Construct Validity

We did not use any particular measure defined for the basic constructs, i.e., the ISO 9126 qualities, of the study. There is no general agreement on how these constructs should be measured, and any measures could be questioned as to whether they actually quantify the quality they purport to measure. An operational measure was defined for the assessment of the mutual influences among qualities. One may wonder whether this was an appropriate way to capture these influences. We chose an ordinal measure because it would have made little sense to choose an interval or ratio measure, since we are interested here in rankings. Also, we provided a measure with 11 integer values (from -5 to +5), so it was sufficiently fine-grained to capture the rankings among influences.

VII. Conclusions and Future Work

The research documented in this paper has investigated empirically whether several software project leaders and developers believed that external software qualities influence each other. The results seem to indicate that, on average, the subjects believed in the existence of a number of such influences, and, more surprisingly, on the fact that these influences are positive. Thus, the need for trade-offs between possibly conflicting qualities does not seem to be perceived by our respondents. Also, the influences seem to be bidirectional, which provides further evidence to this perceived lack of trade-offs. The one real exception is Portability, which is believed to be conflicting with almost all other qualities.

On the other hand, several reasons may provide an explanation for why no mutual influence was detected for a number of pairs of qualities, including:

- there is actually no influence in general for those pairs, i.e., the qualities are mostly independent of each other;
- the course on software quality did not explain adequately the concepts behind the ISO 9126 qualities;
- the ISO 9126 qualities should be provided with more precise explanations; as for this, the introduction of standard sets of measures will provide further aid in the understanding of the definition of the ISO 9126 qualities.

At any rate, a good deal of further work is will need to be carried out, including:

- gathering more data;
- understanding the reasons behind software practitioners' beliefs, so these reasons can be studied and tested;
- studying the effect of providing the new subjects with the new standard sets of measures for the qualities;
- investigating the relationships between internal software qualities and external ones.

Acknowledgment

Abstract

In this paper, we describe our trace monitoring system and a methodology for reverse engineering interface protocols to capture the sequence of method invocations for large C++ applications. To evaluate our system, we present a case study using the networking library in the Mozilla Internet Application Suite, and three Mozilla applications: Firefox, Thunderbird and Sunbird. We use trace monitoring of the library to capture the interface protocols for the classes in the library and our preliminary results support our assumption that interface protocols follow a specific pattern and that these patterns can facilitate comprehension of the underlying interactions among the classes in the system.

1. Introduction

The process of software maintenance, including modification, refactoring, and usage of complex object oriented systems, requires knowledge about the system under study and, in particular, about the interactions among the classes and components of the system. However, software artifacts that describe these interactions are frequently unavailable and for large, open-source C++ applications, they are virtually nonexistent. Thus, much of the research in software engineering has focused on the development of tools to automatically generate information to improve comprehension of the application under study, and thereby facilitate the maintenance effort.

In this paper, we present Hylian, our system for code regeneration and trace monitoring in large C++ applications. Hylian uses an augmented form of the GNU *gcc* parser to output parse trees in XML format, permit modification of the parse trees, and to regenerate a modified version of the source code. We used an earlier version of Hylian to reverse engineer a grammar for the *gcc* C++ parser, version 4.0.0 [5]; the current version permits modification of the parse tree to extract trace information of a C++ application under study.

To demonstrate the utility of Hylian, we generate trace information, extract the sequence of method invocations, and generate regular expression representations of the interface protocols for *Necko*, a large networking library written in C++ [9]. To exercise the *Necko* library, we use three large applications in the Mozilla Internet Application Suite: Firefox, Thunderbird and Sunbird, a browser, mailer and calendar application respectively [8]. We then choose classes in the *Necko* library that are used by the three applications and examine the regular expression representation of the interface protocols for the *Necko* library.

Our preliminary results support our assumption that the interface protocols for these classes follow a specific pattern and that these patterns can be used to facilitate comprehension of the class and to guide usage of the class by developers unfamiliar with the *Necko* library. Moreover, the regular expression representations of the interface protocol for a class can serve as examples, or templates, of correct usage of a class for a large library. We conjecture that these examples of library usage exemplify the comprehension model needed in the maintenance of large libraries and, together with other comprehension tools, can facilitate the maintenance effort.

In the next section, we review the terminology and concepts that we use in our work. In Section 3 we describe our trace monitoring methodology and its use in reverse engineering interface protocols. In Section 4 we present the case study described above and in Section 5 we review related research. In Section 6 we draw conclusions.

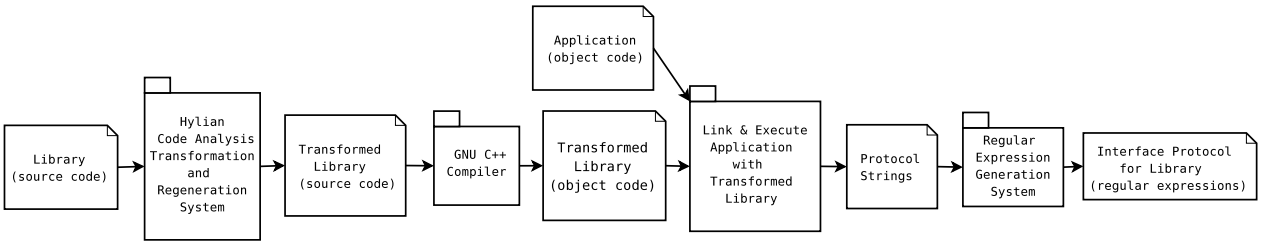

Figure 1. The Hylian **System.** *This figure illustrates* Hylian*, our code analysis and trace monitoring system.*

2. Terminology and Concepts

In this section, we review the terminology and concepts that we use in our work. In Section 2.1 we review grammars and parse trees, and in Section 2.2 we review the concept of *trace monitoring*.

2.1 Grammars, Parse Trees and ASGs

A grammar defines a language by specifying valid sequences of derivation steps that produce sequences of terminals, known as the *sentences* of the language. One procedure for using a grammar to derive a sentence in its language is to begin with the start symbol S and apply the production rules in some sequence until only non-terminals remain. This process defines a tree whose root is the start symbol, whose nodes are non-terminals and whose leaves are terminals. This tree is known as a *parse tree*; the process by which it is produced is known as *parsing*. Our system, Hylian, generates parse trees that we augment to monitor the execution of the libarary unders study.

2.2 Trace Monitoring

A *trace monitor* is a software artifact that observes the actions in a software system and, when certain activities are detected, the monitor executes some code of its own [2]. Trace monitors are especially useful for the detection or verification of runtime behavior. In our work, we use trace monitoring to detect class method invocations and to record a history of these invocations.

3. Protocol Extraction Methodology

In this section, we describe our system for monitoring the execution of an application and its corresponding library, and for reverse engineering interface protocols for C++ classes in the library. In the next section we present the *Hylian* system that we utilize and in Section 3.2 we describe our approach to regular expression generation.

3.1 Overview of the Hylian System

Figure 1 summarizes the flow of information through the system that we use. The source code for a C++ library is shown as input to Hylian, shown as a tabbed box to the left side of the figure. Hylian uses an augmented version of the GNU *gcc* parser, version 4.0.0, to generate a parse tree representation of the library code in XML format [5]. We produce transformed code to monitor the library by augmenting the parse trees with parse subtrees that contain code to trace the method invocations in the library; this phase is illustrated in Figure 1 as a tabbed box labeled Transformed Library. The Transformed Library is compiled into object code by the GNU C++ compiler, which is linked with the object code for the application that will utilize the library. The resulting executable, together with the input to the application, produces the Protocol Strings, which are then transformed into the Interface Protocol for the library, expressed as regular expressions.

3.2 Construction of Regular Expressions

We use an iterative algorithm to convert each protocol string into a regular expression and, for a protocol string of length n, our algorithm runs in $O(n^3)$ time. We first search the protocol string for recurring patterns of size 1, then recurring patterns of size 2, and continue the search, looking for recurring patterns of size $n/2$. For example, in searching for patterns of size 2, the string "abab" will be converted to $(ab)^+$. When the protocol string for each object is converted to a regular expression, we then use a *perl* package, Regexp::Assemble, to construct a single regular expression from the set of protocol strings generated by each instantiation of the class under consideration.

There is an abundance of research describing techniques to recover interface protocols using a finite state machine or regular expression representation [4, 7, 10, 11]. Our future work includes an investigation into these techniques to improve our protocol recovery process.

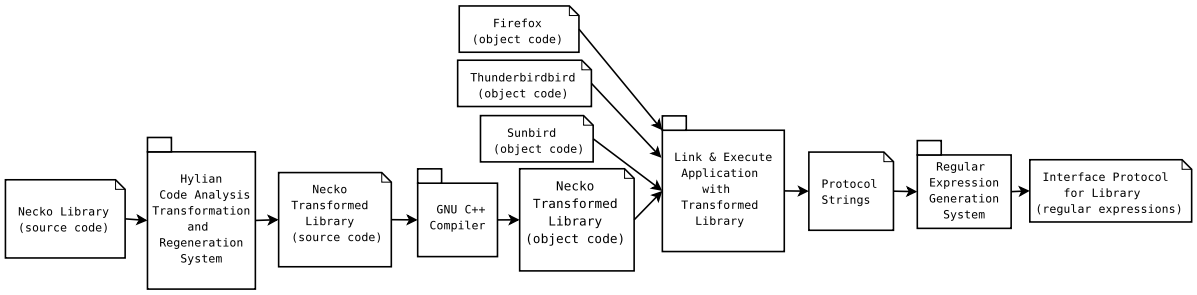

Figure 2. Study Summary. *This figure illustrates our study to evaluate our methodology for generating interface protocols for the Necko Networking Library utilized by the Mozilla Internet Application Suite.*

Application	Version	Units	Parse Tree
Necko	2.0a1pre	101	1,542,653
Firefox	3.0a8	1,262	27,857,127
Sunbird	0.6a1	1,586	33,023,605
Thunderbird	3.0a1pre	1,826	35,190,012

Table 1. Testsuite Statistics.

4. Case Study: The Mozilla Internet Suite

In previous sections of this paper, we described our approach for exploiting dynamic trace monitoring to capture the interface protocols of classes in an object-oriented system. In this section we describe a study that we conducted to evaluate our methodology and to show the utility of our approach. Our study involves an investigation into three applications included in the Mozilla Internet Application Suite: *Firefox*, a commonly used browser; *Thunderbird*, a mailer; and *Sunbird*, a calendar management application [8]. We use these applications to investigate usage of the *Necko* networking library included in the Mozilla Internet Application Suite.

Figure 2 illustrates our use of the Hylian analysis system, presented in Section 3, for transforming library code to provide dynamic trace monitoring and generate interface protocols for the classes in a library. In our study, we use the *Necko* library, listed on the left side of the figure, as input to our system, transform and regenerate the code, and use the GNU C++ compiler to generate object code for the transformed library, *Necko* Transformed Library, shown in the middle part of the figure. We then link the object code representation of the *Necko* Transformed Library, first with an object code representation of the *Firefox* application, and then with an object code representation of the *Thunderbird* application, and finally with an object code representation of the *Sunbird* application to produce protocol strings for each application. We then find the union of the protocol strings generated for *Necko* usage by each application to produce protocol strings for *Necko* classes, Protocol Strings, shown as a folded edge box (folded box) at the middle right of the figure. We then generate an Interface Protocol for Library, as regular expressions.

4.1 The Mozilla Application Suite

The statistics in Table 1 provide information about the version and size of the four applications that we study in this section. The first column lists the application, Application, the second column lists the version number, Version, the third column lists the number of compilation units, Units, and the fourth column lists the number of lines in the parse tree files, Parse Trees, for each application. The applications are ordered in the table by their parse tree size. For example *Necko*, the Mozilla networking library, is listed in the first row of the table and consists of version 2.0a1pre, 101 compilation units and 1,542,653 lines in the parse tree file. The largest application, *Thunderbird*, is listed on the last line of Table 1 and consists of version 3.0a1pre, 1,826 compilation units and 35,190,012 lines in the parse tree file.

4.2 Usage of the *Necko* Networking Library

Table 2 provides detailed information about the usage of *Necko* by the *Firefox*, *Thunderbird*, and *Sunbird* applications, including some information about the generated protocol strings for *Necko* classes. To exercise the *Firefox* browser, we visited medium-sized websites containing a number of images: *nytimes.com*, *washingtonpost.com*, *slashdot.org*, and *digg.com*. To exercise the *Thunderbird* application, we sent two emails consisting of plaintext and HTML markup, and we received an email message with a 1MB file attachment. To exercise the *Sunbird* calendar application, we synchronized the calendar component with three ICL formatted online calendars.

Application	Classes	Instantiations	Protocol Strings		
			Number	Longest String	Average Length
Firefox	76	14,055	14,055	59,070	31
Sunbird	55	1,297	1,297	17,578	68
Thunderbird	54	1,591	1,591	47,649	88

Table 2. Usage of *Necko* by the three Mozilla applications.

The first three columns of Table 2 list the application, Application, the classes used, Classes, and the number of classes instatiated, Instantiations, by the respective application. For example, the *Firefox* application used 76 of the 142 classes in *Necko*, which is 21 more classes than the *Sunbird* application used, and 22 more classes than the *Thunderbird* application used, even though *Firefox* is the smallest of the three applications, as measured by number of compilation units and number of lines of parse tree code (cf. Table 1). The sum of the instantiations in the third column (14,055+1,297+1,591) is 16,943, the total number of class instantiations for all three applications.

The final three columns in Table 2 list information about the protocol strings, Protocol Strings, generated by each of the three applications. The fourth column lists the number, Number, of strings generated and, since each object generates a protocol string, the number of strings is the same as the number of objects listed in the third column of the table. The fifth column lists the length of the longest string, Longest String, generated by each of the respective applications. The *Firefox* application generated the longest protocol string containing $59,070$ method invocations, which means that one of the instantiated classes made $59,070$ invocations of methods in the *Necko* library. The final column of Table 2 lists the average length, Average Length, of the protocol strings generated by the objects of the respective application.

4.3 Class Comprehension in Large Systems: Regular Expressions for Necko

Figure 3 contains two tables that describe information about the use of class nsDiskCacheInputStream in the Necko networking library. The table at the top of the figure contains four columns listing the name of the application, Application, the number of instantiations of nsDiskCacheInputStream, Instantiations, the number of unique sequences of method invocation strings for nsDiskCacheInputStream, Unique Sequences, and the interface protocol expressed as a regular expression, Interface Protocol. The first row of the table at the top of the figure lists information for *Firefox*, which created 166 instantiations of nsDiskCacheInputStream, generated 12 unique method call sequences that are summarized by the regular expression $abc^{+}ded$. The last two rows of the table list information for *Sunbird* and *Thuderbird*, which did not create any instantiations of class nsDiskCacheInputStream and did not use any of the methods.

The table at the bottom of Figure 3 has two columns where the first column, Mapping, specifies the mapping between letters and method names and the second column, Unique Sequences of Method Calls, lists the set of unique sequences of method invocations made by class instantiations of the *Firefox* application on the *Necko* networking library. For example, the first row of the second column of the table lists a sequence of 30 method invocations consisting of calls to ab, followed by a sequence of 25 calls to c, followed by calls to ded. Similarly, the ninth row of the second column of the table summarizes a sequence of 158 method invocations consisting of calls to ab, followed by a sequence of 153 calls to c, followed by calls to ded. Note that we use dots to indicate that some of the 153 calls to c have been elided from the ninth row of the table; however, all of the other sequences are illustrated precisely as they were generated by our test cases.

The regular expression representation of the 12 sequences is listed in the fourth column of the first row of the table at the top of Figure 3, $abc^{+}ded$. In lieu of documentation, UML case tool artifacts or other specification of the usage of a class, the reverse-engineered interface protocol can provide invaluable information about how a class in a large system is used, or may be used. For example, using the mapping, the typical usage of an instantiation of class nsDiskCacheInputStream consists of a call to the constructor, a call to AddRef, followed by one or more calls to Read, then calls to Close, Release and Close.

4.4 Comparison of Class Usage

Figure 4 illustrates a class instantiation history for those classes in the Necko library that were used by the Firefox, Thunderbird and Sunbird applications. Since we are interested in comparing usage by all three applications, the figure only lists those classes that were used more than ten times by each of the applications.

The three bars on the left side of the figure represent usage for the nsFileOutputStream class in the Necko library where the first bar indicates that Firefox created 44 in-

Use of nsDiskCacheInputStream by Three Applications			
Application	Instantiations	Unique Sequences	Interface Protocol
Firefox	166	12	$abc^{+}ded$
Sunbird	0	0	NA
Thunderbird	0	0	NA

Protocol Strings for *Firefox* Application	
Mapping	Unique Sequences of Method Calls
a → nsDiskCacheInputStream b → AddRef c → Read d → Close e → Release	01: abccccccccccccccccccccccded 02: abccccccccccded 03: abcccccccccded 04: abccccccccccccded 05: abcccded 06: abccccccccccccccded 07: abcccccded 08: abcccccccded 09: abccccccccccccccccccccccc . . . ccccccded 10: abccccded 11: abccded 12: abcccccccded

Figure 3. Method Invocation Sequences for Class nsDiskCacheInputStream**.**

stances, Thunderbird created 37 instances and Sunbird create 28 instances of this class. The three bars in the middle of the figure represent usage for the nsBufferedStream class in the necko library where the first bar indicates that Firefox created 66 instances, Thunderbird created 68 instances and Sunbird create 56 instances of this class. The usage of this class is more evenly distributed than the usage of nsDiskCacheInputStream illustrated in Figure 3.

We found that the generated regular expressions for more heavily used classes in Necko can be less readable than the regular expression, $abc^{+}ded$ that we obtained for class nsDiskCacheInputStream. For example, Firefox usage of class nsDiskCacheInputStream generated the expression $abbcdbcb^{*}fbg^{*}ch^{*}(ggh)^{*}c^{*}e^{*}$, which may not be as useful as the one we obtained for class nsDiskCacheInputStream, or may indicate that nsDiskCacheInputStream has more complex usage patterns. Our ongoing work includes an investigation of some of the excellent regular expression generation algorithms in literature [4, 7, 10, 11].

5. Related Work

The generation of interface protocols can be accomplished using either static or dynamic analysis. The static approach has the advantage of finding all possible sequences of method invocations but must address the problems of pointer alias [6] and infeasible paths. Moreover, the static approach may provide interface protocols that are irrelevant to the application under consideration, as we have seen in Section 4.4. the regular expressions can be overly complicated. The dynamic approach has the advantage of providing only those sequences of method invocations that are relevant to the application under consideration and does not suffer the problems of alias or infeasible path resolution. The related work that we review in this section employs the dynamic approach to protocol recovery.

Cornelissen and Moonen describe a technique for addressing the scalability problem in extracting information from execution traces of function calls in Java programs [4]. They observe that certain event sequences are repetitive, where the repitition typically results from the occurrence of method invocations within loops. Their summarization technique entails the use of *similarity matrices* to visualize the repetitive method invocation sequences in the trace. Recurring sequences of method invocations appear as patterns in the matrix. However, the sequences appear in the matrix as diagonal lines and this abstraction results in the loss of information about the identity of the methods in the recurring sequences. The approach that we describe in this paper entails summarizing the recurring sequences of method invocations as regular expressions, which has the advantage of maintaining the identity of the methods involved in the recurring sequences.

Walkinshaw et al. describe the construction of state machines from user supplied scenarios and execution traces of Java programs [10]. They use the scenarios from the user, the execution traces and the QSM state-merging approach to interactively generate a state machine of the system. Our approach differs from that of Walkinshaw et al. in that our technique is fully automated and does not require user supplied scenarios.

Butkevich et al. describe an extension to the Java programming language to facilitate static conformance checking and dynamic debugging of object protocols [3]. *Object protocols* are sequencing constraints on the order in which methods in a Java application may be invoked. In their

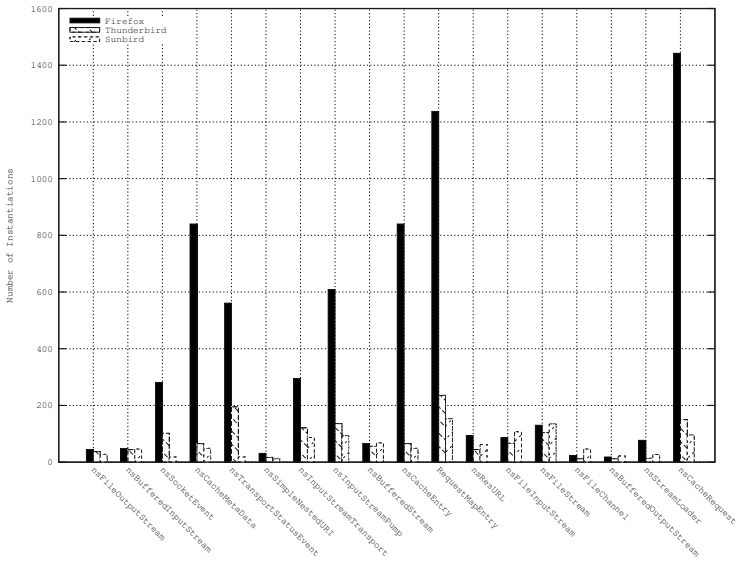

Figure 4. Necko Usage by Firefox, Thunderbird and Sunbird.

work, regular expressions are used to specify the conformance relation between two object protocols. However, the work of Butkevich et al. does not entail the reverse engineering of existing interface protocols, nor do they apply usage of interface protocols to program comprehension.

Archer et al. develop a checkable, executable specification that captures the rules for correctly using an interface in a TinyOS application [1]. They refer to this specification as an *interface contract* and they develop an approach for checking the interface contract using a source-to-source program transformation that adds checks to existing TinyOS applications. However, they do not reverse engineer the contracts and they do not demonstrate the pattern that these contracts typically exemplify.

Quante and Koschke describe a dynamic protocol recovery technique based on *object process graphs* (OPGs) [7]. The advantage of their approach is that OPGs contain information about loops and the context within which a method was called. They introduce a new metric for comparing automata and a case study involving Java and C programs. The focus of Quante and Koschke is on their recovery protocol technique that exploits context to improve the regular expression generation process; their technique improves on our brute force regular expression generation approach.

6. Concluding Remarks

We presented Hylian, our system for code regeneration and trace extraction in large C++ applications. We have demonstrated the utility of Hylian by generating trace information, extracting the sequence of method invocations, and generating regular expression representations of the interface protocols for *Necko*, a large networking library written in C++, utilized by the Mozilla Internet Application Suite [9]. We generated interface protocols for *Necko* using three large applications in the Mozilla Suite that use the *Necko* library: Firefox, Thunderbird and Sunbird [8].

The preliminary results of our case study of *Necko* support our assumption that the interface protocols for these classes follow a specific pattern and that these patterns can be used to facilitate comprehension of a class, to guide usage of the class, or to measure the complexity of usage of the class by developers unfamiliar with the *Necko* library.

***Abstract*—Knowledge Management area has gathered great interest in software development industry and the applicability of its process into an organization, In order to support the requirements of a maturity level, is the main focus of this report. Thus, CMMI requirements were assessed and introduced into a KM project that was run into a CMMI level 3 organization and the results were analyzed to evaluate whether or not it was useful to apply KM into such scope.**

***Index Terms* — CMMI, Knowledge Management, Software Development Process.**

I. Introduction

KNOWLEDGE management discipline is gathering a growing attention on organizations that seek the establishment and tracking of the knowledge disseminated throughout the company. Procedures, processes, tools, among other initiatives are supporting the use and dissemination of such discipline within software development context.

Therefore the objective of this work is to present the knowledge management approach used to support the deployment of a CMMI level 3 process into a software development organization. In addition, to assess the results achieved by the use of such process in order to provide improvement opportunities to the organization.

This report is organized as it follows: Section II presents a general overview on Knowledge Management and the basic concepts used to develop the process, followed by the research of where KM requirements are found on CMMI [1] on Section III. Section IV describes the process approach defined by the organization to adopt KM, Section V details the tool adopted and the reasons that show why such tool is being used, and, Section VI presents the case study results. Finally, Section VII shows the concluding remarks and future work.

II. Knowledge Management Overview

For the last years, the Knowledge Management area is receiving a special attention from organizations, as they search for competitive advantage. The following statics are a simple proof of this attention [2]:

1) A total of 80 percent of Fortune 500 companies have KM staff.
2) Texas Instruments has saved $1 billion since it launched KM programs in the mid-1990s.
3) 95 percent of CEOs polled at the 2001 World Economic Forum in Davos, Switzerland, said that KM was critical to organizational success.
4) 91 percent of Canadian business leaders polled by IpsosReid in 2001, believed that KM practices have a direct impact on organizational effectiveness.

In [3], Polanyi categorized knowledge in two types, the tacit and explicit. The latter is basically what can be documented and distributed, while the tacit knowledge resides in the human mind, behavior and perception, and thus, it is difficult to be formalized and distributed [4].

Each KM program needs to balance which kind of knowledge it is focusing, and based on this focus it can be categorized in one of the four KM styles defined by Choi and Lee [4].

1) Passive: little interest in KM. It is not managed in a systematic manner.
2) System-oriented: put more emphasis on codifying and reusing knowledge. It increases codifiability through IT, and thus, decreases the complexity of accessing and using knowledge.
3) Human-oriented: the emphasis is on acquiring and sharing tacit knowledge and interpersonal experience. Knowledge usually originates from informal social networks. Meaningful knowledge can not be simply retrieved form the database or repository.
4) Dynamic: emphasizes both tacit and explicit knowledge, and does it in a dynamic fashion, similar to a communication-intensive organization. They depend on cultural knowledge.

Independent of style, knowledge management can be seen as a process to create, gather, store, transfer and apply knowledge [5]. There are many different definitions for the stages composing a KM process. In 2004, Bose presented the stages which compose a cyclic process in knowledge management

[2]:

1) Create knowledge: the knowledge comes primarily from the experiences and skills of the employees. Knowledge is created as people find new ways to do things. Sometimes it is necessary to brought in external knowledge when it does no reside in the organization.
2) Capture knowledge: the created knowledge is stored in a database or repository in raw form.
3) Refine knowledge: context is added to knowledge, so it can be easily reused. In this stage the tacit knowledge, usually captured from human experience, is captured and transformed and refined along with explicit knowledge.
4) Store knowledge: This stage includes the codification of tacit and explicit knowledge, after refined, so it can be used later.
5) Manage knowledge: knowledge must be kept current, so it must be reviewed systematically to verify if it is still valid and accurate;
6) Disseminate knowledge: The knowledge is made available so everyone in the organization can easily access it anywhere and anytime. New technologies are usually used to help in the dissemination of knowledge.

Some of the several benefits of the use of a knowledge management strategy are: the reduction in loss of intellectual capital from employees who leave the company; the cost reduction for the development of new products; and the increased productivity by making knowledge easily accessible to all employees [2].

III. KNOWLEDGE MANAGEMENT AND CMMI

Knowledge management process definition was being established together with the adaptation of the organizational process from CMM level 2 into CMMI level 3. Therefore, it was necessary to understand which requirements, from the CMMI model [1], treat knowledge management general aspects.

Accordingly, CMMI level 3 has three process areas (PAs) that address KM's necessities. Table I presents the mapping among these PAs together with a short description.

Based on the sub-practices from CMMI, OPF and OPD process area define the organizational approach to posterior use on projects, as for instance:

- "Conduct periodic reviews of the effectiveness and suitability of the organization's set of standard processes and related organizational process assets relative to the organization's business objectives.
- Obtain feedback about the use of the organizational process assets.
- Derive lessons learned from defining, piloting, implementing, and deploying the organizational process assets.
- Make lessons learned available to the people in the organization as appropriate.
- Design and implement the organization's process asset library, including the library structure and support environment; to specify the criteria for including items in the library.
- Specify the procedures for storing and retrieving items; to enter the selected items into the library and catalog them for easy reference and retrieval.
- Make the items available for use by the projects.
- Periodically review the use of each item and use the results to maintain the library contents.
- Review the organization's process asset library as necessary."

TABLE I
MAPPING BETWEEN CMMI AND KM

Process Area (PA)	Specific Goal (SG)	Specific Practice (SP)	Description
OPF Organization Process Focus	SG 1 Determine Process-Improvement Opportunities	SP 1.3-1 Identify the Organization's Process Improvements	Identify improvements to the organization's processes and process assets.
	SG 2 Plan and Implement Process Improvement Activities	SP 2.4-1 Incorporate Process-Related Experience into the Organizational Process Assets	Incorporate process-related work products, measures, and improvement information derived from planning and performing the process into the organizational process assets.
OPD Organization Process Definition	SG 1 Established Organizational Process Assets	SP 1.5-1 Establish the Organization's Process Asset Library	Establish and maintain the organization's process asset library, like procedures and lessons-learned reports.
IPM Integrated Project Management	SG 1 Use the Project's Defined Process	SP 1.2-1 Use Organizational Process Assets for Planning Project Activities	Use the organizational process assets and measurement repository for estimating and planning the project's activities.
		SP 1.5-1 Contribute to the Organizational Process Assets	Contribute work products, measures, and documented experiences to the organizational process assets. Document lessons learned from the project for inclusion in the organization's process assets library.

The other process area, IPM, is concerned about how the projects will use the organizational process assets for planning new project activities and then how the projects will contribute to the organizational process assets, for example:

- "Use the organization's measurement repository in estimating the project's planning parameters.

- Propose improvements to the organizational process assets.
- Store process and product measures in the organization's measurement repository.
- Submit documentation for possible inclusion in the organization's process asset library.
- Document lessons learned from the project for inclusion in the organization's process asset library."

Based on this research, these requirements were used as a basis to build the KM process, which will be described on the next section.

IV. PROSCES AND KM

According to the characteristics presented on the introduction, the process that will be described intends to *Dynamically Manage* the knowledge acquired, emphasizing both tacit and explicit. Furthermore, the organizational approach to implement a formal knowledge management process is formed by a process definition, a support tool, process templates and guidelines. Such KM process, called *ProSCes*[1], within the context of software development, is considered a *support sub-process*, due to the fact that it permeates the whole software development cycle, and the main purposes are:

- Stimulate the change of knowledge between professionals through the record and use of information in the knowledge organization base.
- Identify and organize lessons learned, that represent the knowledge applied to the projects reality.
- Provide the spread of global knowledge, available to the entire organization areas.

This process can be used by people from all levels of the software engineering activities, such as Project Managers, System Engineers, Quality Engineers, Configuration Management Engineers, Human Resource, Operations Manager, Quality Manager, Project Manager Officer and Engineering Manager.

An important relevant factor is that ProSCes differentiates *knowledge* and *Lessons Learned (LL)*, where the first one is any knowledge acquired by the organization collaborators derived from professional experience, studies and research. While, on the other hand, *Lessons Learned* are the relevant practical results acquired from real situations in projects specifically at C.E.S.A.R.[2].

The process is organized into 6 main activities:

A. Disseminate the identification and use of knowledge into projects

This activity focuses on the identification and registry of existent knowledge, promote continuous and effective use of the knowledge available and stimulate the collection of lessons learned in the projects. It maintains discussion forums about organizational interests and stimulates changes in organizational knowledge.

The main outputs of this activity are lessons learned registered on Mantis (the tool that supports the process and which will be explained in detail on the next section) and knowledge registered either on C.E.S.A.R Wiki[3] or A.M.I.G.O.S[4].

B. Plan lessons learned collection

The main objective of this activity is to plan the collection of lessons learned by the identification of specific milestones in the scope of project or in the scope of the organization. As outputs, the Software Quality Engineer (SQE) updates the project plan with the milestones of project and Software Engineer Process Group (SEPG) updates the organizational plan to contemplate the collection lessons learned in the organization.

C. Execute lessons learned

This activity focuses on the identification of lessons learned in the project/organization. In the scope of the project, SQE configures a questionnaire based on the project milestone and, in the scope of the organization SEPG configures it based on which sub-processes will be assessed. The teams answer the questions based on the knowledge acquire and theses answers are collected and consolidated to be presented by each specific audience (project or organizational).

As a result, a report is generated with all the knowledge consolidated so that the SQE or SEPG selects which of the knowledge can be considered lessons learned. Another possible output are change requests opened for the software development processes, that will be requested by SQE or SEPG to the organization process group.

D. Maintain best documents and lessons learned data

The purpose of the activity is to register the selected lessons learned on Mantis and maintain the information available, so that teams have direct access to the information. The activity steps start with the registration of the lessons learned on Mantis, followed by the facilitation of the lessons learned access for the whole organization, and the maintenance of the Mantis repository with actual and relevant information for all organizational projects.

SQE and SEPG are responsible for the lessons learned registry in the repository, which are registered according to a set of pre-defined parameters that will be described in details on the Section V, which talks about Mantis tool.

This activity generates the register of lessons learned, best documents, recommended and non-recommended practices in the repository.

E. Disseminate lessons learned usage

The proposal of this activity is to encourage the use of projects lessons learned into the organizational context and

[1] **ProSCes**: Software Process of C.E.S.A.R, available at the intranet of the organization, not accessible for outsiders. http://cesar.org.br/prosces

[2] **C.E.S.A.R**. – Recife Center for Advanced Studies and Systems. http://www.cesar.org.br

[3] **C.E.S.A.R Wiki,** Available at the intranet of the organization, not accessible for outsiders. http://cesar.org.br/wiki

[4] **A.M.I.G.O.S** – Multimedia Environment to the Integration of Groups and Social Organizations. http://amigos.cesar.org.br

provide the exchange of experiences among projects.

The responsible for this activity is SEPG, that should promote seminars presenting the content generated the knowledge repository. On the other hand, SQEs should encourage team for the continuous use of the lessons learned repository.

F. Identify process improvement opportunities

This activity focuses on the identification of process improvement opportunities based on the learned generated by the project in the organization.

The SEPG periodically analyzes the lessons learned repository to identify opportunities to improve the organizational process. Typically, lessons learned that are repeated in various projects and lessons learned about a specific sub-process activity are examples such opportunities. Modifications to the process can happen in terms of an inclusion of activity, update an existing on, inclusion of new process techniques, guides elaboration, among other aspects.

V. KM APPLIED TOOL

In order to support the use of knowledge management into an organization, it is necessary to set up an environment that can contribute to the use and improvement of knowledge management processes. In order to choose which environment could be best applied to our context, a formal decision taken process, described as one of the sub-processes available at ProSCes, was run in order to evaluate the existing solutions available.

The first part of this process contemplates the identification of criteria and weighs to evaluate the possible tools, according to what is described on Table II.

TABLE II
TOOLS' CRITERIA

Criteria	Weigh
Integration with the organizational projects base	20
Agility to implement the solution	15
Agility to find the lessons learned	25
Performance to include information (Lessons Learned)	10
Technical risk of the alternative that may exist to implement the solution	30

These criteria were used to analyze three solutions to support KM deployment into the organization:

1) **Mantis**: the implementation of lessons learned repository through the use of mantis tool, which "is a popular free web-based bug tracking system" [6].
2) **Rational Portfolio Manager – RPM**: the implementation of lessons learned repository through the use of RPM, which is a tool to support project integrated management [7]
3) **Mantis with integration**: the implementation of lessons learned repository through the use of mantis tool with an integration with RPM data.

The conclusion of the process led to the results presented in the graphic on Figure 1.

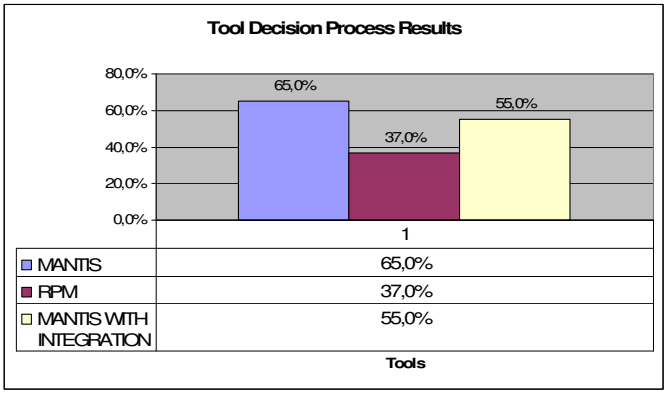

Fig. 1. The results achieved through the application of a formal decision process to decide which tool would best fit the knowledge management process applied by ProSCes.

The results of the decision taken process calculate the percentage of criteria (described on Table II) satisfaction for each tool identified, and, consequently, their ranking in the process. Therefore, 65% of the criteria are satisfied by Mantis tool, against 37% for RPM and 55% for Mantis with integration with RPM.

Based on these considerations, ProSCes adopted Mantis, and although mostly used for a bug tracking system, it can be easy configured in order to achieve desirable levels of usage to a knowledge management support tool. Mantis internal structure was adapted to contemplate the following arrangement, where a lesson learned can be described according to the following parameters:

Categories

- **Best Document**: documents that are considered a model of reference to the organization in a determined sub-process, for example, a requirements specification document or an architectural design document.
- **Recommended Practice**: experiences acquired from the process execution that are considered successful and which could be reproduced in other projects.
- **Non-recommended Practice**: experiences lived by projects team that are not considered successful and should not be reproduced in other project with the same scope.
- **Feedback**: from the team related to the processes releases, regarding whether the change was useful or not for the project and the proposal of changes to the organizational process.

Moment of Collection

- **Process Audit**: during a formal process audit conducted based on a specific sub-process area, where the SQE tries to identify lessons learned gained by the projects.
- **Metrics Analysis**: where the team consolidates process indicators and points out any process improvement or lessons learned from the metrics

analysis.

- **Execution of Lessons Learned**: a formal collection of lessons learned conducted by the SQE through the use of questionnaires applied on specific project teams, where there is a report as the activity output.
- **Other**: any other moment during process development.

Source of Collection

- **Own Initiative**: the source that comprehends to knowledge that comes from individual initiative, that is not formally registered anywhere.
- **Knowledge Repository**: database where all collaborators have free access to input any knowledge, like C.E.S.A.R. Wiki or A.M.I.G.O.S.
- **Lessons Learned Repository**: is related to Mantis tool itself, where lessons learned can be raised from other lessons learned previously registered.

Transitional States

- **Submitted**: the SQE submits the lesson learned to Mantis but it has to be reviewed by SEPG in order to publish it.
- **Published**: a lesson learned that has been published and reviewed by SEPG in order to guarantee that the content can be published to the organization.
- **Rejected**: a lesson learned that has been reviewed by SEPG and is not considered a lesson learned to be published to the organization.

Besides theses characteristics, mantis permits the creation of correlations among all lessons learned submitted, by the settlement of relationship, which can be: (1) one is *parent of* the other; (2) one is *son of* the other; (3) one is *duplicated with* another, and (4) one is *related of* another. These relationships are represented through the use of relationship trees, a graphical and visual representation of the lessons learned available on the knowledge database.

VI. Case Study

A. Scenario and Objectives

The case study was conducted with the main objective to assess the adoption of knowledge management through the use of ProSCes, together with Mantis. The institution applied is C.E.S.A.R., a seven hundred employee company located on the northeast of Brazil which, by the time of the process definition, was on the course of the CMMI level 3 assessment.

C.E.S.A.R.'s software development process considers many technologies (J2ME, J2EE, .NET, etc), distinct lifecycles and project categories, such as embedded software development, mobile applications, client-server applications, mobile games, test automation, among others. For the CMMI level 3 assessment, 4 projects were chosen as the most representative ones in the organization, and approximately 68 people were directly involved in the process to define and institutionalize the CMMI level 3 process.

Accordingly, this case study attempts to present the results of the KM Process execution since the definition of the process, following by the checkpoint of the CMMI appraisal, until the present moment.

The main motivation to asses how KM was introduced into ProSCes are:

- Analyze the results of the process to propose improvements.
- Analyze the use of Mantis as a knowledge management support tool.
- Analyze the involvement of the organization into the knowledge management process.
- Identify the main source of lessons learned within the development process.

B. Collected Data

Based on that scenario, some metrics were collected to support the case study, and the first on is presented on Table III. The numbers show that until the CMMI appraisal, most of the lessons learned were published, and after that period, most of them were just submitted.

TABLE III
Lessons Learned Distribution Along the Time

Lessons Learned	Before CMMI Appraisal From January 2007 until November 1st 2007 (%)	After CMMI appraisal From November 2nd 2007 until March 2008 (%)
Submitted	23 %	62 %
Published	47 %	30%
Rejected	30 %	7%

To better understand the involvement of the organization into the process, we analyzed the moment in which lessons learned were identified. The results show that, from the entire database:

- 30% of the lessons learned reported come from the activity *Execute Lessons Learned*.
- 44% of the lessons learned reported come from the activity to *Realize Process Audit*.
- 4% of the lessons learned reported come from the activity *Analyze Metrics*.
- 22% come from any other activity in the project.

It was also important to evaluate the percentage of distribution of the lessons learned categories, where they are divided into:

- 33% are *Best Document*
- 59% are *Recommended Practice*.
- 4% are *Non-recommended Practice*.
- 4% are *Feedback.*

Besides that, another relevant aspect is that 82% of the lessons learned available appear with *Own Initiative* as the source of information, against 12% of the others (6% *Knowledge Repository* and *6% Lessons Learned Repository*).

Another important number to evaluate is related to the submission of changes request opened in the bug tracking system for the organizational process, and only 2% are related

to the Knowledge management sub-process.

C. Results Analysis

According to the numbers collected, the characteristics which presented the greater percentage are summed up on Table IV.

TABLE IV
CHARACTERISTIC AND PERCENTAGE ACHIEVED

Characteristic	Percentage
Process Audit	44%
Recommended Practices	59%
Own Initiative	82%

By analyzing this Table we can conclude that *Process Audit* is the moments in which lessons learned were mostly collected, a moment when the SQE directly asks the team about any lessons learned. This indicates the other moments to collect LA are not being well explored either because of the process or the teams are not having enough maturity to identify Lessons Learned on those moments.

Recommended practices are the ones that have the greater appearance on Mantis database, and we can infer that the maturity of the organization tends to the discovery of practices that can be replicated on other projects. Non-recommended practices and feedbacks are not being frequently reported.

Another consideration is that 82% of the lessons learned reported are from the source *Own Initiative* which shows that the other source of information are not being effectively used. It is necessary to analyze whether the other repositories are necessary to the KM process, or are not suitable to its goals.

The number of change requests opened for the knowledge management sub-process, either for a process improvement or for adaptation represents only 2%, which does not mean that it is not relevant. This is due to the fact that we have 23 other sub-process that change requests can be opened.

Another representative analysis is based on the numbers of Table III, where we see that less lessons learned are being published after CMMI appraisal. This situation reflects the idea that SEPG has changed its priorities after the formal appraisal.

D. Improvement Opportunities

Based on the results analyzed, some improvement opportunities were raised to request changes on knowledge management sub-process, according to what is presented:

- Improve the process of lessons learned publication, by assessing if there can be added more agility to this process, in order not to be so dependant on the SEPG.
- Review Mantis tool in order to detail what is being effective, in terms of the existing categories, access to the submission of lessons learned, and collect an opinion of the organization about it through a formal research.
- Evaluate all source of information available on ProSCes and question whether or not all these disseminated knowledge and lessons learned could be integrated into one tool.

VII. CONCLUSION AND FUTURE WORK

The deployment of knowledge management process into a software development organization, during the process of improving a maturity level, has presented considerable results indicating positive remarks to the organization. By trying to achieve tacit and explicit knowledge, the process is improving its definition and applicability into projects.

On the other hand, the results presented on the case study induces us to the idea that there is a long path to run, in terms of process definition and tools to support and get the organization's involvement.

According to the stages presented by Bose [2], with the process definition and execution, we intend to follow all phases from the cycle process:

- Create: with the definition of the process.
- Capture: by the execution of the process.
- Refine: through process improvement change requests, and through new projects, with new contexts, using and registering its experiences with already existing knowledge.
- Store: with the use of mantis tool.
- Manage: together with SEPG that helps the maintenance of the process and database.
- Disseminate knowledge: which is a consequence of the process and their execution.

Code Transformation Techniques and Management Architecture for Self-manageable Distributed Applications

M. Muztaba Fuad
Department of Computer Science
Winston-Salem State University
Winston-Salem, NC 27110, USA
E-mail: fuadmo@wssu.edu

Abstract

Injecting autonomous behaviors into existing non-autonomous programs is desirable but requires a high degree of code transformation. Such code transformation is complicated and requires different level of code insertion and transformation to provide the required functionality. Proper underlying software architecture is required for managing the code once it is transformed into autonomous entities. All this is even become complicated when existing programs (whose source code is no longer available) want to utilize such code transformation and service architecture. This paper discusses techniques to transformation existing code into autonomous entities and presents underlying management architecture to run such transformed application.

1. Introduction

Programming a distributed application is a tedious task and programmers need expert knowledge of handling the distribution related management issues along with programming the problem at hand. This becomes even daunting when programmers have to incorporate autonomic behaviors into the system also. The scenario gets even complicated when developers want to transform existing non-autonomic distributed system (whose source code is no longer available) into an autonomic system. In real life, programmers' want to concentrate on the problem in hand, rather than spend time on incorporating autonomic behaviors in their system or deal with the distribution management issues. It will be tremendously beneficial to programmers if such autonomic behaviors can be added automatically and transparently to existing systems and distribution related issues can be addressed without spending much time for it. Although object oriented technology provides programmers with advantage of rapid program development in a networked environment, it becomes overwhelming when it is necessary to handle the autonomic computing aspects of the program as well. Towards this goal, the initial phase would be to how to convert an existing object oriented program into self-manageable chunks and access them autonomously across the system so that autonomic behaviors can be added into those autonomous entities as needed. This paper presents such code transformation techniques to produce autonomously accessible program component from existing object oriented programs and identifies issues related to such code transformations. Although the technique presented in this paper works with Java byte code, any interpreted code such as C#, that utilizes standard object oriented primitives can utilize it with minor modifications.

2. Related Works

There are several code transformation techniques in Java actively researched by a number of researchers [1-10] in different aspects of software development. However, these approaches either work towards traditional hard coded method or have different goals than this work:

- Although Addistant [1] works with Java bytecode, it uses a separate user specified placement policy to translate user code to a distributed version and requires placement policies be specified at the class level, limiting the opportunity to exploit object-level control. J-Orchestra [2] is similar research work that rewrites user code and replaces local data exchange with remote communication.
- Operate at the source code level [3].
- Program through pre-defined interfaces to utilize such approaches [4].
- Use monitoring and profiling during run time [5, 6].
- Use a modified Java Virtual Machine [7, 8], and sacrifices portability and interoperability for doing so.
- Use different programming languages [9, 10].

Please see [11] for detailed description and contrast of these works (most of the related work is not mentioned here for space constraints) with the work presented in this paper.

3. Code Transformations

After the user presented the code (computationally intensive, large parallel applications) to the system, a static code analyzer builds an object graph from the user supplied byte code. See reference [12] for more details on the static code analyzer. Once it generates the object graph, the graph is partitioned [13] according to the underlying system configuration, communication requirements or any user supplied policy. The underlying system comprises a collection of platform-agnostic autonomic elements [14] as an interface to the service providers and the associated pre-processor for comprehensive byte code to byte code translation, so that the resultant transformation produces a self-adaptive version of the user code. The transformed program is based on self-contained concurrent objects communicating through standard object based communication protocols and incorporates salient features (such as

Broker architecture and asynchronous call) from existing middleware technologies.

3.1 Autonomic transformations

Since the transformed program runs as a distributed program, any single node in the system could have one or more objects executing on it. As all of the related objects within any single node have to be manipulated transparently, several different scenarios present themselves for consideration:

a. *One AE(Autonomic Element) per node with each object as a ME (Managed Element* [14]*)*: The traditional proxy approach [1] could be employed; however, the full computation power of a particular node is not utilized in this scenario. The traditional proxy approach only supports a single object per proxy, but multiple objects per proxy are required for the approach presented in this paper.
b. *One AE per node with multiple objects as ME*: This is the most common scenario where multiple objects run concurrently in one node. The traditional proxy notation must be extended to address this scenario.
c. *Multiple AEs per node with multiple objects as a ME*: Although this scenario is possible, it is not supported by the autonomic computing paradigm and is not considered further.

A proxy structure is implemented that encapsulates one or more runtime objects into a single manageable entity that communicates with other such entities in the system with a single communication channel provided by the proxy object. Having an encapsulating proxy object allows us to incorporate the autonomic functionalities seamlessly into the user objects with the help of sensors, actuators and control interfaces. Any inter-object communication inside a single ME proceeds as usual; however, any inter-object communication between two different MEs is delegated to the encapsulating proxy object. There are two possible choices to create such an encapsulating proxy:

a. *The proxy class inherits the original class*: This works for only one class as Java does not support multiple inheritance. This can be overcome by creating a new interface with all the methods of each of the target classes and then having the proxy implement that interface by copying the method's body into the proxy class.
b. *Renaming the original class with the proxy class*: This is the traditional approach and does not work without modification for the proposed approach as it is difficult to delegate all proxy invocations separately. This approach needs to be extended by creating a clone of the original class structure as the new proxy structure and, at the byte code level, redirect all calls to the proxy class. This allows the existing methods to be overridden with additional functionalities and the class to be extended with new methods. Since all associated transformations are performed at the byte code level, users do not need to be concerned about following any specific programming rules.

For such transformations of user code, the following issues need to be addressed:

i. *Methods (M) and constructors (C)*: There are more methods in the proxy class to interact with the AE and also to manipulate the object itself. So, if M_n , $C_n \in$ *Original Class* $\rightarrow$ $M_{n'}$, $C_{n'} \in$ *Proxy Class,* where $n' > n$. The original methods are overridden with the following structure:

Pre-processing
Original method call
Post-processing

Instead of instrumenting each method, a wrapper method is created to ensure consistency with the existing line number table for debugging purpose.
ii. *Polymorphic method calls*: To determine the original calls of a method in a polymorphic call requires a stack oriented emulator such as that in the JVM. Creating such an emulator is a separate research problem and in the initial version of the transformations, polymorphic method calls are not considered.
iii. *Direct field access*: All direct field access is converted to getter and setter methods to facilitate remote method invocation.
iv. *System classes*: Since the system classes cannot be modified, the same techniques as used in J-Orchestra [2] are adopted. System objects are either moved with the user objects or, if they use any platform dependent code, remain on the same node and other proxies access these system objects using a callback facility.
v. *Handling distributed I/O*: It is undesirable to have user code produce output in a remote machine or ask for input somewhere other than it is intended to. Therefore all input/output operations need to be redirected. This leads to the following possible transformations: Standard output and error, Standard input, File input and File output.
vi. *Exception handling*: Reference [14] illustrates the approach adapted for handling exceptions.
vii. *'final' class*: To extend the functionality of a un-modifiable class in the proxy, the final keyword is removed from the *classpool* [15] inside the class file. In this way, the semantic and functional consistency of the class remains the same but now extra methods can now be added and existing methods can be overridden in the proxy to add the extra functionality.
viii. *Existing interfaces*: Since Java allows a single class to implement as many interfaces as required, no changes are required in this case.
ix. *Static methods and fields*: Any class that has static methods and fields is divided into two subclasses where one has all the static methods and fields and another has the non-static entities. Separate proxies are created for each subclass and the static subclass is

anchored in one node and interacts with other proxies using RMI callbacks.

x. *Use of 'this' and 'super'*: Use of *super* does not cause any problem in the transformed code. However, the use of *this* needs to be delegated to the appropriate proxy class.

xi. *Use of reflection*: Reflection in the user code is not considered due to the added complexity in the byte code rewriting phase. A separate package on reflection that delegates user enforced reflection must be developed to address this issue.

To handle other Java language features, the techniques used have similarities with the techniques used in J-Orchestra [2]. The major distinction with the approach in this paper is that object level distribution is attempted, whereas J-Orchestra uses class-level distribution. One significant drawback with both of these approaches is that it incurs extra space and time cost to run the resulting distributed application. Since new proxy classes are created and segments of byte code are inserted into the exiting byte code, some inflation in the resulting code size is expected.

3.2 Distribution Transformation

Once a group of objects has been identified as a managed element of an autonomic element, the corresponding class files must be transformed accordingly to facilitate insertion of autonomic primitives into the code. The static portion of the class is first moved to a separate class by the static analyser [12] and corresponding redirection is established to preserve the semantic and functional flow of the original execution. Communication between distributed objects is permitted, but such interaction should be kept to a minimum in order to reduce the communication overheads. The assumption is that the distributed classes are multi-threaded to allow asynchronous execution. This assumption is true for the problem domain of the research where the whole program is modelled as a collection of concurrent objects.

For each of the distributed objects, the code transformer transforms the byte code by instrumenting code to provide autonomic properties. Specifically the points where distributed objects are declared and called are now transformed to call and invoke corresponding proxy object classes. The proxy can itself redirect that call to a distributed autonomic element depending on the system level distribution policy. Every distributable class is transformed and the distribution transformer makes the following changes:

- The distributed class is modified to implement a new interface which holds distribution primitives.
- Any input/output statements in the user code are marked for redirection as specified by system level policy. The reason for redirecting all input/output is explained in the next section.
- The constructor is replaced with an *initialize* method.
- Based on the parameter-passing mode (*pass-by-value* or *pass-by-reference*), all parameters and corresponding local variables are changed. Please see [11] for more details on the techniques used for parameter passing.
- All public methods in the distributed class are modified to throw a *RemoteException* (to satisfy RMI requirements) and *MigratedException* (to satisfy runtime migration) along with any other existing exception thrown by the method.
- To make remote objects migratable, they are transformed to implement the *Serializable* interface. The code transformer checks whether the class itself or any of the class in its inheritance tree implements *Serializable*, and adds it if necessary. However, not every class in Java can be made *Serializable* in that way because of the language level constraints. Such objects have to be anchored in one single node during the execution of the program.

Other than making these changes, the remainder of the code remains intact. As a requirement of RMI, all methods must be public so that they can be called remotely. So the code transformer checks that all access rights are maintained. Only after the semantic check and transformation, the methods in the generated class are made public.

4. Performance Analysis

Experiments were conducted to find the time requirement of delegated method calls using proxy-based managed elements. After code transformation, every remote method call now takes place through the autonomic element. Therefore the call can be broken down into several parts:

i. Call to local proxy.
ii. Call from local proxy to remote proxy (AE).
iii. AE locates the remote class, loads it and uses runtime reflection to delegate the execution to the corresponding method.

To explain the process, consider the UML diagram of an example program presented in Figure 1 (a). The application class (which is the starting point of this application) creates an instance of *classA* which is run as a threaded object. For instance, we like to transform the instance of *classA* into a managed element of an autonomic element. The class diagram is now transformed into three separate portions with separate transformations as follows:

1. *Application Class*: Instead of referring to *classA*, it will now refer to the proxy instance of *classA* (Figure 1 (b)). A new wrapper class is created for *classA* that acts as the proxy of the original class. Along with the traditional proxy transformation, a new private variable that holds the reference (local or remote) of the actual object, and a new method that helps initialize the actual object reference, is inserted into the proxy class.
2. *Used classes inside the managed instance*: Objects of any class that *classA* is using must now implement the *java.lang.Serializable* interface to help the system

to transfer the instance over the network if needed (Figure 1 (c). All such classes are checked to see whether they implement either the *Serializable* interface or a subclass of that interface. If not, then it is added automatically. If such classes use any object instance which is not serializable (for instance having another thread inside that object), then that particular managed element must be anchored on a single machine during the life time of the application.

3. *Original class*: The original class relationship is kept unchanged (Figure 1 (d)). Only the constructor is now replaced by a new method *initialize* to create an instance of the class during runtime by the autonomic element using a consistent interface.
   A new class is designed to house the managed object

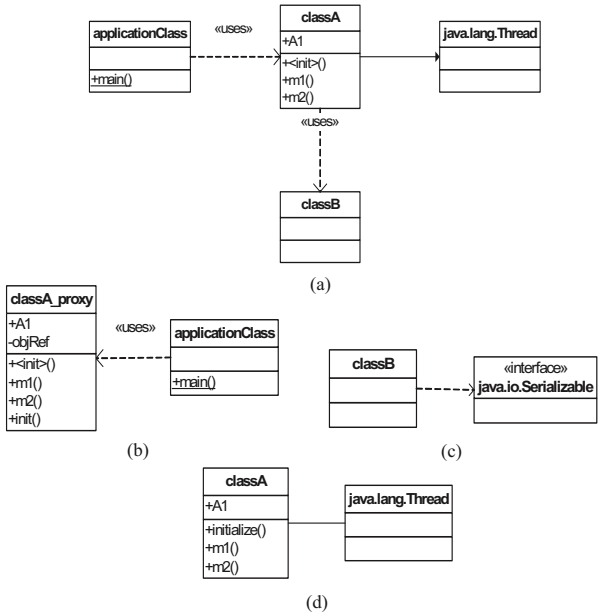

Figure 1. Example Class Diagram.

instance which implements a pre-defined interface. The *AutonomicElement* class creates an instance of the *managedElement* class. Figure 2 shows the runtime structure of each proxy class in the system. The *init* method in the proxy class is responsible for gathering necessary information (such as location of an available AE and naming of the AE) and establishing the deployment of the object to an autonomic element. Once all necessary information is gathered and processed, the proxy initially invokes the *setup* method of the corresponding *managedElement* with necessary information (such as class name for object instance, location of class and generated name for identifying that instance) as arguments. Next, the *init* method is invoked to create the actual object instance in the autonomic element with any initializing arguments. Any further method call from the proxy is then delegated by using the *invoke* method inside the proxy class. Figure 3 shows the timing for such remote calls, where other denotes the time it takes for local proxy class loading and locating the

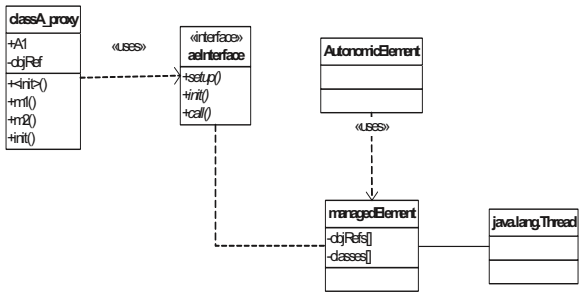

Figure 2. Transformed Runtime Program Structure.

remote AE using the standard naming protocol. For a single remote call using the delegated proxy pattern, the increase in execution time is approximately 45%. With several calls to the same AE, this reduces to less then 10% as the JVM normally caches classes and for subsequent calls class loading and reflection occur faster than the initial time. Table 1 shows this behavior of the proxy based remote invocation. Code inflation for the transformations is linier (around 10% for distribution transformation and 30% for autonomic transformation) and depends on the number of objects and classes in the user code.

The benefit of having a double delegated structure is that the distribution concerns and the self-management concerns are separated at the code level. This allows future code extension, since adding the two level delegations work in two separate processes and in sequence. Programmers can add their own transformations in the future if they wish following a similar approach; however the penalties for doing so are further increased code inflation and reduced response time due to extra code execution and class loading.

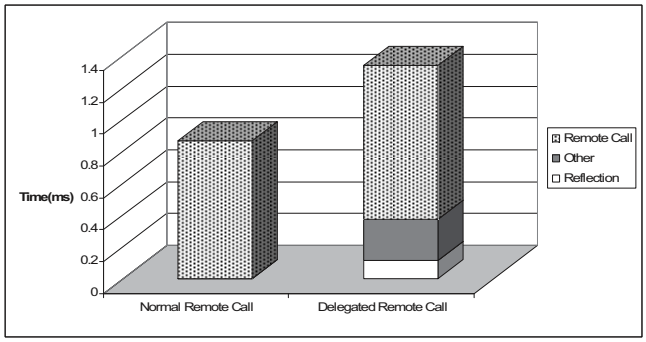

Figure 3. Timing Information for Delegated Invocation.

Table 1. Effects of Multiple Calls on Respnose Time.

Number of calls	Standard Remote Call (ms)	Delegated Remote Call (ms)	% Change
1000	391	476	21.74
10000	2289	2593	13.28
100000	19372	20261	4.59

5. Management Architecture

The design of the management architecture is driven by the desire to produce a transparent and easy to use

system that can be self-managed. The architecture provides services (physical resources) to the submitted workload (user application), where services are defined as an engagement of resources (service providers) for a period of time according to a contractual relationship (Service Level Agreement or SLA) with a service requester (application user). Figure 4 shows the overall system architecture. The architecture is broken into two views: *structural* and *managerial*. In the structural view, the lowest layer consists of the actual physical resources that are providing the services. This layer is abstracted by a virtual resource layer to hide the interface complexity of the actual physical devices. Having this virtual layer with a pre-defined interface allows the architecture to incorporate new physical devices in the future without re-programming the whole architecture for each new device. The upper layers provide a set of predefined services dependant on the state the current autonomic element is currently in. Some of the autonomic elements are directed to act as managerial elements to provide certain services across the entire system, so that other autonomic elements can work smoothly and can provide the service as requested. The application layer, normally kept dormant, can be brought alive if needed by either the user or by another autonomic element. The autonomic element layer is responsible for the management of autonomic elements and general system wide management. The middleware service layer performs actual communication services which are used for inter autonomic element communication, repository update, notification of migration of managed elements etc. The managerial view consists of the management functions necessary to

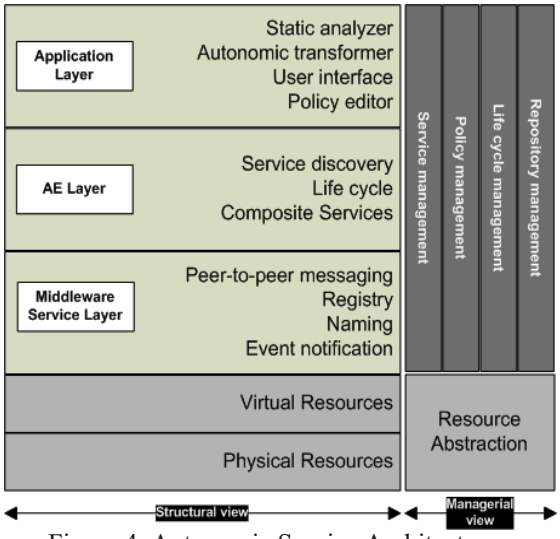

Figure 4. Autonomic Service Architecture.

manage the services delivered. Management functions primarily involve policy management, resource management, service management and life-cycle management. All management functions are performed by autonomic elements which are self-managing and whose role is to ensure automated delivery of services.

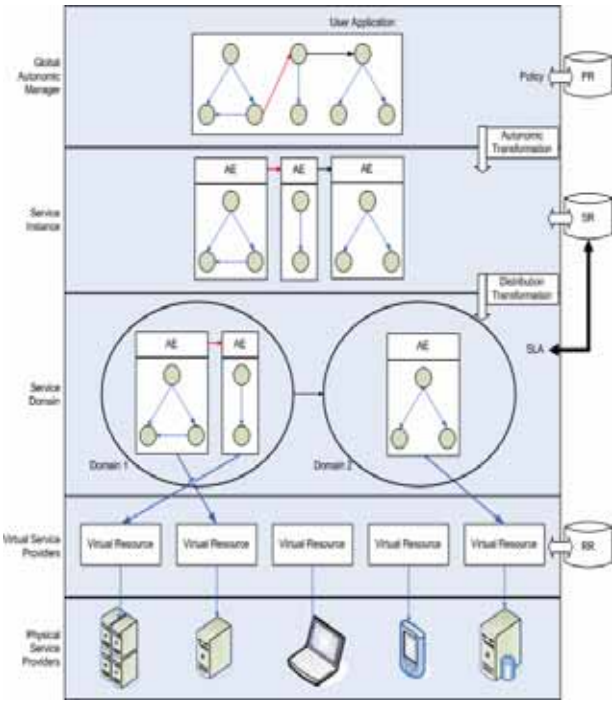

Figure 5. Hierarchical Management of System.

Figure 5 shows the hierarchical management view of the architecture. The global autonomic manager acts as the interface between the user and the underlying system. Each of the program partitions is treated as a service instance and encapsulated by an autonomic element for self-management. Each of the service instances are assigned to resource domains that best suit the instance's needs. See reference [13] for more information on devising such service instance to domain composition details. Each of the actual physical resources has a corresponding virtual resource adapter that provides a uniform and consistent interface to the physical resources. This simplifies resource management, service composition and dynamic resource addition/deletion. In order to perform autonomic service management, the system must maintain appropriate information about the different components of the runtime environment in repositories (databases). Repositories are classified into three distinct types:

- *Policy repository (PR)*: This repository contains the policies created at runtime or pre-defined by operators or users following a template policy implementation. The user can browse through existing policies and can use them to create new policies using a policy editor interface.
- *Service repository (SR)*: The service repository contains information (such as parties involved in a service level agreement) about the different service instances activated by the global autonomic manager, types of resource used, amount of resource being used and past operation history.
- *Resource repository (RR)*: This repository holds information about the resources available to the

service providers at any given time. Information that may be stored for each resource includes type of resource, resource performance matrices, communication matrices, etc.

The implementation of these repositories is performed hierarchically to avoid a single point of failure.

6. Management Operations

In this three tier peer to peer architecture (Figure 4), each autonomic element can also act as a managerial element. All autonomic elements operate over a unified management model that provides a set of operations and interface common to all autonomic elements. Normal autonomic elements access this model to retrieve their current configuration and save their current state, whereas managerial elements use it to discover other elements in the system. Representation of management information is a crucial part of any self-management architecture. The representation should be easy to manipulate and should follow an open standard for faster incorporation and future extensibility. XML-based WSDL is used to represent such management operations for these reasons. Currently, there are four types of management information kept by the system:

i. *Resource information*: Resource and service provider properties are expressed by this type of information. Care should be taken so that there are no duplicate entries and periodically (heuristically decided) this information needs to be updated to keep it consistent and non-redundant.
ii. *Performance information*: This type of information represents the performance status of a running autonomic element. Before two autonomic elements come to a service agreement, they transfer performance information to learn more about each other, which includes different performance measurements and current operational state.
iii. *Configuration information*: This type of information is used to configure the behavior of an autonomic element. Concurrency control has to be in place so that multiple configuration information is in play at the same time.
iv. *Relationship information*: This type of information expresses dependency relationships between autonomic elements.

A model similar to DNS revolver is employed to discover autonomic elements in the system.

7. Conclusions

The approach to transform code to add distribution concerns and self-management concerns is presented and evaluated in this paper. The software architecture to support such transformed code is also presented and different aspects of it is discussed. Architectural choices have a profound effect on the capabilities of any autonomic system and affect many of the design decisions during its implementation. The presented architecture supports computational and data intensive centralized applications where the computation-to-communication ratio is significant.

Abstract

Software architecture design is a knowledge-intensive activity. Existing design methods mostly provide high-level processes and guidelines. The generic design knowledge, e.g., patterns, falls short of incorporating into specific design methods. Emerging research on Architectural Knowledge (AK) mostly focuses on its recording and comprehension, whereas how to leverage the knowledge to support architecting is still a very open issue. In this paper, we present a decision-centric architecture design method, explicate four kinds of design knowledge pertaining to this method, and propose a schema to record the knowledge. Because of their natural correspondence to the design notions and activities, these kinds of knowledge can be captured and retrieved for reuse at the right point of need, according to the design context. We illustrate how our architecture design tool automatically helps architects reserve the design knowledge and promotes potential reusable knowledge for them to accomplish the design more efficiently.

1. Introduction

Architecture design plays a crucial role in the whole lifecycle of software. Software development is a human and knowledge-intensive creative activity [1]. This claim is especially true for architecture design. Various kinds of knowledge, e.g., design knowledge, analysis knowledge, and realization knowledge, are all critical inputs to the design process [2]. The success and efficiency of the design depend on not only the tacit experience and skills of architects, but also the explicit form of the knowledge and the way to utilize it.

Existing architecture design methods [2] mostly provide high-level processes and guidelines for design, whereas still lacks pragmatic support for architects to discover solutions and make decisions. On the other hand, the wide-accepted design knowledge, e.g., patterns, though useful to codify successful expertise and improve architects' competence, is often too generic and lacks incorporation into specific design methods, so still falls short of supporting the architecting process directly and effectively.

The software architecture community has an emerging focus on Architectural Knowledge (AK), which is defined as the integrated representation of the software architecture of a software-intensive system or family along with architectural decisions and their rationale, external influence and the development environment [3]. Existing research on AK mostly focuses on the recording and comprehension of architecture decisions and rationale. How to leverage the accumulated knowledge to support architecting activities is still a very open issue.

We have proposed a decision-centric architecture design method [4], which models the core notions and provides a semi-automated process for architecture design. In this paper, we explicate four kinds of design knowledge specially pertaining to this design method, i.e., issue knowledge, solution knowledge, decision knowledge, and rationale knowledge. Because of their natural correspondence to the design notions and activities, these kinds of knowledge can be captured and retrieved for reuse at the right point of need, according to the design context. We have developed a tool to support the design method and leverage the design knowledge. We illustrate how this tool automatically helps architects reserve the design knowledge and promotes the potential reusable knowledge for them to accomplish the design more efficiently.

* Corresponding author

The rest of this paper is organized as follows. Section 2 presents related work. Section 3 gives an overview of our decision-centric meta-model and architecture design process. Section 4 describes the design knowledge pertaining to our design method. Section 5 and 6 describes the capture and reuse of design knowledge within the design process. Finally, Section 7 presents concluding remarks and future work.

2. Related work

A number of methods have been proposed for software architecture design, e.g., QASAR [5], ADD[6], Siemens Four-Views (S4V) [7], RUP's 4+1 View [8], etc. Many methods derive the resulting architecture via a series of transformations and provide design knowledge in the forms of guidelines, patterns, tactics, etc. For example, QASAR [5] formulates design guidelines to indicate suitable transformations. ADD [6] applies architectural tactics and patterns that satisfy the driving quality attribute requirements. Our approach implements automated synthesis of candidate architecture solutions, and the capture and reuse of design knowledge during the design process.

The effort on Architectural Knowledge (AK) in the architecture community [3] is to make AK explicit to facilitate its sharing and reusing. Bosch [9] promotes that design decisions should be represented as first-class entities in software architectures. Kruchten et al. [10] describe a use-case model for an architectural knowledge base, together with its underlying ontology. Habli and Kelly [11] address the reuse of architectural knowledge through the use of derivational analogy. Ali Babar and Gorton [12] develop a framework and tool for capturing and using architectural knowledge to improve the architecture process. We tailor the architecture design knowledge to our specific design method, so that the knowledge can be leveraged efficiently for architecting.

Knowledge Management (KM) is an emerging discipline that promises to capitalize on organizations' intellectual capital, and the KM in software engineering is also drawn considerable attention [1]. Basili [13] proposes a framework where Experience Factory develops and packages experience for reuse. Henninger et al. [14] propose the organizational learning approach to software development. Rich and Waters [15] point out that the software engineering tools will need more knowledge intensive approaches. We follow the theme of knowledge-based approach for software development, and aim to take advantage of the knowledge in software architecture design with a lightweight knowledge management effort.

3. Overview of the decision-centric architecture design method

Figure 1 shows the meta-model to describe the notions in our decision-centric architecture design.

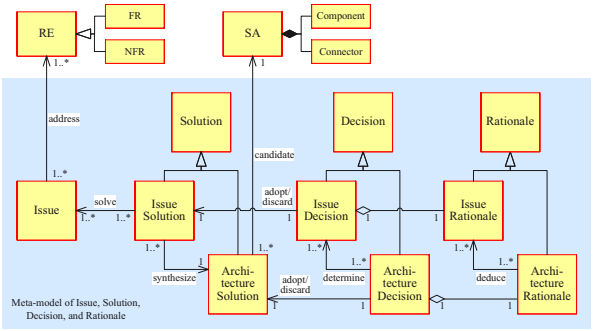

Figure 1. The decision-centric meta-model

An *issue* is an architecturally significant problem that must be solved by the architecture design. Issues address specific aspects of requirements or any other considerations at the architecture level.

Solutions are specialized into *issue solutions* and *architecture solutions*. An issue solution provides a possible way of solving an issue. An architecture solution is a candidate architecture design that has addressed all of the issues. Architecture solutions can be synthesized from issue solutions.

Decisions are specialized into *issue decisions* and *architecture decisions*. An issue decision means adopting or discarding one candidate issue solution. An architecture decision means adopting or discarding one candidate architecture solution. Issue decisions can be determined by architecture decisions.

Rationale is specialized into *issue rationale* and *architecture rationale*. Issue rationale is the reason behind issue decisions. Architecture rationale is the reason behind architecture decisions. Issue rationale can be deduced from architecture rationale.

Figure 2 shows the iterative process to implement our decision-centric architecture design. The main inputs to this process are software requirements and (optional) original architecture. The main outputs of this process are decided architecture, recorded decisions, and captured rationale.

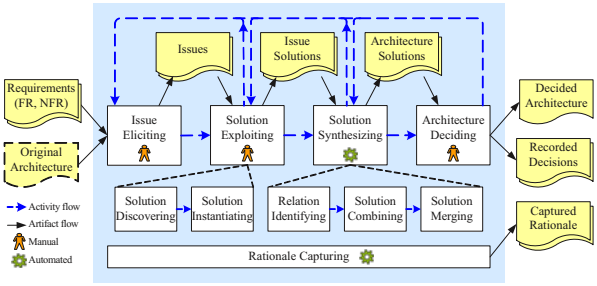

Figure 2. The decision-centric design process

In the *issue eliciting* activity, stakeholders deliberate and determine architecturally significant issues, based on the requirements, the original architecture, and the design considerations.

In the *solution exploiting* activity, architects derive candidate solutions to each issue. First, they discover solutions, according to reusable design knowledge or newly developed technologies. Second, they instantiate these solutions from informal descriptions to concrete design models.

The *solution synthesizing* activity automatically synthesizes the candidate architecture solutions from various issue solutions. First, the relations between issue solutions (e.g., inclusive, conflictive, etc.) are identified to indicate whether they can be combined together. Second, a combination tree is built to explore all feasible combinations of issue solutions. Finally, the issue solutions within every feasible combination are merged to generate candidate architecture solutions.

In the *architecture deciding* activity, stakeholders select the target architecture solution from the synthesized candidate architectures. They need to evaluate the candidate architecture solutions according to the requirements, compare them by multiple criteria, make trade-offs between the competing objectives, etc.

The *rationale capturing* activity automatically deduces issue decisions and rationale from the settled architecture decisions and rationale, based on the synthesis relationship between architecture solutions and issue solutions. If one issue solution participates in synthesizing the architecture solution that is adopted, then the decision on this issue solution is adopting too. Otherwise the decision on this issue solution is discarding. Moreover, the rationale of the architecture decisions can be used to explain the reasons for adopting or discarding the issue solutions that participate in synthesizing the architecture solutions.

4. The design knowledge pertaining to the design method

The design knowledge here refers to the problem-solving expertise within our architecture design process. We explicate four kinds of design knowledge: *issue knowledge* (illuminates how to elicit issues from requirements), *solution knowledge* (illuminates how to exploit issue solutions and architecture solutions), *decision knowledge* (illuminates how to make architecture decisions and issue decisions), and *rationale knowledge* (illuminates the rationale of architecture decisions and issue decisions).

To preserve all these kinds of design knowledge, we codify comprehensive information about each architecture design, including not only the resulting architecture, but also the decisions and rationale, the candidate solutions, the issues, and the requirements, etc. Furthermore, we record all the relations between these entities, as specified in the meta-model, including the tracing relations from issue solutions to issues and to requirements, the synthesizing relations from issue solutions to architecture solutions, the deducing relations from architecture decisions and rationale to issue decisions and rationale, etc.

We define the structure of above information with an XML schema, where the architecture design repository (*ADRepository*) includes information about every architecture design project (*ADProject*). Figure 3 shows the schema of *ADProject*.

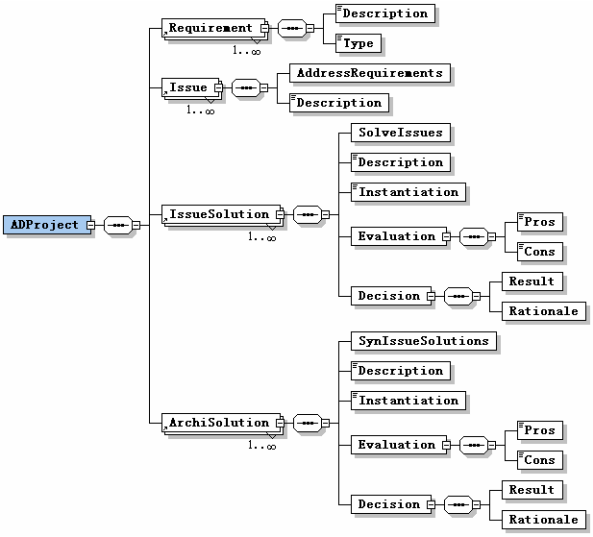

Figure 3. The XML schema of design information

The *ADProject* schema specifies four kinds of information items:

- *Requirement*, represents one requirement. The *Type* specifies whether it is a functional (*FR*) or non-functional requirement (*NFR*).
- *Issue*, represents one issue. The *AddressRequirements* specifies the requirements it addresses.
- *IssueSolution*, represents one candidate issue solution. The *SolveIssues* specifies the issues it solves. The *Instantiation* is an URI pointing to the concrete ADL model of this solution. The *Evaluation* includes *Pros* and *Cons* of this solution. As aforementioned, the issue decision is determined by the decisions on the architectures that this issue solution participates in synthesizing. If this issue solution participates in synthesizing the architecture solution that is adopted, the *Result* of this issue solution's *Decision* is *ADOPT*, otherwise is *DISCARD*. The *Rationale* is the link to the *Decision*s of the architecture solutions that this issue solution participates in synthesizing.

- *ArchiSolution*, represents one candidate architecture solution. The *SynIssueSolutions* specifies the issue solutions that participate in synthesizing this architecture solution. The *Instantiation* is an URI pointing to the concrete ADL model of this solution. The *Evaluation* includes the *Pros* and *Cons* of this solution. The *Result* of this architecture solution's *Decision* may be *ADOPT* or *DISCARD*. This *Result* is specified by the architects. The *Rationale* is a statement of the reason behind this decision, and it is also specified by the architects.

The above comprehensive information manifests the four kinds of design knowledge. In concrete terms, the knowledge is embodied in these information items and their correlations: the issue knowledge is embodied in the *Issue* items, and their relations to the requirements they address (*AddressRequirements*); the solution knowledge is embodied in the *IssueSolution* items and their relations to the issues they solve (*SolveIssues*), as well as the *ArchiSolution* items; the decision knowledge and rationale knowledge is embodied in the *Decision* and *Rationale* elements of the *IssueSolution* and *ArchiSolution* items.

Section 5 and 6 illustrate these kinds of knowledge, as well as their capture and reuse, based on a case of Commanding Display System (CDS) [4]. The target of CDS architecture design is to achieve a real-time, high dependency system for live and history data display.

5. Capture of the design knowledge within the design process

Capture issue knowledge. The issue knowledge can be captured within the context of issue eliciting activity. Our tool provides interfaces for users to specify the elicited issues, as shown in Figure 4. The tool then automatically records the issues and their relations to the requirements. Figure 5 shows a sample of the recorded requirements and issues that embody issue knowledge.

Capture solution knowledge. The solution knowledge can be captured within the context of solution exploiting and solution synthesizing activities. In the solution exploiting activity, our tool provides interfaces for users to specify the exploited issue solutions. The tool then automatically records the solutions and their relations to the issues. In the solution synthesizing activity, the tool automatically synthesizes candidate architecture solutions from various issue solutions, and records the synthesized architecture solutions. Figure 6 shows a sample of the recorded issue solutions and architecture solutions that embody solution knowledge.

      </Rationale>
   </Decision>
</ArchiSolution>
```

Figure 6. The captured solution knowledge, and the decision and rationale knowledge

Capture decision and rationale knowledge. The decision and rationale knowledge can be captured within the context of architecture deciding and rationale capturing activities. In the architecture deciding activity, our tool provides interfaces for users to specify their decisions on the candidate architecture solutions and the rationale of their decisions. The tool then automatically records these decisions and rationale. Moreover, the tool automatically deduces issue decisions and rationale from the architecture decisions and rationale, and records them. Figure 6 also shows a sample of the recorded decisions and rationale.

6. Reuse of the design knowledge within the design process

Reuse issue knowledge. The issue knowledge can be reused in the issue eliciting activity, to help users elicit issues according to the specified requirements. Within this context, our tool automatically retrieves potential reusable issues from the design repository via a background query. The query finds the issues whose *AddressRequirements*s include the *Requirement*s whose *Description*s include the keywords of the current project's requirements.

Besides the automatically suggested issues, users can also conduct several kinds of queries manually to find other potential reusable issues. For example:

- Query the *Issue*s whose *Description*s include the specified keywords.
- Query the *Issue*s whose *AddressRequirements*s include the *Requirement*s whose *Description*s include the specified keywords.

Figure 7 shows the interface automatically suggesting issues for reuse when users specify a new issue (the left dialog), and the interface for users to query the issue knowledge manually (the right dialog).

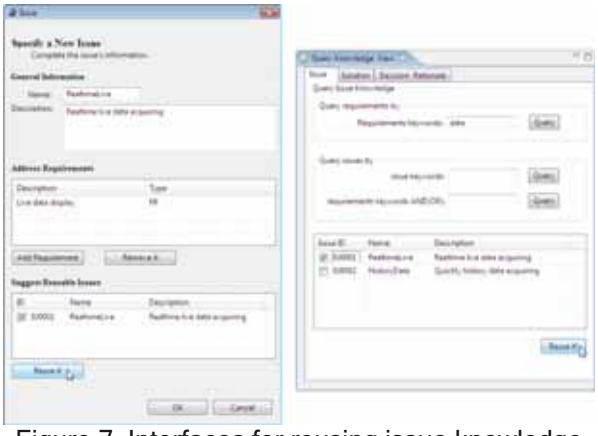

Figure 7. Interfaces for reusing issue knowledge

All above queries can be implemented on the recorded issue knowledge. For example, a query of the *Issue*s by the requirement keyword "Live" is implemented with XPath:

```
//Issue[contains(AddressRequirements/@IDREFS,//Requirement[contains(Description,"Live")]/@ID)][//Requirement[contains(Description,"Live")]]
```

Reuse solution knowledge. The solution knowledge can be reused in the solution exploiting activity, to help users exploit solutions to the specified issues. Within this context, our tool automatically retrieves potential reusable solutions from the design repository. For the reused issues, the tool retrieves their solutions in the design repository directly and promotes for reuse. For the newly elicited issues, the tool query the issues whose *Description*s include the keywords of the new issues, then retrieves the solutions to these similar issues and promotes for reuse.

Besides the automatically suggested solutions, users can also conduct several kinds of queries manually to find other potential reusable issue solutions. For example:

- Query the *IssueSolution*s whose *Description*s include the specified keywords.
- Query the *IssueSolution*s whose *SolveIssue*ss include the *Issue*s whose *Description*s include the specified keywords.
- Query the *IssueSolution*s that are included in the *SynIssueSolutions*s of the *ArchiSolution*s whose *Description*s include the specified keywords.

Architecture solutions are not prone to be directly reusable, because of their relative coarse granularity and the diversity of different projects. However, they can also be queried to provide references. For example:

- Query the *ArchiSolution*s whose *Decsription*s include the specified keywords.
- Query the *ArchiSolution*s whose *SynIssueSolutions*s include the *IssueSolution*s whose Descriptions include the specified keywords.

All above queries can be implemented on the recorded solution knowledge. For example, a query of the *ArchiSolution*s by the issue solution keyword "push" is implemented with XPath:

```
//ArchiSolution[contains(SynIssueSolutions/@IDREFS,//IssueSolution[contains(Description,"push")]/@ID)][//IssueSolution[contains(Description,"push")]]
```

Reuse decision and rationale knowledge. The decision and rationale knowledge can be reused in the architecture deciding activity, to help users make decisions on the specified solutions. Within this context, our tool automatically retrieves potential reusable decisions and rationale from the design repository. For the reused issue solutions, the tool

retrieves their decisions and rationale directly and provides references for users.

Besides the automatically suggested decisions and rationale, the user can also conduct several kinds of queries manually to find the relative decisions and rationale for reference. For example:

- Query the *Decision*s and *Rationale* on the *IssueSolution*s by the decision *Result*.
- Query the *Decision*s and Rationale on the *IssueSolution*s whose *Description*s include the specified keywords.

As aforementioned, architecture solutions are not prone to be directly reusable, neither are their decisions and rationale. However they can also be queried to provide references for users. For example:

- Query the *Decision*s and *Rationale* on the *ArchiSolution*s by the decision *Result*.
- Query the *Decision*s and *Rationale* on the *ArchiSolution*s whose *Description*s include the specified keywords.

All above queries can be implemented on the recorded decision and rationale knowledge. For example, a query of the *Decision*s on the architecture solutions by the keyword "real-time DB" is implemented with XPath:

```
//ArchiSolution[contains(Description,"real-time DB")]/Decision
```

7. Conclusions and future work

We have proposed a decision-centric architecture design method and explicated four kinds of design knowledge pertaining to this design method. The architecture design method can facilitate the capture and reuse of the design knowledge within the context of various design activities. The tool we developed can provide semi-automated support for the architecting and the capture and reuse of the design knowledge.

This paper presents our ongoing work towards practical architecture design method and tool support. Future work includes the further elaboration of the architecture design knowledge and the validation of this method and tool in real-life applications.

System architecture induces document architecture

Peter Henderson, Nishadi De Silva

p.henderson@ecs.soton.ac.uk, n.desilva@ecs.soton.ac.uk

Abstract

The documentation of an architecture is as important as the architecture itself. Tasked with communicating the structure and behaviour of a system and its constituent components to various stakeholders, the documentation is not trivial to produce. It becomes even harder in open, modular systems where components can be replaced and reused in each progressive build. How should documentation for such systems be produced and how can it be made to easily evolve along with the system it describes? We propose that there is a close mapping between the system architecture and its documentation. We describe a relational model for the architecture of open systems, paying close attention to the property that certain components can be reused or replaced. We then use ideas from storytelling and a discourse theory called Rhetorical Structure Theory (RST) to propose a narrative-based approach to architecture documentation; giving both a generic narrative template for component descriptions and a RST-based relational model for the document architecture. We show how the two models (system and documentation) map onto each other and use this mapping to demonstrate how document fragments can be stored, automatically extracted and collated to closely reflect the system's architecture.

Keywords

System architecture, documentation, narratives, RST

1. INTRODUCTION

An architecture is the partitioning of a whole into parts (components), with specific relationships between these parts [1-3]. There is an increasing need for faster software development, and much of this is now dependent on modular architectures with reusable components that allow for quicker evolution and localised updates [4]. Documenting the architectures of such evolving systems is not trivial. Of all the potential stakeholders, we are concerned primarily with the documentation required by developers who are charged with evolving the product. So, the question we ask is - how does one produce documentation for a developer who has to revise the software and thus use most of its documentation?

There are various techniques and guidelines on how to document architectures [1, 5-7]. Our approach, however, looks at this problem from a narratives perspective based on the hypothesis that 'saying it like a story' improves document coherence and readability. There are two issues that need to be considered: each component needs to be documented well and coherently; and, secondly, these component descriptions need to be collated in some way to produce the documentation for a system. For the first, we argue that a document conveys an implicit narrative (or story) to the reader, and that fine-tuning this improves the overall document. We use ideas from Rhetorical Structure Theory (RST) [8] to study and enhance the coherence of this implicit narrative (which we call a **document narrative or DN**) [9]. In this paper, we present a generic DN to document a component's structure and behaviour.

To address the second issue, we develop a relational model for the system architecture (comparable to other relational models in this field [10]) and a RST-based relational model for the document architecture, and show how the two map onto each other. We use this mapping to describe how aspects of the system architecture can be used to guide the structure and sequence of the documentation.

A mapping between the two models as shown here has two major benefits. Firstly, it allows a database to be created that can store the architecture details and the set of associated document fragments. When queried, it is able to return a narrative-based document that reflects the system architecture. Better still, it allows documentation to be reused or replaced where appropriate. Secondly, since there is a strong correlation between the models, system architects will be forced to think of the accompanying documentation from an early stage which will benefit both the system and the documentation. We conjecture that architectures that are easier to document using our technique are better architectures.

The rest of this paper is set out as follows: Section 2 gives some background information; section 3 introduces the relational model for the system architecture and a generic DN for documenting a component; section 4 presents the RST-based relational model for the documentation and illustrates the mapping between the two models; in section 5, we demonstrate our ideas using a simple example and section 6 concludes the paper and discusses future work.

2. BACKGROUND

A significant proportion of a software architect's time is spent interacting with stakeholders and communicating the architecture [11]. A majority of this communication is done via documentation. Architecture documentation is expected to cater to three categories of readers: those selecting this system, those learning to develop typical applications using this system and those intending to modify its architecture

[6]. The work presented in this paper addresses documentation targeted at the third category (even though it could be of use to the first group too).

Because architectures can be so complex, several practitioners and researchers have developed techniques that divide the documentation into **views** which help separate the different aspects of the architecture [1, 5, 12]. The documentation is then composed of the relevant views along with any documentation that applies to more than one view (the 'glue' that binds the views together). Similarly, Kruchten introduced a 4+1 model for an architecture [5] which is a generic way to describe architecture using five concurrent views, each addressing a specific set of concerns important to different stakeholders: the logical view, process view, physical view, development view and a fifth view that contains use cases or scenarios.

We recognise from these previous approaches that it is impossible to capture everything about an architecture in one document. We, therefore, abstract away from development and physical details to a much higher level. At this level, we only focus on descriptions about the software components, what they are made up of and how they interact with other components. We recognise that other audiences may require other types of documentation but they are beyond the scope of this paper.

We are also not the first to employ documenting strategies from another domain in architecture documentation. The **pyramid principle** [13], for instance, has been used to structure architecture documentation [6]. The pyramid principle is based on structuring the document around developing a question-answer dialogue with the reader. So, information is exposed incrementally as answers to questions that arise in the reader's mind. Also, **storyboarding** has been used to identify requirements and select COTS components [14]. In this paper, we make use of our previous work on **narrative-based writing** [9] and apply it to architecture documentation. This combination of narratives and RST in this domain is a novel approach. (A brief introduction to RST is given in section 4 and the features of narrative-based writing required for this paper are included where necessary. More can be found in [9].)

3. A RELATIONAL MODEL FOR SOFTWARE

As with most architectural descriptions, the central concept in our model is a **component**. A component can either be atomic or have subcomponents plugged into appropriate **slots**[1]. These subcomponents, in turn, can be made of sub-subcomponents and so on. This continues until a level is reached where the components can be considered as 'black boxes' (i.e., it is unnecessary and beyond the scope of the documentation to dwell deeper into the hierarchy of decomposition). This leads us to the first relation in our model:

contains (container:component, slot, component:component)

Components also have dependencies on other components. This is, in fact, essential for modular systems where the behaviour of the whole is only realised when the constituent components work together. We call this the *uses* relation. Component A *uses* B if A (user) uses an interface provided by B (service).

uses (user:component, service:component)

A particular benefit with open, modular architectures like the ones we focus on is that a component can be replaced by another component if it provides the similar functionality and interfaces. This can happen, for example, when two suppliers manufacture comparable components leaving the implementer to pick one depending on other criteria such as price and reliability. Of course, this option to replace usually works only in one direction. A superior component B' that can perform all the functions of an inferior component B (and more) can be used to replace B. However, B cannot be used in situations where a B' is required. This brings about the third relation *replaces*:

replaces (superior:component, inferior:component)

A diagrammatic representation of the three relations is shown below.

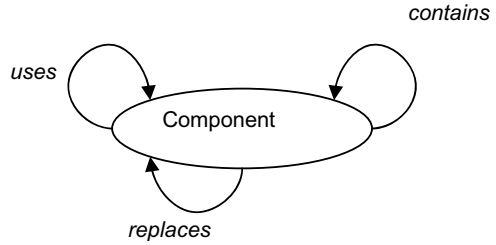

Fig. 1. Diagrammatic representation of our relational model for the system architecture

We realise that, when compared to languages such as UML with numerous relations, our model may appear limited. However, for the purposes of this paper, the model given above is sufficient.

4. A RELATIONAL MODEL FOR DOCUMENTATION

In our previous work, we have researched and developed a technique called narrative-based writing [9] to improve the coherence of technical documents such as research proposals. The technique required authors to first formulate a "document narrative" (DN): an explicit précis of what the authors wanted to convey to the readers in a story-like

[1] The idea of a 'slot' gives us a the flexibility to have multiple subcomponents of the same type plugged into different slots within the same component.

form. The DN is then analysed using a discourse theory called Rhetorical Structure Theory (RST) [8]. RST helps add more meaning and supportive reasoning to the DN and also gives an indication of how well it is structured. The DN and the corresponding RST analysis are then used to produce the document. The technique was particularly useful in collaborative writing where multiple authors had differing opinions about the document's objectives and structure.

We use this technique here to compose fragments of documentation corresponding to the components in the architecture. However, before proceedings, it is necessary to give a brief overview of RST and how it can be applied to text.

Rhetorical Structure Theory (RST)

RST was developed in 1988 by Mann and Thompson [8]. The theory attributes the coherence of a text to implicit logical relationships that exist between parts (usually called segments) of that text. So, for instance, segment A and B can be involved in a MOTIVATION relationship which means that segment B provides some information to motivate the action(s) in segment A. In Mann and Thompson's original paper, they define 23 such relationships with precise definitions of the sorts of text that can be involved in each.

In RST, the segments of text are classified as nuclei or satellites. Nuclei are considered essential to the understanding of the text. Satellites provide supporting material to the nuclei but are not absolutely necessary. Most relationships exist between a nucleus and a satellite. Returning to the example of the MOTIVATION relationship before, it can be illustrated using the diagram below. Note that the arrow always goes from the satellite to the nucleus.

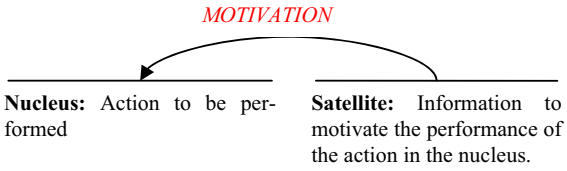

Fig. 2. A MOTIVATION relationship in RST

Some relationships like SEQUENCE can exist between more than two segments of equal importance (so, two or more nuclei). We have briefly described the RST relationships that appear in this paper in Table 1.

In order to do a RST analysis, the first step is to divide the text into segments. Each segment should have functional integrity and is often a clause or a sentence. The next step in a bottom-up analysis is to identify relationships that exist between pairs of segments. Segments involved in a relationship can, in turn, become involved in another relationship. Hence, the process is recursive and continues until all the segments can be assembled into a tree of relationships called a RS-tree. Mann and Thompson conjecture that if a RS-tree can be formed involving all the segments, then the text is coherent. However, if there are non-sequitors or difficulties producing this tree, then the text may need restructuring. This is a valuable guide when evaluating the structure and coherence of a text [8].

Relationship	Description
Background	Satellite provides background information to the nucleus
Elaboration	Satellite elaborates the information in the nucleus
Justify	Satellite justifies the information presented in the nucleus
Motivation	Satellite motivates the reader to perform the action in the nucleus
Sequence	Multiple nuclei that follow each other in sequence
Restatement	Satellite is a restatement of the information in the nucleus

Table 1. The RST relationships used in this paper

A Narrative-based Component Description

We look first at applying the narrative-based writing technique to describing each component. What we want to end up with is a generic structure that can be used for all components. Bearing in mind that a 'component' in our case can mean anything from a composite system to an atomic sub-component, some of the key concepts that need to be conveyed in the documentation are its behaviour, subcomponents (if any), whether it is able to interact with other components and, if appropriate, brief comparisons to similar products that are available. However, what is the best order to place this information in? This is where a DN can help. Trying to construct a narrative helps identify the natural sequence to the information and even recognise segments that are missing. A generic DN for the component descriptions (divided into 7 segments) is presented below along with a possible RST analysis of it. We say "a possible analysis" because it is viable that different analysts will produce different RS-Trees. The important point is to agree with the co-authors on the analysis and be able to form a tree (see Figure 3) which helps gauge the level of coherence of the text.

"[Select component X][1] [because it meets the set requirements and has some advantages over comparable technologies in the market.][2] [It is also a vast improvement from previous versions.][3] [It can receive the following instructions and perform the necessary tasks in response.][4] [The behaviour was grouped as it is done in this component for several good reasons.][5] [Furthermore, X can also interact with other components that it needs to in the following ways to produce the desired effect.][6] [On closer inspection, X is composed of multiple subcomponents that, when combined, enable its functionality. These components are x_1-x_n and they will be described later.][7]"

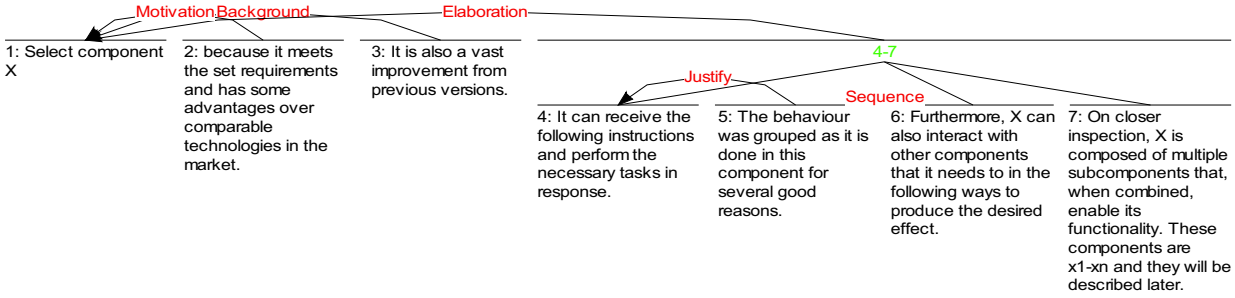

Fig. 3. A possible RST analysis of the generic DN above

Some parts of the narrative may not apply to all components of course. For instance, when describing components that are not going to be further decomposed, segment 7 about subcomponents is not relevant. Segment 2 is seen to provide motivation to convince the reader to choose (or buy) component X in the case where a decision has not yet been made.

It is worth mentioning that this narrative structure applies to the *body* of the document. Additionally, there would be other sections such as the introduction and conclusions which are compulsory in most documents. We call the description of a component adopting this narrative a **FRAGMENT**. A fragment is a self-contained description of an architectural component. Note that a fragment will be divided into several segments prior to doing a RST analysis. For a structured component, the fragments describing its contained components will be organised into a narrative structure where the fragments at the lower level are taken to be RST segments at the higher level.

A Relational Model for Document Architectures

From the above, we see that, for an architecture involving many different components at different levels in the hierarchy, there will be as many document fragments. For a document about the architecture, several of these fragments will need to be placed in a suitable order. Our eventual target is to develop a system where document fragments can be automatically extracted according to the architecture. To this end, we have developed a relational model for the documentation that corresponds to the system architecture. The novelty about this model is that these relations are also from RST. A fragment is central to our documentation model. Conceptually, this is similar to the component in the system architecture model.

Firstly, it needs to be noted that a fragment can be made up of other fragments. This is similar to the *contains* relation in the system architecture except that in the document model, a fragment's *narrative* is composed of other fragments' *narratives*. So, the topmost fragment will contain an description of the system and this is elaborated by fragments about overview of the system which is expanded by subsequent fragments (like sub-sections). We equate this to the RST ELABORATION relationship.

elaboration (fragment, fragment)

For components at the same level, the corresponding fragments need to be presented in an appropriate sequence. We propose using the *uses* relationship from the system architecture to determine the sequence. So, if component A uses component B, then we propose that the most suitable way to document it is to make fragment(A) appear before fragment(B). We call this second relationship SEQUENCE (also a RST relationship). We need to break loops in the *uses* relation by a suitable forward-reference mechanism. We recognise that even then the *uses* relation is only a partial order, but it seems not to matter which order unrelated fragments appear, as long as all the descriptions of the components that use them appear first.

sequence (fragment, fragment)

If components can be replaced by other components, it must be the case that the corresponding fragments can be replaced too. However, it is important to note that the replacement of document fragments works in the *opposite direction* to the replaces in the system architecture. Say, for instance, a newer component A' with more functionality is used to replace component A in a build. However, if fragment(A') is not yet ready, it is still possible to use fragment(A) in this case because only the capabilities of A are expected and realised. However, fragment(A) cannot be used in an instance where A' is required because it will not describe the extended functionality. The closest relationship in RST for this is RESTATEMENT. In RST, this means that one segment says the same thing as another in a different way.

restatement (fragment, fragment)

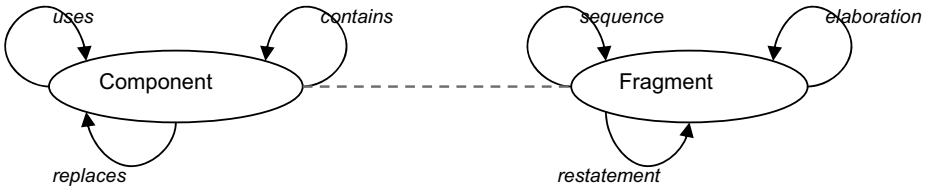

Fig. 4. The mapping between the system architecture model (left) and the document architecture model (right)

The figure above shows the mapping between the system architecture model and the document architecture model.

5. A SIMPLE EXAMPLE

We demonstrate the storage and extraction of document fragments using a simple example of a toaster T. T is made up of two subcomponents: the heating element (H) and the control module (C) which instructs H to start heating when the lever is pushed (thus, C uses H). Furthermore, H has a sub-subcomponent M, the timer.

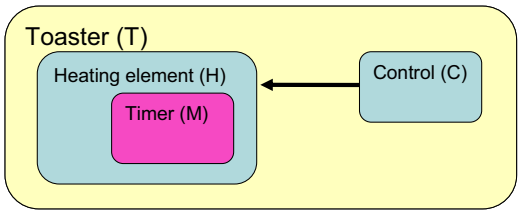

Fig. 5. A simple toaster T

Additionally, we know that a newer version of C, C', that can respond to changes in the 'browning level' made by the user can replace C. Similarly H' is more advanced and can vary the time of heat depending on the browning level. This information can be recorded using relational tables:

contains

container	slot	component
T	h	H
T	c	C
H	m	M

uses

user	service
C	H

replaces

superior	inferior
C′	C
H′	H

A sample document fragment structured according to the DN in Fig 3 for the toaster T is shown below:

> T is a basic toaster that can detect when the user has pressed down the lever and start heating the toast for a set time. Once this time has passed, the heating is switched off and the lever returned to its original position. T is composed of two subcomponents: the heating element (H) and the control module (C). These will be described later in the document.

Similar fragments exist for all the components except C' and H'. However, this does not affect the documentation for T which will have the fragments in the order shown below:

fragment (T)
- fragment (C)
- fragment (H)
  - fragment(M)

The hierarchical structure is obtained by the *contains* relation and the sequence from *uses* relation.

Another build of T (T') is made but since component C is not available it is replaced by C'. Fragment(C') does not exist but since only the functionality of C will be realised in this build, the documentation can remain unchanged.

A third build is now made based on T' (T'') which has H' instead of H. However, this time the fragment C cannot be used to describe C' since the additional functionality can now be used because the heating element is able to deal with temperature (browning) changes. Hence, the documentation cannot be completed until fragment(C') and fragment(H') are ready.

With a data model as the one shown, it is possible to determine whether all the fragments are available to produce documentation for a given build. For a simple example like this toaster, this may seem trivial. However, for large systems with hundreds of components where the documentation is received from many sources, the searching of fragments and generation of documentation becomes correspondingly hard.

6. CONCLUSIONS AND FUTURE WORK

Previously, we have worked on architectures and software reuse [15, 16], and more recently on the structure of technical documentation [9, 17]. In this paper we have brought these two strands of research together.

As future work, we will investigate the relevance of this documentation model in different varieties of system evolution. So far we have only studied the case where the components in a system become progressively more advanced. Other changes include re-factoring the system functionality (logically related components can be grouped to form one, say) and the production of a family of products that are based on a common core [4]. Is it then the case that the author starts with a core document that is relevant to all the products and extends it to fit each product?

The data model in this paper has also been implemented so that we are able to carry out further experiments with real systems.

Just as software components are reused to increase productivity, document fragments should also be reused. However, traditional documentation does not lend itself very well to reuse [18]. In order to reuse a component, one has to understand its functionality and how it can be used in a specific context. We cater for this requirement by arguing that successful reuse can be achieved by defining a common structure, extracting common information and extending current documentation.

Producing high-quality documentation is a complex task. It should ideally parallel the development of the artefact [19] and can benefit from reflecting the structure of the system being described [20]. We have shown that there is a strong mapping between the system architecture and the way in which its documentation is composed and thought about. We believe this will improve the quality of both the architecture and the documentation, and increase the extent to which both can be reused.

A Software Framework for Integrative Physiological Model Simulation

E. Zeynep Erson and M. Cenk Çavuşoğlu

Department of Electrical Engineering and Computer Science, Case Western Reserve University
10900 Euclid Av., 44106-7221, Cleveland, OH,USA *

Abstract

Emergence of systems biology motivated more comprehensive and integrative approaches for modeling physiological processes. Presented study proposes a software framework to integrate multilevel and multiscale models for physiological processes. The aim of the study is to provide the interfacing mechanisms to facilitate the integration of models from multiple research groups increasing the ability to construct complex simulations of physiological models. In this paper, high level design of the proposed system, integration of physiological models and the architecture to modularize the integration are presented. As the proposed system targets a multiscale and multilevel integration of mathematical models, complex diseases or physiological processes effecting many organs or organ systems, like diabetes, are within in the application areas. Besides enhancing the model development processes; the presented study will accelerate the development, analysis and testing of integration approaches for multiscale and multilevel physiological models.

1. Introduction

Emergence of systems biology provided a comprehensive and integrative perspective to examine the structure and function at the cellular and organism levels instead of focusing on the isolated parts [6, 14]. However the challenge of building medical simulations where multiscale and multilevel physiological processes are developed together is often too great for any individual group since expertise from different fields is required. Therefore it is necessary to have frameworks where various models can be integrated leading to new simulation models from independently developed models. The present study addresses this challenge and proposes a software framework to integrate mathematical models of physiological processes ranging from intra cellular level up to organ, organ system and organism levels. Specifically; the aim is to facilitate the integration of multiscale and multilevel models of physiological processes in a modular framework. To achieve this task, instead of building the architecture based on the domain specific components such as anatomical and physiological information; we are focusing on the application enforced functionality, *integration of information*.

Mathematical models for the physiological processes represent the regulation, control and modification of a physiological variable which has an effect on defining the current state of the whole system [7]. A change in a physiological variable has a direct or indirect effect on processes determining other physiological variables. In other words, every physiological variable carries an information which needs to be accessed, used, modified or integrated by other variables. Therefore integration of physiological processes is conceptualized by the transfer, access or sharing of information among the models representing the processes, and will be referred as *information flow* throughout the paper.

In the proposed framework, models to be integrated are decoupled by separating the mechanisms of information flow from the information itself. Information flow architecture, which is a crucial part for the model integration is the focus for this paper.

In addition to the integration of various physiological processes, the software will also enable using different integration algorithms and approaches with the interfacing mechanism. Therefore developers will have control on what to integrate as well as on how to do the integration. With these attributes, the framework will provide a user friendly, plug-and-play type environment where both individual models of physiological processes and different integration approaches can be used.

In the next Section (Section 2), studies that are using integrative approaches and their attributes which motivated the proposed architecture are summarized. The rest of the presentation for the framework will be based on a case sce-

nario using a circulatory system model [3] coupled with an IV drug model and its effects on a target organ [20]. In Section 3 details of the problem and the conceptualization of the system for integrating physiological processes is discussed. High level design of the proposed solution and overview about the system components are presented in Section 4. Design of the information flow idea, being the focus of this paper is discussed in Section 5 accompanied with the implications on the case scenario. Implementation details for the current status of the project are given in Section 6 to show how the components, which are not discussed in detail in this paper are integrated with the information flow mechanism.

2. Background

Integrating multilevel physiological processes requires both structural and functional hierarchical information for the contributing models. The hierarchical structure of the anatomy represents the organization starting from DNA sequences, RNA and protein, protein-protein interactions and protein-DNA interactions, to cells, tissues, organs, organ systems to the whole organism [6]. Modularity concept is also expanded for functionality in biological systems [10]. Importance of modularization is realized more as the multiscale modeling came into consideration for integrative physiology studies as modularization simplifies multiscale modeling [15]. Therefore in the proposed software framework, anatomical and physiological knowledge is defined using a modular, systematic representation.

One of the successful studies in cell level modeling, with an integrative approach, is the BioSPICE Project, which provides a framework for modeling, simulating intra and inter-cell processes. BioSPICE project also provides an integrative software environment that enables access to different computational biological tools [11].

Physiome Project [3], has a database of physiological models with different scale and levels. With the hierarchy of models from cell level to organ level, the project aims to analyse integrative biological function models and test the hypothesis using mathematical models [12]. JSIM [1], which is a Java-based system, is used to simulate the models in Physiome model repository. Although the models to be simulated vary from cellular level to organ and system level, they can only be simulated independently.

With the emergence of systems biology, development of modeling and simulation tools for this domain increased, such as, SCIRun [5] and Systems Biology Toolbox for Matlab [19]. Although SCIRun is a general purpose problem solving environment for physical and biological systems, it does not provide a simulation and modeling framework. It uses a data-flow architecture to integrate the steps of preparing, executing, and visualizing simulations of physical and

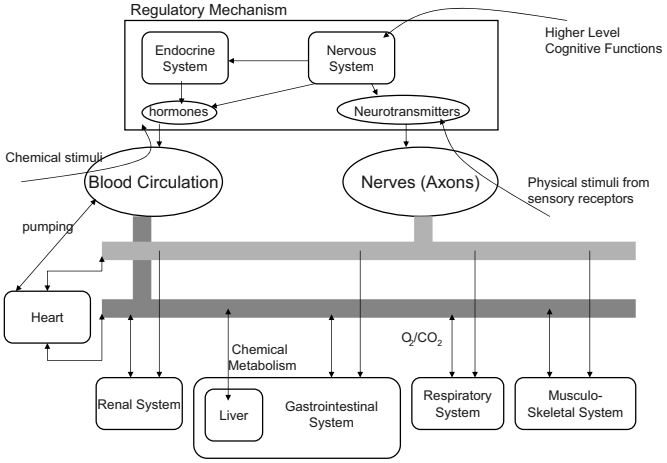

Figure 1. Information flow among physiological processes through circulatory and nervous systems.

biological systems. The Systems Biology Toolbox for Matlab provides an extensible environment for modeling, simulation, importing SBML (Systems Biology Markup Language) models and analysis tools.

Modeling and simulation of complex physical systems have been extensively studied outside the biology domain. There are tools and languages, such as, Modelica [4], Matlab Simulink [2] and Ptolemy [9] that provide creation and simulation of mathematical models for physical systems as well as integration of submodels. However none of these tools or languages are designed for the specific domain of biological systems.

3. Problem Specification

Every physiological property (blood pressure, blood glucose level, body temperature etc.) is associated with an anatomical structure; and the mechanism that controls, modifies and regulates is represented with a physiological process [8]. Circulatory and nervous systems are the mechanisms that manage the flow of information among the processes and physiological properties. The flow of information in the circulatory system can be thought of as a broadcasting mechanism, where information in the form of physiological variables are transported in the blood stream. On the other hand, the nervous system can thought as a point-to-point communication mechanism where the information in the form of electrical signals are transmitted (See Figure 1). Once the information is disseminated among the processes, individual models representing the processes integrate the available information.

A case scenario is used to present the proposed solu-

tion for the problem of handling information flow among physiological processes and integration of the information. In the presented case, concentration of an intravenous(IV) drug is the information to be carried through the circulatory system. Cardiopulmonary mechanics model from the Physiome Project Model repository [3] is used to model the circulatory system. The cardiopulmonary mechanics model is composed of a four-chamber varying-elastance heart, pericardium, systemic circulation, pulmonary circulation, coronary circulation, baroreceptors, and airway mechanics. Model for the IV drug represents the changes in the concentration of the injected drug in the injection site, vascular mixing, concentration in the arterial tree and concentration at the target organ [20].

4. High Level Design of the System

As seen in Figure 2, a layered design separating the structural and functional information from the information flow mechanism is proposed. The dependency among the layers are in one direction keeping the coupling among separate layers low. The design decision for separating the anatomical and physiological ontology and functionality, has an advantage for the reusability and extendability of the framework. The developers will be getting advantage of a higher level of reuse, which is an important advantage of using ontology based architecture [21].

Mathematical models are used to represent the dynamics of the physiological attributes. Mathematical representation of any processes is independent of the physiological variable that it controls, regulates or modifies. However every biological process depends on the mathematical model as it has different concurrency and time constraints. While some processes occur at discrete time steps and can be described by algebraic equations, some processes span a continuous time frame and can be described with differential equations. On the other hand some processes may not show a regular behavior, and can occur at specific times. Models of computation can be thought of as design patterns in object oriented paradigm, which will behave as the core of the solution [13]. Based on this analogy, the models of computation are modularized in *Computational Layer* and are classified according to the ways they deal with concurrency and time concepts, as: *Continuous Time Models*, *Discrete Time Models*, *Discrete Event Models*.

In order to have a modular representation of physiological processes and variables, a high level ontology is developed. Physiological processes are defined based on their qualitative, quantitative and temporal attributes. The systematic representation of the physiological information is modularized in *Physiological Layer*.

Anatomical associations of the processes are defined with the hierarchy represented through the anatomical ontology. Foundational Model of Anatomy, FMA [16, 17, 18], is used to represent the taxonomy and part-whole relations for the anatomical information. Ontological representation of the anatomical information is defined in *Anatomical Layer* and is independent from all other layers.

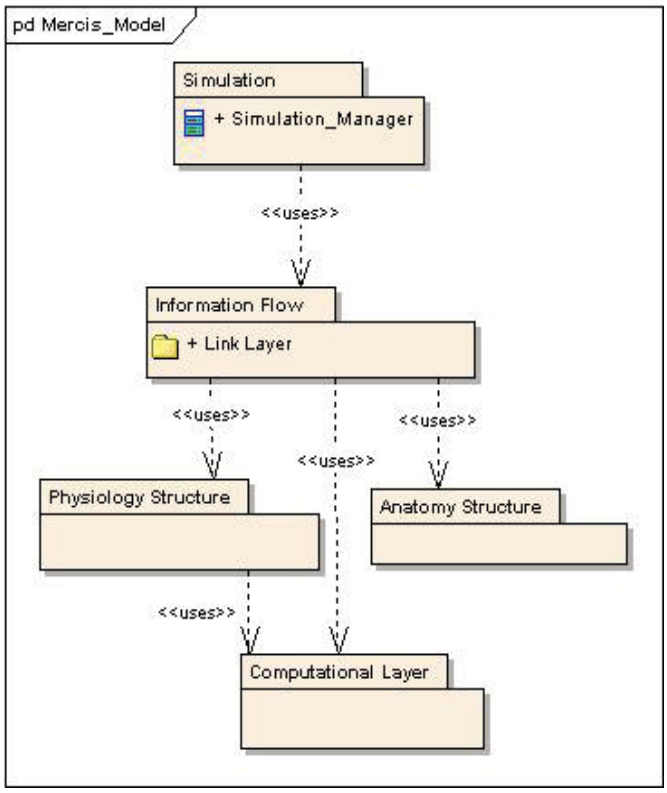

Figure 2. High Level Design

In the architecture shown in Figure 2,link layer handles the flow of information and integration of the information uses the anatomical and physiological information from the lower levels (See Section 5). Simulation of the integrated models is managed by the *Simulation Layer*, behaving as an application layer. In the following section details for the *Link Layer* is given within the realm of information flow and information integration.

5. Information Flow

Link Layer which sits on top of the physiological and anatomical layers, is designed as in Figure 3. Structural and functional information is encapsulated in *Component*s, which correspond to a single physiological variable and a corresponding model. A number of components come together to represent a physiological process. In the presented sample models, cardiopulmonary mechanics is composed of 182 *component*s each of which correspond to a physiological property with a mathematical model. The depen-

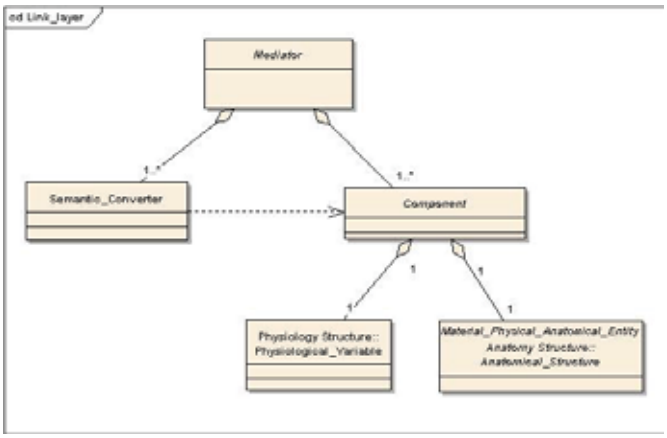

Figure 3. Design for the layer responsible of the information flow among the individual physiological models.

dency among physiological variables are defined through *Semantic Converters*. These units decouple physiological variables by encapsulating the semantics of the dependency. In the case of the cardiopulmonary mechanics model, mathematical model regulating the cardiac output depends on the values of the flow through the aortic valve which depends on other variables. Such dependencies among variables are also used to determine the simulation order. Therefore the semantics of the dependency among the *Components* is defined in the *Semantic converter*s and is used by the *Mediator* to pass to the upper layer, *Simulation Layer*.

Mediator is responsible for compiling the integrated models to handle mediation of information, results of which will be passed to the simulation layer to run the models. In order to have a serializable simulation order of components, the dependencies among components should be resolved. The *Mediator*, resolves the cyclic dependencies in the compilation process. Except for the algebraic loops, *Mediator* will resolve the cycles and create a sequential order of components using the dependencies defined by the *Semantic Converters*.

For the case of the circulatory system, information flow idea presented above is extended. Components that are part of the circulatory system are grouped as *Extrinsic* and *Intrinsic*. Intrinsic components correspond to the physiological variables and models that determine the mechanics of the flow of information, such as the cardiac output, flow of blood at the arterial tree, blood pressure, etc. Extrinsic components correspond to variables representing the information carried through the blood stream, using the intrinsic information. In the presented case, cardiopulmonary mechanics model constitutes as the intrinsic model. Model determining the concentration of the IV drug corresponds to the extrinsic model. Therefore, components in the IV drug model integrates the information from the cardiopulmonary mechanics model and transports the information about the concentration of the injected drug in to the circulatory system. These two models are integrated over the cardiac output variable which is defined as an intrinsic component. If the IV drug model were to be simulated as is, the cardiac output variable will be a constant and its regulations, changes will not be considered. By integrating the cardiopulmonary mechanics model with the IV drug model as an integration of intrinsic and extrinsic models, we were able to see the effect of change in cardiac output on the drug concentration in the blood stream.

Two types of integration schemes are used in the proposed system. The presented case of integration of information through the circulatory system, is an example of *horizontal* integration. Horizontal integration refers to the flow of information and integration among the physiological variables which have the same level anatomical structure associations. In the presented case scenario,the variables for the cardiac output in the IV drug model and the cardiopulmonary mechanics model were horizontally integrated. The integration mechanism replaces the constant representation of one variable in IV drug model with the regulated variable in cardiopulmonary mechanics model. Anatomical information associated with the physiological processes guide the integration process and determine the choice for the semantics of the integration. In the IV drug model, the cardiac output, defined as the blood flow through heart is an attribute associated with the heart. The variable to be integrated on the cardiopulmonary mechanics model is associated with an anatomical structure, the same structure in this case, which is in the same level in the anatomical ontology representation.

The other type of integration is the *vertical* integration. Multiscale and multilevel integration of physiological processes will be handled with this type of integration mechanisms. In the case of multilevel integration, the variables to be integrated are associated with anatomical structures having part-whole or parent-child relationships. Semantic converters will implement the vertical integration approaches. Aggregation and dispersion of the variables are the basic approaches proposed for implementing semantics of the vertical integration of multilevel models. For the case of the multiscale integration, the real challenge is at the computational side. There are two approaches to simulate multiscale models. The first approach is a brute force technique, and relies on simulation of all the individual (low level) subcomponents to aggregate and compute the high level behavior. This type of aggregation is naturally supported by the object-oriented design, which allows hierarchical construction. However there is a practical limitation of this approach, the computational cost. The second ap-

proach tries to reduce the computational complexity by relying on model reduction techniques. Since mathematical models for complex biological systems both contain linear and nonlinear models, an approach handling both of these systems should be adopted. Model reduction for large scale nonlinear dynamical systems is an open problem and is outside the scope of this paper.

6. Implementation Details

Current implementation of the proposed system uses models from the Physiome Project repository. Physiological processes in this repository systematically describes models from the literature using the Mathematical Modeling Language (MML). Presented system preprocesses MML models to create the library of mathematical models to be used by the physiological processes. MML files are parsed on line to create *Component*s with the physiological variables. On line parsing also creates *Semantic Converters* extracting the dependencies among the physiological variables from the model equations. Model developers can choose to associate these components with anatomical structures using the ontology representation in the framework.

In Figure 4, a prototype is presented to build the integrated system for the aforementioned system with the cardiopulmonary mechanics and the IV drug model. The first step is to build the medium for the flow of information, circulatory system. As stated in Section 5, models contributing to the mechanics of the circulatory system are modeled as *intrinsic* models. Having defined the intrinsic variables for the circulatory system, the second step is to add the extrinsic information to the model. Users can load the selected .mml file and add the information to the circulatory system by declaring the model as an *extrinsic* model. Third step is presented to show how the information flow mechanism can be used to access the variables in the circulatory system. In Figure 4, the third model loaded is the part of the IV drug model which calculates the effect of the drug at a target organ. This model accesses both the intrinsic variables, such as the blood flow and extrinsic variables like the drug concentration in the blood stream. Although the dependencies within a single model are extracted automatically by the parser, the points of integration for the loaded models should be user controlled. The last step handles the horizontal integration among the user defined integration points, which are the cardiac output and concentration of the drug in arterial system for the presented case. Having the required information to compile the model to prepare for the simulation, *Mediator* compiles the models, performs the integration, and passes the required information to the simulation step.

7. Conclusion

In addition to providing an integrative simulation environment for complex biological systems, the presented architecture will facilitate shared model development as well as data and model sharing among multiple research groups. Therefore the proposed framework will bring a new perspective with the multiscale, multilevel model integration approach.

Although major components of the system are complete, the development step is being pursued in the context of possible applications. As we are targeting a multiscale and multilevel integration of mathematical models, diseases or physiological processes effecting many organs or organ systems are within in the application areas. Diabetes, which has complications such as heart diseases, blindness, nerve damage and kidney damage, is one of the most interesting application areas, having effects on many organs and organ systems. Another complex process which presents an application area for the proposed framework is Orthostatic Tolerance. It is a very critical measure for astronauts or anyone who faces sudden gravitations changes and gravitational stress. Orthostatic tolerance is dependent on the degree of vasoconstriction and the magnitude of plasma volume, which in turn determines the tendency to faint when standing upright. This mechanism, having effects on circulatory system and nervous system is another very interesting application area to integrate different models in our software framework.

Abstract

This paper summarizes the results of an industry case study that introduced a cross-system business process automation solution based on a combination of SOA and BPM standard technologies (i.e., BPMN, BPEL, WSDL). Besides discussing major weaknesses of the existing, custom-built, solution and comparing them against experiences with the developed prototype, the paper presents a course of action for transforming the current solution into the proposed solution. This includes a general approach, consisting of four distinct steps, as well as specific action items that are to be performed for every step. The discussion also covers language and tool support and challenges arising from the transformation.

Keywords: SOA, BPM, BPMN, BPEL, WSDL, standards, application integration, BPIOAI, web services

1. Introduction

As part of their efforts to automate enterprise-wide business processes, organizations are often faced with the challenge of integrating the data and business logic of several independent application silos [6]. This issue is traditionally addressed through custom-made solutions that are expensive to build and maintain, inflexible to changing requirements, error-prone and often poorly aligned with the enterprise's business goals. One promising and increasingly recognized approach to this problem is to combine Business Process Management (BPM) and Service Oriented Architecture (SOA) concepts and technologies with the goal of forging a flexible and cost-efficient process automation and system integration solution. In combination, both paradigms appear to be of significant benefit to each other. BPM's lack of focus on architectural principles (e.g., loose coupling, service reusability) and its poor flexibility in regard to technology choice (i.e., vendor lock) are addressed by SOA. SOA on the other hand can benefit from BPM's top-down, requirements-oriented, and visualization-focused approach that considers the entire life cycle of business processes.

Despite the general recognition of a SOA and BPM convergence and the resulting synergy [3, 7, 9], there is still an extensive lack of best-practice examples and real-life industry adoption, in particular in medium-sized and small enterprises. One reason for this is a shortage of resources paired with the common believe that SOA and BPM initiatives only bring return on investment (ROI) if applied on a large scale. While this assumption may hold some cases, we argue that using the suggested paradigms results, even in small-scale scenarios, in considerable benefits that have the potential of significantly outweighing the anticipated costs.

To back this proposition, we conducted an industry case study with the goal of applying a combination of SOA and BPM concepts and technologies as a replacement for a custom-made, proprietary process automation solution. Our focus was the universal use of standards, specifically the Business Process Modeling Notation (BPMN) and the Business Process Execution Language (BPEL). In particular, we identified weaknesses of the currently deployed solution and specified a transformation of this solution to the envisioned replacement, including a roadmap with specific required action items along with the selection of pertinent tools. Finally, to address financial considerations as well as several other concerns, we thoroughly evaluated and compared both solutions, with special emphasis on addressing the previously identified weaknesses. The study was conducted in the setting of a top-five global hosting company with the intent of delivering a proof of concept for the feasibility and impact of the proposed approach. The transformation itself was realized in the form of a prototype (PT) that included process-models (BPMN) and -code (BPEL), service interfaces (WSDL) and "dummy" implementations of services, but no end-to-end implementation with the actual enterprise applications.

Our work was influenced by recent publications addressing the SOA/BPM convergence (e.g., [3, 7, 9]) as well as general literature on approaches to application integration [5] and SOA [1, 4, 6]. During the PT development, we have relied extensively on the BPMN-to-BPEL mapping rules [8].

The remainder of this paper is organized as follows. In section 2, after briefly describing the existing solution and its weaknesses, we introduce the chosen pilot process. In section 3, we present the approach and results of the transformation, while section 4 compares both solutions and discusses how the issues from section 2 are addressed. We conclude with a summary and a discussion of future work.

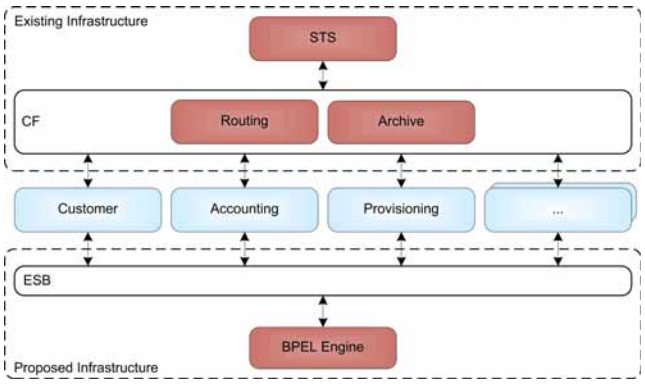

Figure 1. Enterprise Architecture

2. Initial Situation

The environment's system landscape comprises ten physically separated back-office applications that each take over a distinct business or auxiliary function (e.g., Accounting System, cf. Fig. 1). Together, these systems fully automate most of the company's business processes including sales, billing, and provisioning, to name a few.

2.1. Existing Process Automation Solution

The company's process automation approach integrates a custom-made state transition system (STS) for process state management and business rule enforcement with a custom-made communication framework (CF) for system integration (cf. Fig. 1 top). Information exchange between back-office systems is realized via asynchronous XML-based messaging. Typically, a new process is brought to life inside the STS, which is triggered by an external event such as the submission of a new sales order. The STS manages the process execution by sequentially starting various integration flows via the CF. Integration flows commonly visit several back-office systems (sequentially and without the involvement of centralized coordinator), cause business logic updates and/or collect data, which is attached to the message and used later inside a different system as part of the overall process. Each integration flow eventually returns to the STS causing a process status update, which results in further actions.

2.2. Solution Benchmark

We have identified four high-level issues: initial development and setup costs, maintenance costs (i.e., integration of new systems, implementation of new business requirements, etc.), technology and solution learning curve and the likelihood of introducing errors during the mapping of business requirements to process implementations. Upon examining these issues, we have detected four problems as their respective root causes. In turn, these problems give rise to the criteria for the evaluation and comparison with the suggested solution.

1. *Lack of Sufficient and Practical Documentation*

Acquiring sufficient knowledge to understand and work with the existing solution requires collecting and aggregating information from various sources (e.g., people, documents, code) and was experienced as a highly time-consuming part of the case study. Also, the poor documentation increases the likelihood of introducing errors. Besides a lack of language and technology tutorials, which can be ascribed to the proprietary nature of the solution, the environment also misses a common communication basis in the form of a process model that can be shared among business analysts, architects and programmers. Without such a model, new requirements are likely to be misinterpreted when handed to a programmer. Finally, even if sufficient documentation in the form of state-transition (ST) tables, ST diagrams and flow diagrams were available, it would not provide a complete and practical picture.

2. *Complexity of Solution and Process Setup*

First, the initial setup required building most components from scratch. This includes the STS with database setup, database triggers, stored procedures, the event module as well as the CF with its routing and archive modules, message parser but also the development of the message structure (i.e., routing information) and other rules for new process setup. Merely the message queues (MQ) (one per system) could be acquired from a third-party vendor. Second, new processes or even slight adjustments in existing processes require careful and complicated planning and design. States, state transitions and events need to be designed and set up. Routing information has to be added or changed, integration flows and additional message parsers have to be implemented. This high effort of process maintenance is even further intensified by the solution's poor separation of concern (SoC). Although process implementations are distributed across two components (i.e., STS and CF), the solution places some of the process-specific behavior inside the back-office systems (i.e., in some instances, the route of an integration flow is changed during system invocation). This again requires most systems to be aware that they are part of a higher-level process and hence prevents them from being reused by other processes.

3. *Poor Deployment and Testing Conditions*

Process deployment requires manual addition or replacement of routing information, states, events, etc. "One-click" deployment is not supported. The effort for process testing has been indicated by responsible personnel as being extremely high. First, the various steps of a process (i.e., the systems invocations) cannot be tested individually but only as part of an integration flow. Second, process debugging is only possible in retrospect by evaluating the log files of completed flows. Third, the solution does not allow for design-time code validation through respective tools.

4. *Degree of Business-IT Alignment*

The solution is clearly deficient with respect to the alignment of the enterprise's processes with its IT infrastructure. The nature of the solution generally makes it difficult to translate business requirements into implementations. Every process, coming as a whole from the business side, needs to be split up into several flows that are tied together via the STS. It

is often difficult to decide which parts of the process should be realized through flows and which parts require state and corresponding state transitions. Also, the question arises whether process-specific rules should be enforced inside the STS or inside the pertinent back-office system. In addition, the implementer must sometimes deviate from the order of steps provided by the business analyst.

2.3. Selected Business Scenario

As the basis for our PT, we chose the company's sales process as the pilot to be implemented with the suggested approach. We picked the sales process because of its universality (i.e., industry neutrality), its size and complexity (involving all of the organization's back-office systems), and its volatile nature that would emphasize the benefits of the proposed solution. At a glance, after an order has been placed via an online shopping cart environment, the back-end process is started performing various steps including the creation of a customer account, a fraud check, the processing of financial transactions and the initiation of product provisioning. Each step is implemented by a different back-office system.

3. Solution Transformation

After analyzing the existing process automation solution and taking a closer look at the selected pilot process, it became clear that a simple transformation to the suggested technologies and paradigms would be insufficient to best demonstrate their benefits. First, a mere transformation without addressing the poor SoC of the current setup including its weak service reusability potential did not appear to be meaningful or at least would not allow us to demonstrate the potential for reusability in the long run. Second, during the reverse-engineering effort of the sales process from source code and residual process documentation, we were able to discover several crucial errors in process logic that could easily be repaired with the new approach. Finally, the current solution does not implement process-wide transactional behavior; this issue could also be addressed effortlessly and hence was added to the list of objectives.

To reduce the complexity of the transformation process, we decided to address the various goals and objectives in four sequential steps. This so-called "transformation lifecycle" (Fig. 2) can be reused for porting additional business processes in the future. Phase one sought to integrate the existing systems using BPEL. This implies exposing the respective functionality via web services (WS). Additionally, the issues of SoC and reusability have been addressed by shifting some functionality between systems and by applying well-deliberate service design. Phase two aimed to bridge the gap to the business side by providing a visual, more business-oriented representation of the sales process using BPMN. Based on the newly created models from phase two, phase three directly repaired process errors and added business transactions from a requirements-oriented standpoint. Finally, phase four synchronized the adapted process models with the previously created implementation. Each of the four

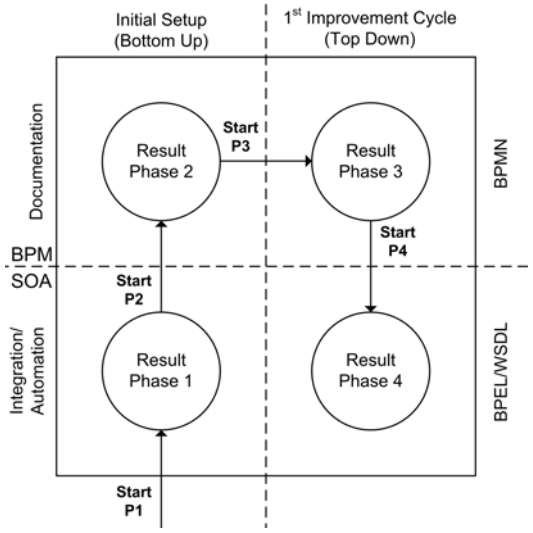

Figure 2. Transformation Life Cycle

steps will be discussed in detail below.

Phase 1: Bottom-Up Process Automation

In phase one BPEL v1.1 and WSDL v1.1 where used with Oracle's JDeveloper tool that supports various SOA-related development tasks including service-stub generation from WSDL-files and visual BPEL modeling.

First, we exposed the existing systems as WS. As a result, 100% of the systems' functionality (i.e., business logic) was reused and system access has merely been transformed from the CF to WSDL-based access. One important task was the definition of service inputs and outputs: business documents, such as an invoice, that are specified through XML schemas. The challenge was to transform the structure of the existing XML message into various modular schemas that can each be passed into the respective service, individually or in aggregated form. The transformation was required for adopting BPEL's orchestration approach. A BPEL process locally stores process data, such as a sales order (consisting of a quote, customer data, product selection, etc.), and extracts data (e.g., one specific product item) in the course of a service invocation as needed. A second challenge was to improve SoC and potential for reusability. To this end, we moved some functionality between systems as well as from the systems into the process. The newly created services have been designed accordingly (i.e., assuming the functionality in the new place).

Second, we implemented the sales process in BPEL by orchestrating the previously designed services. This required a transformation of the state- and flow-based solution into an activity-based solution. Process state management and routing of messages is now realized transparently by the respective infrastructure, and the various integration flows were combined into one process. Our experience was that all aspects of the sales process could be expressed in BPEL with no restrictions.

As our deployment and testing environment, we installed the Oracle SOA Suite. It ships with an Enterprise Service

Bus (ESB) and a BPEL engine and integrates nicely with the chosen IDE (JDeveloper), allowing BPEL processes and services to be deployed from within the IDE. The installation of the BPEL engine and ESB, or optionally a lightweight WS framework, makes the STS and CF obsolete (cf. Fig. 1). With some careful planning, it should also be possible to run both solutions concurrently until all processes have been ported.

Phase 2: Bottom-Up Process Visualization

The potential of the proposed solution can be fully utilized only with the addition of a process model that may be used as a communication basis among participating stakeholders. In phase two, we performed a mapping from the created BPEL code to a visual BPMN-based process model using BPMN v1.0. The model was created with the Microsoft Visio stencil extension from ITP Commerce. The resulting business process diagram (BPD) is illustrated in Fig. 3 (exclusive the highlighted parts). The mapping was done based on the rules by [8] and turned out to be very straightforward. All aspects of the BPEL code could be transformed to the BPD.

Phase 3: Top-Down Process Adaptation

The objective of phase three was to repair flaws, to add additional functionality and to make the process transaction-safe. Tool and language support is identical to phase two. As a first task, we swapped some steps in the process, which were out of order in the existing implementation. Secondly, we added one extra step at the end (i.e., "Send Order Completed Notification"), which was missing in the original solution. Thirdly, we extended the BPD with a manual order verification option and finally added rollback processes that would reverse prior system updates in case of process failure. The resulting artifact is an extended version of the BPD from phase two (i.e., Fig. 3, inclusive the high-lighted parts) as well as additional BPDs for rollback- and related processes (not shown here). It is important to recognize that phase three is entirely requirements-driven and independent of the underlying process and system implementations. Nevertheless, the new functionality was modeled based on design decisions that determined which system had to implement the new requirements in the future.

Phase 4: Top-Down Process Implementation

The final step in our life cycle was the synchronization of the BPDs from phase three with the existing implementation from phase one. Tool and language support are the same as in phase one. Most parts of the BPDs were implemented with no effort by using the visual process modeler of the IDE.

The implementation of the manual verification step and the transactional behavior is of interest. The latter was necessary to map the rollback processes from the BPD to the BPEL implementation. BPEL realizes loosely-coupled business transactions with its built-in compensation and fault handlers. A very convenient BPEL feature is the automatic execution of compensation handlers of those scopes that are already completed when the error occurs. An example for our case is the deletion of the sales order in the Sales System and the reversal of the "Create Customer Account"-sub process (e.g., after an order expired while waiting for manual payment, cf. Fig. 3). Both steps required an extension of the previously created WSDL interfaces with additional operations that simply reverse the existing operations.

The manual verification of orders naturally requires human involvement. Unfortunately, BPEL does not support human interaction in a standardized way. On the other side, we purposely refrained from using Oracle's proprietary BPEL extension for human workflows to avoid vendor lock. We rather addressed this issue by simply hiding the human involvement behind a custom-made service. In this case, the process asynchronously submits the sales order to an "Order Escalation Service," which prompts the need for order-verification to a user interface. The process waits in the current status until it is called back by the service after the issues has been resolved.

4. Evaluation and Solution Benchmark

This section benchmarks the existing solution against the proposed solution. We will discuss the issues identified in section 2.2 and outline how they are addressed in the new solution. We also provide some specific figures (i.e., cost savings) based on our experiences with the PT development. Nevertheless, the results presented here are conjectures that have not been measured owing to time restrictions. Determining the actual ROI would require operation and observation of the new solution in production environment over a period of several months.

In summary, the proposed approach combines state-transitions and integration flows into one artifact (i.e., BPEL process) whereas the BPEL engine orchestrates the various services into one enterprise-wide process. Changes in routes are now handled inside the process. Messages are transmitted per service invocation and not per flow. Service reusability is improved and process-wide transactional behavior is provided. The solution comprises an end-to-end process model clearly displaying all business requirements. Finally, the STS and CF are replaced by SOA and BPM infrastructure components (cf. Fig. 1).

1. *Documentation*

With the BPD (cf. Fig. 3) most information about the sales process and participating services is available at a glance. Aggregation of information from several sources (including source code review) is not necessary. The process clearly visualizes all steps, service invocations, possible faults, events, branches and business rules (e.g., expected values for decision points). The translation from the model to the implementation is unambiguous and the error likelihood is reduced. Since BPMN is specifically designed to be stakeholder neutral [8], it allows all participants to understand the model quickly. By contrast, ST- and flow diagrams may be harder to understand by purely business-focused staff. Furthermore, new stakeholders can quickly acquire

information about languages (i.e., BPEL, BPMN, WSDL) and infrastructure (i.e., BPEL engine, ESB) used in the project by studying some of the myriads of available tutorials and code examples. It will also be easier to recruit new stakeholders (e.g., engineers) that already carry the respective knowledge; this is not possible with a proprietary solution.

2. *Complexity of Solution and Process Setup*

The proposed solution has the potential of significantly reducing time-to market of the initial setup and of new requirements. Infrastructure is entirely replaced by third-party offers, which greatly reduces the setup time of the initial solution. Design and implementation of the generic parts of the STS and CF was indicated by the responsible manager with approximately US$70,000 (including purchase of several MQ licenses), which is already above the purchase price of a commercial SOA Suite license (US$50-65,000 assuming that one license will be sufficient). Nevertheless, despite the possibility of relying on open source infrastructure, we argue that even higher investments will pay off as the maintenance costs of enterprise applications commonly are much more significant [2] and this is where the suggested solution scores big points. Setup of new processes and adjustments in existing processes is far less time consuming. This is besides the improved testing conditions especially also ascribed to BPEL's predefined language constructs for process behavior as well as the tool support with its visual BPEL modeler, code generation etc. Furthermore, services can be designed for reuse, which again may reduce development time in the future. In particular, we anticipated savings of approximately US$10,000 in personnel cost only for the initial setup of the sales process. Simple adjustments in process logic can save up to 80% of implementation and testing time. With more complicated adjustments (e.g., the addition of a new payment option), this is even more significant.

3. *Deployment and Testing Conditions*

The solution's testing and deployment conditions have improved significantly. The infrastructure ships with built-in features that facilitate testing and debugging. Processes can be deployed effortlessly via the respective user interface or directly from within the IDE. Versioning is supported transparently (i.e., changed processes are deployed under a new version, running processes are completed in their old version). Furthermore, pre-deployment code verification is provided by the IDE and greatly reduces runtime errors. Finally, all services can be tested individually before attaching them to a process. The improved testing and deployment situation has a significant impact on the cost savings already discussed.

4. *Degree of Business-IT Alignment*

BPEL's orchestration approach in conjunction with the BPDs improves the solution's general degree of business-IT alignment. The process is visualized and implemented in a more natural way. Process behavior (e.g., branching, business rules, etc.) is integrated into one artifact and not distributed across several components. The number of steps in the process that cannot directly be mapped to a business requirement is reduced, thus, the gap between requirements and implementation is smaller.

5. Conclusion and Future Work

In this paper, we argued that a cross-system process automation solution leveraging SOA and BPM technologies can be significantly superior to a custom-built solution. We also presented an approach for porting the existing processes to the suggested solution. The study showed how the chosen concepts and technologies can be applied to a real-life scenario. All aspects of the pilot project (i.e. process model and implementation, services, etc.) were realized with the selected languages, and the PT was successfully tested. In conclusion, the study was a considerable success and demonstrated the merits of using a combination of SOA and BPM for process automation and system integration purposes. The resulting value gain was greatly recognized by the responsible personnel in the chosen environment.

Finally, to guarantee feasibility and long-term success, we recommend performing a more thorough analysis and evaluation of infrastructure and tool support for the specifics of the environment, including, for instance, issues such as tool selection. Second, an in-depth evaluation of quality of service aspects (e.g., scalability, security, reliability) should be performed. Furthermore, it may be advisable to extend the PT with an end-to-end implementation that involves the pertinent systems. As a last step, we believe that drafting an adoption strategy (i.e., guidelines, education of staff, adoption schedule) will help to discover other possible issues.

In general, the transformation life-cycle introduced in section 3 requires more case studies in order to adjust and generalize the porting process outlined in Fig. 2 in a way that it becomes useful also under different settings.

Ontology-Enabled Generation of Embedded Web Services

Klaus Marius Hansen and Weishan Zhang and Goncalo Soares
Department of Computer Science, University of Aarhus
Aabogade 34, 8200 Århus N, Denmark
{klaus.m.hansen,zhangws,afonso}@daimi.au.dk

Abstract

Web services are increasingly adopted as a service provision mechanism in pervasive computing environments. Implementing web services on networked, embedded devices raises a number of challenges, for example efficiency of web services, handling of variability and dependencies of hardware and software platforms, and of device state and context changes. To address these challenges, we developed a web service compiler, Limbo*, in which Web Ontology Language (OWL) ontologies are used to make the Limbo compiler aware of its compilation context, such as targeted hardware and software. At the same time, knowledge on device details, platform dependencies, and resource/power consumption is built into the supporting ontologies, which are used to configure Limbo for generating resource efficient web service code. A state machine ontology is used to generate stub code to facilitate handling of state changes of a device. A number of evaluations show that the design of the Limbo compiler is successful in terms of performance of the generated web service, completeness in being applicable to a variety of embedded devices, and usability for developers in creating new services.*

1 Motivation and introduction

Pervasive computing is becoming a reality. Because of their increasing ubiquity in business environments, web services are increasingly needed to be adopted as service provision mechanisms in pervasive computing environment. Consequently, in a number of applications, web services are deployed on resource-constrained embedded and networked devices. Implementing web services on embedded devices raises a number of challenges. First, embedded devices are constrained in memory, processor and energy resources. The web services should be sufficiently resource efficient in order to provide usable services. Second, development environments for embedded web services must be able to handle the variability of hardware and software, power supply, and possible dependencies between platform properties. At the same time, pervasive computing environments are highly dynamic, with, e.g., device statuses changing very often; something that affects end user applications.

A number of tools and approaches focusing on making web services available on small embedded platforms exist. One example is Microsoft's Web Services on Devices[1], and Fast Infoset[2]. Fast Infoset is not a web service technology per se, but provides a binary encoding of XML that may be used to make web services more efficient in the sense that they use less bandwidth in communication. These tools, however, fall short in the flexibility of code generation and complexity hiding of device details and web service details for the developer. At the same time, they lack the extensibility for using new protocols and technologies, when considering the huge variance of embedded and networked devices.

To address these issues, in this paper, we present *Limbo*, an ontology-enabled compiler for the generation of embedded web services. A number of Web Ontology Language (OWL[3]) ontologies are used to encode device details, platform dependencies, resource/power consumption, and valid Limbo components combinations, which are used to make the Limbo compiler aware its compilation context, such as the appropriate hardware and software for a given service. Runtime states of a device are handled with a state machine ontology and stub code is generated to support reporting device state changes.

The development of Limbo is part of a large, European research project, Hydra[4] that develops secure, service-oriented, and self-managed middleware for pervasive computing application scenarios.

The rest of the paper is structured as follows: in Section 2, we present the design and implementation of Limbo; followed by is the section on how to use the generated code

[1] http://www.microsoft.com/whdc/rally/Rallywsd.mspx
[2] https://fi.dev.java.net/
[3] http://www.w3.org/2004/OWL/
[4] http://www.hydra.eu.com/

for the development of web services. Section 3 discusses ontologies used in Limbo. In Section 4, we present the configuration algorithm used in Limbo. Then we evaluate the Limbo compiler in Section 5, from the perspective of complexity, usability and performance. We compare our work with related work in section 6. Conclusions and future work ends the paper.

2 Limbo design, implementation, and usage

2.1 Limbo design and implementation

Figure 1 shows the module structure of the Limbo compiler. The software architecture of Limbo follows the "Repository" architectural pattern [5] in which a central *Repository* stores data related to the transformation process and on which *Frontends* and *Backends* operate to read and write information. Frontends process source artifacts (in particular web service interface descriptions in the form of WSDL [5] files and ontology descriptions in the form of OWL files). Conversely, Backends produce target artefact's in the form of code (primarily state machine stubs, web service stubs and skeletons) and configuration files.

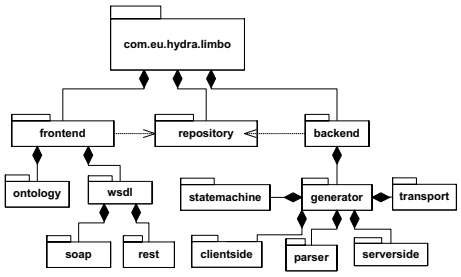

Figure 1. Module structure of Limbo

Backends implement different features. An essential feature is the parser backends with different implementation languages such as Java SE and Java ME (Java Standard Edition/Java Micro Edition). An example of generation can be the generation of client-side stubs and/or server-side skeletons or transport code for network communication between client and a server. To provide the possibility of handling dynamicity of device state changes, a state machine backend generates state machine stubs. Figure 2 shows the compilation process of the Limbo compiler. A "thermometer service" is used to illustrate the compilation and the usage of the generated artifacts. In the example, the service runs on a thermometer device, Pico TH03, and provides a temperature measurement upon request. The following steps are involved:

[5]Web Services Description Language 1.1. `http://www.w3.org/TR/wsdl`

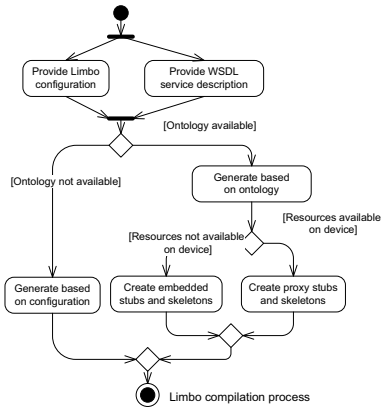

Figure 2. Limbo compiling process

- *Provide WSDL service description*: The main input for Limbo is WSDL file, and Limbo also supports that WSDL files references the Hydra device ontology. An example of a Hydra ontology binding for the thermometer in WSDL would be the following:

```
<hydra:binding device="http://hydra.eu.com/ontology/
                       Device.owl#thermometer"/>
```

  The Limbo ontology front end will resolve this URI and retrieve thermometer hardware and software information.

- *Generation based on configuration or ontology.* If an ontology instance for the device is available, device specific platform information will be used to generate client and/or server code. If the device associated state machine instance available, state machine stub code will be generated. Otherwise, generation configuration is based solely on the developer-supplied parameters.

- *Create embedded/proxy stubs and skeletons.* Stubs and skeletons for the device service are created according to the device's capabilities. If code cannot be directly embedded on the device, proxy code is generated based that will run on OSGi[6]. For the thermometer, as it does not have any computing capability itself, according to the the retrieved platform information from the ontology, proxy code will be generated using OSGi.

2.2 Implementing services based on generated code

For the thermometer with a configuration of a standalone server using Java SE, the following classes are generated:

[6]`http://www.osgi.org`

- *EndPoint.java* - Abstract class that defines the endpoints (i.e. services) that are provided by the server
- *th03OpsImpl.java* - Implementation of the service methods
- *th03Service.java* - A service class that handles requests and returns the respective results
- *LimboServer.java* - Limbo server main class
- *StateMachineStub_Thermometer.java* - State machine stub for thermometer

An OSGi configuration (Java SE) or a Java ME server can be chosen, and Limbo can also generate clients either for Java ME or Java SE. The generation of OSGi code is following the OSGi specification (e.g., an Activator instead of an EndPoint, a servlet instead of a "th03Service"). Classes are also generated to support this in the form of a state machine stub that will allow the service developer to model and notify upon state changes. The following code is generated for the thermometer state machine shown in Figure 3, and the measuring state of the thermometer is linked to the getTemperature service.

```
public class StateMachineStub_Thermometer {
 public void  ThermometerStopping() {  ...  }
 public void  ThermometerStarting(){  ...  }
 public void  ThermometerMeauring(){
  event ev = new event();
  ...
  ev.parts_add(new part("Result",
    "" + service.getTemperature(this.deviceID)));
  eventManager.publish("/statemachine/statechange", ev);
 }
 ...
}
```

Based on the generated artifacts, the device developer needs to implement the device service. This entails:

- *Binding the device services to the actual device.* For the thermometer service this would include, e.g., creating a thread that continuously calculates the temperature and stores the temperature in a local variable. The actual service implementation would then read the value of this variable and return the temperature.
- *Sending state notifications.* The state machine stub needs to be invoked at proper places. In the case of the thermometer, each successive call will at runtime trigger an event being sent through the event manager (Figure 3), when the thermometer is started, when it is measuring, and when it stops as shown in the thermometer state machine in the lower part of Figure 3.
- *Create deployment artifacts.* Next, device and container-specific deployment artifacts (JAR files, OSGi bundles etc.) need to be created in order to be able to deploy the service.

The upper part of Figure 3 shows a typical runtime of a deployed Limbo service. The thermometer service is deployed on a Thermometer Device. A service that needs temperature data ("Thermometer Client") then uses the thermometer service through its web service interface. Thermometer state changes trigger events sent through a publish/subscribe mechanism.

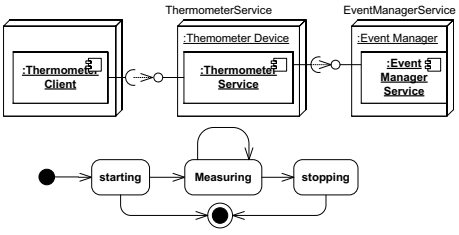

Figure 3. Thermometer runtime and thermometer state machine

3 Ontologies in Limbo

There are a number of reasons for us to use ontologies in Limbo: first, details of device hardware and software, and possible dependencies between them, are hidden in the related ontologies. Web service developers only need to know about the device URI and the service they are implementing, as shown in the Thermometer example. Second, in order to generate resource-efficient code, knowledge on device software platform and resource/power consumption comparisons are built into the related ontologies, and used during the configuration of Limbo for code generation.

We have developed the supporting ontologies for Limbo as shown in Figure 4. The usage of these ontologies can be summarized as follows:

- *LimboConfiguation ontology*. Not all the combinations of the frontends and backends in Limbo are valid. For example, for OSGi, there is no need for the Server generator as a web server is built into OSGi frameworks. Therefore it is very important to regulate the valid combinations of different Limbo components and resolve dependencies among them, whether combinations are explicit in the feature model or implicit. As proposed in [6], we develop a LimboConfiguration ontology to formally specify what the legal feature combinations are.
- *Device ontology and associated hardware platform and software platform ontologies*. These ontologies are used to retrieve device specific information in order to generate resource/power-awareness code for a certain device. The Device ontology is used to define high

level only information of a device, for example device type classification (e.g., an alarm device is a sensor).

The HardwarePlatform ontology includes concepts such as CPU, Memory and so on, and also relationships between them, for example ”hasCPU”. Power consumption concepts and properties for different wireless network are added to the HardwarePlatform ontology to facilitate power-awareness.

The SoftwarePlatform ontology defines VirtualMachine, Middleware and object properties such as *requiresMoreMemory*, *reuqiresFasterCPU*, and their reverse properties. In the Java ontology we define concepts such as JavaVM, JavaByteCode and specify that a specific Java platform (e.g., CLDC) provides a certain Library or Rendering Engine etc.

The OperatingSystem ontology provides a classification of an operating system based on its characteristics and version for example Win32/Win16, which can facilitate the restrictions on which operating system consumes more memory than others.

- *StateMachine ontology*.

  For every type of device in the Device ontology, there is a corresponding state machine instance in the StateMachine ontology. This state machine instance is used to generate state machine stubs.

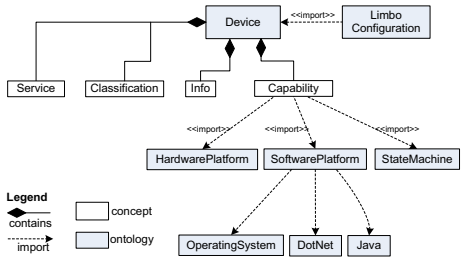

Figure 4. Structure of ontologies used in Limbo

4 Limbo configurations with ontologies

In order to generate resource efficient code, Limbo will utilize the resource/power consumption knowledge built in the ontologies. Therefore the LimboConfiguration ontology imports the Device ontology, and hence all other ontologies through the ontology import mechanism. Object properties in the LimboConfiguration ontology (*requireCPU*, *requireOS*, *requireVM* and *requireLibrary*) are used to specify a backend's detailed requirements for the CPU, operating system, virtual machine, and libraries. The Limbo configuration algorithm is shown as a UML activity diagram in Figure 5 and described next.

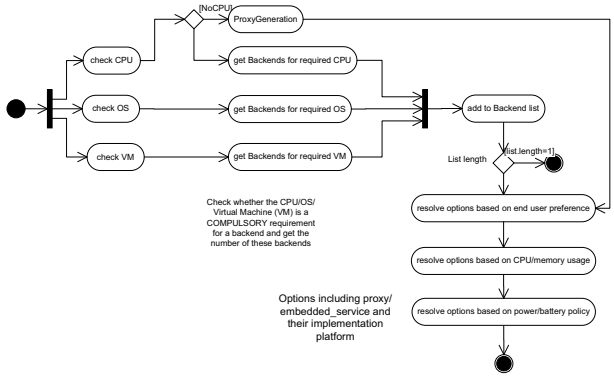

Figure 5. Limbo configuration algorithm

Step 1. Checking CPU/OS/VM details When a compiling task is needed for a certain device, first the detailed software and hardware information, especially CPU, operating system, virtual machine will be retrieved using the ontology frontend.

Step 2. Iteratively checking the backends' required CPU/OS/VM After the detailed information on CPU, operating system and virtual machine has been obtained from related ontologies, this information will be checked iteratively for whether this version of CPU, operating system and virtual machine are required for the backends. This kind of information is stored within instances of the backends associated with the *requireCPU*, *requireOS*, *requireVM* object properties.

Step 3. Resolving choices using user preferences There are situations where we can get multiple options for backends. For example, Motorola MPx220 has Windows Mobile as its operating system, but at the same time it has J2ME MIDP2, which will be compared with end user preferences. Then the generation can go ahead with the chosen platform.

Step 4. Resolving choices based on CPU/Memory usage For situations where memory and CPU usage should be decided, for example J2SE, CDC and CLDC as options, we will choose the one that consumes less memory and requires a slower CPU for small devices as default.

Step 5. Resolve options based on power/energy policy The power consumption of various bearers supported by a device is checked, and choose a corresponding bearer according to the power consumption expectation.

In our implementation of the above algorithm, we are using SWRL[7] to resolve options for multiple platforms as detailed in [2].

5 Evaluation of Limbo

We have evaluated Limbo according to the evaluation framework of one.world [1]. This includes evaluating: *Completeness*: can useful services be generated; *Performance*: is the generated services sufficiently resource efficient; *Complexity and utility*: how hard is it to create services and can others build upon it.

5.1 Completeness

We evaluate this through the generation of services for a set of prototypes for a home automation scenario to testify whether useful services can be generated by Limbo. Here services were primarily created by a member of the Hydra team who has not participated in the development of Limbo (four services) and by a member of the Limbo compiler team (one service). For all services, Hydra helped in hiding web service complexity and in generating efficient web services. The generated services were:

- *Nokia N80 SMS service*. The service uses Limbo's Midlet generation option and runs a Limbo-generated web server.
- *Pico TH03 thermometer service*, *Grundfos Magna 32 pump service* and *Abloy EL582 door lock service*. These services run as proxies on an OSGi gateway and interface with devices via device-specific protocols.

5.2 Performance

Here we report on time and memory usage measurements compared to Apache Axis[8]. The purpose is not to compare to Apache Axis per se since it was designed for a multi-threaded server environment, but rather to see that Limbo-generated services used significantly fewer resources than a popular web service framework.

For measuring resource utilization, we used a setup with a SOAP-based web service implementing an SMS service. This web service was requested by a Limbo-generated client and implemented using Apache Axis and using Limbo on both Java SE and Java ME (on a Nokia N80 mobile phone). For the Apache Axis and Limbo SE implementations a PC (an Apple Mac Book Pro with a 2.33 GHz Intel Core 2 Duo processor, 2 GB DDR2 SDRAM, MAC OS X 10.4.10). The left part of Figure 6 shows the result

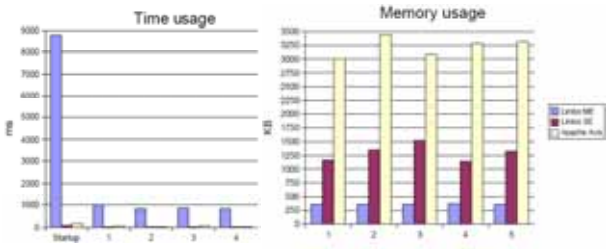

Figure 6. Limbo time and memory usage measurements

of our time measurements with the total execution time for five consecutive calls made to the SMS web service. For all implementations there is a high start-up cost due to the establishment of sockets – in particular so in the Java ME case. The Limbo ME implementation is also orders of magnitudes slower than the SE implementations, a fact that is due to the network setup of the Nokia N80 – and to the fact that the ME implementation actually sends an SMS – since the Limbo SE and Apache Axis implementations are comparable with respect to time usage.

The right part of Figure 6 shows the memory measurements of Limbo and Apache Axis. Both the Limbo SE and the Limbo ME versions use significantly less memory than Apache Axis. In the SE cases, the measurements were made using a JMX agent to measure the maximum amount of memory used during processing of requests. In the ME case, we measured maximum memory with SUN's Wireless Tool Kit (Version 2.5). On average, the Limbo ME service used 362.4 Kb memory. In conclusion, the resource usage of Limbo generated services is significantly smaller than that for Apache Axis-generated services.

5.3 Complexity and utility

Complexity and utility were evaluated by members of the Hydra project that had not participated in the development of Limbo. Two partial evaluations were made on evaluation of ontology construction and code generation. For both, a case of implementing a blood pressure service on an HTCP3300 smartphone[9] was used.

It was possible to create a model of the HTCP3300 device including a state machine within a day of work for an ontology engineer unfamiliar with the device and the associated service. The Limbo compiler has been successfully used to generate small applications to test their compatibility with Windows Mobile Smartphone and Eclipse ME-generated classes.

[7] SWRL homepage. http://www.w3.org/Submission/SWRL/
[8] Apache Axis. http://ws.apache.org/axis
[9] `http://www.europe.htc.com/en/products/htcp3300.html`

5.4 Evaluation conclusions

The Limbo compiler has been shown to be useful with good resource consumption of the generated code. Clearly there is a need for better documentation for both Limbo and the used ontologies, and Windows Mobile concepts of the OperatingSystem ontology need to be improved.

6 Related work

As said in the introduction, existing tools such as Microsoft's Web Services on Devices and Fast Infoset, fall short of the necessary flexibility of generating different code artifacts for the large variant of devices based on different protocols. These tools lack the versatility of being used for different embedded devices.

In Limbo, we translate WSDL files into a local Regular Tree Grammar (RTG) [4] that describes allowed SOAP envelopes as defined by the WSDL files. Though some frameworks can produce grammar-specific parser of XML data such as done by, e.g., XML Screamer [3], our work leverages this work but casts it in the context of web services, where ontologies are used to support the needed configuration during the generation process. The ontologies are helping to achieve generation-context-awareness and help to make decisions on the targeted platform, with the objective of generating resource efficient code.

Apache Muse[10] can simplify the building of web service interfaces for manageable resources. While Muse has a very specialized objective for the targeted specifications, Limbo has a highly flexible architecture which can be easily extended with the generation of code for .NET code, and other specialized platform such as LeJOS[11]. And more importantly is that we are using ontologies and rule languages to rigorously regulate and instruct the compilation, which can bring us some wiser decisions that is not easily achieved by Apache Muse and other existing approaches.

7 Conclusions and future work

There is an increasing requirement to run web services on resource constrained devices in pervasive computing. In this paper, we present an ontology-enabled compiler called Limbo for the generation of embedded web services. Limbo has followed the Repository architecture style where different frontends and backends can be easily added.

Limbo gets device information from the targeted device in compilation from a Device ontology that imports HardwarePlatform ontology and software platform related ontologies, where resource/power consumption comparisons are specified, and used by Limbo to achieve the generation of resource-efficient web services. A StateMachine ontology is used to generate state machine stub code and using an event mechanism to publish the state change events. We are using a LimboConfiguration ontology to rigorously specify the legal feature combination of Limbo compiler.

Our evaluations through the first Hydra prototype show that the design of the Limbo compiler is successful in terms of resource consumption of the generated web services, complexity hiding of the web service itself and that developers can use Limbo to develop resource efficient web services for a variant of different embedded devices.

A more flexible implementation using OSGi is under development. Web service code generation for .Net platform is planed. And more other hardware platform for example LeJOS is also under exploration.

Abstract

Using Information and Communication Technologies (ICT) to enable the daily activities and interests such as dining, medicine, lifestyle, traffic, education and entertainment has recently become a world wide trend. Moreover, Service-Oriented Architecture (SOA) is nowadays one of the most important techniques to realize services in industry.

Therefore, we would attempt to give attention to what type of services ICT could realize for chronic patients and how this concept should contribute to their recovery. In this paper, we would like to share our experiences in creating innovative home-care business models. We first discuss the business modeling process, which contains generating care services concepts, investigating market, defining Key Services scenarios and cooperative policies. Second, we present the constructed SOA healthcare platform. Specifically, we explain the technical issues during the development of our business models. Finally, the business models and platform are evaluated using the Key Performance Indicators (KPI) developed in the study.

Keywords: business modeling, SOA design, KPI evaluation, digital home-care

1. Introduction

As information and communication technologies (ICT) has continued to advance, the application of ICT has evolved in the different aspects of our lives such as work and entertainment. In fact, ICT has been gradually infused into our daily lives. Through network techniques, computers could provide many remote services. Interestingly, a large number of innovative service models, such as YouTube, WRETCH, Google, Amazon, etc. are continuously emerging. Using ICT to create innovative services models, many have become famous enterprises worldwide. One of their identical characteristics is that they have applied specific information techniques to integrate network techniques. Also, these models have successfully provided content services to promote business values.

The application of ICT has become a worldwide trend. Infusing Service-Oriented Architecture (SOA) to provide common activities and interests such as dining, medicine, lifestyle, traffic, education and entertainment has also become an objective of industry. Through the SOA platform, we could integrate individual providers into similar service processes. Modeling distinct business providers may also be interesting work. Through this process, researchers would be able to communicate with various stakeholders as well as design systematic platforms.

In this paper, we focus on the domain of patient-centered healthcare in digital home. We then construct the SOA healthcare platform and its application system which provide innovative business models. In the following sections, we will describe the progress of its construction and at the same time share our experiences from this study.

2. Related Works

2.1 SOA principles

Service-Oriented Architecture (SOA) is a software architectural style for realizing and constructing business processes, which are packaged as software services during their life cycle ([1], [2]). SOA defines and reserves IT infrastructure to allow various applications that exchange data in business processes. SOA also separates services into distinct units (components or modules), which can be deployed over the Internet, and can be combined and re-used for business applications. In clearly defined layers of SOA, requirements for business processes could be distinguished and identified. Business requirements are also implemented and combined by distinct software services. Typical layers for SOA are business process layer, business service layer, application integration layer, and technology layer.

Consequently, the general architectural principles [3] point out the ground rules of SOA for its development, maintenance, and use. These are the following:

- Usability - Components or modules would be re-used in various business processes, and even mobile services.
- Compliance to standards - Data exchanges between platforms are important to SOA. These exchanges will extend significant issues for standardization, identification, authorization, etc.
- Service identification and categorization, deployment and delivery, monitoring and tracking, and KPI definition, etc.

One standardizing service could provide diverse and

innovative business processes. A typical example is the service of agential cash-receivers of 7-11 stores in Taiwan which has allowed payments by credit card, telephone, and on-line shopping, to name a few. In addition, the specific architectural principles for design and service definition are categorized into two types. The first type is the interaction between the service consumer and provider. The second type includes the design guidelines of service providers. They are described as:

- Service encapsulation - Various services in the Internet are consolidated with web services under the SOA platform.
- Service loose coupling - Services maintain a relationship that minimizes dependencies on one another.
- Service abstraction - Services are logically hidden from the outside world, beyond what is described in the service contract.
- Service contract - Services attached to the communicable agreements, and defined in service description documents.
- Service reusability – A service is divided into units with extended re-uses.
- Service composition - Collections of units of services can be coordinated and combined to create services.
- Service autonomy – Services have control over the business processes they encapsulated.
- Service optimization – High-quality services are generally considered more than low-quality ones.
- Service discoverability – Services are designed to be accessible to the public, therefore they can be found and assessed via available discovery mechanisms.

Constructing SOA is not only a technical but also a business challenge. In the visions of SOA, relationships between the service consumer and provider are not tightly stipulated. Their relations are loose coupling [4]. Thus, consumer services are not forcefully influenced by the changes made by the providers. Secondly, consumer service interacts with the service provider based on the service contract. Moreover, designing the Service Level Agreement (SLA) is an important task. SLA should also satisfy some general and specific principles.

2.2 CVA Market Demands

Apoplexy, also known as Cerebrovascular Accident (CVA), breaks out when the cerebrovascular suddenly oppilates or fractures. Some patients only experience slightly pathological changes. Others experience paraplegia, and others simply expire. Diseases are distinct based on the position and size of infarcts or hemorrhages. In developed countries [5], CVA is one of the main diseases which result in death or disability. Its occurrence rate is 1.2 - 2.5/1000 [6]. The survival rate is 2/3, but, most patients would suffer disability. Some apoplectics would be discharged from the hospital and taken cared of at home. According to the official statistical data in Taiwan [7], CVA is also included among the top ten causes of diseases. Apoplectics would not only be a difficult illness to manage for the patient, but also to the family and society. Patients with apoplectic diseases need long-term care to reduce pathologies. If they are hospitalized over a long period of time, it will pose financial and emotional burden on their families and will also be a waste of resources in hospitals. Therefore, one effective solution for this situation is to take care of chronic patients at home; this could be a challenge for the family. Because of these perceived needs, the research team poses the following questions:

- What could Information and Communication Technologies (ICT) do for apoplexy patients?
- How should ICT contribute to the apoplectics' recovery?

3. Business Modeling

Business modeling is a critical starting point when we would like to provide care-services on SOA. Before constructing the services platform in SOA, we should ensure our care business models, which include market demands, key services items, services scenarios, market prices, even more cooperative policies, etc. The research process of business modeling for cerebrovascular patients' home-care is described in following figure.

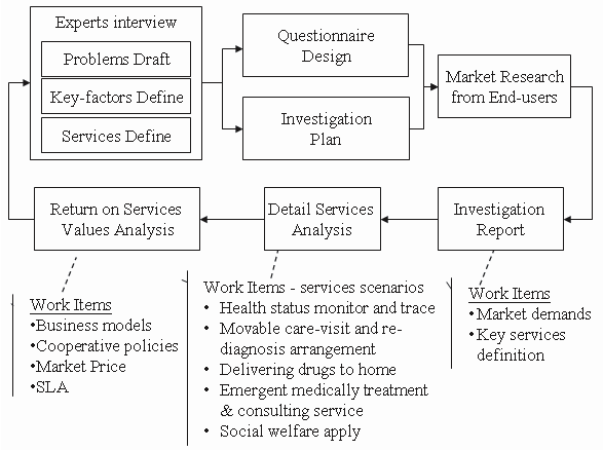

Figure 1. Business Modeling Process

Figure 2. Services Concept

3.1 Services concept

First, researchers iteratively interviewed the domain

experts to draw out the services concept. This was a critical initial step in business modeling. The research efforts were really demanding as about 30% cost of whole project. The services concept is presented in figure 2. Particularly, there are services, roles, proprietors and devices that were included in the services concept.

3.2 Market Investigation

To obtain a good perspective of the market demands, a large-scale market investigation was carried out. The investigation focused on people who lived in Kaohsiung at southern Taiwan. Moreover, the patients' home-care is assumed as the research domain. In addition, the questionnaire was designed based on the services concept. Consequently, the investigation was divided into two parts namely the quantitative investigation and qualitative investigation, and were performed concurrently. Details of the investigation were recorded in the technical report [8]. Quantitative Investigation Results were significantly listed in table 1.

Table 1. Quantitative Investigation Results

Items	Demands of home-care	Percentage
1	health status inspection (Notify / Arrange / Trace)	61.2%
2	Health status monitoring, tracing and unusual alerting by medical equipments	56.2%
3	Assisting or accompanying to take medical treatment (register at a hospital / ambulance)	23.1%
4	Emergency medical treatment and notifying family members	48.5%
5	Consulting Medical treatment	47.7%
6	Providing supplementary instruments for home-care	49.2%
7	Serving routines at home	21.5%
8	Nutrition consulting	26.9%
9	Psychological consulting	26.2%
10	Assisting to call an ambulance	20.8%
11	Assisting to apply for social services	53.1%
12	Entertainment activities	21.5%

The results of the qualitative investigation are as follows:

1. For the cerebrovascular patients, restoring limbs at home has positive effects as they enhance the patients' movability.
2. The majority of the caregivers are female. When family members work during day time, caregivers who majorly come from overseas take care of the patients.
3. The major economic resources of the elders are their children as they depend on their previous savings.
4. Members of the family trend to drive their patients from their homes to the hospitals by themselves. However, when special equipment is needed, they choose to access the transportation services provided by the care centers.
5. Persons who have work hope that elders' day to day needs could be taken cared of by the hospitals or governments which are supported by community volunteers. Workers hope that care center could directly provide them more of the information about their volunteers.
6. There should be a higher provision of equipment to the patients who need them more, especially the equipment that regularly monitors the patients' status and alerts emergency situations. This is considered an innovative concept. Through the equipment, someone could efficiently take care of patients whose statuses were unusual.
7. Hospitals should charge a minimal fee for these types of services. The families would like to pay the services within the limit of their income. The maximum amount they would like to pay is 5,000 NT dollars per month.

3.3 Define Key Services to Develop

We would like to identify important services that should be developed from this investigation report. Based from our market analysis, we could first fund six items whose percentages are more than 40%. Their item numbers are 1, 2, 4, 5, 6 and 11. The other items, whose percentages are less than 40%, are filtered out. Second, we would only select item 1, 2, 4, 5 and 6 into key services group. The reasons are listed in last two columns of table 2. We filtered out item 11 since it could be supported without information techniques. Key service items in the group would be analyzed to form services scenarios for future development. Services scenarios were recorded into document [9].

3.4 Cooperative Policies and Market Prices

Home-care services are considered comprehensive solutions for patients at home because single service provider could not successfully provide these services. In addition, service providers should be organized into a virtual organization as they serve as care centers in the community, hospitals, IT companies, transporters, and insurance companies. Partnerships and agreements among these stakeholders have to be documented through contracts. Through this strategy, they could merge the services supply chains. Specifically, the insurance companies play a special role in the business models. During the services life cycle, service providers should review insurance policies, since there might be some risks in caring patients at home.

After planning the cooperative policies, we should also define the market prices for each service item. Care centers could sell services to end-users and enter into contracts with them based on the market prices of the combined services. In addition, market prices would be defined based on the previous investigation and the cost of different service scenarios. Thus, the cost of each service should be calculated. We listed the factors of each service's cost in the table 3.

Table 2. Select Services Items into Key Services Group

Discussion / Key Services Group	Investigation Results	Baseline to develop	Techniques / Business issues
Freelance care supervisors and re-diagnosis arrangement	health status inspection (Notify / Arrange / Trace) **61.2%**	In order to save medical resources for severe patients, doctor would suggest patients, who do not need much medical attention, to go to local clinics. This means that patients who only experience slight discomfort should just go to the clinics for medical. This system will make the distribution of patients in the hospitals even	To exchange diagnoses records
	Consulting Medical treatment **47.7%**		
Delivery of medicines to the patient's home	Providing supplementary instruments for home-care **49.2%**	By providing this innovative service, hospitals would have an increase in extra income. Patients could also get their medication more conveniently.	To integrate distinct industries
Health status monitor and trace	Health status monitoring, tracing and unusual alerting through modern medical facilities **56.2%**	Collecting bio-signals from patients at home and monitoring their variations are critical techniques. Hospitals could precisely get the patients' conditions.	To collect and to store bio-signals
	Emergency medical treatment and notification of the patients' condition to family members **48.5%**		

Table 3. Factors of Service Cost for Business Models

Factors	Price Unit
Expected number of centre-carer visiting	person-time/month
Human resources and qualifications	Person Quantity
Budget for human resources	dollars/year
Budget for IT systems and devices	dollars/month
Transporter's fee	dollars/month
Total budget	Dollars/year
Fees to be charged against user for their remaining balance	dollars/one person a month

4. Architecture Constructing

Developing SOA services platform and its application is another important task in providing SOA business models. To support this initiative, we employed and adopted software lifecycles [10] to develop them. Development process and its work items are described in figure 3. In the high-level design phase, we designed the SOA healthcare platform based on the services demands. An application system was analyzed through knowledge engineering in the requirement phase, and was designed using the MVC methodology in detail design phase. The required functions of these application systems were divided into three parts - user interfaces, business logics, and data models. User interfaces would be implemented in the application level while business logics and data models would be supported by SOA services platform. More detailed functions for each module are categorized into functional, non-functional, interface, and security. The high-level modules of the application system are showed in figure 4.

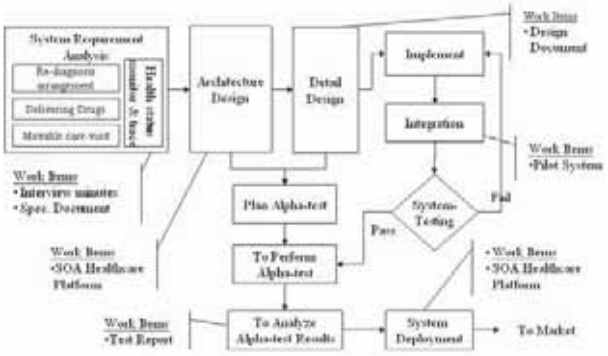

Figure 3. Developing Process of SOA Healthcare Platform

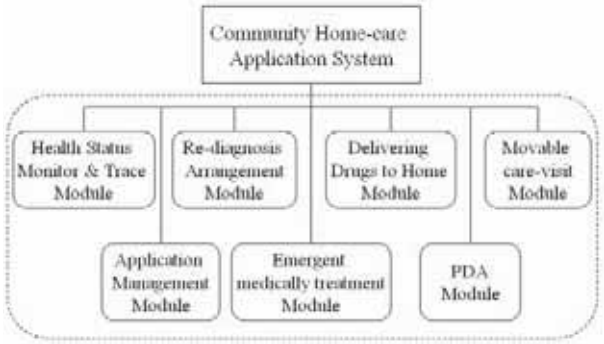

Figure 4. Functional Architecture of Application

4.1 SOA healthcare Platform

SOA healthcare platform was designed to provide executable environments which support standardized messages, various interfaces and flexible connections.

Different services techniques could cooperate with each others on this platform. In this platform, each module and component should be developed under MVC methodology. Business logics and data presentations should be separated into different independent components. Developing business services should focus on the design of business logics. The other technical components could be simply dealt through the SOA platform. SOA Healthcare Platform is showed in figure 5. Services-flow control tool contains three main modules, specifically the service executing engine, service process defining and services monitoring. The module of service process defining is used to identify service processes of application system. Moreover, the module of services monitoring is used to check the current statuses of service objects in the application system. Finally, the module of service executing engine is used to bind service objects and the other modules in platform. There are three healthcare tools that are used by patients in the platform. These include bio-signals management, messages management and end-users management. The module of bio-signals management is used to supervise patient's bio-signals from the homebox, an end-device installed in the patient's house. Meanwhile, the module of end-users management is used to handle users' profiles and personal descriptions. The module of messages management is used to handle messages passing between internal and external objects. In addition, the logger module is used to record the histories of the events while the module of exception handler is used for tracing run-time defects in platform. We would like to call these modules' components based on the coding style below:

```
try {
    // call regular components…
} catch {
    // call exception handler's components …
} finally {
     // call logger's components…
}
```

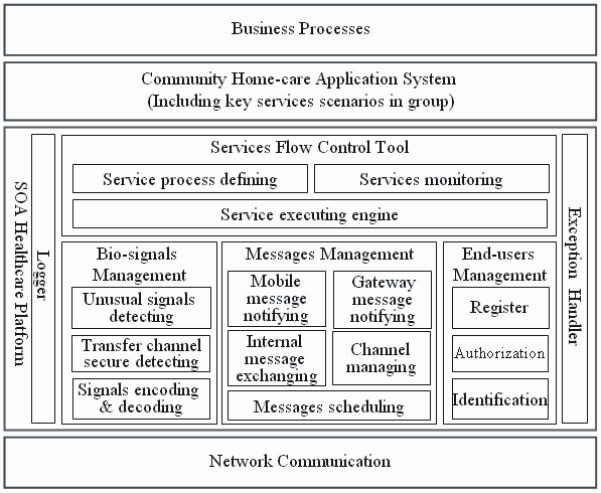

Figure 5. SOA Healthcare Platform

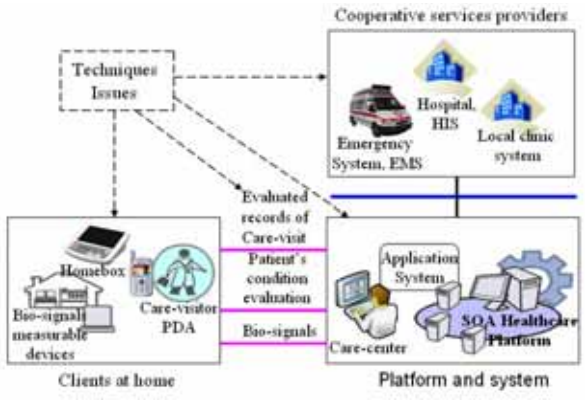

Figure 6. Deployment Overview of Systems

4.2 Surmounting Techniques Issues

We plan to deploy our systems in a real environment based on the services concept. The SOA healthcare platform was deployed to administer the services in the care center side and manage the homebox, bio-signal devices installed in the clients' house. The care center supervisor would regularly bring his/her PDA and visit the patients at their homes. Some cooperative services providers, such as hospitals HIS, local clinic system and emergency system, are also showed in figure 6. Since this is considered as a home-care solution really deployed in three sides, some technical issues about home-care will occur. By then, we will have to address these issues using the SOA platform. Furthermore, technical issues in home-care are addressed and shortly described as follows:

- Transferring bio-signals from clients to the application server in real-time
  - Transfer channels are always maintained by the platform which supports the message exchange.
  - Unusual bio-signals are monitored and handled by the platform through the application server.
  - End-users' profiles are managed by the platform. Private profiles should be shared in a secure way.
  - Messages and bio-signals should be standardized between systems through the platform.
- Integrating multiple bio-signals devices
  - Homebox would integrate multiple bio-signal devices. The condition of the homebox should be regularly checked by the platform, since it was registered there.
  - Within the homebox, user interfaces will simply be implemented to interact remotely. The interactions are executed through the platform.
  - If abnormal network occurs, homebox could detect and reconstruct by itself. After its reconnection, the homebox should pass exceptional logs to the platform.
- Integrating homogeneous providers
  - Business services processes should be composed and executed in an efficient way through the platform. The status of the executing services should also be monitored through the platform.
  - Caregivers should maintain terminal systems, which directly connect them to the platform.

Diagnostic records should be carefully shared using a standardized format between providers.

- Homogeneous systems should be integrated through the platform using for healthcare area.

Detailed specifications of this design are documented in technical report [11].

5. Key Performance Indicators Evaluation

The business models are evaluated using the Key Performance Indicators (KPI). We define our KPI by referring to the Balanced Scorecard (BSC) models [12]. For the SOA healthcare platform and business models, we planned to have four presentations of KPI. They are categorized as system quality, customers' satisfaction, business achievements and financial achievements. The measurements are described in the following.

1. System quality would be measured and analyzed according to its user-friendliness, level of security and privacy during the data transfer, the defects rates, the services response time and the used times.

2. Customers' satisfaction would be measured and analyzed according to the following criteria: marketing share, customers' continuity, increase in the number of customers, increase in customers' satisfaction, and stakeholders' satisfaction.

3. Business achievements would be measured and evaluated according to business quantity, number of customers, number of, transactions and profit growth.

4. Financial achievements would be measured and evaluated based on the profit growth and service packages, management performance and financial forecast that are based on the three phases, which are establishing phase, increasing phase and mature phase.

6. Conclusions

As information and communication technology (ICT) advances, the applications of ICT should provide convenience and business solutions to people. As revealed in our study, Service-Oriented Architecture (SOA) platforms could smoothly integrate business models and combine distinct services providers for innovative services. In this paper, we shared our experiences on creating innovative home-care business models. We presented how we created the SOA healthcare platform and addressed technical issues that emerged during its development. Finally, we demonstrated how we plan to evaluate the business models and platform using the four presentations of KPI. We believe that this is an interesting concept and a good case study on modeling services for the Service-Oriented Architecture in business processes.

7. Acknowledgements

This research was supported by the Applied Information Services Development and Integration project of the Institute for Information Industry (III) and sponsored by MOEA, Taiwan R.O.C.

Interviewed care-experts and investigated patients were supported by the Department of Medical Information, Chung-Ho Memorial Hospital in Kaohsing, Taiwan R.O.C.

Abstract

Databases are employed to store a great amount of data extremely important for business operations. Database test evaluates if a database meets its requirements. In this context, to test the database schemas is a fundamental activity to increase the confidence on the integrity of the data being manipulated by the database applications. There are few works that address this subject. Approaches to test database schemas can help to find faults related to the incorrect or absent definitions of constraints in the data and can contribute to avoid failures in the applications. With this in mind, we present a fault-based testing approach for database schemas and introduce testing criteria based on the classification of the most common types of fault in database schemas. In our approach database instances and queries are used to test the schemas. The instances are generated according to patterns defined for fault classes and represent possible faults. Preliminary results are discussed.

1. Introduction

Testing activity in software development contributes to generate reliable products and to evaluate software quality. Test techniques and criteria have been proposed to guide the test process, which may involve many correctness issues in software applications. For instance, database testing aims to evaluate how well a database meets its requirements and can determine query response time, data integrity, data validity and data recovery [10]. Database system testing involves many correctness aspects, such as [4]: application behaviour with respect to the specification; how well the database schema models the real world; accuracy of data in the database; safety and privacy; and correct execution of insertions, updates and deletions of data and information from data schemas.

Schemas are frequently used in data base applications to define the logical structure and the relationships among data. Schemas are designed according to the data specification. Testing of database schemas can contribute to increase the confidence in the integrity and accuracy of the data being manipulated. If incorrect data is validated by a schema and passed to the application, this may cause a failure. In spite of its importance, the testing of schemas has not been a popular subject in the area. Most of the works address data generation, application and database design testing [2, 3, 4, 5, 7, 11, 14, 16, 17].

In a previous work [9] we introduced an approach to test schemas which considers generic fault classes and which can be applied to any schema that can be represented by a model based on a MOF specification [13]. We have explored its use mainly in the context of XML [8]. The promising results motivated us to investigate the use of such approach in the context of relational database schemas [15], a largely used kind of schema.

To do this, we instantiated the generic fault classes, proposed in [9], for the context of relational database and of the entity-relationship (ER) model [6], a very popular model employed in database applications. By considering the approach and the presented fault classes, we introduced a set of testing criteria to be used for evaluating the testing activity. We implemented a support tool and conducted experiments to evaluate the criteria in this new context.

The remainder of this paper is organized as follows. Section 2 presents the fault-based testing approach adapted to the relational database context. This section introduces the fault classes and the testing criteria. Section 3 presents the experimental results. Section 4 describes related work. Section 5 contains the conclusions and directions for future work.

2. Alternative Data Instance Analysis

In this paper, the proposed fault-based testing approach is named Alternative Data Instance Analysis (ADIA) and is adapted to the context of relational database schemas. It has the goal of revealing constraint faults related to the definition of entities, attributes, relationships and semantics in a database schema. These faults can be related to issues such as incorrect or absent restriction definitions for those schema elements. The idea is to evaluate these issues to avoid faults in the database schema that can affect data integrity in the database and cause failures in the database application.

ADIA is fault-based and includes database instance alternatives and queries to reveal the faults. The data models that represent schemas, the fault classes identified in the database schema, the schema representation and the test process are presented next.

2.1. Data Model

The data model is represented by a metamodel *M* defined according to the MOF (Meta-Object Facility) Specification [13]. Figure 1 illustrates the metamodel *M*, described in UML notation [1], consisting of the following classes: Element (elements or entities); Attribute (properties of the elements) and Constraint (restrictions associated to elements and attributes).

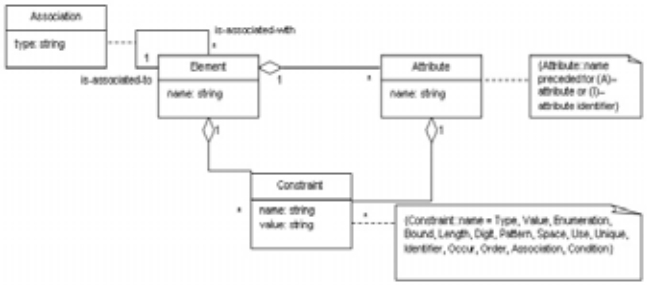

Figure 1. Metamodel *M*

To illustrate the data model in this context, consider a fragment of an ER diagram (Figure 2). The diagram describes data on students from a university: course and type of course. Figure 3 shows the correspondent class diagram based on *M*.

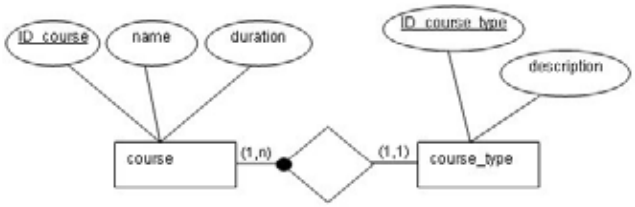

Figure 2. Fragment of an ER diagram

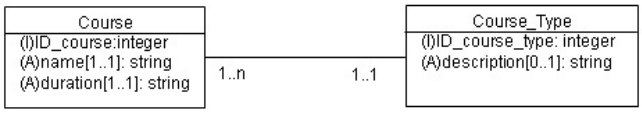

Figure 3. Data Schema for Course Data concerning the Metamodel *M*

2.2. Fault Classes

ADIA is fault-based; hence, common faults introduced during the conceptual design of a schema are organized into four groups of constraints: domain, definition, relationship and semantic. These faults are identified through analyses of data schemas. In this paper, the fault classes presented previously were instanced for relational database schemas. Table 1 presents the fault classes concerning relational database schemas.

Table 1. Fault classes for relational database schemas

Fault Class	Description
Group 1 (G1) - Domain Constraints	**faults related to domain definition of attribute values**
IDT - Incorrect Data Type	incorrect definition of data type
IV - Incorrect Value	incorrect definition of default value
IEV - Incorrect Enumerated Value	incorrect definition of the list of acceptable values
IMMV - Incorrect Maximum and Minimum Values	incorrect definition of upper and lower bound values
IL - Incorrect Length	incorrect definition of number of characters allowed for values
ID - Incorrect Digits	incorrect definition of total amount of digits for numeric values
IWSC – Incorrect White Space Characters	incorrect definition of how white space characters must be treated
Group 2 (G2) - Definition constraints	**faults related to data integrity**
IU - Incorrect Use	the attribute is defined incorrectly as optional or obligatory
IN – Incorrect Uniqueness	the attribute is defined incorrectly as unique
IK - Incorrect Key	the attribute is defined incorrectly as primary key or foreign key
Group 3 (G3) - Relationship Constraints	**faults related to relationship definition among entities**
IO - Incorrect Occurrence	incorrect definition of number of times a same entity may occur
IC - Incorrect Association	incorrect definition of an association: cardinality, generalization/specialization, aggregation, associative element
Group 4 (G4) - Semantic Constraints	**faults related to constraints definition in relation to data content expressed by business rules**
IO - Incorrect Condition	incorrect definition of predicate expressed for a condition that must be satisfied by attributes

2.3. Formal Representation

A formal representation is used to process data schemas, by providing the identification of the entities, attributes, constraints and of the associations among them. A data schema S is denoted by $S = (E, A, R, P)$, where:

- E is a finite set of entities;
- A is a finite set of attributes;
- R is a finite set of constraints concerning domain, definition, relationship and semantics associated to the elements and attributes;
- P is a finite set of association rules among elements, attributes and constraints. Consider $U = E \cup A$. The association rules are represented by:
  - $p(x, y) \mid x, y \in E \wedge x \neq y$;
  - $p(x, r) \mid x \in E \wedge r \in R$;

- $p(x, r, SU) \mid x \in U \wedge r \in R \wedge SU = \{u_1, u_2, ..., u_m\} \subset U$, $\forall u_i \neq x,\ 1 \leq i \leq m, m \geq 1$, where m is the number of elements and attributes in SU.

Example 1 shows the notation used to describe a data schema.

Example 1: Formal representation for ER diagram of Fig. 2

$S = (E, A, R, P)$

$E = \{course, course\_type\}$

$A = \{ID\_course, name, duration, ID\_course\_type, description\}$

$R = \{type,\ key, use, length, uniqueness, association\}$

$P = \{p_1(course, ID\_course), p_2(course, name), p_3(course, duration),$
$p_4(course, association, course\_type),$
$p_5(course, key, course\_type),$
$p_6(ID\_course, type), p_7(ID\_course, key), p_8(name, type),$
$p_9(name, use), p_{10}(name,\ length), p_{11}(duration, type),$
$p_{12}(duration, use), p_{13}(course\_type, ID\_course\_type),$
$p_{14}(course\_type,\ description),$
$p_{15}(course\_type,\ associative, course),$
$p_{16}(ID\_course\_type, type), p_{17}(ID\_course\_type, key),$
$p_{18}(description, type), p_{19}(description, use),$
$p_{20}(description, length), p_{21}(description, uniqueness)\}$

2.4. Testing Process

The schema under test and the corresponding database instance (original database instance) are provided by the tester. These entries to the testing process are presented in Examples 2 and 3. Example 2 shows a fragment of the schema written in the DDL (Data Definition Language) script related to the ER diagram of Figure 2. Example 3 presents a sample of the original database instance associated to the schema of Example 1.

Example 2. DDL related to the ER diagram of Fig 2.

```
CREATE TABLE course (
        id_course           int IDENTITY,
        name                varchar(40) NOT NULL,
        id_course_type      int NOT NULL,
        duration            int NOT NULL
)
go
ALTER TABLE course
        ADD PRIMARY KEY NONCLUSTERED (id_course)
go
```

Example 3. A sample of the original database instance

Course			
Id_course	**Name**	**id_course_type**	**duration**
1	Computer science	1	4
2	Computation Engineering	1	5
3	Database	3	2
4	Images Processing	4	2

Initially, the representation S of the schema under test is built (Example 1). Based on S, schema elements (entities, attributes, relationships among entities and semantic constraints related to attributes) are associated to the fault classes. These associations are named fault associations. Table 2 presents some associations identified in S for its entities and attributes.

Table 2. Fault associations identified in S

Entity/Attribute	Fault Class
Course	Incorrect Association (cardinality)
	Incorrect Key
ID_course	Incorrect Data Type
name	Incorrect Use
	Incorrect Data Type
	Incorrect Length

Additionally, the tester can identify other fault associations among schema elements and fault classes. This provides the detection of faults that could not be detected with the fault associations identified through representation S. Thus, the tester can determine fault associations to reveal faults related to absent constraint definitions. These are faults covered by the fault classes.

Next, these fault associations are selected. The selected fault associations are used to guide the generation of the alternative database instances, indicating the schema elements that should be modified in the original database instance and the fault classes which define the modification patterns that should be applied.

The alternative database instances are generated through modifications in the original database instance. These single modifications are made by insertions and changes into records of the original database instance according to patterns defined for each fault class. These modifications are representative and sufficient to detect the fault of each fault class. For example, to reveal a fault related to G1-IL (Group 1 - Incorrect Length) in the attribute $a \in A$ of the database schema S, a record should be altered, for example, with a number x of characters out of the bound allowed for attribute a in an alternative database instance generated. Example 4 illustrates an alternative database instance for table Course of the original database instance presented in Example 3. In Example 4, the attribute name is associated to fault class G1-IL (Group 1 - Incorrect Length).

The records of the generated alternative database instances are separated into valid or invalid with respect to the schema under test; that is, a record generated by modification patterns may not be in conformity with the schema under test. An invalid record is not accepted in the alternative instance; thus, this alternative instance is not queried, but it is part of the test result.

Example 4. Alternative database instance

Course			
Id_course	**Name**	**id_course_type**	**Duration**
1	Computer science xxxxxxxxxxxxxxx xxxxxxxxxxxxx	1	4
2	Computation Engineering	1	5
3	Database	3	2
4	Images Processing	4	2

The selected fault associations also guide the generation of the queries. The queries are automatically generated as SQL statements according to the query patterns associated to each fault class which can be detected in the schema. Queries for each selected fault association are generated and executed for each correspondent valid alternative database instance.

A test data is formed by a valid alternative database instance and a query to this alternative instance. Expected results for the test data are obtained from the database specification. The tester compares test results with the specification to discover faults in the database schema.

2.5. Testing Criteria

The testing criteria based on the fault classes aim to guide the testing process by selecting fault associations to be exercised and, consequently, by reducing the application costs of the ADIA through the selection of a subset of fault associations. The costs are related to the number of alternative database instances and queries generated. However, the effectiveness of the ADIA to reveal data schema faults should not be reduced.

In that way, the testing criteria are used to select fault associations to be exercised in the testing process. These criteria are based on the fault classes for relational database schemas. They request that the fault associations are exercised through query execution on the alternative data instances related to these associations. Consider z an element or attribute. These criteria are:

All constraints – all fault associations with regard to z related to fault classes of the groups of domain, definition, relationship, and semantic constraints must be exercised;

All domain constraints - all fault associations with regard to z related to fault classes of the group of domain constraints must be exercised;

All definition constraints - all fault associations with regard to z related to fault classes of the group of definition constraints must be exercised;

All relationship constraints - all fault associations with regard to z related to fault classes of the group of relationship constraints must be exercised;

All semantic constraints - all fault associations with regard to z related to fault classes of the group of semantic constraints must be exercised;

All constraints groups – at least one fault association with regard to z related to each group of domain, definition, relationship and semantics constraints must be exercised, if such association exists.

3. Case Study

Our case study uses a database application developed by graduate students, containing data on university students: personal, academic and professional data. Testing process was performed during the development of the database. The ER schema for the application has 19 entities and 20 relationships. Relational database application was implemented using PostGreSQL.

The testing process was performed using XTool [12], a tool that supports the testing approach for database schemas described in the Section 2.4. XTool was developed in Java and tests relational database schemas by using JDBC (Java Database Connectivity) to manipulate and query the information in PostGreSQL database.

XTool found 19 entities and 73 attributes in *S*. These entities and attributes were automatically associated to fault classes in the schema under test. Moreover, the tester found other fault associations among schema elements and fault classes. By using the selected fault associations, XTool generates alternative database instances and SQL queries automatically. The total number of fault associations (identified by XTool and the tester) was 297 and 1,240 queries were executed.

We used all the testing criteria to select the fault associations, except the "all constraints groups" criterion. The idea is to compare the use of the testing criteria by analyzing costs and revealed faults in this database schema.

Table 3 presents an example of fault associations, the number of records modified in the original database instance to generate the alternative instances and the number of generated queries for the entity "Academic_records" and some of its attributes according to the testing criteria.

The tester had the task of comparing the queries results with the expected ones. Records of invalid alternative database instances generated were also considered test results and used during the testing analysis. Table 4 shows the number of generated queries and valid alternative instances by faults revealed for the testing criteria applied by using XTool.

The faults revealed in the test process are related to: the incorrect definition of data type and length constraints; the absence of constraints and enumerated values for attributes; and, incorrect cardinality for a relationship. Faults of absence of constraints were revealed with the fault associations found by the tester.

The testing criteria that revealed faults are: "all domains constraints", "all definition constraints" and "all relationship constraints". Hence, when we applied the testing criterion "all constraints", all faults detected with the other criteria were also revealed. In this case, we can see that the number of queries that revealed faults was 14% of the total number of queries generated and the number of

valid alternative instances that represented revealed faults was 15% of the total number of valid alternative instances generated. Those results are an indication that the testing criteria can help to reduce the application costs of ADIA.

Table 3. Fault associations found in S, number of modified records and generated queries for entity Academic_records

Testing Criterion	Fault Associations		Number of records	Number of queries
	Entity/ Attribute	Fault Class		
All Relationship Constraints	Academic_ records	Incorrect Association (cardinality)	41	12
		Incorrect Association (Associative Element)	6	1
All Definition Constraints	Academic_ records	Incorrect Key	1	1
		Incorrect Uniqueness	1	1
All Domain Constraints	Begin_date	Incorrect Data Type	7	1
All Definition Constraints	Begin_date	Incorrect Use	4	1
All Semantic Constraints	Begin_date	Incorrect Condition	48	25

Table 4. Faults revealed

Testing criterion	Fault classes	Number of queries	Number of valid alternatives	Number of faults revealed
All Domain Constraints	Incorrect Data Type	18	13	5
	Incorrect Length	15	12	3
	Incorrect Digits	44	40	4
	Incorrect Enumerated Value	5	3	1
Total by criterion		**82**	**68**	**13**
All Definition Constraints	Incorrect Use	85	72	13
Total by criterion		**85**	**72**	**13**
All Relationship Constraints	Incorrect Association (cardinality)	7	6	1
Total by criterion		**7**	**6**	**1**
All Constraints	Incorrect Data Type, Length, Digits, Enumerated Value, Use, Association (cardinality)	174	146	27
Total by criterion		**174**	**146**	**27**

Revealed faults were removed and the use of ADIA contributed to improve the quality of the tested application.

It is important to remark that the original database instances are not replicated by XTool to generate the alternative instances. The original instance is updated with a single modification pattern, queried by the generated query and the modification is undone.

4. Related Work

As mentioned previously, many works in the literature address the testing of database applications [2, 4, 5, 7, 11, 16, 17]. Some of them [3, 14] propose the use of schema information to test the application. Robbert and Maryanski [14] use information obtained from the database schema to generate a test plan for the database application, indicating points that should be verified in the test. Chan et al. [3] propose a fault-based approach to test SQL statements of database applications using information captured from the conceptual data model to generate SQL statement mutants. They use schema information to test the application or SQL statements, but they do not address schema testing.

The abovementioned works do not have the goal of validating schemas, the focus of the present paper. Our approach has a different objective and contributes to increase the reliability of the data stored in the database.

5. Conclusions

The fault-based approach ADIA for database schemas and the testing criteria were derived from our previous work [8, 9]. The main goal of this testing approach is to reveal faults in the database schema to ensure the quality of the data stored in the database and, consequently, to contribute to increase the reliability of the database application. Data integrity in databases is fundamental to avoid incorrect data processing resulting in failures in the database application.

ADIA contributes by: presenting a metamodel and a formal representation for database schemas; defining fault classes for database schemas based on the entity-relationship model; introducing testing criteria based on fault associations, generating alternative database instances based on fault classes; and using queries to reveal faults.

XTool was implemented to support ADIA and it does not need the database application to test the database schema. XTool needs only the schema to be tested and the original database instance. In addition to that, the alternative database instances generated automatically by XTool could be used to test the applications that access the database.

The case study performed by using XTool shows that ADIA is effective in revealing faults covered by the fault classes in database schema and that the largest cost is related to the analysis of the results by the tester; the tester compares the test results with the expected ones from data specification. In addition to that, the results indicate that the

testing criteria can help to reduce the application costs of the ADIA.

ADIA was used to reveal faults in schemas of relational database model. It can also be used to detect faults in schemas of other database models, for instance, XML databases.

Other experiments are necessary to better evaluate the effectiveness of the testing approach and criteria for detection of faults in the context of database models. We intend to use the testing approach to reveal faults in more complex integrity constraints or faults involving several relations.

In addition to that, in future work we intend to analyze the relationship between the number of faults/fault classes and instances/queries that can be redundant; furthermore, a way to reduce the number of instances/queries by using test criteria should be proposed and evaluated empirically.

Abstract

Active rules allow software systems to execute actions automatically in response to events. Two desirable properties of active rule behavior are termination and confluence. In this paper we present a Petri net based approach to analyze termination and confluence in a rule base. Our approach is performed in two steps: first, we identify those rules which may not terminate and may not be confluent using their Conditional Colored Petri net representation. Second, we use semantic analysis to decide about termination and confluence of the detected rules. The great advantage of our approach is that it allows us to derive results about termination and confluence without analyzing all the rules.

1 Introduction

Active rules allow software systems behave automatically in response to inner or outer events. Using active rules, modern applications can be effectively developed. However, due to unstructured nature of rule processing it is quite difficult to predict the rule set behavior. Two desirable properties of active rule behavior are *termination* and *confluence*. A rule set is guaranteed to terminate if rule execution processing cannot continue indefinitely. A rule set is confluent if the final state is independent of the rule execution order.

Several works have been proposed in the literature to analyze termination and confluence. Some approaches tackled the problem based on triggering and execution graphs analysis [1], [2]. The triggering graph is directed graph whose nodes represent the rules and whose edges indicate that a rule produces an event that may trigger another rule. If the graph is acyclic, rule execution terminates. In execution graphs, nodes represent the state and directed edges are labeled with the name of the rule whose execution makes the system switch from one state to another. If the graph is acyclic and every pair of rules commute, the rule execution process is confluent. In [3] authors propagate the effect of the action part of a condition - action rule to the condition part of another rule to determine if the arcs of the triggering graph have to be included in the graph and to verify if two rules commute. In this work, all the rules have to be compared in pairs to accurately conclude about termination and confluence. In [4] authors translate a set of active rules into logical clauses and then apply results about termination and confluence available in the literature for deductive rules. In [5], confluence is investigated by using a rewriting technique. A user-defined transaction is translated by means of active rules into an induced one(s) and then they check their equivalence. This approach doesn't provide a general conclusion about confluence since its analysis is done on each initial user-defined transaction.

In this paper we present a Petri net based analysis approach for analyzing termination and confluence in an active rule base. One important aspect of our approach is that it avoids unnecessary rule analysis by identifying the Petri net structures of non-termination and non-confluence.

2 Active Rules

Generally, an active rule consists of three parts: an *Event*, a *Condition*, and an *Action*. So, they are also called ECA rules. The most common form of active rules is the following: **ON** *event* **IF** *condition* **THEN** *action.* An event is something that occurs at a point in time. The condition examines the context in which the event has taken place. The action describes the task to be carried out by the rule if the condition is fulfilled

once an event has taken place. From now onwards, we refer to an active rule as $R_i(E_i, C_i, Ai)$ where E_i, C_i and A_i are the event, condition and action of R_i, respectively.

Example 1. *Bank's policies for managing customers' accounts.*

An active database system (ADBS), which integrates active rule processing with traditional database functionality, is able to react automatically to meaningful events that are taking place inside or outside de database system. The following ADBS example is about a bank's policies for managing customer's accounts which is taken from [3]. It is based on the relation schemes `account(`*num, name, balance, rate*) and `low-acc(`*num, start, end*`)`, which contain information about bank's accounts, and a history of all time periods in which an account had a low balance, respectively. Policies are described below.

Policy 1: When an account's interest rate is modified, if that account has a balance less than 500 and an interest rate greater than 0%, then that account's interest rate is lowered to 0%.

Policy 2: When a new account is registered, if the account has an interest rate greater than 1% but less than 2%, then that account's interest rate is raised to 2%.

Policy 3: When a new account is registered, if that account has a balance less than 500 and is not yet recorded with a null end date in the `low-acc` relation, then the account is inserted into the `low-acc` relation with the current date as start and a null end date.

Policy 4: When a new account is registered, if the total number of low days for an account (as recorded in the `low-acc` relation) is greater than 50 and its current balance is between 500 and 1000, then its interest rate is set to 1% in the `account` relation.

Above policies are depicted as active rules as follows:

R1
`ON` update `account`.*rate*
`IF` update.*balance* $<$ 500 and update.*rate* $>$0
`THEN` update `account` set *rate* = 0
where *balance* $<$ 500 and *rate* $>$ 0

R2
`ON` insert `account`
`IF` update.*rate* $>$1 and update.*rate* $<$ 2
`THEN` update `account` set *rate* = 2
where *rate* $>$ 1 and *rate* $<$ 2

R3
`ON` insert `account`
`IF` insert.*balance* $<$ 500 and (not exists (select * from `low-acc` where `low-acc`.*num* = insert.*num* and *end* is null))
`THEN` insert into `low-acc`(*num*, *start*, *end*) (select *num*, today( ), null from `account` where *balance* $<$ 500 and not exists (select * from `low-acc` where `low-acc`.*num* = `account`.*num* and *end* is null))

R4
`ON` insert `account`
`IF` exists(select * from `account` where *rate* $>$ 1 and *balance* $>$ 500 and *balance* $<$ 1000 and *num* in (select *num* from `low-acc` group by *num* having sum(*end-start*)$>$50))
`THEN` update `account` set *rate* = 1 where *rate* $>$ 1 and *balance* $>$ 500 and *balance* $<$ 1000 and *num* in (select *num* from `low-acc` group by *num* having sum(*end-start*)$>$50)

Suppose the event "insert `account`" has been detected, then **R2**, **R3** and **R4** are triggered and their conditions must be evaluated. Let's suppose all conditions true, then, for simplicity, rule execution will be done by following the order of rules in the list. Therefore, **R2**'s action will be executed first, then **R3**'s action and **R4**'s action is executed finally. After **R2**'s action execution, the event "update `account`.*rate*" is signaled, so **R1** is triggered and execution process continues until there is no rule eligible to trigger. On the other hand, when **R3**'s action is executed, rule processing finishes since there is no rule triggered by the event "insert `low-acc`". Finally, when **R4**'s action is executed, the event "update `account`.*rate*" is raised and rule processing continues.

3 Active Rule Base Modeling

An active rule base as well as its interaction can be represented by the Conditional Colored Petri Net (CCPN) [6]. Unlike other graphical models, CCPN depicts each element of an active rule including composite events and condition evaluation.

As Figure 1(a) shows, an active rule is mapped to a CCPN structure as follows: a rule is mapped to a transition where its condition is attached, event and action parts are mapped to input and output places of the transition, respectively. Matching between events and input places has the following characteristics:

(1) *Primitive* places, represent primitive events;

(2) *Composite* places, represent composite events;

(3) *Copy* places, are used when one event triggers two or more rules. An event can be shared by two or more rules, but in Petri net theory, one token needs to be duplicated for sharing. A copy place takes the same information as its original one;

(4) *Virtual* places are used for accumulating different events that trigger the same rule. For example, to represent the composite event OR.

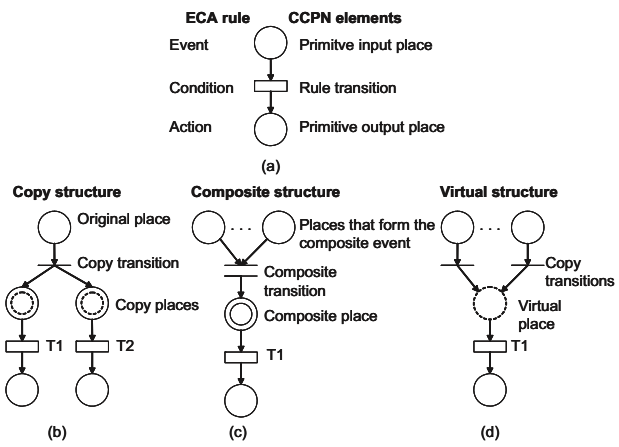

Figure 1. Basic CCPN structures of an active rule

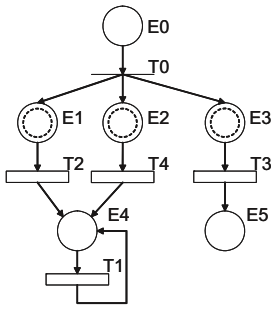

Place [Type]	Event/Action
E0 [primitive]	insert account
E4 [primitive]	update account.rate
E5 [primitive]	insert low-acc
E1, E2, E3 [copy]	Insert account

Transition [Type]	Rule
T1[rule]	**R1**
T2 [rule]	**R2**
T3 [rule]	**R3**
T4 [rule]	**R4**
T0 [copy]	-

Figure 2. CCPN of the rule base of Example 1

Rules and transitions are related in the following form:

(1) *Rule* transitions, represent rules;

(2) *Composite* transitions, represent composite event generation;

(3) *Copy* transitions, duplicate one event for each triggered rule.

Whenever an event triggers two or more rules it has to be duplicated by means the copy structure depicted in Figure 1(b). Composite events formation is considered in CCPN using the composite structure drawn in Figure 1(c). Composite transition's input places represent all the events needed to form a composite event while its output place correspond to the whole composite event. Finally, we use the virtual structure to model the composite event `OR` as standing for in Figure 1(d). The CCPN model of a set of ECA rules is formed by connecting those places that represent both the action of one rule and the event of another rule. Figure 2 shows the CCPN model of the rules of Example 1. Correspondence between events/actions and places as well as matching between rules and transitions, are described in the figure too.

4 Termination and Confluence Analysis

Based on the CCPN model of a given active rule base we can analyze its termination and confluence properties. First, we represent the active rule base as a CCPN model and we identify the structures that may have non-termination and non-confluence problems. Since transitions in CCPN stand for rules, we actually obtain the rules that may exhibit abnormal behavior. Second, termination and confluence are investigated by analyzing rule semantic and rule interaction of rules computed during the first step.

Non-termination and non-confluence CCPN structures. In CCPN termination is depicted by cycles. If in the obtained CCPN model there is no cycles then rule processing is guaranteed to terminate. Otherwise, we will analyze the rules involved in the loop to ascertain if their processing finishes. Through CCPN model of Figure 2 we found the cycle formed by the sequence of places/transitions E4, T1, E4. So, **R1** in Example 1 triggers itself.

On the other hand, confluence problems appear when several rules are triggered at the same time since there are different ways to perform rule execution. In CCPN confluence is represented by the following CCPN structures: (1) copy typed transitions. In the CCPN of Figure 2 transition T0 is a copy typed transition, so, we need to analyze the execution order of transitions (rules) T2 (**R2**), T3 (**R3**), and T4 (**R4**). (2) rule typed transitions which evaluate the same condition. This kind of rules are identified in the CCPN by labeling them with the same index. Each rule in Example 1 evaluates different conditions, so, we don't need to analyze any transition of this type. (3) primitive places which have more than one input arc. The place E4 in the CCPN of Figure 2 has more than one input arc, so, we will examine the rule execution order of transitions (rules): T1 (**R1**), T2 (**R2**), and T4 (**R4**).

Rule semantic and rule interaction analysis. Once we have computed rules that may not terminate and may not be confluent, we analyze them taking into account their semantics and interaction. To analyze rule semantics, first we divide each rule action as following: (1) a modification operation, (2) a relation schema name, (3) attribute names of the relation schema, (4) new values for each attribute, and (5) a condition over attributes. We identify as Comm(A),

Table(A), Att(A), Val(A) and Cond(A) each one of the above elements, respectively. Let's see action A_1 = "update `account` set *rate* = 0 where *balance* < 500 and *rate* > 0". Its elements are: Comm(A) = update, Table(A) = `account`, Att(A) = rate, Val(A) = rate = 0, and Cond(A) = *balance* < 500 and *rate* > 0. Second, we compute the *target of a condition C*, denoted by Targ(C), which is the set of tuples which satisfies a condition C. In example 1, Tar(Cond(A_1)) ={t|t is a tuple and t.*balance* < 500 and t.*rate* > 0}.

Rules can interact in the following ways: activation, deactivation and commutativity. R_i can activate (deactivate) R_j if the execution of A_i makes condition C_j true (false) when it is evaluated. In our case R_i activates R_j if the following conditions are met:

(1) Comm(A_i) ="update" or "insert"
(2) Table(A_i)∩Table(A_j)≠ ∅
(3) $I \neq \emptyset$
(4) Val(I) ∈ Targ(Cond$_I$(C_j))
(5)Targ(Cond(A_i))∩Targ(C_j)≠ ∅
where I = Att(A_i)∩Att(C_j).

Let's consider rule **R1** of Example 1. Since A_1 and C_1 don't satisfy above condition (4), **R1** cannot activate itself.

Actions A_i and A_j commute, if for all database states, the execution of A_i followed by A_j (and vice versa) produce the same final database state. In our approach A_i and A_j commute if *Targ*(Cond(A_i))∩*Targ*(Cond(A_j))=∅. In Example 1 A_2 and A_4 don't commute since Targ(Cond(A_2))(={t|1<t.*rate* <2}) ⊂Targ(Cond(A_4))(={t|t.*rate*>0}).

Termination analysis is performed on the rule activation analysis. If in a cycle formed by rules R_1, R_2, ..., R_n ($A_n = E_1$) the rule R_k doesn't activate (or deactivate) the rule R_l, then the cycle finishes. Before, we found that **R1** in Example 1 triggers itself. However, it cannot activate itself. Then, its execution process finishes and rule base processing of Example 1 is guaranteed to terminate.

Conclusion about confluence is achieved by analyzing rule (de)activation and action commutativity. If simultaneously triggered rules don't (de)activate each other, and their actions commute, then the result of their processing is confluent and the rule base is also confluent. Through CCPN analysis we identify the rule sets which may trigger at the same time, namely {**R2**, **R3**, **R4**} and {**R1**, **R2**, **R4**}. Therefore, we need to analyze the following rule pairs: (**R2**, **R3**), (**R2**, **R4**), (**R3**, **R4**), (**R1**, **R2**), (**R1**, **R4**). If each one of those rule pairs is confluent, the rule base in Example 1 is confluent. Previously we have demonstrated that **R2** and **R4** actions don't commute, so, **R2** and **R4** are not confluent. In consequence, the rule base of Example 1 is not confluent.

5 Conclusion and future work

A Petri net based approach is proposed to analyze termination and confluence properties of an active rule base. Our approach has the great advantage of eliminating unnecessary rule analysis, since we don't need to analyze all the pairs of rules to draw conclusion about termination and confluence. In the future we will implement our approach so that the analysis could be done automatically.

A Fuzzy Trigger Language for Relational Database Systems

Ying Jin Tejaswitha Bhavsar
Computer Science Department
California State University, Sacramento, CA - 95819, USA
jiny@ecs.csus.edu

Abstract - With the ever-increasing demands for data management, crisp data presentation, storage, and retrieval are not enough for complicated situations in real-life. Some kind of non-crisp or fuzzy semantics are desirable to better handle the situations where human judgment, evaluation and decisions are important. This project proposes a fuzzy language, named FZ-Trigger, for relational database systems. A trigger specifies the event raised by activities such as inserting a row, the condition to check upon event occurrence, and the corresponding action to perform when the condition is true. Incorporating fuzzy expression into the condition part of a trigger allows database users to specify the reaction to database events in a flexible manner. Uncertainty and imprecision factors are handled by linguistic variables. This paper describes the language specification of FZ-Trigger, the system architecture, and the implementation. A motivating example is also provided to illustrate the syntax and the use of FZ-Trigger.

1. INTRODUCTION

A relational database management system (DBMS) is based on the relational model that represents relations in a tabular form. Active database systems [1] are built on top of traditional passive databases by providing reactive services that automatically support monitoring and reacting to events. Active rules are the languages for active databases. The concept of active rules has been incorporated by modern commercial database systems, such as Oracle [2], in a simplified format of triggers. Triggers are database facilities that allow users to define the semantics of reactions with respect to different types of events. Triggers have a significant role in database systems for consistency control and business logic specification. A trigger consists of three parts, an event, a condition, and an action. The event is used to specify the origination of what happened, such as insert a row. The condition is evaluated upon the event occurrence to query over data sources. If the condition evaluation returns true, the action is performed to update the database or execute application procedures.

Triggers in traditional database systems are crisp, meaning that there is no vagueness and uncertainty. However, it is not sufficient to ever-increasing needs of data management. When users specify integrity constraints or business logics, they are limited to use precise expressions. A new language to use fuzzy semantics, named FZ-Trigger, is proposed in this paper to incorporate fuzzy concepts into database triggers. FZ-Trigger can be used over traditional crisp databases. FZ-trigger allows relational database users to define triggers using fuzzy conditions over crisp data.

For example, in traditional non-fuzzy trigger, we can specify "*When an item is sold, check the quantity of item in stock. If the quantity is less than 20 and the popularity rating of the item is 90, place a purchase order*". In the FZ-Trigger system, we can define "*if the item quantity is **less** and popularity is **high**, place a purchase order*". People are more familiar with this type of expression in natural language. Moreover, it is reasonable that cases such as "item quantity is 19 and popularity is 88" (in addition to "item quantity is 20 and popularity is 90") are also considered to cause the action to be performed. Our trigger specification is consistent with SQL3 [2]. It is well-known that different relational database vendors provide different relational database implementations with small variation from SQL standard. This paper uses the popularly used DBMS Oracle as the implementation system to illustrate the use of FZ-triggers.

The paper is further organized as follows. Section 2 covers the related work in the areas of fuzzy triggers and fuzzy relational database systems. Section 3 illustrates the motivating example used in this work and describes fuzzy concepts. Section 4 describes the FZ-trigger language. Section 5 presents the system architecture and implementation. We conclude the paper with summary and future directions in Section 6. The non-fuzzy trigger is referred to as crisp trigger in this paper.

2. RELATED WORK

Applying fuzzy concepts to database systems has been a research topic over years, such as in [4] [5],

including how to add fuzziness in the stored data as well as how to process fuzzy queries. Galindo [6] proposed a fuzzy query language called FSQL for fuzzy relational databases. FSQL is an extension to the SQL query language standard to allow flexible queries. Limited research has been done on triggers so far. C-fuzzy and CA-fuzzy triggers are proposed by [7] and [8] to incorporate fuzziness into active database system named as TEMPO. C-fuzzy triggers are limited to its active database system for a specific control system. Neither the language nor the architecture design can be applied to other systems easily without major modifications. In this proposed project, we will specify fuzzy triggers based on the trigger specification of SQL3 standard. We also incorporate the concepts of fulfillment of thresholds to the conditions using linguistic variables. The existing relational database retains the crisp values, which allows all existing database applications unaltered.

3. MOTIVATING EXAMPLES AND FUZZY CONCEPTS

To illustrate our approach of incorporating fuzziness into triggers, we use a motivating example of Fashion Store Inventory, in which the store maintains information such as product, price, item-code, quantity available, and category. It keeps track of the transaction history after each item is sold. Discount offer information, yearly/monthly sales of each product and order placement priority is also maintained. Purchase orders are placed for the items which are popular and less in quantity. Items which have high quantity left in the inventory can be declared with a clearance discount or seasonal discount. This is a typical database application that stores crisp information in all the tables. In this paper, we present our approach of specifying fuzzy triggers over crisp underlying data.

An important concept in fuzzy theory is linguistic variables, whose values are words rather than numbers. The linguistic variable is represented by a quintuple that characterizes the fuzzy number along with the linguistic concepts interpreted in a particular context.

The quintuple is **<v, T(v), X, g, m>**, where *v* is name of the linguistic variable, *T(v)* is a set of linguistic terms applicable to variable *v*, *X* is a universal set of values, *g* is grammar for generating the linguistic term, and *m* is the semantic rule that assigns to each term. For example, for a linguistic variable *Quantity,* the set of linguistic terms could be T (*Quantity*) = {**Very_Low, Low, Sufficient, High, Very_High**}. Among many other presentations, trapezoidal distribution is chosen to use in this research. For example, as shown in Figure 1, the linguistic term, **Low,** for linguistic variable *Quantity,* is represented using trapezoidal function as **Low** (8,10,16,18), where $\alpha = 8$, $\beta = 10$, $\gamma = 16$, and $\delta = 18$.

To specify fuzzy triggers over crisp data in our implementation, we create an additional table to store information related to linguistic variables, without altering any existing tables to avoid the effect on existing applications. We also store α, β, γ, and δ values of each trapezoidal distribution in this table. The table contains the information about linguistic variable (e.g. **Low**), the name of table (e.g. *Item* table) related to this linguistic variable, the attribute name (e.g. *Quantity*) related to this linguistic variable, as well as the values for α, β, γ, and δ. The table serves as the metadata for fuzzy knowledge to allow other architectural components to retrieve fuzzy knowledge at run time.

Fulfillment threshold specifies the degree $d \in [0, 1]$ for the specification of a condition. For example, we can specify a grade of 0.75 (the variable named as THOLD) when we state a condition like "*Quantity* is **Low**", as shown in Figure 1, which eventually forms a range of (9.5, 16.5). Using **Low** instead of the range of (9.5, 16.5) to describe the *Quantity* is more near to nature languages used by human beings.

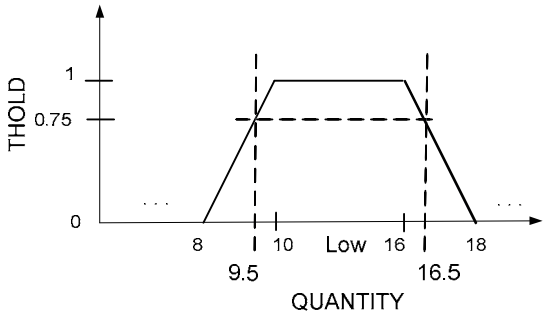

Figure 1: Example to show trapezoidal function

4. LANGUAGE

This section describes the language and example of FZ-Trigger. FZ-Triggers are defined as:

$$\textbf{\textit{when E, if }}\{C \times S_i \times S_j\}\textbf{\textit{, then A}}$$

When event occurs, if the condition is true, then the action is performed. In this definition, ***C*** is a set of fuzzy conditions connected by *AND* and *OR*. Each condition in ***C*** consists of two elements (v Θ g, d), where ***v*** is a linguistic variable defined in the quintuple in Section 3. ***Θ*** is a comparison operator which includes =, <, <=, >, >=, !=. ***g*** is linguistic term where ***g ∈ T(v)***, ***T(v)*** is defined in the quintuple in Section 3. ***d*** is fulfillment threshold which applies to "v Θ g", ***d*** ∈ [0, 1]. S_i and S_j are the current and previous database states, which are referred as *new* and *old* in triggers.

The syntax of the proposed FZ-Trigger language is shown in Figure 2. A trigger consists of three parts: event, condition, and action. The event is the data manipulation command, such as Insert. The condition part of the trigger can be specified in two places (bold in Figure 2): 1) In the "WHEN <condition>", 2) In the "IF <condition>" within a PL/SQL statement. Both crisp and fuzzy expressions can be specified in these two places (Crisp expressions are also allowed in FZ-trigger). The action part of the trigger is specified in the PL/SQL statement. In traditional crisp triggers, users can specify an expression such as "*new*.*Quantity* = 8". In FZ-Trigger, users can alternatively specify a fuzzy expression such as "*new*.*Quantity* = **$Low**" along with the specification of fulfillment threshold such as "WITH THOLD = ***0.8***". As a result, users specify the semantic of "Quantity is high with the degree of 0.8" using the fuzzy expression. We use '**$**' to identify fuzzy values, and 'THOLD' to indicate a fulfillment threshold. 'THOLD' is optional and the default value taken is ***1*** if nothing is specified. Multiple fuzzy expressions can be connected by *AND* or *OR*.

An example of FZ-trigger is illustrated in Figure 3, which is based on the motivating example. In this example, we specify the fuzzy condition in the "IF" statement within a PL/SQL block (in bold). The trigger specifies the constraints that when the *Quantity* of an item is **Low** with the fulfillment threshold of ***0.8***, and when the *Popularity* is **High** with the degree of ***0.7***, we should create a pending order if we have not already placed a purchase order for this item. The trigger also updates the *Item* table to maintain the consistency between *Item* table and *Transaction_History* table.

```
CREATE TRIGGER trigger name
(AFTER | BEFORE) triggering events ON table name
[FOR EACH ROW]
[WHEN [crispExpression] [[and|or] [fuzzyExpression [with THOLD =
TholdValue]]]*]
BEGIN
  PL/SQL Block
  [IF [crispExpression] [[and|or] [fuzzyExpression [with THOLD =
TholdValue]]]*]
  PL/SQL Block
END;
/
```

Figure 2: Syntax of FZ-Trigger

```
CREATE OR REPLACE TRIGGER ON_SOLD_PENDING_ORDER
AFTER INSERT ON TRANSACTION_HISTORY
REFERENCING NEW AS NEW
FOR EACH ROW
DECLARE
   ItemObj   Item%rowtype;
   Count1    Number;
BEGIN
   select * into ItemObj from Item I where I.Item_ID = :new.Item_ID;
   select count(*) into Count1 from Pending_Orders where Item_ID =
:new.Item_ID;
   IF(ItemObj.Quantity = $Low WITH THOLD = 0.8) AND
     (ItemObj.Popularity = $High WITH THOLD = 0.7) THEN
   if Count1 = 0 then
      insert into Pending_Orders values(:new.Item_ID, 21, 'High');
   end if;
   end if;
   update Item set Quantity = Quantity - :new.Quantity,
                   Popularity = Popularity + :new.Quantity
                   where Item_ID = :new.Item_ID;
END;
/
```

Figure 3: Example of FZ-Trigger

5. ARCHITECTURE AND SYSTEM IMPLEMENTATION

The system architecture is shown in Figure 4. A FZ-Trigger system has been implemented to allow users to specify fuzzy triggers. The *User Interface* provides an interface for users to enter a fuzzy trigger and view the output. This interface passes the fuzzy trigger creation request to the *Coordinator*. Then the *Parser* parses the given fuzzy trigger, consults the metadata for fuzzy knowledge, and then translates the fuzzy trigger into a crisp trigger. The parser is implemented using JavaCC [9]. Using *JDBC* (Java Database Connectivity), the newly generated trigger is passed to the underlying database. The result (e.g. the fuzzy trigger is successfully generated) is passed to the *Coordinator* and then to the users through the *User Interface*. For an existing DBMS, the execution model of crisp triggers has already been established. We utilize the existing DBMS environment for the execution of the newly generated trigger at run time.

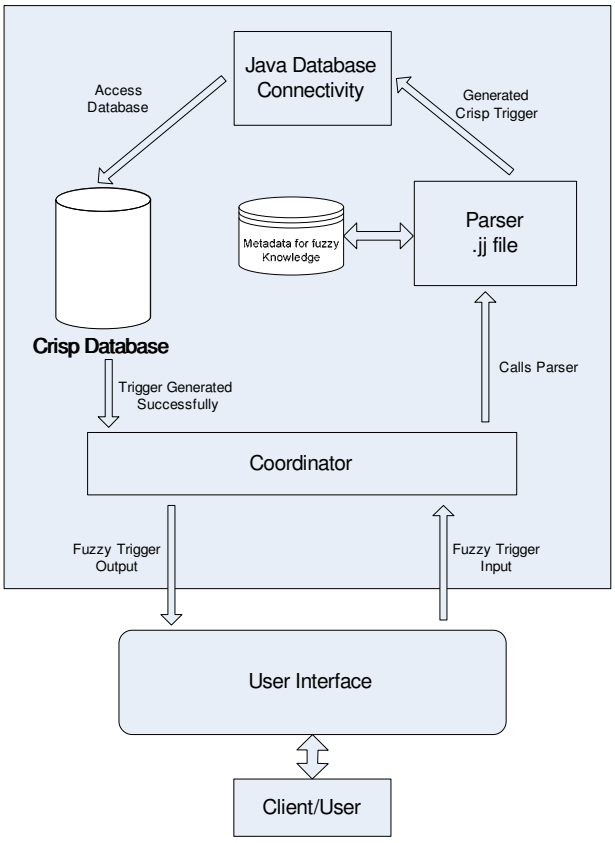

Figure 4: Architecture of FZ-Trigger System

6. SUMMARY AND FUTURE DIRECTIONS

To support vague expressions over crisp data in databases, we developed the FZ-Trigger language that supports fuzziness in relational database triggers. Fuzzy triggers can be applied in various real-world applications to allow flexible expressions of business logic. This paper describes the syntax and use of the language, the system architecture, and the implementation details. One of our future directions is to provide better interface to allow users to express FZ-Trigger easily with minimum requirements of syntax. Another direction is towards the evaluation of the performance of the FZ-Trigger system.

Abstract - **In the modern world text documents play an important role in most of the organizations. Their constant growth widens the scope of document storage. As a result, there is a potential need for effective text retrieval and search capabilities. This paper suggests two document preprocessing methods. The objective of this study is to find an appropriate data representation for text categorization by comparing two data representation approaches. The first approach groups the documents based on their title and the second approach considers the document body to group documents. Both methods apply the same clustering and classification techniques on the test data sets. It applies clustering to divide the documents into categories and uses classification techniques to validate the clustering results. This study shows that the text documents grouping based on document titles has high performances than the other approach.**

Keywords — Title data representation, Document body data representation, K-mean clustering, Naïve Bayes classification, WEKA data mining tool.

I. INTRODUCTION

Information has a strategic importance for most of the organizations as well as for every citizen. The constant growth of text documents widen the document storage scope and make it difficult to retrieve information. The growing importance of electronic media for storing and exchanging text documents has led to an increasing interest in tools and approaches for dealing with information included in the text documents. Therefore there is a requirement for advance analysis of those documents to group them according to the content as well as semantic search and document comparisons.

Text categorization is the process of grouping documents into classes based on their content. It assigns unseen documents into categories and handles the exponential growth in available text documents [1]. Text mining extracts high quality information from text documents by considering the patterns in the data set. Patterns are found when there are relationships among data sets. A careful study of the business case and the correlation of the data sets have to be considered to discover a pattern.

When text clustering is carried out manually, the analysts need a special knowledge in vocabulary and knowledge processing. In the categorizing process the analysts have to read the full text document, memorize all class definitions and also it consumes more time. Today most of the applications such as news dispatching and e-mail filtering deal with a large collection of documents and it is difficult to cluster them manually based on their content. By using an automatic text categorizing system it is possible to cluster documents more accurately within a short period of time.

Data sets are rich with hidden information that can be used for making intelligent decisions. Most of the text mining and information retrieval techniques rely on word matching. Clustering can be used as an alternative technique for information retrieval. Clustering is the process of partitioning of the data sets into subsets, so that the data in each cluster share common characteristics. Clustering gives an overview of a document collection, manages a large number of text documents and provides efficient information retrieval [1]. Classification and prediction can be used to extract models describing important data classes or predict future data trends, where as visualization has the ability to describe the structure of a classifier in an understandable way by converting the data into usable knowledge [2].

Most of the full text documents are rather long and potentially with a loose structure. Previous studies show that word clusters can reduce the feature space dimensionality, with only a slight change in classification precision [3]. Most common approaches start by evaluating the co-occurrence of words versus documents [1]. However the count matrices tend to be sparse and noisy when the data set is relatively small. Although the documents are represented in a high dimensional sparse feature space, it is not optimal for classification algorithms [4]. Considering all practical settings it is difficult to apply clustering in a high dimensional space. Furthermore it is hard to explain well, why the text clusters have been constructed the way they are [5]. It is difficult to obtain a categorization that is both meaningful and complete [5].

This paper considers the problem of categorizing abstracts, which describes the NSF (National Science Foundation) awards for basic research. This study is based on the comparison of two document categorization approaches. One

approach categorizes documents based on the title of the article, where as the other is based on the article body. These approaches use both clustering and classification techniques to extract knowledge, based on the content of the documents. The objective is to show that the approach based on article titles, gives better performance than the approach based on article body. The study finds an acceptable data preprocessing method which can be used to categorize similar documents into one category.

This paper, describes the data set, tools and techniques used in this study. Next it explains the methodology and finally it includes the results obtained and concludes the results.

II. DATA SETS

Data sets are rich with hidden information that can be used for making intelligent decision. The selected data set for this study is publicly available at UCI Knowledge Discovery in Databases archive. The 'nsfabs', (NSF abstracts), data set consists of 129,000 abstracts, one per file. It describes the NSF awards for basic research during the period 1990-2003 [6]. For simplicity we used only 500 abstracts for testing.

III. RESEARCH METHODOLOGY

A. Outline

This approach used word frequency counts to determine the significant words in each document. Every word is represented only once in the text representation.

Data consists of textual data with noise; hence some attributes may be irrelevant to the clustering and classification tasks. Since the data is extracted from raw data files, relevance analysis on data was performed to remove redundant attributes from learning process. A data cleaning and preprocessing algorithm was used to avoid the interference of irrelevant words during the clustering by extracting, removing noise and cleaning the textual data. After applying cleaning on the original data set, it is easy to extract words with a high occurrence, which leads to the main idea represented in the document. We have recognized and classified significant vocabulary items from the text.

B. K-Means clustering algorithm

The K-means algorithm is simple to use and can run on large data sets. It is a widely used central clustering technique that minimizes the average distance between an observation and its cluster center. The algorithm first selects the number of clusters and determines the cluster centers. It assigns each collection of words to the nearest cluster center by minimizing the average squared Euclidean distance between the words and its cluster center and re-computes the new cluster centers.

This procedure is repeated until some convergence criterion is met [2], [1].

C. Waikato Environment for Knowledge Analysis (WEKA) data mining tool

This is an easy to use, extensible package which contains a collection of machine learning algorithms for solving real world data mining problems. It is written in JAVA and runs on most platforms. Implemented schemes for classification, numeric prediction and meta-schemes are three main schemes in WEKA [9].

D. Classifiers

Naïve Bayes is a simple, popular text classification algorithm which classifies using estimator classes. This allows for a detailed analysis of the effects of using word clusters instead of words as features [4]. It uses joint probabilities of words and categories to estimate the probabilities of categories in a given document [10].

J48 classification algorithm generates a C4.5 decision tree. A decision tree builds classification models to predict classes for unseen entities. It is a simple structure where non-terminal nodes represent tests on one or more attributes and terminal nodes reflect decision outcomes [9].

E. Test Options

Following test modes have applied with classifiers.

i. Use training set: evaluates on how well it predicts the class of the instances it was trained on.

ii. Cross-validation. The classifier is evaluated by cross-validation, using the number of folds that are entered in the Folds text field.

iii. Percentage split: evaluates on how well it predicts a certain percentage of the data which is held out for testing [9].

F. Methodology:

i. Acquire text documents: Gathered text document in a common format and name the text files in a standard format in a suitable way which can be used for the data preprocessing task.

ii. Data cleaning: Applied a data cleaning and noise removal algorithm which extracts only the necessary words from each text file. The algorithm eliminates prepositions, symbols; numeric form of numbers, proper names, punctuation marks, commonly used words, abbreviations and other non-alphabet characters.

iii. Data pre-processing: This study experimented with two approaches. The first approach extracts the first five words from the title without considering any other content in the document. The extracted words are stored in one file, so that each row represents the keywords relevant to one document title. The second approach counts the number of occurrences of each word in the document body and extracts five words with the highest frequency, from each document. All extracted words were stored in a matrix, so that each row represents the words with the highest frequency for a given document.

iv. Document categorization: Applied K-means clustering algorithm on the pre-processed data and identified different clusters, which each document belongs to. The experiment

was done with both 35 and 50 clusters. The number of clusters is decided based on the number of available documents.

v. Document classification: Applied three classifiers Naïve Bayes and J48 on the categorized data to verify the precision of the categorization in order to compare the two data representations suggested in this work.

vi. Analyze results: Computed the mean, median, maximum, minimum, and standard deviation of the obtained results to analyze clustering process. Next we compared the cluster distribution and the accuracy of the two approaches and identified the better approach.

IV. EXPERIMENTAL RESULTS

This study considered several criteria to evaluate the quality of clustering. The results obtained using WEKA tool, after classification according to the number of clusters in both data representations are shown in the Table 1 and Table 2.

According to the results it is not necessary to increase the number of clusters to improve the accuracy, because in some cases the accuracy with 35 clusters is better than the accuracy with 50 clusters.

A. Test 1: Data representation using document titles

TABLE 1
Results obtained by applying classifiers on the data set which is clustered using K-means technique.

Technique	Option	With 35 clusters		With 50 clusters	
		Accuracy	Mean absolute error	Accuracy	Mean absolute error
Naïve Bayes	Using training set	92.4%	0.0109	91.2%	0.0086
	Cross validation (with 10 folds)	60%	0.0299	63.4%	0.0223
	Percentage Split 66%	62.3%	0.0319	58.2%	0.0237
J48	Using training set	87.6%	0.0105	85.2%	0.0087
	Cross validation (with 10 folds)	71.2%	0.0274	66.4%	0.0213
	Percentage Split 66%	67%	0.0285	59.4%	0.0224

B. Test 2 : Data representation using document body

TABLE 2
Results obtained by applying classifiers on the data set which is clustered using K-means technique

Technique	option	With 35 clusters		With 50 clusters	
		Accuracy	Mean absolute error	Accuracy	Mean absolute error
Naïve Bayes	Using training set	99.6%	0.0016	99.8%	0.001
	Cross validation (with 10 folds)	43.4%	0.0438	43.2%	0.032
	Percentage Split 66%	40.5%	0.0458	32.3%	0.0341
J48	Using training set	43.6%	0.0454	34.4%	0.0347
	Cross validation (with 10 folds)	43.6%	0.0454	35.2%	0.0342
	Percentage Split 66%	40%	0.0459	32.3%	0.0349

According to the results Naïve Bayes classifier gives high accuracy with the 'Training set data' option compared to other tests. Moreover, the 'Title' data representation gives better quality, more than 58%, in almost all the cases when compared to the data representation based on the 'Document body'.

C. *Analysis of cluster Performance*

Considering all the 12 accuracy results for each representation separately, Table 3 depicts the analysis results for the classification process.

TABLE 3
Analysis of Results

Statistics on Accuracy	Title Data Representation	Document body Representation
Max	92.40%	99.80%
Min	58.20%	32.30%
Mean	72.03%	48.99%
Median	66.70%	41.85%
Standard Deviation	13.214	24.081

As the results depict, 'Title' data representation has a higher value for the mean, and a lower value for the standard deviation than the 'Abstract' data representation. It can be seen that the 'Title' data representation leads to cluster the data better than the 'abstract content' representation.

V. DISCUSSION

We compared two data representation approaches that can be used to divide text documents into groups. By extracting words that maximize the information about the documents, we could obtain low dimensional representation of the documents. On the basis of the experimental results it can be seen that the K-Means clustering algorithm and Naïve Bayes classification algorithm can be used to group the text documents with significant accuracy. Moreover the data representation plays an important role in the clustering.

According to the results 'Title' data representation is important because it captures the main idea of the document. The document body may not include words with high frequency, which give the main idea of the text. We considered proper names, multiword terms, abbreviations, and other useful things such as numerical forms of numbers, percentages and money. Moreover the document body can contain synonyms, phonemes and words with different tenses which may not account for the word frequency in this study. This can be enhanced by defining some test cases manually and by training the data set based on the test cases.

VI. CONCLUSION

Large collection of documents may afford a lot of useful information to people. However, it is a challenge to find out the useful information from a large collection of documents. Successfully implemented text mining techniques help to identify the category of a text document, which it belongs to. The results of this study are generally applicable to any domain with textual data and helps when dealing with large amount of data. It verifies the clustering results by applying classification on clustered data. Moreover it is not necessary to increase the number of clusters to gain better results. The data representation in this study enables to improve the clustering quality. However the clustering approaches which are based on frequency of terms may not exhibit significant structural information as their data points are not similar to each other. The data preprocessing step guarantees completeness by solving this problem.

This approach can be practically applied to group news articles according to their subject and for other applications such as analyzing insurance claims, fax processing, e-mail filtering.

ACKNOWLEDGEMENTS

This research was carried out as a partial requirement for the M.Sc. in computer science, University of Moratuwa.

Abstract

Economics-driven software mining (EDSM) sifts through the repository data to extract information that could be useful for reasoning about not only the technical aspects but also the economics properties related to the development and/or evolution of software systems, and in relation to the environments in which they are procured, developed, evolved and used. The objective is to provide the analyst with insights into investment decisions related to the development, maintenance, and evolution of software systems. We describe a scenario for realizing EDSM through an example. The example represents a small-size component-based distributed architecture, where we mined existing performance repositories to value the ranges in which a given software architecture can scale to support likely changes in load. The mining is based on a financial analogy. The mining step is then complemented with real options analysis to predict the values resulted from the ranges in which an architecture can scale under uncertainty, where uncertainty is attributed to the unpredicted change in load. The example shows the usefulness of EDSM in informing tradeoffs analysis in software design decision making.

1. Introduction

Effort on Mining Software Repositories (MSR) [MSR 1-4] has revolved around approaches which analyze the data stored in software repositories to assist in program understanding and visualization; predict and gauge the reliability and quality of software systems; study the evolution of software systems through discovering patterns of change and refactorings; modeling defects and their repair; and understand the origins of code cloning and design changes. Contributions have also included case studies showing how data can be extracted from software repositories to improve software design and reuse. The overall goal is utilize the mined data for predicting and planning various aspects of software projects. Meanwhile, software engineers are faced with general lack of adequate models and methods, which connect technical engineering concepts to economics and value creation under given circumstances [EDSR 1-8]. Reflecting on the Software Engineering discipline, [Sul99] note that the problem in the field is that "no serious attempt is made to characterize the link between structural decisions and value added". That is, the traditional focus of software engineering is more on structural and technical perfection than on value added [EDSR 1-8; Boe00; Erd00]. This argument is applicable to the emerging MSR discipline, where the current focus appears to be purely a technical endeavor with little attention paid to economics context. For example, software repositories are often mined and analyzed ignoring the link between technical properties, economics, and value creation under a given circumstances. Such a link may provide the software analyst with a powerful tool for predicting cost/value information for developing and evolving dependable software; understanding the economics of refactoring and reengineering; assisting in resource planning and utilization; and understanding the economics ramification of the change; defects and their repair; on the system and its design artifacts (e.g., architectures); and informing design trade-offs. The objective is to utilize data buried in software repositories to provide insights into investment decisions related to the development and evolution of software systems to assist in resource planning and utilization. Conversely, mining software repositories could be seen as an effort for empirically developing economics-driven software engineering models and methods, which could have the promise in addressing the need indicated by [Sul99; Boe00; EDSR 1-8].

In this paper, we describe a scenario for realizing EDSM. Drawing on a case study that adequately represents a medium-size component-based distributed architecture, we mined existing performance repositories to value the ranges in which a given software architecture can scale to support likely changes in load. The mining is based on a financial analogy, where we utilize the concept of twin asset in financial engineering to justify mining relevant repositories. The mining process in then complemented with real options analysis for predicting the values resulted from the ranges in which an architecture can scale under uncertainty, where uncertainty is attributed to the unpredicted change in load. As the exact method for analyzing scalability is subject to debate, we focus the analysis on *throughput* as a way for measuring scalability. The provided pointers describe how EDSM can inform tradeoffs in software design decision making.

The paper is further structured as follows. Section 2 defines EDSM. Section 3 presents an example on realizing EDSM. Section 4 briefly outlines related work. Section 5 concludes.

2. Economics-Driven Software Mining

Economics-driven software mining (EDSM) is based on the premise that non-trivial, unknown, and valuable information lies in an existing data repository, where the goal of the mining is to sift through the repository data to extract information that could be useful for reasoning about not only the technical aspects but also the economics properties of the development and/or evolution of software systems, with the environments in which they are procured, developed, evolved and used [Bah07].

According to [Min99], the process of mining software repositories encompasses: (i) *Data extraction* from repositories;

(ii) *preprocessing the data for analysis*, where the extracted data has to be formatted (e.g., treating noisy or missing data), sampled, and often need to be adapted to the mining algorithm(s). The data is then ready to be mined by a data mining algorithm(s); (iii) *data mining* which aims at extracting patterns of interesting and potentially useful, unknown, non-trivial information from the data; and (iv) *data interpretation* where the patterns identified are interpreted into knowledge, which can then be used to support decision-making. Different mining techniques may be used to achieve this step. EDSM poses several challenges. For example, how can we decide on which data to be extracted and be mined? Which of the mined data could be revealing to both the technical and economical properties of a software system and relative to the mining objectives? What are the mining tools that could be used for extracting meaningful inputs for the economics-driven software engineering analysis? How can we ensure that the mining objectives have been satisfied and the obtained knowledge is meaningful inputs to the economics-driven software engineering analysis? What are the appropriate analyses tools that could be used for supporting EDSM? The challenge, therefore, is to realize EDSM in light of these questions.

The process of mining software repositories includes (i) setting a goal for the analysis (i.e. the mining objective); (ii) selecting the economics models which can perform the analysis; (iii) developing the mining tools for extracting and mining information, which could serve as inputs for the models in (ii); (iv) capturing and interpreting the derived patterns; (v) modeling and computation; and (vi) result interpretations, analysis and reflection, where the mining step can be complemented by economics analysis to provide an answer for queries related to the economics of software artifacts, project utilization, and management. The queries could range from simple to compound ones. For example, let us assume that the query is to understand the evolution pattern of component X in a given architecture and the cost trends of evolving X over a time period. The change history of X could be mined using existing approaches and can be then complemented by cost estimation to cast effort of evolving X over a given period to cost (in £). Note, these models could be adapted from finance, economics, etc. on condition that the model assumptions are plausible or simplified to serve the software engineering mining objectives. The drawn analogy, the model inputs, and the made assumptions can then justify mining relevant repositories. In some cases, the analysis tool tends to shape the mining tool. An example is provided in Section 3, where adopting options analysis from financial engineering has constrained the way we extract and mined data.

3. An Example

We provide an example on realizing EDSM from our application of real options theory in software engineering [Bah08].

Setting. Let us consider a three-tier architecture of an online banking system application, referred to as Duke's. This architecture will be built on middleware, such as Java 2 Enterprise Edition (J2EE) and the Common Object Request Broker Architecture (CORBA). Depending on which middleware is chosen, different architectures may be induced [DiN99]. Given the choice of either CORBA or J2EE to induce an architecture, let us assume that the Duke's Bank system needs to scale to accommodate the growing number of clients in one-year time. An architecture which can scale to address such changes in load with limited resources and shorter time-to-market is a significant asset for surviving the business, cutting down maintenance costs, utilizing resources, and creating value. In particular, the cost and value derived from *the flexibility* in scaling up due to inducing the architecture with either CORBA or J2EE can inform the decision tradeoffs in considering either. Hence, the value added can inform the selection of application server products to induce Duke's. We show how existing *performance benchmark repositories* are utilized and mined to predict the values in which Duke's architecture, when induced by each middleware, can scale to support changes in load. We mined relevant performance benchmarks to understand how the architecture of the system may behave once induced with either and with respect to throughput, which is a scalability and load measure. The mining is based on a financial analogy, where we "mimic" the concept of *twin asse*t in financial engineering to justify minin*g* relevant repositories and for valuing throughput using historical data. The approach utilizes online data and benchmarks, submitted from different practitioners and vendors. The mining process is then complemented with real options analysis for predicting the values resulted from the ranges in which an architecture can scale under uncertainty, where uncertainty is attributed to the unpredicted change in load. The rationale is that the combination could provide the architect/analyst with a useful tool for understanding the extent to which the software system is can accommodate the change in load and starting from early stages of the software lifecycle, where the system need not be implemented.

Setting the mining objectives. Let us assume that we are given the choice of two middleware M_0 and M_1 to induce the architecture of a particular system as it is the case of Duke's. Let us assume that S_0, S_1 are the architectures obtained from inducing M_0 and M_1 respectively. Say, M_1 is an economical choice, if it adds value to S_1 relative to S_0. We attribute the added value to the enhanced flexibility of S_1 over S_0 in scaling up the architecture. But the added value is uncertain, as the demand and the nature of the future change and load are uncertain. We set some queries: (i) How valuable is the flexibility of either alternative, relative to likely change in scalability, will be in the long-run? (ii) Which solution is more valuable under uncertainty, where uncertainty is attributed to the unanticipated changes in load? (iii) What is the impact of volatility on value creation under given consideration? (iv) What is the impact of uncertainty on our choice? (v) Can high uncertainty, due to the likely future load, make the less favorable technology more appealing for the decision maker (and vice versa)? The challenge now is to select the economics model(s), which could be suited for addressing the said objectives. The value of flexibility under uncertainty is critical to choice of the economics models.

Selecting economics models, which can serve the analysis of the said objective(s). We argued that options theory is well suited to address the above mining objectives. Real options analysis recognizes that the value of the capital investment lies not only in the amount of direct revenues that the investment is expected to generate, but also in the future op-

portunities that flexibility creates. An option is an asset that provides its owner the right without a symmetric obligation to make an investment decision under given terms for a period of time into the future ending with an expiration date [Tri95]. If conditions favorable to investing arise, the owner can exercise the option by investing the exercise price defined by the option. A *call option* gives the right to acquire an asset of uncertain future value for the strike price [Tri95].

ArchOptions[Bah05; Bah04], a real options based model which values the *growth* options of an architecture relative to some future changes, as a way for understanding the architectural flexibility with respect to changes in requirements. A growth option is a real option to expand with strategic importance [Tri95] and is common in infrastructure-based investments, as it is the case with software architectures. Since the future changes are generally unanticipated, the value of the growth options lies in the enhanced flexibility of the architecture to cope with uncertainty. ArchOptions builds on a simple and intuitive analogy with Black and Scholes [1973]. In ArchOptions, the flexibility of the middleware induced-architecture in coping with changes in load has a value in the form of growth options. This value is strategic in essence, uncertain as the demand on the future changes are uncertain, and may not be immediate. The added value may take the form of (i) accumulated savings through coping with the change without "breaking" the architecture, mostly these are changes in non-functional requirements; (ii) extending the range of services while leaving the architecture intact; and (iii) the ability to respond to competitive forces and changing market conditions that may pose higher Quality of Service (QoS) requirements, such as the demands for higher availability, scalability, etc.

Choosing a particular middleware to induce the architecture of the software system can be seen as an investment to purchase flexibility in the induced software architecture. The ranges, in which the load changes, influence the choice. A "wise" selection is seen as an investment to buy flexibility, which could be valued as future *growth options* [Tri96] on the architecture of the software system. These *options* enhance the upside potentials of the structure when the load change; they differ from one middleware to another. That is, S_1 is said to be more accommodating to the change than S_0 when S_1 holds more growth options than S_0. For a valuation point of view *p*, we focus the analysis on the calls of the ArchOptions model for valuing the growth options, as given in (1) accounting for both the expected value and exercise cost to accommodate future requirements i_i, for $i \leq n$. Valuing the expectation E of expression *(1)* uses the assumptions of Black and Scholes[Bla73] and detailed in previous work[Bah05; Bah04].

$$\sum_{i=1\ldots n} E\,[\max (x_i V_p - C_{eip}, 0)] \qquad (1)$$

The payoff of the constructed call option gives an indication of how valuable the flexibility of an architecture is, when enduring some likely changes in requirements. The selection has to be guided by the expected payoff in $(\sum_{i=1\ldots n} E\,[\max (x_i V_p - C_{eip}, 0)]_{S1}$ relative to that of $(\sum_{i=1\ldots n} E\,[\max (x_i V_p - C_{eip}, 0)]_{S0}$. That is, if $(- I_e + \sum_{i=1\ldots n} E\,[\max (x_i Vp - C_{eip}, 0)]_{S1} > \sum_{i=1\ldots n} E\,[\max (x_i V_p - C_{eip}, 0)]_{S0})$ for some likely changes, then it is worth investing in M_1, as the investment in M_1 is likely to generate more growth options for S_1 than for S_0 and relative to the p valuation point of view. If $(E\,[\max (x_k V_p - C_{epk}, 0)])_{S1}=0)$, then M_1 is not likely to payoff, relative to M_0, as the flexibility of the architecture to the change is not likely to add a value for S_1 on *p*, if the change need to be exercised. Two interpretations might be possible: (i) the architecture is overly flexible in the sense that its response to the change(s) has not "pulled" the options relative to *p*. This implies that the embedded flexibility (or the resources invested in implementing flexibility- if any) are wasted and unutilized to reveal the options relative to the changes and relative to *p* (ii) the other case is when the architecture is inflexible relative to the change. This is when the cost of accommodating the change on S_1 is much more than the cumulative expected value of the architecture responsiveness to the change.

Developing the mining tools for extracting patterns serving the chosen economics model(s). Options valuation using Black and Scholes[1973] techniques determine the value of an asset in question in span of the market value using a correlated *twin asset* [Tri95]. The twin asset is an asset that has the same risks as the asset in question will have when the investment has been completed [Sch00]. To understand the behavior of the asset in question, we can use a twin asset, also referred to as a replicated portfolio. The assumption is that under similar conditions the twin asset and the asset in question are interchangeable for all practical purposes and should be worth the same.

Throughput, a scalability measure, expresses the amount of work performed by the system under test during a unit of time. This criterion is based on the observation that for a fixed system with a given throughput (e.g., a single host), there is an inverse relationship between the response time and the number of clients. In other words, the more clients submitting requests, the longer are the delays. A well-known throughput metric is the Total Operations Per Second (TOPS) completed during the measurement interval, referred to as TOPS [http://www.spec.org/]. TOPS is composed of the total number of business transactions completed in the customer domain, added to the total number of work orders completed in the manufacturing domain, normalized per second.

We have mined relevant performance benchmarks, published in (http://www.spec.org/) to understand how the architecture of the system may behave once induced with either J2EE or CORBA with respect to throughput. We appealed to the use of published benchmarks, for the following reasons: First, the system of the given architecture need not be implemented during the evaluation. Thus, performance measures may not be available. Second, we argue that using published benchmarks mimics the concept of the twin asset for we are relying on historical information (though not traded in span of the market, but still hold market information) which shows possible variations in performance in connection to change in load and relative to the candidate implementations. Third, these benchmarks often hint that the throughput is dependent on and can be estimated from the middle-tier "processing power" of the architecture. The advantage of this approach is that the published benchmarks could reveal risks of the operating environment on the choice. Benchmarks are revealing on

the performance dimension because, for example, if multiple benchmarks are conducted with a suitable mix of relevant factors, it may be possible to obtain a set of basic scalability results that can be used for estimating the throughput of possible configurations of the architecture. Depending on the benchmarking algorithm, the relevant scalability factors can be, for example, the number of objects, the number of clients, or the number of nodes in the system etc. supported in response to growing load. A major problem in comparing benchmark results, however, is that different hardware platforms and configurations (e.g., memory, disk drives etc) often produce different results making the comparisons difficult. Fourth, vendors often try many different ways to optimize performance, including adding cache memory and putting cache buffers on disk arrays. This can give a spectrum of worst and best scenarios that could mimics fluctuation, which is a volatility measure, of the option approach.

Analyzing and interpreting the derived patterns. Figure 1 shows the likely throughput trend that the J2EE-induced architecture may exhibit relative to the CORBA-induced one, upon varying the TOPS and the number of hosts. For the J2EE-induced architecture, we provide throughput estimations for two possible implementations: one with JBoss and the other with WLS. For the CORBA-induced architecture, we provide estimates upon the use of JacORB to induce the architecture. Table 1 depicts the upper limit of TOPS supported per host for each of WLS, JBOSS, JacORB induced architectures for 1 to 4 hosts. Figure 2 shows the likely cost-trend upon inducing the Duke's bank architecture with J2EE (using either WLS or JBOSS) and with CORBA (using JacORB). The likely cost is plotted against the number of hosts (1 to 4). The cost refers to the lifecycle cost of the System Under Test (SUT). The cost includes Application Servers/Containers, Database Servers, network connections, etc. Assuming, for example, a five-year lifecycle, cost would include all hardware (purchase price), software including license charges, and hardware maintenance. For the CORBA version, it assumed that the investment incurs an upfront cost to the development of the replication mechanism to support fault-tolerance and load-balancing services for high load scenarios [Bah05]. For the J2EE version of WLS, a license cost is incurred per host.

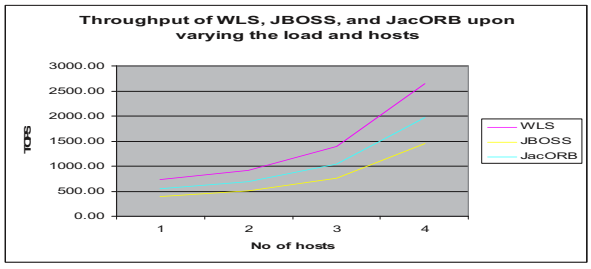

Figure 1. TOPS/host for each of WLS, JBOSS, JacORB (1- 4 hosts)

In [bah05], we have seen that the structural analysis is in favor of the J2EE-induced architecture, the throughput analysis may reveal a different trend upon scaling up each version. From the throughput valuation point of view, Figure 2 shows that when the Duke's architecture will be induced with JBOSS, a J2EE implementation, the system is likely to be slower than that of the JacORB one. This is because JBOSS uses reflection [http://www.jboss.org]. This also implies that there are some chances for the JBOSS-induced architecture to require more hardware for addressing this deficiency. When inducing the Duke's architecture with WLS, another J2EE implementation, the system is very likely to be faster than that of the JacORB implementation. WLS, however, comes with significant licenses costs; this cost grows with the number of hosts, as the load increases. Coining the TOPS with their associated costs, Figure 1, Figure 2 and Table 1, hint that there might be a case for JacORB in certain throughput range. Moreover, once the services for realizing scalability (e.g., the fault-tolerance and load balancing service) are implemented, the cost is incurred once and amortized across the hosts.

Table 1. Upper limit of TOPS/host for WLS, JBOSS, JacORB

Hosts	WLS	JBOSS	JacORB
1	732.00	400.26	546.80
2	918.36	502.16	686.01
3	1395.44	763.03	1042.39
4	2640.96	1444.08	1972.79

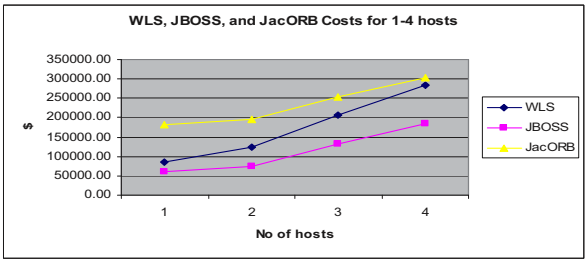

Figure 2. Likely cost-trend upon inducing the Duke's bank architecture with J2EE-(WLS/JBOSS) and with CORBA (JacORB)

Modeling and computation. The case of valuing throughput is appealing to ArchOptions for the following major reasons: First, there is cone of uncertainty associated with the growing load and consequently in the value added as result of our choice. Moreover, the TOPS are of straightforward contribution to value. That is, the more operations are completed per second, the more value is added to the enterprise. However, TOPS incur a price upon executing the operations. The price again is dependent on several factors such as the number of hosts, the hardware, the license cost, and any additional costs that are necessary for making the middleware adaptable to the growing load. In the context of the Duke's Bank, the TOPS range is often uncertain as it is dependent on the customers' behavior at a time. The *uncertainty* in the likely range (i.e., TOPS), the associated costs for executing the TOPS, and the "fluctuation" in the value added as a result make the case very appealing to the use of ArchOptions. Below, we estimate the parameters for computing throughput, Pthro using ArchOptions to address the set mining objectives.

Estimating ($C_{eiPthro}$). TOPS denotes the Total Operations completed per Second. For simplicity of explanation, let us assume that the system of the induced architecture needs to

scale up to support an additional operation per unit-time. An additional operation buys an architectural potential paying an exercise price. In terms of throughput, architectural potential is a performance measure. Hence, what an extra operation pays, if materializes, is a bandwidth for performing that operation. Inducing the Duke's bank with either J2EE or CORBA provide different bandwidth capabilities for performing the operation at different prices. If the implementation of either happens to hold embedded growth options in supporting the extra operation, then the operation is said to pay an exercise price to buy options on the architecture. For the exercise price, we use a well-known normalization factor, which is the *price/performance* [http://www.spec.org/jAppServer2005/] (i.e., the lifecycle cost of the System Under Test (SUT) as configured for the benchmark divided by the throughput). This is provided in the data mined. As an example, assuming five-year lifecycle, the cost would include all hardware (purchase price), software including license charges, and hardware/software maintenance. If the total price is $5,734,417 and the reported throughput is 105.12 TOPS, then the price/performance is $54,551.16/TOPS.

Estimating volatility (σ_{Pthro}). Volatility represents uncertainty attributed to the likely growing of load. For some computation, we abide to the real options principles in computing volatility: we use the standard deviation of x_iV_{Pthro}s due supporting extra operations for a range of load at a host (as the range is said to be revealing to the fluctuation in the value). For other computations, we use modeling estimates for volatility, representing uncertainty to demonstrate how volatility influences the choice and as a way to answer the mining objectives.

Estimating (x_iV_{Pthro}). For simplicity, we estimate x_iV_{Pthro} relevant to the business domain. For every completed online operation, Duke's would not have to serve a customer in person at a branch; the Duke's savings are in the manual-effort for not serving clients at a branch.

Exercise time (t_{Pthro}) and free risk interest rate(r_{Pthro}). As a simulation assumption, we set the exercise time to one year, assuming that the Duke's Bank needs to accommodate the change in one-year time. We set the free risk interest rate to zero (i.e., assuming that the value of money today is the same as that in one year's time).

Results interpretations and analysis. Now, we answer and reflect on the mining objectives to demonstrate usefulness of EDSM. We complement the observed patterns with options computation to inform the problem of tradeoff analyses and decision making in selecting a candidate middleware to induce an architecture, relative to P_{thro}. The likely change in load is the major source of uncertainty that faces Duke's Bank. To address uncertainty and provide better insights on value creation, we have appealed to the use of real options theory. Let us have a close look at the impact of the volatility parameter, which is an expression of uncertainty to address the mining objectives: volatility estimates the "cone of uncertainty" in the future value of the asset, rooted as its current value and extending over time as a function of volatility. As volatility increases, total uncertainty around the benefits also increases. The more TOPS a host is likely to support, the more likely that the actual benefits to "wander" up and down and deviate from the expected present value if the load grows. Let us assume that the present load is in the range of 30- 50 TOPS. Based on the mined data, 30-50 TOPS could be easily addressed by one host using either M_0 (JacORB) or M_1 (Jboss or WLS). For such a low throughput requirements, inducing the architecture with M_0 may appear to be more attractive as when compared to inducing the architecture with M_1 (using either JBOSS or WLS). This is because M_1 incurs license costs for WLS. Moreover, looking at S_1 when induced with JBOSS, S_1 is likely to be in magnitude slower than S_0 as when induced with JacORB due to its use of reflection. This means that S_1 (JBOSS) will support fewer TOPS and consequently will create less value added per second as when compared to S_0. For such low load, the fault-tolerance and load-balancing services need not be implemented on S_0 [Bah 05]. If options analysis is not used, M_0 will be a no-brain choice for inducing the Duke's Bank architecture. Though inducing the architecture S_1 with M_1 (using WLS) appears less attractive than M_0 (JacORB), S_1 may still carry embedded growth options which will only materialize if the load grows. If we use a Present Value (PV), the computation will based on the benefits of supporting the TOPS less their costs (i.e., the computation does not account for uncertainty). The resulted valuation will compute the present value as realized and ignore the growth options. In other words, inducing the architecture with WLS if undertaken, PV would hint that S_1 would destroy value rather than create it. That is, *Value* S_1 = PV. However, *Value*S_1 is actually *Value* S_1 = PV + *Opt*. That is, M_1 carry embedded growth options, *Opt*. The *Opt*, if left unexercised, are ignored by the non-options analysis. Hence, *Value* for S_1 is then said to be underestimated. As a result, S_0 may look more attractive (Table 2). The Present Value calculation of Table 2 shows that S_1 is the least attractive for this range of load. The computation is based on the benefits of supporting 100 TOPS less their costs. However, the computation ignores the growth options on S_1 in supporting additional 632 TOPS using the first host. Similarly, PV systematically undervalues the growth potential of S_1 (JBOSS) and S_0 (JacORB) in respectively supporting 300.26 TOPS and 446.26 TOPS. That is, PV ignores the flexibility value of S_1 and S_0 in responding to the growing load at host 1.

Table 2. Illustration PV per second ($) for low throughput (100 TOPS)

100 TOPS	Max TOPS	$C_{atPThro}$	X_{VPThro}	PV	Value Ignored (TOPS)
S_1(WLS)	732.00	853.11	12.63	-840.48	-632
S_1(JBOSS)	400.26	603.11	12.63	-590.48	-300.26
S_0(JacORB)	546.80	603.11	12.63	-590.48	-446.80

It is a fact that PV does not work well for projects with future decisions that depend on how uncertainty resolves. Though they can be used to evaluate the operational benefits in a stable environment with well-understood and measurable costs and benefits, they have little to offer when capturing additional value due to flexibility under uncertainty, such as strategic opportunities and the ability to respond to changing

conditions. Using PV, S_1, when induced with WLS, reports negative values upon inducing the architecture with WLS for this range of load. However, the situation indicates that these results underestimate the value of S_1, as S_1 can better respond to uncertainty, where the load is likely to grow over 100 TOPS. In Table 3, we turn to ArchOptions to capture the growth options on S_1 and S_0. The volatility parameter is an expression of the range of "benefits" at a host. For S_1 (WLS): the benefits could "wander" from zero (i.e., idle state with no operations executing at a second) to the benefits derived from full utilization of capacity (i.e., in the support of 732 TOPS). That is, the volatility of 66% for S_1 (WLS) indicates that the benefits of executing the TOPS is in the range of $0(idle) to $92.42(full utilization) per second on host 1. Similarly, for S_0 (JacORB): the 45% volatility for S_0 (JacORB) indicates that the benefits of executing the TOPS are in the range of $0(idle) to $69.04 (full utilization) per second on host 1. As for the options on S_1(WLS), S_1 has "pulled" the options on one host for this range of load. This is because we have accounted for the possible fluctuation in the derived values from supporting the TOPS. Considering such "fluctuation" provides us with better insights on the architectural potential of S_1 in support of this likely change in load. Table 3 suggests S_1 has reported a value added of $0.017 on 1 host.

Table 3. Illustration options per second ($) very low throughput scenario (100 TOPS)

100 TOPS	$C_{eiPThro}$	$X_{iVP\text{-}Thro}$	σ_{Pthro}	Options	Actual Value (TOPS)
S_1(WLS)	853.11	92.42	66%	0.01700	100 + 632
S_1(JBOSS)	603.11	50.53	35%	0+	100 + 300.26
S_0(JacORB)	603.11	69.04	49%	0.00001	100 + 446.80

4. Related Work

Mining Software Repositories (MSR) [MSR 1-5] is a growing community in Software Engineering. [http://msr.uwaterloo.ca/] provides excellent up-to-date reference to MSRs. These contributions, however, are essentially technical endeavor with no attention paid to the economics context: software repositories are often mined and analyzed ignoring the link between technical properties, economics, and value creation under a given circumstances. Our contribution is novel in addressing this gap. [EDSR 1-8] community is interested in linking technical engineering concepts to economics and value creation. No contribution has been reported on EDSM, except for [Bah07] bridging the gap between these two communities.

5. Conclusion

We have highlighted a scenario for realizing EDSM through an example. The example describes how software repositories could be mined to value the ranges in which a given software architecture can scale to support likely changes in load. The exposed arguments provide an example of the invaluable insights that the analyst might benefit from upon complementing the mined data with economics computation. Such analysis has the promise to provide the software analyst with a powerful tool for predicting cost/value information for developing and evolving dependable software and understanding the economics ramification of the change on the system and its design artifacts (e.g., architectures); and informing design trade-offs. The objective is to provide insights into investment decisions related to the development and evolution of software systems and assisting in resource planning and utilization. Ongoing work includes designing an automated infrastructure and tools support. Effort includes designing a semi-automated support for executing the EDSM process, deriving interesting patterns, facilitating the computation, visualizing the results, assisting in interpretations, and supporting sensitivity analyses. Interestingly, MSR [1-5] drew the attention to a new challenge faced by empirical studies: whereas previous studies suffered from lack of data, current studies face challenges dealing with enormous amounts of freely available data from easily accessible repositories online such as forums, code, and bug reports repositories. Though this fact may have implications on the quality of the mined data and the resulted analysis, this could also hint to opportunities for EDSM, where existing knowledge could provide insights into investment decisions related to development and evolution of systems. This could, for example, be based on analogies and similar to the way we have "mimicked" the concept of twin asset.

Abstract *– Frequent itemset mining is one of the important problems in data mining. The task is to discover frequent occurring patterns in large databases. Many algorithms have been proposed for frequent itemset mining, such as the Aprioir and FP-growth algorithms. In this paper, we propose the Virtual Partition Algorithm (VP) for frequent itemset mining. The VP algorithm treats a database as small partitions (projected databases) and mines frequent itemsets from each partition. The search space is a lexicographical tree. A node of the tree, denoted P_F, represents a distinct partition of the database, where all transactions in the partition contain the frequent itemset F. The VP algorithm uses strategies such as virtual partition, transaction assignment, transaction reassignment, and pruning techniques to improve the efficiency and memory utilization. We compared our algorithm with other frequent itemset mining algorithms and the experimental results show that VP is efficient for frequent itemset mining on both sparse and dense databases.*

I. INTRODUCTION

Frequent itemset mining is an important problem in data mining. The task is to identify items that are frequently occurring together in databases. Frequent itemset mining is a sub-task and also the major task in association rule mining [3, 4]. Association rule mining aims to discover relationships (such as associations and correlations) among different items in database. An association rule is in the format of "X => Y" where X and Y are set of items, called itemsets. This rule indicates that the presence of X implies a strong possibility of the presence of Y. Two measurements, support and confidence, are used to indicate the strength of an association rule. The support of the rule X => Y is the fraction of the transactions containing both X and Y. The confidence of X => Y is the fraction of transactions containing X which also contain Y. To discover all the association rules in a database, most algorithms first identify frequent itemsets, which are itemsets with support above a minimum support threshold.

A number of algorithms have been proposed for frequent itemset mining, one of which is Apriori algorithm [4]. Apriori is a step-wise algorithm using candidate generation. Candidate itemsets are potentially frequent itemsets. Apriori iteratively generates candidate (k+1)-itemsets from the complete frequent k-itemsets and then tests the candidates against the database. It utilizes the Apriori property that if an itemset is frequent then all of its subsets must also be frequent to reduce the size of the candidate set significantly. However, when the number of frequent itemsets is large and/or long frequent itemsets exist, it still suffers from generating a considerable number of candidates and from performing tedious database scans and pattern matching to determine the support of each candidate.

Apriori-based algorithms are not efficient to mine frequent itemsets from dense databases. A dense database has any or all of the following properties: many frequently occurring items, strong correlations between several items, and many items in each transaction. On the other hand, in sparse databases, items do not occur frequently and in general frequent itemsets are relatively short. In order to deal with dense databases or long frequent itemsets, strategies trying to avoid the candidate generation have been proposed, among which is the FP-growth algorithm [9]. Instead of generating candidates, FP-growth utilizes a special tree structure, FP-tree, to maintain the necessary information, and then mines frequent itemsets in a bottom-up manner along the tree. FP-growth is efficient as it avoids the candidate generation and it needs only two database scans. Nevertheless, FP-growth is known as a very memory-consuming approach because it requires significant memory space when recursively constructing conditional FP-trees and it is especially true if the database is huge and sparse.

Generally speaking, the difficulties of the frequent itemset mining problem are candidate generation, pattern matching, and the requirement of large memory space. In this paper we propose the Virtual Partition (VP) algorithm to solve this problem and to achieve the following goals:

- Deal with different types of databases efficiently
- Mine frequent itemsets without candidate generation
- Avoid pattern matching, i.e., checking candidate itemsets against each transaction
- Reduce database scans and the search space
- Minimize the usage of memory space
- Allow for scalability and reliability

It should be noted that in this paper we assume that the employed representation of the database fits in main

memory. If it is not the case, an approach based on opportunistic projection [10] can be applied, but this is beyond the scope of our work.

The rest of this paper is organized as follows. Section II discusses related work. Section III details the Virtual Partition (VP) algorithm. The experimental results are given in Section IV, and Section V concludes the paper.

II. RELATED WORK

Apriori and FP-growth algorithm represent two categories of approaches used in frequent itemset mining, one using candidate generation and one without. The Apriori algorithm and some Apriori-like algorithms are widely used in mining frequent itemsets. However, if the database size is large and/or the minimum support threshold is low, the large number of candidates plus the cost of database scans will degrade the performance. FP-growth algorithm does not need to generate candidate itemsets. It has been proved to be one of the most efficient algorithms for the frequent itemset mining problem; it is especially true when mining frequent itemsets in dense databases. However, FP-growth is a very memory-consuming algorithm.

Besides Apriori and FP-growth, there are a number of other algorithms for mining frequent itemsets, such as Eclat [18] and Partition [15]. Eclat uses vertical layout of transactions instead of traditional horizontal layout. The partition algorithm divides a large database into a number of smaller databases that can fit in memory and finds local frequent itemsets in each partition and then combine them into global frequent itemsets.

In general, no single approach outperforms others for all cases in frequent itemset mining because of the variety of databases. Different databases have different sizes, densities, and layouts. Therefore, choosing a proper approach is nontrivial. Recently, researchers have put efforts in developing hybrid methods such as H-mine [13], kDCI [11], and Nonordfp [14]. They employ two alternative strategies to deal with sparse and dense databases, and switch adaptively from one to the other according to the information collected during execution phases. However, questions including what should be the appropriate situations that one strategy is more preferable over the other and how to determine when such a strategy switching should happen are still nontrivial.

III. VP: THE VIRTUAL PARTITION ALGORITHM

A. Algorithm Overview

In order to mine frequent itemsets without candidate generation and pattern matching, we first propose the Tree Generation algorithm (TG). The TG algorithm mines the complete set of frequent itemsets from a database by constructing a Prefix-Pattern Tree (PP-Tree). A node of the tree is denoted P_F , where F is a frequent itemset and we call it a prefix-pattern since all frequent itemsets that can be recursively mined from P_F must have F as their prefix. For example, the frequent itemsets that can be recursively mined from $P_{\{1, 3\}}$ must have itemset {1, 3} as their prefix. Each prefix of F is the prefix-pattern of a corresponding ascendant node of P_F. For example, $P_{\{2\}}$ and $P_{\{2, 3\}}$ are the ascendant nodes of $P_{\{2, 3, 4\}}$. Moreover, $P_{F'}$ is one of the ascendant nodes of P_F if and only if $P_{F'}$ is a prefix of F.

TreeProjection [1], another tree-based algorithm, mines frequent itemsets by projecting transactions of a given database in a divide-and-conquer manner. Instead of projecting transactions, TG constructs a PP-Tree by dividing a large database into smaller portions and then recursively mines frequent itemsets from each portion in a depth-first manner. Such a portion is called a partition of the database, or a partition. Each node of the tree corresponds to a distinct partition. When no further nodes can be generated, the mining task completes, and each node of the tree indicates a distinct frequent itemset. The prerequisite of this algorithm is that an ascending or lexicographical ordering exists among the items in the database.

To overcome difficulties of TG, including transaction replication and physical partition, we propose the Virtual Partition algorithm (VP). VP is based on TG, and we use the term "virtual" because VP mines frequent itemsets without physically partitioning a database. VP constructs and utilizes an Item Linked-list Structure (ILS) to simulate behaviors including node generation, transaction assignment, and transaction reassignment involved in TG.

B. Search Space

The search space of TG is considered a PP-Tree. We define ζ to be the last item in prefix-pattern F. For example, if F = {2, 3, 4}, ζ = 4. Each node P_F of the tree is labeled by ζ and corresponds to a distinct partition of a database, where F is the set of ζ on the path from the root to P_F itself. For example, in node $P_{\{\varnothing, I1, I2, \ldots, Ii, \ldots, \zeta\}}$, F = {$\varnothing$, I_1, I_2, …, I_i, …, ζ}, and the path $P_{\{\varnothing\}} \rightarrow P_{\{\varnothing, I1\}} \rightarrow P_{\{\varnothing, I1, I2\}} \ldots \rightarrow P_{\{\varnothing, I1, I2, \ldots, Ii\}} \ldots \rightarrow P_{\{\varnothing, I1, I2, \ldots, \zeta\}}$ must exist. The i^{th} node is at $Level_i$, the i^{th} level of the PP-Tree. For simplicity, we ignore $\varnothing$ since the root represents the empty set; therefore, the cardinality of F is the level of the tree.

Given a database D comprising I: {1, 2, 3, 4, 5}, the maximum PP-Tree is shown in Fig. 1. This tree is a lexicographical tree that consists of I except for the last item 5. The last item of I can be ignored because no superset of such item exists. A node P_F of the tree is the node from which the complete set of frequent itemsets containing F can be recursively mined. For example, the frequent itemsets containing itemset {2, 3, 4}, if existing, can be recursively mined from $P_{\{2, 3, 4\}}$.

If frequent k-itemsets exist, the complete set of frequent k-itemsets can only be mined from nodes at $Level_{k-1}$. All transactions in node P_F at $Level_k$ contain the same frequent k-itemset F. The frequent supersets that contain F can only be mined from P_F and its descendant nodes. Since any frequent itemset is a subset of I, the maximum level of the prefix tree is smaller than the cardinality of I. For example, the maximum frequent itemsets is {1, 2, 3, 4, 5}, and it can

be mined from $P_{\{1, 2, 3, 4\}}$ at $Level_4$; thus, the maximum level of the PP-Tree is 4.

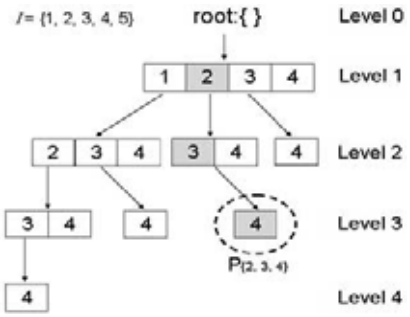

Fig. 1. The Maximum PP-tree

C. Algorithm Details

The TG algorithm is primarily based on the breadth-first strategy for node generation, combined with the depth-first strategy for database partition and transaction reassignment. A PP-Tree is constructed in a top-down fashion by starting from the root node and successively generating nodes until no further nodes can be generated.

The mining process consists of constructing a PP-tree, where each node of the tree corresponds to a distinct frequent itemset of a database. A node PF is generated if and only if frequent itemset F is mined. TG eventually constructs a PP-Tree once a mining task completes. The finally constructed PP-Tree depends on the value of the minimum support threshold ξ, and this tree is part of the maximum PP-Tree, i.e, only some nodes of the maximum PP-Tree are generated during mining.

Fig. 2 illustrates the Tree Generation algorithm. To mine the transactional database D, TG scans D to determine the frequent 1-itemsets R. Next, according to R, it generates nodes. Nodes are initially active. A node is inactive if no further frequent itemsets can be mined from it and its descendants, otherwise it is active. Assuming R = $\{I_1, I_2, \ldots, I_n\}$, the newly generated nodes are $P_{I_1}, P_{I_2}, \ldots, P_{I_{n-1}}$, and P_{I_n} is not generated. After the node generation, TG partitions D by assigning transactions onto the newly generated nodes at $Level_1$.

For each node P_F, if some frequent itemsets exist, TG calls the recursive procedure SEARCH to mine the complete set of frequent itemsets containing F. Once no further frequent itemsets can be mined in P_F and its descendant nodes, P_F becomes inactive, and those transactions in P_F must be reassigned onto other active sibling nodes because some frequent itemsets that do not contain F are still un-mined and can be mined in such active nodes. In other words, in order to reflect the actual support of those un-mined frequent itemsets, a transaction T containing any of such frequent itemsets in P_F needs to be eventually reassigned onto some corresponding active nodes.

The number of transactions that need to be assigned and reassigned significantly decreases as the mining process proceeds. In addition, TG counts frequent items locally, avoids pattern matching, and maintains only a portion of the database during mining.

Input: A transactional database D and the minimum support threshold ξ
Output: *Result*: the complete set of frequent itemsets in D.

```
1)  Let Result, R = ∅;
2)  Scan D to do counting; R ← frequent 1-itemsets;
3)  if R ≠ ∅ do {
4)      Result ← R; Set R = ∅;
5)      Generate active nodes at Level_1;
6)      Scan D again to assign transactions from D onto nodes at Level_1;
7)      for each node P_F at Level_1 do { //F is the prefix-pattern of the node
8)          Let k = 2;
9)          SEARCH(P_F, k); //Mine the complete set of frequent itemsets containing F
10)         Set P inactive;
11)         Reassign transactions from P onto active sibling nodes;
12)     }
13) }

14) Procedure SEARCH(node P_F, int k) {
15)     Scan P_F to do counting; R ← frequent 1-itemsets;
16)     if R ≠ ∅ do {
17)         Result ← GetResult(F, R); Set R = ∅;
18)         Generate its active child nodes at Level_k;
19)         Scan P_F again to assign transactions from P_F onto its child nodes at Level_k;
20)         for each child node of P_F, P_F', do {
21)             SEARCH(P_F', k + 1);
22)             Set P_F' inactive;
23)             Reassign transactions from P_F' onto other active sibling nodes;
24)         }
25)     }
26) }

27) Procedure GetResult(prefix pattern F, frequent 1-itemsets R) {
28)     Let R̄ = ∅;
29)     for each item α in R do {
30)         R̄ ← F ∪ α; //each F ∪ α is a new frequent itemset
31)     }
32)     return R̄;//R̄ is the complete set of frequent (k + 1)-itemsets containing F,
                //where k is the cardinality of F
33) }
```

Fig. 2. The Tree Generation Algorithm

IV. EXPERIMENTAL RESULTS

We implemented VP in C++. Our experiments were conducted on a 2.4GHz Intel Pentium IV processor with 512MB main memory running Linux Debian.

The algorithms were tested on the datasets shown in Table 1, available on the FIMI'03 frequent itemset mining benchmark website. The two synthetic datasets, T10I4D100K and T40I10D100K, were generated using the generator2 from the IBM Almaden Quest research group that simulates the buying behavior of customers in retail business. The parameters for generating a synthetic dataset include the number of transactions D (in thousands), the average transaction size T, and the average length I of so-called maximal potentially large itemsets. For example, dataset "T10I4D100K" has an average transaction size of 10, an average size of the maximal potentially frequent itemsets of 4, and 100,000 generated transactions. Clearly the T40I10D100K dataset is denser than the T10I4D100K dataset. The Mushroom dataset contains characteristics from different species of mushrooms. The Chess dataset contains different game configurations. The Retail dataset is the retail market basket data set supplied by an anonymous Belgian retail supermarket store.

Table 1. Test Datasets

Dataset	# of Items	Avg. Length	# of Transactions
T10I4D100K	1000	10.0	100,000
T40I10D100K	1000	39.6	100,000
Chess	75	37	3,169
Mushroom	119	23	8,124
Retail	16,469	10.3	88,162

We examined the execution time and the memory utilization in our tests. The execution time is in seconds and excludes the preprocessing for each algorithm, which includes reading databases from files and constructing data structures, or tries, representing such databases before mining. It also excludes the time needed to print the resulting itemsets. These excluded processes together usually take a few seconds. In the experiments, we did not record the execution time of a mining task if its runtime exceeded 10 minutes, and we recorded a task as a "timeout" if it was unable to complete mining within 10 minutes. To measure the memory utilization of a process, we monitored the value of VIRT, associated with such process, in top output, where "top" is a traditional Unix memory management tool and VIRT stands for the virtual size of a process. The domain of VIRT includes the sum of memory a process is actually using, memory it has mapped into itself, and memory shared with other processes. In short, VIRT represents the amount of memory that a process can access at the present moment. The unit of VIRT is in KB when the memory utilization is less than 100MB, and it converts to MB when the memory utilization exceeds 100MB. The approximate memory utilization is suitable to our test because we can observe the trend and variation of the memory utilization as the minimum support threshold decreases. In the experiments, we terminated a task if its memory utilization was large enough to potentially crash the system, and we recorded a task as "aborted" if its memory utilization was too large.

We compared VP with the following frequent itemset mining algorithms: APRIORI [5], COFI [12], and CT-PRO [16]. Categorically speaking, VP and APRIORI are counting-based algorithms, and the other two algorithms are based on FP-growth. APRIORI is one of the most efficient implementations for Apriori-based algorithms. COFI introduces a simple and non-recursive mining process to replace the memory-based FP-tree. CT-PRO uses a more compact data structure, the Compressed FP-Tree (CFP-Tree), to non-recursively mine frequent itemsets in a bottom-up fashion. CT-PRO performs better than OpportuneProject [10], FP-Growth [9], Apriori [4], LCM [17], and kDCI [11], where LCM and kCDI are known as the two best algorithms in FIMI 2003 repository.

The minimum support greatly affects the runtime. In a dense dataset, items are strongly correlated; therefore, given the same support value, the number of frequent itemsets that can be mined from dense datasets is much larger than the number of frequent itemsets that can be mined from sparse datasets. Mining more frequent itemsets requires more execution time. Accordingly, in our experiments, we used very small support values for T10I4D100K, T40I10D100K, and Retail datasets. In contrast, the support values used for Chess and Mushroom were very high. Moreover, in order to examine the efficiency, reliability, and scalability of the four algorithms, we used extremely small support values for each experiment so that we can test which algorithms can complete mining tasks under those situations.

Tables 2, 3, 4, 5, and 6 summarize the runtimes (in seconds) of the four algorithms on these datasets along with the total number of frequent itemsets (# of FISets) and the length of the maximum frequent itemsets (MaxLen of FISets) for each given minimum support threshold value (Minsup).

Table 2. Execution Time (in seconds) for Mining T10I4D100K

Minsup(%)	APRIORI	COFI	VP	CT-PRO	# of FISets	MaxLen of FISets

0.01	**24.46**	aborted	43.38	aborted	240,852	13

By observation, as the support value declined, the length of maximum frequent itemsets grew evenly and the number of frequent itemsets escalated significantly. When the support value was relatively high, most frequent itemsets were of short lengths and thus the four algorithms had similar performances; on the other hand, most items were frequent when support values became small.

For datasets T10I4D100K and T40I10D100K, APRIORI and VP had good performance. In particular, VP outperformed the other three algorithms when support values were very small. As indicated in Table 2, COFI and CT-PRO had similar performance, and both aborted when the support was 0.01%. When the support declined from 0.01% to 0.005%, the number of frequent itemsets increased approximately 4.68 times, and VP completed the task in only 7.59 seconds while others failed. Compared to T10D4I100K, T40D10I100K is larger and denser. In Table 3, VP was still the best algorithm. In general, VP was competitive for most given support values, and it was even more obvious when the support value was very small. For instance, VP was 2.34 times faster than APRIORI and 3.27 times faster than CT-PRO when the support value was 0.5%, while COFI aborted when the support value was 1.5%.

When mining in very dense datasets such as Chess and Mushroom, the FP-growth-based algorithms outperformed the counting-based algorithms. However, it was true only when available memory was sufficient. CT-PRO utilizes the CFP-tree data structure, known to be very memory efficient for very dense datasets. Accordingly, although both COFI and CT-PRO are FP-growth based algorithms, CT-PRO was very efficient (as shown in Tables 4 and 5) as COFI suffered from inefficient memory utilization.

VP was unable to outperform CT-PRO in dense datasets, but it was reliable in that it never aborted for any given support value. Although VP was recorded timeout in Table 4.4 when the support value was 30%, we found that it can finish the task eventually if we let it continue. Moreover, in Table 5, when the support value was 1.5%, VP completed the task while CT-PRO was not able to do so.

Retail is a very sparse dataset. It consists of 16,469 items and the average length of transactions is short. When mining Retail, most algorithms were efficient, and the runtimes had the same orders of magnitude. The performance of VP was better than that of APRIORI when the support value was larger than or equal to 0.02%. Furthermore, VP was more reliable than COFI and CT-PRO because VP survived when the support value was as small as 0.1%, while COFI and CT-PRO both aborted. We found that VP was not as fast as we expected since the number of items was very large.

VP created header tables in each iteration and the sizes of tables were decided by the size of items. The time for memory allocation became relatively expensive as the computational cost was relatively slight for all algorithms in very sparse datasets. Moreover, each header table needs to be scanned for the node generation. To improve the performance of VP for mining datasets with large set of items, reusing the header table may be a promising strategy.

Tables 7 and 8 illustrated the memory utilization, in megabytes (MB), of the four algorithms for mining T40D10I100K and Retail, respectively. We found that COFI is a very memory demanding algorithm even though [12] declared that it can significantly reduce the candidate generation and avoid recursion. COFI was the most unscalable algorithm among the four since it was very sensitive to the length of maximum frequent itemsets. CT-PRO usually took more memory utilization than others and it was infeasible for mining very large datasets. The memory utilization of APRIORI is based on the size of number of frequent itemsets. For instance, as illustrated in Table 7, when the support value decreased from 0.75% to 0.5%, the memory utilization of APRIORI increased 105.6% while the number of frequent itemsets increased 158.8%. On the other hand, given the same condition, the memory utilization of VP increased only 0.4%.

Table 7. Memory Utilization (in MB) for Mining T10I4D100K

Minsupt(%)	APRIORI	COFI	VP	CT-PRO	# of FISets	MaxLen of FISets
5.0	**15**	74.8	24.6	124	317	2

0.75	55	-	**34.3**	208	496,883	18
0.5	113	-	**34.5**	222	1,286,038	18
0.3	309	-	**34.7**	309	5,058,313	20

Table 8. Memory Utilization (in MB) for Mining T40D10I100K

Minsup(%)	APRIORI	COFI	VP	CT-PRO	# of FISets	MaxLen of FISets
0.05	37.4	18.2	**9.3**	150	19,837	7
0.025	76.2	44.9	**10.5**	285	50,481	8
0.02	95.1	50.2	**11.1**	392	67,186	9
0.015	112	62.5	**11.5**	499	113,119	9
0.0125	128	73.3	**11.6**	548	155,111	10
0.01	159	537	**11.8**	> 600	240,852	13
0.0075	190	> 600	**12**	-	480,621	15
0.005	354	-	**12.8**	-	1,506,775	17

During mining, the memory utilization of COFI varied because of the requirement of memory allocation, deallocation, and reallocation. The memory utilization of CT-PRO does not change once the CFP-tree was established, and the memory utilization of APRIORI steadily climbed up because it recorded frequent (k + 1)-itemsets generated from candidate k-itemsets.

VP was insensitive to the length of maximum frequent itemsets and/or the number of frequent itemsets. Similar to CT-PRO, the memory utilization of VP increased slightly once ºA was established where ºA is a vector used to represent a loaded database. During the rest of mining, VP did not generate extra complicated data structures or tries such as hash-tables or FP-trees, except for some smaller header tables. Moreover, the memory utilization of VP was always relatively small for any given dataset and any given Minsup. In fact, the memory utilization of VP was the sum of the size of ºA and the size of header tables, and we can always expect the approximate memory utilization in advance. In short, VP is very scalable and efficient for the

memory utilization and hence it is the most reliable algorithm in our experiment.

V. CONCLUSIONS AND FUTURE WORK

Frequent itemset mining is an important task in data mining. Various algorithms have been proposed for frequent itemset mining. In this paper we proposed an algorithm called "Virtual Partition" (VP) to deal with different kinds of databases in an efficient way to mine frequent itemsets. VP utilizes the ILS structure to simulate the database partition and transaction reassignment involved in the tree projection algorithm. It mines frequent itemsets without candidate generation, avoids actual data moving, and maintains minimum memory utilization. We compared VP with several other algorithms on different datasets, including dense and sparse datasets. Our experimental results are generally quite competitive, although we do not excel in every case. Nonetheless, VP never aborted while other algorithms sometimes failed. We conclude that VP is scalable and reliable for frequent itemset mining problem.

To improve our algorithm in mining very dense databases, we may combine VP with CT-PRO or other algorithms that can mine dense databases more efficiently. Furthermore, instead of using the lexicographical ordering, we may consider sorting items in frequency order for each transaction. This could increase the preprocessing time for sorting the items of each transaction, but the performance gain may be promising.

Abstract

Despite that reuse libraries are now well adopted during software development step, software evolution step is not yet covered by this kind of beneficial approach. In this paper we present the "evolution shelf", a generic infrastructure to achieve for-reuse and by-reuse techniques within the field of software evolution. The basic idea behind that is to propose and encourage the reuse of recurring and reliable expertises to achieve the structural evolution of a software system at the architectural level. For that purpose, the shelf assists architects in classifying, storing and selecting reusable architectural evolutions. The underlying concept that we propose to capitalize the expertises is called "evolution style", mixing a syntactic and a semantic description format. These ideas form a core for a long-term vision in which it is possible to build a business model of evolution-off-the-shelf (EOTS) with the special objective to decrease the efforts and the risks related to the evolution activities.

1. Introduction

Traditionally, the primary focus of reuse research has been on the reuse of software entities, such as objects or components [11], often at code-level but also at more abstract levels. While there have been significant improvements in reuse technology and methods, these artifacts are not the only ones that can be profitably reused. In this paper we describe an approach and supporting infrastructure for a class of skill reuse – namely, architectural evolution reuse.

An increasingly important requirement for software-based systems is the ability to embrace change. From a theoretical point of view, embracing change aims at integrating the change as a natural ingredient of modern software systems and be prepared to challenge it. From a practical point of view, embracing change aims at reacting to unanticipated events by the way of predictable means. Especially, in this research, we deal with the evolution of the structure of component-based architectures. An architectural design is concerned with the gross decomposition of a system into a set of interacting components [15, 10]. At this level of abstraction, key issues include the assignment of functionality to design elements, protocols of interaction, system extensibility, and broad system properties such as throughput, schedulability, and overall performance. The reuse problem for architectural designs then becomes how to exploit the basic elements of architectural design (large-scale components and connectors), as well as common processes for their evolution over time.

But what exactly is evolution reuse and how can it be exploited ? The basic idea is to capitalize know-how on a specific domain, providing specific facilities for a fairly narrow class of system. For this purpose, we lean our work on the concept of architectural style [18, 14], used for representing and reusing architectural designs and design fragments for a family of architectures. An architectural style is a powerful design artifact which captures the aspects of a particular domain of application and can provide assurance that elements built following the stylistic guidelines are interoperable. A crucial observation here is that architectural styles are analogous to domain-specific languages [1]. Throughout refinements of a previous work [16], we propose the concept of evolution style for the enrichment of the concept of architectural style, and to turn it into a run-time ar-

tifact. The evolution styles are used for representing and reusing the evolution of architectural designs. Further, the use of evolution style supplements traditional mechanisms for classifying evolution processes, storing those processes in a repository, and narrowing the search space to more accurately locate potential process matches in a given context.

We begin by contrasting our approach to existing work in the area of reuse and knowledge engineering, in the field of software architecture. In Section 3, we show how the concept of evolution style can extend the concept of architectural style. As a demonstration of how these ideas can be used, in Section 4 we describe a prototype infrastructure called the "Evolution Shelf" which provides a repository for reusable architectural evolutions. We give some concluding remarks in Section 5.

2. Related Work

The research presented here lies at the intersection of two related areas: the reuse engineering and the knowledge engineering. In our context, we put a special focus on the software architecture field.

Some of the more impressive examples of reuse today involve a strong component of design reuse that can be separated into three classes of granularity of abstraction [4]: architectural patterns and styles, design patterns and idioms. Prominent examples include the book of object-oriented design patterns by Gamma et al. [8] or the book of architectural patterns by Bushman et al. [5]. Broadly speaking, our work is motivated by the same concerns – providing high-level abstractions for evolving systems based on previous efforts and proven know-how. While we also exploit architectural commonalities (in our use of "architectural style"), we address an orthogonal issue. In our context, the term of "style" refers to the more formal aspect of the descriptions of solutions and thus the possible construction of an automated support. This last point naturally introduces a second crucial aspect: the desired organization of such an amount of knowledge into libraries, able to support efficient reuse techniques. As an example, a preliminary classification of architectural styles was presented in Shaw and Clements [17], in which a two-dimensional, tabular classification strategy was used with control and data issues as the primary axes, organized by the following categories of features: which kinds of components and connectors are used in the style; how control is shared, allocated, and transferred among the components; how data is communicated through the system; how data and control interact; and, what type of reasoning is compatible with the style. The primary purpose of the taxonomy was to identify style characteristics, rather than to assist in their comparison. Hence, organizing the classification in that fashion does not help a designer find a style that corresponds to their needs. As another example, Zimmer [20] organized design patterns using a graph based on their relationships, making it easier to understand the overall structure of the patterns in the Gamma et al. catalog. The classification was based exclusively on derivation or use relationship, but no infrastructure was provided to exploit it. In [13], Monroe and Garlan built a software repository that assists designers in selecting design elements and patterns based on stylistic information and design constraints. Their repository was evaluated on the Aesop system with a great size of elements and can be queried with a specific language based on stylistic attributes, as well as traditional string and keyword matching. Like reported in [7], despite that there has been disagreement in the reuse research community about the importance of libraries for reuse, the reuse activity shows that in order to be reused an asset must be available, findable, and understandable. A reuse library supports all of these and should be used in the field of evolution engineering.

3. Style-based Evolution Model

Basically, architectural evolution includes modifications for general purposes, in terms of additions, removals and modifications on first-class entities, namely, the component, the connector, the interface (derived into port and role) and the configuration. Domain-specific architectural evolution extends the aforesaid principle to take into account the specific aspects provided by an architectural style. For example, the *Pipe&Filter* architectural style supports particular evolutions such as *Become-a-sink*, for setting a filter solely as a data consumer by deleting all its output interfaces. Hence, the evolution styles we deal with in this paper are specifically designed for a family of applications that satisfy a given architectural style. In this section we explain the description format of an evolution style and we provide a small example.

3.1. Specification of Evolution Styles

The language we propose is captured by the metamodel given in Figure 1, represented in an object-oriented context with the UML notation. Within this metamodel, an architectural style encompasses:

- a set of types of architectural element, derived into types of configuration, types of component, types of connector and types of interface. An architectural style is simply viewed as a type of configuration. These types provide a domain-specific design vocabulary.

- constraints that define how components can be integrated. Constraints may be topological, behavioral, communication-oriented. In this research we are only

interested by rules that govern the structure of the architecture, that is, the topological rules.

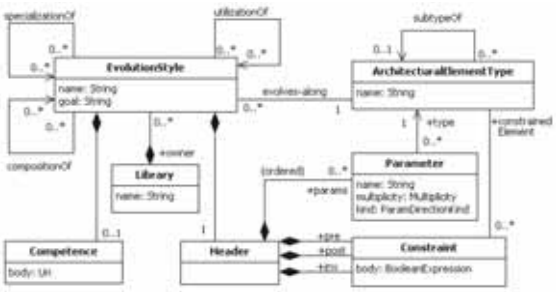

Figure 1. Metamodel of the concept of evolution style (UML class diagram).

Any of these types of architectural element is likely to evolve along some predefined archetypes, the so-called evolution styles. The two basic information of an evolution style are an evocative name and the textual description of its goal. Then, the proposed specification of an evolution style is formed by two complementary parts: the header and the competence. From a theoretic point of view, in the spirit of the "Components of Expertise" approach [19], the header denotes an evolution task while the competence denotes a problem solving method (PSM) to achieve the task. From a practical point of view, the purpose of the header is to publish the interface and the behavior of the evolution while the purpose of the competence is to give an implementation to realize the header following a particular strategy. This decoupling follows the information hiding principle and enables more flexible specifications.

Syntactic description – The header publishes the interface of the evolution by mentioning an ordered set of parameters typed with the types of design elements provided by a particular architectural style. Each parameter has a multiplicity (i.e., multi-valued parameters are supported) and a direction kind (In/Out/InOut/Return). The header also publishes the behavior of the evolution by mentioning three assertions: a precondition, an invariant and a postcondition. These assertions are constraints expressed with a first order predicate logic similar to UML's OCL, augmented with a small set of architectural functions. The precondition and the postcondition are user-defined while the invariant is virtually imported from the one imposed on the considered design element. Constraints are essential both to preserve the initial design choices and to leave the architecture in a consistent state after its evolution.

The competence realizes the header by a particular implementation. Unlike the header, sometimes the competence cannot be identified. When the competence part is missing, the evolution style is abstract (and plays a major role in knowledge structuring). Otherwise, the evolution style is concrete and its competence part refers to an operation tied to a technological context: a C function or procedure, a JAVA object method or a model transformation, etc. Hence, to have a technologically-neutral competence, the concrete implementation is considered as an external resource located with an URI (Uniform Resource Identifier). Of course, an implementation is required to turn the evolution style into an executable form.

Semantic description – The evolution styles can be interrelated in three various ways: with the (i) specialization relation, with the (ii) composition relation and with the (iii) utilization relation. These relations bring a semantic dimension to the purely syntactic description of the concept of evolution style. The specialization and the composition define hierarchies amongst a set of evolution styles: the former defines a conceptual hierarchy (i.e., general vs. specialized evolutions) while the latter defines a descriptive hierarchy (i.e., coarse-grained vs. fine-grained evolutions). The utilization does not define any hierarchy amongst a set of evolution styles but enables important collaborations. From an operational viewpoint, these relations play different roles, but all convey invocations – or calls. The specialization is useful at design-time to build new description from older ones. A specific inheritance mechanism allows the user to overload a header and/or to override a competence. The composition is useful at design-time to assembly descriptions into a composite one and the utilization is crucial at run-time to properly propagate the impacts of an evolution throughout a chaining of styles. Finally, a set of inter-related evolution styles designed for a particular architectural style forms an evolution library. From the end-user point of view, such a library is a black-box that is intended to be enriched and queried via an infrastructure specifically designed to hold it, so-called a "shelf".

3.2. Sample Illustration

We illustrate a client-server architectural style on which a preliminary evolution library is designed, inspired from a scenario found in [6]. The architectural style is described using the ACMEADL [9] and the ARMANI constraint language [12]. On the other hand, the evolution styles are described using the UML 2.0 language extended with a specific profile (i.e., stereotypes, tagged values and constraints) that we have developed for representing the content of the evolution libraries in a diagrammatic fashion.

The first step specifies a generic *client-server* architectural style (called a family in ACME). It defines a set of component types: a client type (`ClientT`), a server group

type (ServerGroupT) and a server type (ServerT). It also defines a connector type (LinkT). Constraints on the style (appearing in the definition of LinkT) guarantee that the link has only one role for the server and more than one role for the client. Other constraints, not shown, define further structural rules (for example, each client must be connected to a server). The corresponding code snipet is given in Figure 2.

```
1: Family ClientServer = {
2:     Component Type ClientT = {...};
3:     Component Type ServerT = {...};
4:     Component Type ServerGroupT = {
5:      Property AverageLoad : float
6:       ...
7:     };
8:     Role Type ClientRoleT = {...};
9:     Role Type ServerRoleT = {...};
10:    Connector Type LinkT = {
11:      invariant size(select r : role in Self.Roles |
                 declaresType(r, ServerRoleT)) == 1;
12:      invariant size(select r : role in Self.Roles |
                 declaresType(r, ClientRoleT)) >= 1;
13:      Role ClientRole1 : ClientRoleT;
14:      Role ServerRole : ServerRoleT;
15:    };
16: }
```

Figure 2. A Client-Server architectural style in ACME.

The second step specifies a *MoveClient* evolution style designed for the client-server architectural style above. The purpose of this evolution is to reconnect a client to another server group. Practically, the latter is applied to a client and deletes the role currently connecting the client to the connector that connects it to a server group. This style also performs the necessary attachment to a connector that will connect it to the server group passed in as a parameter. The diagram on Figure 3 shows the *MoveClient* evolution style but also some of its adjoining evolution styles, through different semantic links. Due to place restrictions, the constraints (usually expressed in OCL) and the goals (usually expressed with a UML note) are not shown on the diagram.

At glance, moving a client to another group of servers is viewed as an evolution decomposable into disconnecting a client from an older group and then reconnecting it to a new group. Accordingly, disconnection or connection propagates the evolution to update the load of the group of servers involved. All these evolution styles are specializations of an abstract evolution style that is the "top" of the specialization hierarchy. From now, the *MoveClient* evolution style can be specialized, composed or utilized in order to define more complex evolution strategies. However, it remains to provide reuse facilities to experts for enabling them to create further expertises more easily.

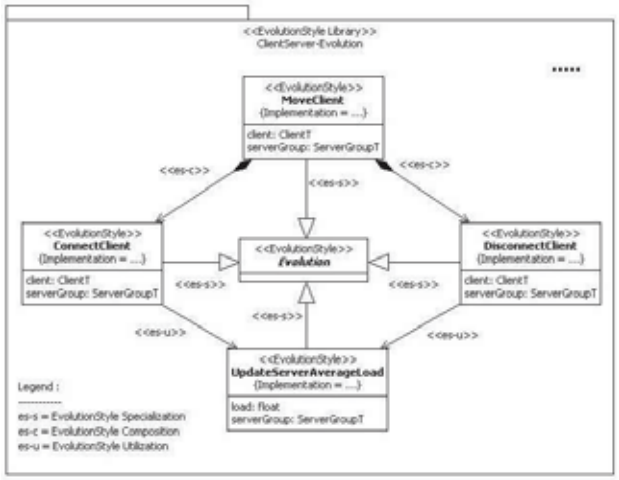

Figure 3. UML-based evolution style diagram depicting an excerpt of the evolution library associated to the client-server architectural style.

4. The Evolution Shelf

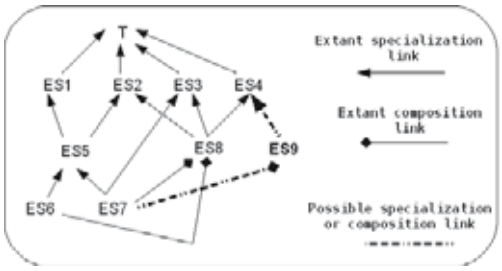
The Evolution Shelf is an infrastructure to support the classification, storage and retrieval of evolution styles. We now describe the strategy taken to implement this functionality. Many of the underlying mechanisms that we use are not new. Our intention is to leverage well-known repository techniques while updating them to support and exploit the concept of evolution style.

4.1. Classification

The evolution styles grouped into libraries and stored on the shelf are organized along three semantic relations introduced in Section 3.1. The primary benefits that the use of evolution styles brings to this taxonomical scheme is that users are able to determine a lot about a reusable style based solely on its three-dimensional organization. From a knowledge-oriented standpoint, a library is a knowledge base which organizes knowledge fragments to deal with some recurring problem/solution pairs in the software evolution field. From an operational standpoint, a library is a directed graph where the nodes are evolution styles and the edges are instances of the three semantic relations. Views can be created on the graph in order to put the focus on subgraphs from a given semantic perspective, namely the specialization graph, the composition graph and the utilization graph.

The term "classification" is not used to refer to a hierarchical structure; it refers to the mechanism that aims at

Figure 4. Result of the classification of an evolution style ES9 into an evolution library.



determining the relevant position of an evolution style in a hierarchical structure. Precisely, the classification process computes the position of a new style into the specialization graph and the composition graph (See Fig.4). As stated before, the utilization graph does not define hierarchy and hence is not concerned by this process. The process relies on a subsumption function – widely used in the area of concept lattices – to discover a semantic relation between two non-connected evolution styles. The storage and retrieval mechanisms are both based on the same classification process. Let us now detail the approach.

4.2. Storage

Due to the great size of a library, the addition of a new evolution style is difficult: to find its correct position is complicated because the user does not know exactly the whole base entities, and might thus introduce some inconsistencies. It is proper to have an automation of the structural acquisition process: it will be used to find a correct position both in the specialization hierarchy and in the composition hierarchy. Notice that a library can be entirely built from scratch following this process.

The general storage process to insert a new evolution style X into a hierarchy operates according to a three-phase loop:

1. retrieve the most specific subsuming evolution styles that subsume X (the "immediate ascendants" of X, denoted $MSS(X)$ further),
2. retrieve the most general evolution styles subsumed by X (the "immediate descendants" of X, denoted $MGS(X)$ further),
3. (possibly) update the links in the hierarchy while inserting the new evolution style; the link updates may generate loop in this process.

In the first step, the set of evolution styles that subsume X is computed thanks to a top-down traversal of the hierarchy. In the second step, the set of evolution styles that are subsumed by X are determined by, roughly, exploring the descendants of the $MSS(X)$ computed in the first step. The specialization graph defines a single hierarchy rooted at a "Top" node (denoted $\top$), from which the step 1 is started once. The composition graph may define multiple hierarchies where each node is a potential root, from which the step 1 is repeated. From an algorithmic standpoint, the composition-centered classification procedure is nested in the specialization-centered classification procedure.

Broadly speaking, having an infrastructure for the maintenance of various semantic links between knowledge base entities is very important. Indeed, these links hold up the consistency and the correctness of library, and are challenged whenever an insertion of a new evolution style occurs. A management only performed by the user could be very dangerous, even impossible, whenever the size of the library reaches a certain threshold.

4.3. Retrieval

Besides to a traditional keyword-based search technique, a query is represented as an abstract evolution style Q. We remember that an abstract evolution style does not define any competence. This is not surprising since the competence is the important information expected by the user. One should notice that this uniformity has at least three benefits: (i) the user does not need to learn a further language for querying the libraries, (ii) the infrastructure is "code-saving" and (iii) tools built on top of the concept of evolution style (for exportation, visualization, etc.) can be reapplied to the queries. From our concern, this approach closely related to description logics used in the database domain [2, 3], is used for query purpose with the special objective to produce more than "Yes or No" results. For that reason, the query evaluation consists of "situating" Q both into the specialization graph and the composition graph. In both cases, the result of the query is obtained thanks to the computing of $MSS(Q)$ and $MGS(Q)$, excluding the abstract styles (i.e., without competence and hence not executable). Let us informally summarize the various situations:

- Case 1: The results exactly satisfy the request. This case arises when $MSS(Q) = MGS(Q)$, both in the specialization *and* the composition hierarchy. In other words, a single evolution style satisfies the query and hence it can be reused with confidence.
- Case 2: The results satisfy the request in half. This case arises when $MSS(Q) = MGS(Q)$, in the specialization *or* the composition hierarchy. In other words, a single evolution style satisfies the query from one given semantic perspective and hence it can probably be reused.

- Case 3: The $MSS(Q)$ computed in the specialization hierarchy are more general evolution styles. Any one of them can be reused without errors because they can substitute to the query (due to "style substyping").
- Case 4: The $MSS(Q)$ computed in the composition hierarchy are more fine-grained evolution styles. Hence, they are intended to be reused "together".
- Case 5: No results satisfy the request. This case arises when $MSS(Q)$ and $MGS(Q)$ are empty sets, both in the specialization *and* the composition hierarchy. This means that the user is facing a problem not covered by the library.

At glance, cases 1 and 5 provide a binary result (i.e., Success or Failure), like provided by any repository search techniques. In contrast, cases 2,3 and 4 provide an intermediate range of probable results that extends the reuse possibilities one step further.

5. Concluding Remarks

Evolution reuse would appear to be one of the more promising avenues for improving the prospects for software reuse. We have shown in this paper that our motivation is to provide abstractions for encapsulating evolution expertise independently of any technological environment. To a larger extent, the basic idea behind that is to use the concept of evolution style as an neutral interchange format to capitalize and transfer knowledge about evolution tasks.

Architectural styles leverage the construction phase of software architectures. We have been exploring a different but complementary approach: Evolution styles leverage the evolution phase of software architectures. The primary contribution of this work is the integration of the concept of evolution style with traditional mechanisms for performing standard software reuse tasks. Finally, to integrate our approach into realistic developments, the Evolution Shelf we have presented in this paper should be embedded into conventional CASE tools.

Abstract

The use of explicit environment models for test case generation allows to exercise a system under test in ways that are not possible when only considering the system by itself. Modeling a system's environment, however, is not an easy task. Qualitative Reasoning (QR), which is a well known artificial intelligence technique to represent and reason about physical behavior, is well suited to describe such environments. In this paper, we define a set of coverage criteria that allow an evaluation of how well the behavior of a system's environment and interactions with the environment are exercised with a given test suite. Using a popular QR modeling tool, we show how to derive test cases satisfying these coverage criteria automatically, and illustrate these results on an example application.

1 Introduction

Software testing remains the most important technique to ensure sufficient quality of software. The amount of software included in everyday products constantly increases, and so does its complexity. Especially when considering safety relevant applications like many of the control units in modern cars, the need for thorough testing methods becomes apparent. Unfortunately, testing is a very complex task, particularly in the context of reactive and embedded systems. Here, the complexity of testing is further increased because there is a lot of interaction between a system and its environment. A high level of interaction between system and environment requires extensive testing of the system's reactions to environment stimuli. However, many available testing techniques consider only the system under test, and not its environment.

To overcome this drawback, we propose a methodology for testing embedded systems in terms of their environmental interactions. Qualitative Reasoning (QR), a well-known artificial intelligence technique, is used to describe the environmental behavior in an abstract form. Qualitative abstraction maps large or infinite domains to discrete intervals, which enables QR engines to infer all possible behaviors from a model. The possible behaviors are represented as a transition system – a classical modeling formalism often used for automated testing. The benefit of QR is the ability to reason about domain intervals and physical behavior.

Given a transition system derived from a QR model, we are facing the classical testing problem of which test cases to select out of a very large possible number. In this paper, this problem is solved by defining a set of coverage criteria with information provided by the QR model. This allows to determine how well a system is tested with respect to its environment. As existing testing techniques possibly do not perform well on testing the environmental interactions, we describe a method to automatically derive test suites for the presented coverage criteria. The resulting technique can be seen as a complementary technique for traditional testing methods.

In detail, the contributions of this paper are as follows:

- Testing based on environmental models exercises a system under test in ways that might not be possible with traditional behavioral models.
- QR, a well-known AI technique to represent and reason about physical systems, is adapted to software testing.
- A set of coverage criteria for QR models allows evaluation of test suites with regard to the environment.
- A method for automated coverage based test case generation for QR models is proposed.

This paper is organized as follows: First we give a brief introduction to QR modeling in Section 2, then we define several coverage criteria based on QR models in Section 3. In Section 4 we describe how to automatically derive test

*Authors are listed in alphabetical order.

cases for the discussed coverage criteria and present the results of applying the test case generation to a case study model. Finally, we consider related research in Section 5 and conclude the paper in Section 6.

2 Qualitative Reasoning

The initial idea that lead to the development of QR was to formalize and finally implement commonsense reasoning about physical systems. The objective was to enable a computer to use the same reasoning capabilities as humans have. Typical application areas include trouble shooting of physical systems and tutoring systems. Because QR offers techniques for representing physical knowledge in an abstract way it fits well for testing embedded systems in terms of their environmental interactions. In the case of testing embedded systems we consider the system software as a black box with an interface to the environment comprising sensors and actuators; this interface has to be tested with respect to all possible interactions.

In most cases system environments have infinite rather than finite domains like a switch with four positions. Although infinite domain environments are made finite by quantization during Analog to Digital conversion the state space is still too large for enumeration. In addition, such environmental quantities with infinite domains show continuous behavior that can be expressed by differential equations. We use Qualitative Reasoning (QR) to express environmental behavior in an abstract form. Qualitative abstraction maps large or infinite domains to intervals separated by points (landmarks), which enables QR engines to infer all possible behaviors from a model. This is in contrast to traditional testing techniques, where the test engineer has to develop test scenarios that reflect possible traces of the environment and thus very likely forgets some important traces.

Modeling in QR might follow different branches like qualitative simulation [8] or qualitative process theory [6]. In this paper we use qualitative process theory as the underlying QR modeling paradigm because of the general availability of tools like Garp3 [4]. For a detailed description of the functionality and QR modeling capabilities of Garp3 we refer the reader to [2, 5]. In order to be self contained we briefly introduce the basic concepts of modeling in QR and Garp3. Garp3 models comprise a set of model fragments. Two main types of fragments can be distinguished: static and process model fragments. Static fragments represent behavior that is invariant with regard to time, such as proportional relations between quantities, like, for example *"the amount of water in a vessel is proportional to the water level"*. A dynamic fragment introduces changes via influences between quantities, for example *"a positive flow rate into a vessel will increase the amount of liquid and hence the liquid level over time"*.

The behavior of a system comprises at least one but usually more model fragments that are activated when certain boundary conditions are met. Garp3 adds the consequences of a model fragment as new facts to the knowledge base, unless they contradict existing facts. Model fragments enable the designer to partition the system domain into qualitative equivalence classes that capture certain behavior. During simulation the set of fragments collected in a library changes between being active and inactive as the system evolves over time.

Within a model fragment the main modeling primitives are entities, quantities, proportionalities, and a set of ordinal relations. In dynamic model fragments there are additional influences. Entities are the components of the system that have certain properties expressed through associated quantities. For example, an entity "tank" has quantities like "level" and "inflow rate". Proportionalities establish a mathematical relation between two quantities in the form of a monotonic increasing or decreasing function. The notation P+ (Q1,Q2) expresses that a change of Q2 causes a change of Q1 in the same direction. A proportionality with a minus sign states that a change of the cause quantity induces a change in the opposite direction of the effected quantity.

Ordinal relations called inequalities provide means to constrain possible behavior. Influences cause dynamic changes of the system and provide means for integration. For instance, I+ (Q1,Q2) means that the value of Q2 determines the change of direction of Q1. If Q1 is positive Q2 increases, if Q1 is zero Q2 does not change, and if Q2 is negative Q1 decreases. The graphical notation used in Garp3 states relations with arrows between quantities.

The initial state of the system is captured with scenarios. This initial state and the model fragments serve as inputs to the simulation engine. Simulation is used to generate the behavior of a QR system. The simulation engine derives everything that does not contradict the boundary conditions, i.e, inequalities between quantities. QR models can only describe systems with continuously changing quantities, as stated by the continuity law [6]. In general, model creation is an iterative process: One has to find the right level of abstraction and check if the simulation output satisfies the requirements. If there are discrepancies, the model has to be adapted and simulated again.

Example: Consider the two-tank system from Figure 1. The two tanks are connected via a pipe at the bottom. Water can flow in both directions through the pipe. The flow rate depends on the difference of water levels. The control system has to hold the water level of *tank2* constant at a specified height while the water level and inflow rate of *tank1* varies. The control system can set the inflow to *tank1* and the outflow of *tank2* via controlling the valves. The water levels of both tanks are inputs of the control system. We use

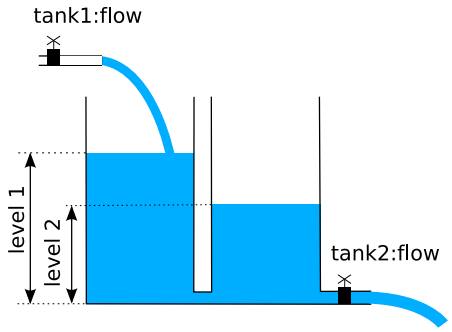

Figure 1. Two-Tank Example System.

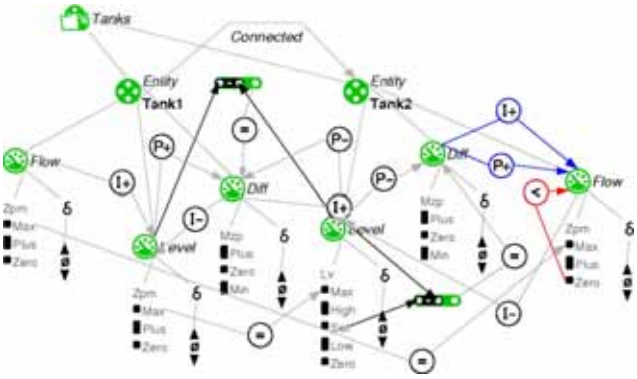

Figure 2. Model Fragment of the Two-Tank System.

this model as a case study in this paper. Figure 2 shows the Garp3 model fragment representing the physical relations and the control loop of the two-tank system.

The water level of *tank1* is the integral of the inflow rate over time, represented via a positive influence from *flow* to *level*. *Tank1* has an auxiliary quantity *diff* for calculating the difference in water levels. This difference determines the water flow through the pipe while influencing the water levels of both tanks. The quantity space of *level* in *tank2* contains a *set* point for controlling the water level. We use the auxiliary quantity *diff* of *tank2* to calculate the control deviation. The control loop is closed via a P and an I arrow to the actuator controlling the outflow valve resulting in a PI-controller. According to control theory the proportional part ensures quick response to changes and the integration part eliminates permanent control deviations. The setting of the outflow valve has a negative influence to the water level of *tank2*. Finally, equalities between the maximum tank water levels and valve flow rates makes them comparable while reducing ambiguity.

3 Coverage Criteria for QR Models

In general, one of the main problems one has to face when generating test cases is which test cases out of a large or infinite set to choose. Coverage criteria have been successfully used as stopping criteria when generating test cases, to evaluate test suites, and to automatically derive test cases.

A coverage criterion describes a set of items that the testing process should exercise. Many different coverage criteria have been defined based on both source code and specifications. For example, given a transition system we might aim to cover each transition of every state at least once.

When using explicit environment models the question of which test cases to select remains. Therefore, we define a set of coverage criteria for QR models: domain coverage, delta coverage, full delta coverage, as well as the traditional state and transition coverage.

The simulation of a QR models results in a state space representation of all possible behaviors that may evolve over time, starting with an initial scenario. This output is a QR transition system (QR TS) $M = (S, T, s_0, Q, qs, QS, v, \delta)$, where S is the set of states, T is the transition relation $T \subseteq S \times S$, and $s_0 \in S$ is the initial state.

Every quantity $q \in Q$ has an associated quantity space in the domain of quantity spaces QS, and the function $qs : Q \rightarrow QS$ maps each quantity to its associated quantity space. Each state $s \in S$ binds each quantity to a distinct value and delta. The value v for quantities in Q and states in S is defined as $v : S \times Q \rightarrow qs(Q)$, and the delta δ is defined as $\delta : S \times Q \rightarrow \{min, zero, plus\}$. The $delta$ of a value stands for its direction of change over time, $\delta \sim \frac{\partial value}{\partial t}$.

Below we define a set of different coverage criteria. A coverage value according to these coverage criteria can be measured as the ratio of covered items to items in total as defined in the coverage criterion. As will be described in Section 4, a test case created from a QR TS is itself a QR TS $t = (S_t, T_t, s_{0,t}, Q_t, qs_t, QS_t, v_t, \delta_t)$. A test suite $\mathcal{T}$ is a set of test cases.

In a QR transition system, the state of the environment is given by a value assignment to the model's quantities. Each quantity $q \in Q$ has a finite domain, its quantity space: $qs(q) = \{d_0, d_1, \ldots, d_n\}$, therefore it is feasible to require each quantity to take on all of its values. This coverage criterion is called *Domain Coverage*.

Definition 1 (Domain Coverage) *A test suite $\mathcal{T}$ achieves domain coverage, if for each quantity $q \in Q$, q there is a test case $t = (S_t, T_t, s_{0,t}, Q_t, qs_t, QS_t, v_t, \delta_t) \in \mathcal{T}$ for each $d \in qs(q)$, such that $s \in S_t : v(s, q) = d$.*

Because testing all possible environment states might be impractical, domain coverage offers a compromise by en-

suring that each possible domain value occurs at some point. That is, given a test suite that satisfies domain coverage we know that each possible environment value has been exercised at least once.

As quantities change their values according to the description given in the QR Model, errors might only be detected when considering value changes. In QR models, the direction of change of a quantity is given by its delta, which can be min, $zero$, or $plus$. Consequently, we define *Delta Coverage* such that each quantity has changed its value in every direction at least once.

Definition 2 (Delta Coverage) *A test suite $\mathcal{T}$ achieves delta coverage, if for each quantity $q \in Q$, q there are test cases $t_1 \in \mathcal{T}$, $t_2 \in \mathcal{T}$, and $t_3 \in \mathcal{T}$ such that $s_1 \in S_{t_1} \wedge \delta(s_1, q) = min$, $s_2 \in S_{t_2} \wedge \delta(s_2, q) = zero$, and $s_3 \in S_{t_3} \wedge \delta(s_3, q) = max$.*

Delta coverage ensures that every relevant quantity eventually changes its direction. Note that in Definition 2 t_1, t_2, and t_3 can be the same test case. Changes of direction adhere to the continuity law [6]. This means that a quantity has to increase, stay steady, and then decrease or vice versa. Sudden, non-continuous jumps on domain values or deltas cannot happen.

Delta coverage can miss cases where some value change causes an error but a different value change for the same delta is chosen for testing. Consequently, we define *Complete Delta Coverage* as a stricter variant of delta coverage.

Definition 3 (Complete Delta Coverage) *A test suite $\mathcal{T}$ achieves complete delta coverage, if for each quantity $q \in Q$ with quantity space $qs(Q)$, there are test cases t_1, t_2, and t_3 for each $d \in qs(Q)$ such that $s_1 \in S_{t_1} \wedge \delta(s_1, q) = min \wedge v(s_1, q) = d$, $s_2 \in S_{t_2} \wedge \delta(s_2, q) = zero \wedge v(s_2, q) = d$, and $s_3 \in S_{t_3} \wedge \delta(s_3, q) = max \wedge v(s_3, q) = d$.*

Complete delta coverage is a combination of delta and domain coverage demanding that every domain value of a quantity changes its direction. Depending on the number of quantities and the sizes of their quantity spaces, complete delta coverage might be hard to achieve. Complete delta coverage might also contain infeasible test goals; for example it might not be possible to decrease a value (delta min) at the lower bound of a quantity's domain.

In addition to the above coverage criteria, we can apply traditional coverage criteria for transition systems to the QR TS. *State coverage* requires that each state of the QR TS is visited at least once, and *Transition coverage* requires that every transition of the QR TS is executed.

Definition 4 (State Coverage) *A test suite $\mathcal{T}$ achieves state coverage for QR TS $M = (S, T, s_0, Q, qs, QS, v, \delta)$, if for every $s \in S$ there is a test case $t = (S_t, T_t, s_{0,t}, Q_t, qs_t, QS_t, v_t, \delta_t) \in \mathcal{T}$ such that $s \in S_t$.*

Definition 5 (Transition Coverage) *A test suite $\mathcal{T}$ achieves transition coverage for QR TS $M = (S, T, s_0, Q, qs, QS, v, \delta)$, if for every $(s, s') \in T$ there is a test case $t = (S_t, T_t, s_{0,t}, Q_t, qs_t, QS_t, v_t, \delta_t) \in \mathcal{T}$ such that $(s, s') \in T_t$.*

4 Automated Coverage Based Test Case Generation

So far we have defined coverage criteria to evaluate existing test suites. In this section we describe how to automatically derive test suites that satisfy these coverage criteria using QR models. For this we use a recently proposed method [3] for deriving test cases from QR models with formally defined test purposes.

4.1 Test Case Generation for QR Models

In general, test case generation with test purposes requires a test engineer to write test purposes in a formal notation. In the case of QR models, the approach described in [3] uses properties defined with regard to quantities to label the transitions of a QR TS. These properties are used to turn the QR TS into a labeled transition system, and to describe test purposes. For instance a property $a := tank1 : level\ gt\ zero$, referenced by symbol a, denotes that the water level of tank1 is greater than zero. The test purpose is specified via a regular expression over property symbols. For example $p\{3\}q$ denotes a sequence of states, where property p holds in the first three states followed by a state which satisfies property q. The regular expression is converted to a finite automaton, and the synchronous product of QR TS and test purpose results in a Complete Test Graph (CTG), from which test cases are extracted.

As a QR TS can be nondeterministic, special care has to be taken to ensure controllability, i.e., to make sure that a test case can handle all decisions between different inputs for the implementation. Consequently, test cases are not linear sequences but transition systems that can handle alternative outputs. Given a CTG, test cases are created by searching backwards to the start state and forward to an accept state. Then the path is traversed and all parts of the CTG that are reachable considering the implementation's nondeterministic outputs are added to the test case.

A resulting test case is a QR TS, which includes all information needed for its execution in its states. Each QR state comprises a set of quantities with their current values and deltas. For test case execution, these abstract values have to be mapped to concrete quantity values.

During test case execution, the concrete values are updated regularly based on a time step Δt according to the current state. The behavior of the output quantities decides

which transitions are taken, and a state is left as soon as it becomes inconsistent with the input quantities it controls and the observed output quantities. If there is no matching successor state that is consistent with the observed outputs, then the implementation fails the test case. When an accepting state is reached the implementation passes the test case.

4.2 Coverage-based Test Purposes

Based on a given coverage criterion we automatically generate test properties and regular expressions specifying a test purpose satisfying the coverage criterion.

With the domain's boundary values a and b we can formulate a test purpose $([\hat{}a]*a[\hat{}b]*b)|([\hat{}b]*b[\hat{}a]*a)$ ensuring domain coverage. It reads as follows: start from any value in the domain but a boundary value, then reach one of the boundary values, and finally the other one. Such a test purpose covers all domain values of a certain quantity. We generate test purposes and furthermore test cases for all input and output quantities of the test model (relevant quantities).

We can describe delta coverage with the same regular expression as for domain coverage, but with fixed boundary values min and $plus$ since $\delta \in \{min, zero, plus\}$. In order to express complete delta coverage we generate test purposes for each possible pair of domain value and delta, e.g., (value1, min), (value1, zero), (value1, plus), ..., resulting in $\{3 \cdot card(qs(q))|q \in Q\}$ combinations. Such a test purpose looks like $[\hat{}p] * p$, where p is the property to be searched for.

For state coverage we create test purposes like for complete delta coverage but the properties we search for are complete quantity assignments corresponding to a certain state. We generate test purposes for every state in the specification. To ensure transition coverage we use a test purpose for every transition in the specification, e.g., $. * pq$. Here p specifies the start state and q the end state of the transition to be covered.

4.3 Demonstration and Results

The QR TS resulting from simulation of the two-tank example system introduced in Section 2 comprises 113 states with 305 transitions. In order to evaluate our proposed coverage criteria we use transition coverage of obtained test suites on the specification as reference measure. Tables 1 and 2 list from left to right the coverage criterion, the number of generated test purposes *#TPs*, the number of obtained test purposes *#TCs*, and the transitions coverage on the specification. For Table 1 we exhaustively extract test cases from CTGs until all transitions of the according CTG have been considered. Table 2 lists each criterion for only one generated test case per test purpose.

Table 1. All Test Cases per Test Purpose

Coverage Criterion	#TPs	#TCs	Transition Cov.
Domain	5	120	220/305
Delta	5	133	217/305
Complete Delta	60	850	297/305
State	113	1434	305/305
Transition	305	2256	305/305

Table 2. One Test Case per Test Purpose

Coverage Criterion	#TPs	#TCs	Transition Cov.
Domain	5	5	35/305
Delta	5	5	60/305
Complete Delta	60	42	119/305
State	113	113	168/305
Transition	305	305	305/305

Figure 3 depicts an example test case created for domain coverage on quantity *Tank2:Diff*. Figure 3(a) shows a state sequence leading to an accept state and Figure 3(b) shows the according value history. With regard to delta coverage this test case covers $\delta = zero$ and $\delta = plus$ for quantity $Tank2 : Flow$. The test case also covers 3 out of 8 possible value/δ combinations for complete delta coverage, and 5 states and 4 transitions.

5 Related research

Tretmans [9] described test case generation for Labeled Transition Systems (LTS). The paper focused on Input-Output-LTS (IOLTS) and introduced conformance relations for them. The proposed testing theory also deals with states

where quiescence is allowed. Jard and Jeron [7] presented a tool for automatic conformance test generation from formal specifications. They used IOLTS as formal models and defined the *ioco* conformance relation for weak input enabled systems. Test cases are generated using defined test purposes.

Auguston et al. [1] introduced the use of attributed event grammars for generating test-cases from environment models for reactive systems. In the paper the authors use the grammar for representing an event-based model. Possible execution traces of the model form the test-cases. Insofar the underlying idea for test-case generation as described in this paper is very similar, but can be distinguished with respect to the underlying modeling language. Whereas Auguston et al. are using attributed event grammars, in this paper we are proposing the use of qualitative models for test-case generation.

6 Conclusions

In this paper we presented a set of coverage criteria based on QR models: Domain coverage, delta coverage, and complete delta coverage, as well as state and transition coverage for QR TS resulting from simulation of QR models. In contrast to previous work, these coverage criteria can be used to measure how thoroughly testing is done with regard to a model that includes an qualitative environmental description. Qualitative models represent all possible physical behaviors of systems and their environments, and can be used to find test cases which might not be considered when only using a system's specification. The approach is especially well suited when a physical model is available, e.g., in the embedded systems area. We described a method to automatically derive test cases for the proposed criteria, and illustrated the feasibility on a case study.

Initial results on a case study application show that useful test cases can automatically be generated from QR models using the described coverage criteria. As expected, the experiments show that the different criteria can be used to vary the amount of test cases generated from a QR model. We are currently in the process of evaluating the approach on models derived from Matlab Simulink models via qualitative abstraction. First experiments indicate a sound test case execution, and resulting test cases exercise the interactions of a system under test with its environment. Future work will include application of the presented methods to larger models.

Abstract

Model-Driven Development and Aspect-Oriented Software Development are paradigms that provide mechanisms to support the requirement evolution. While model-driven development contributes with a standard way to make model transformations through different abstraction levels, aspect-oriented software development provides mechanisms to separate concerns and compose crosscutting concerns. In this paper, we present Traceability Models as patterns to control the model transformations during the architectural separation of concerns. Thus, we can achieve quality features in the development process such as decreasing conflicts between stakeholders, avoiding invasive changes, and wrapping traceability in the modeling tasks.

1. Introduction

Controlling software requirement evolution is one of the most important activities in the development process to achieve reliable software products. Although several traceability approaches have been proposed, this topic is still under research [1-4]. In our investigation, we have found some issues that could frustrate a good traceability practice: (1) the software development process complexity; (2) requirements evolve, but the corresponding model elements are not changed accordingly in remaining abstraction levels; (3) the changes might be invasive (tangled or scattered); (4) development models change, but support artifacts such as traceability matrices are not updated. Moreover, in the software industry, traceability is carried out as an additional task to the modeling tasks, and its use and maintenance depends on quality standards and model information adopted by the developers.

Nevertheless, new development paradigms could provide model elements and development strategies that might help to resolve traceability issues during requirement evolution.

Model-Driven Software Development (MDSD) provides transformation mechanisms based on patterns that provide rules to transform models in different abstraction levels, and thus to preserve the architectural separation of concerns. But, the model complexity and the transformation of relationships are not dealt with. On the other hand, traceability is commonly understood as the information retrieved from transformation operations [5-7].

Aspect-Oriented Software Development (AOSD) provides mechanisms to promote separation of concerns throughout the software lifecycle, by identifying, modularizing and later composing crosscutting concerns. These features might help with the control of the concern traceability [8-12].

In our approach, we use MDSD and AOSD to control requirement evolution. Thus, we define traceability as the skill to control transformation of concerns and change propagation in different abstraction levels, maintaining decomposition and composition of crosscutting concerns by means of traceability models. This approach considers the following objectives:

1. To establish traceability models to control the concern transformations and propagate changes in different abstraction levels.
2. To deal with the decomposition of concerns and composition of crosscutting concerns through the architectural separation of concerns.

The structure of this paper is as follows. Section 2 defines traceability models. Section 3 establishes traceable model elements. Section 4 defines the concern roles. Section 5 presents related works and compares them with our approach. Finally, Section 6 concludes and shows directions for future work.

2. Traceability Models

Traceability models are instances of the metamodel shown in Figure 1. A Traceability Model is a pattern to control the model transformations, support the concerns evolution, and help in complementary tracing tasks such as the change cost-benefit analysis, and verification of consistency and completeness of system models. Each traceability model is composed by traceable model elements defined in a meta concern space where they can be identified by means of following roles: axis of tracing, predecessor, and successor. In order to achieve concern transformations, the concerns that act as axis of tracing are the *sourceElement* of the transformation and have associated a set of rules (*TransformationRule* class) to determine predecessors and successor elements (*targetElements*). They control the transformation and change propagation of concerns by means of the *TraceabilityModel – Engine*, which is supported by two classes: V*ersionController* and *PropagationController*.

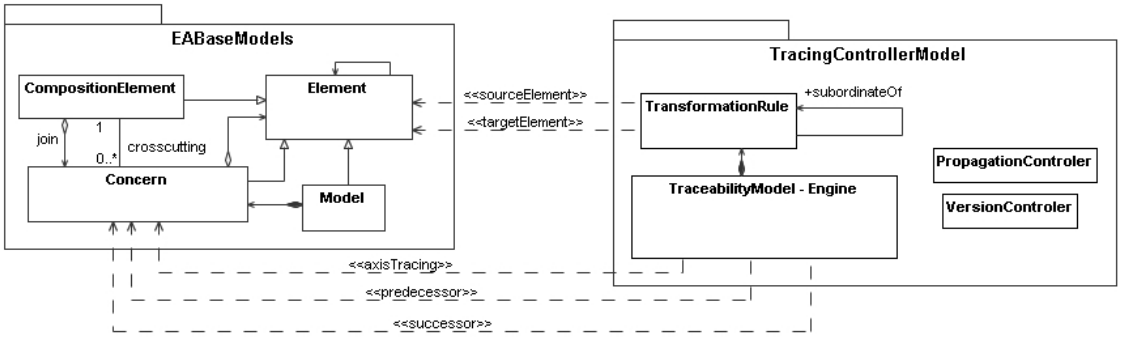

Figure 1. Meta Model for Traceability

3. Traceable Model Elements

A traceable model element is a *concern* which we see as a coherent collection of model elements, e.g., requirements, use cases, classes, collaborations, etc; this describes or represent a specific objective or function in the system. Each concern is represented by a UML package that uses a specific stereotype to identify the type of behavior or information grouped in it.

In order to reduce the complexity and provide a standard modeling for traceability practice, we make the following separation of concerns:

<<*Functional Concern*>>: this concern gathers model elements that represent a basic function of a system.

<<*QualityService Concern*>>: this concern gathers model elements that represent quality services for the system. For example: usability, security, persistency, etc.

<<*BusinessRules Concerns*>>: this concern gathers model elements that represent either functional constraints or business rules. For example: taxes, discounts, statistics, etc.

<<*Information Concern*>>: this concern gathers model elements that represent requirements or entities of information.

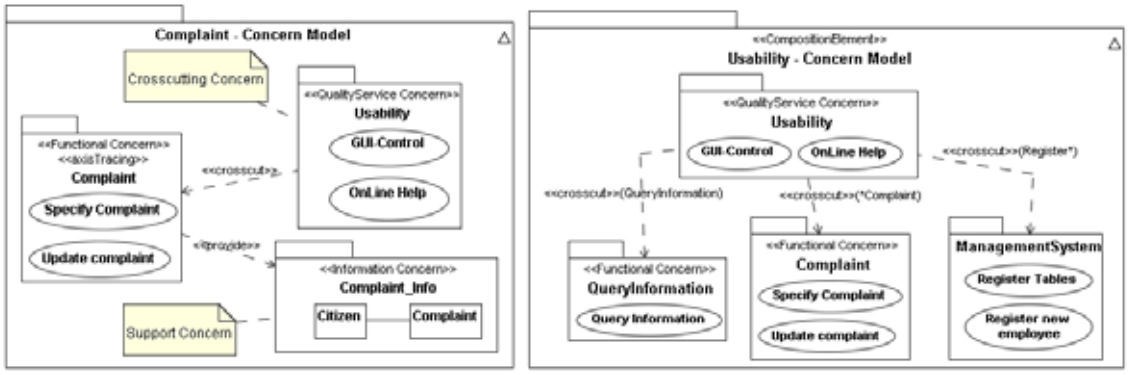
<<*Context Concern*>>: this concern gathers model elements that represent internal or external subjects or entities that generate input or output events.

Concerns such as Information, and Context are called *Support Concerns* since they help to achieve the objectives of Functional Concerns. Between these concerns, we use relationships such as <<provide>> or <<use>>. Concerns such as Quality Service, and Business Rules are called *Crosscutting Concerns* because they crosscut with additional functionality several Functional Concerns (they are considered *Support Concerns* when they only contribute with one Functional concern). Specifically, the <<crosscut>> relationship establishes the

composition between a crosscutting concern and Functional concerns.

Furthermore, an architectural separation of concerns is achieved by means of *concern models*. They are a set of interrelated concerns that represent the decomposition and composition of a problem in an abstraction level (e.g., requirements or architectural levels). Relationships between concerns are stereotypes (e.g., <<provide>>, <<crosscut>>) defined according to the types of concerns related.

In order to illustrate our ideas, we use the case study that deals with the Health Watcher System (HWS) case study. The HWS is a web-based application to manage health complaints [13]. Several concerns and their model elements have been identified, but due to lack of space we will concentrate on the concerns *Complaint*, and *Usability*. Figure 2(a) shows a view of the <<Functional Concern>> *Complaint* which is supported with the <<Information Concern>> *Complaint-Info* and crosscut by the <<Quality Service Concern>> *Usability*. Figure 2(b) shows the <<QualityService Concern>> *Usability* crosscutting the <<Functional Concern>>: *Login*, *QueryInformation*, *Complaint*, and *ManagementSystem*. Both views are constructed in the requirement level.



(a) **(b)**

Figure 2. Two Requirements Concern Models views, for the Health Watcher System.

4. Concern Roles in the Traceability Model

Traceable model elements play three basic roles in traceability models:

axisTracing (C, {r_i}). A kind of concern ***C*** is declared as an axis of tracing jointly with its transformation rules (r_i). An *axisTracing* concern controls transformations, change operations and their propagation.

Predecessor. A predecessor concern C_{Pr} precedes an *axisTracing* concern that has matched backward transformation rules to generate it.

Successors. A successor concern C_{Sc} succeeds the *axisTracing* concern that has matched forward transformation rules to generate it.

The tracing links between them are realization <<realize>> and refinement <<refine>> UML relationships:

<<realize>>(source, target). Trace relationship between *axisTracing* and *successor* tracing elements. The source is the *successor*, and the target is the *axisTracing*. Commonly, they are in different abstraction level, and *target* elements realize *source* elements.

<<refine>>(source, target). Trace relationship between *axisTracing* and *predecessor* tracing elements. The source is the *axisTracing*, and target is the *predecessor*. They can be in the same abstraction level, and source elements refine target elements.

In order to avoid invasive changes in the system and verify easier consistency and completeness quality attributes in the models, we define two kinds of traceability models:

(i) *Centered in Functional Concerns*: the *axisTracing* concern is a Functional Concern that gather use cases (see Figure 3).

(ii) *Centered in Composition Elements*: the *axisTracing* concern is a model element identified as crosscutting concern and is part of a <<CompositionElement>>.

Other ones might be defined by developers according to necessity of tracing and evolution of model elements.

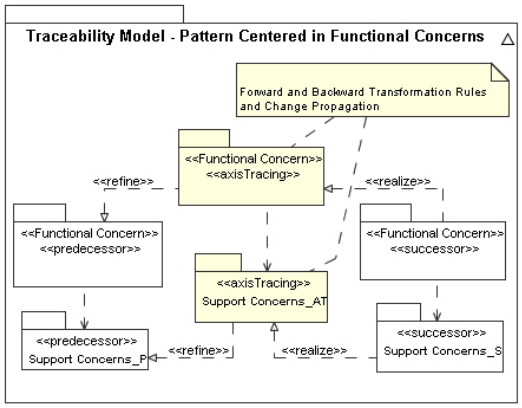


Figure 3. Pattern Centered in Functional Concerns.

Figure 4 shows a first version of a traceability model centered in Functional concerns for the *Complaint* concern. <<Functional Concern>> Complaint and <<Information Concern>> Complaint_Info have been declared as <<axisTracing>> concerns. The first gathers both Specify Complaint and Update Complaint use cases as model elements that represent the complaint function. The second (support concern) helps to make the complaint actions and gathers the Complaint class. Each one has a set of transformation rules to generate predecessors and successors concerns. In this example we consider concern models in two abstraction levels: *Requirements Concern Model (RCM)* whose instances are created at the requirement level, and their concerns gather model elements such as requirements, use cases and entities; *Architectural Concern Model (ACM)* whose instances are created (by means of transformation rules) at the architectural level, and their concerns gather model elements such as use case realizations, classes, operations, etc.

Each transformation rule is unique and consistent to guarantee the homogeneity of the concerns in different abstraction levels. Two types of rules are defined: *Root rules*, which transform concerns and their relationships, and *Subordinate rules* which transform model elements of the concerns. Each rule is composed by source and target elements. The transformation is bidirectional (forward and backward), horizontal (between concerns of the same abstraction level), and vertical (between concerns of different abstraction levels).

Table 1 show some rules performed from the *axisTracing* elements where the source concern model is in requirement level, and the target concern model is in architectural level (i.e., analysis architecture).

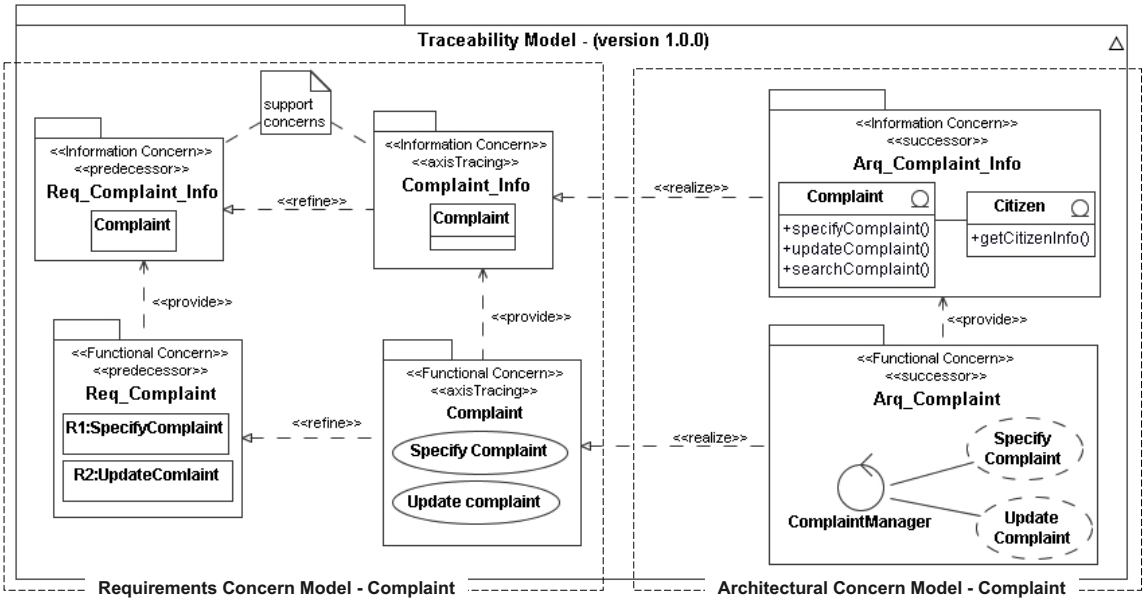

Figure 4. Traceability Model for the Complaint Concern.

Table 1. An Example of Transformation Rules.

Rule (*source2target*)	Description
Root rule #1: Req_FunctionalConcern2Arq_FuctionalConcern (Forward, vertical)	A Function concern from RCM (e.g., Complaint) is transformed into a Functional concern in the ACM.
Subordinate rule #1.1: UseCase2RealizationUC+ControlClass+Operation	A base use case (e.g., Specify Complaint) of a Functional Concern (e.g., Complaint) in the RCM is transformed into the following target model elements in the ACM: use case realization, a control class, its operation, and the association relationship with the entity class in the Information Concern of the ACM (transformed by other rule). ACM model is illustrated in the Figure 4.
Root rule #2: Req_InformationConcern2Arq_InformationConcern (Forward, vertical)	A Information concern from RCM is transformed into an Information concern in the ACM; e.g.,
Subordinate rule #2.1: Entity2EntityClass+Ops	An Entity (e.g., Complaint) of an Information Concern in the RCM is transformed into an analysis Entity Class and their basic operations, all as target model elements in the ACM.

Although these rules are written in a natural language, also they might be written in some formal transformation language.

Transformation rules have to be very well defined to make accurate change propagation. Thus, since <<axisTracing>> elements the developer can measure the change impact and execute a sequence of chained rules defined according to relationships among concerns.

5. Related Work

Almeida et al. provide a methodological framework that allows designers to relate requirements to the different design process products driven to models. This framework is a base used to trace requirements and quality evaluation of the model transformation specifications for metamodels, models and realizations. The traceability is presented in a cross reference table between requirements and models on different abstraction levels [14].

Berg et al. define crosscutting concerns based on a traceability pattern; besides, the impact analysis is based on traceability of dependencies between elements in software artifacts in both metamodel and model [15].

Kurtev et al. tackle analysis of change in the model transformation, generating traces between source and target model elements. Each trace is formed by sets of source and target elements and a rule that uses theses elements. The trace model is generated after the execution of a transformation [16]. In our approach, traceability models are patterns to control the concerns transformation and change propagation. These models help to assess the change impact analysis by means of a change management method.

6. Conclusions and Future Work

Our approach incorporates traceability as part of the development process, defining traceability models as patterns to control concerns evolution based on architectural separation of concerns, and concern transformations.

Architectural separation of concerns by means of concern models allows us to trace type of concerns, preserving their decomposition and composition in different abstraction levels. In other words, we achieve horizontal and vertical separation of concerns from requirement to architecture using stereotyped packages and concern models. In addition, crosscutting concerns can be traced independently, without losing the consistency with the basic models, since we define horizontal and vertical composition of concerns and its transformations. These features help to diminish the complexity in the development process, avoid invasive changes, and resolve conflicts between stakeholders from requirement specification.

In traceability models, the transformation is controlled by means of concerns that act as axis of tracing. They have a set of root and subordinate rules which guarantee concerns homogeneity from requirements to architecture, and propagate the change to predecessor and successor concerns. These models are used in a method to support the changes management. Hence, both models and matrices of traceability are instances of them and their update is automatic.

We are currently developing a traceability method based on the traceability models in an academic modeling CASE tool.

Knowledge-based system development with scripting technology – a recommender system example

Dietmar Jannach
Department of Computer Science
Dortmund University of Technology, Germany
e-mail: dietmar.jannach@udo.edu

Abstract

The core functionality of many knowledge-based systems is built with the help of special-purpose software components and programming environments such as rule engines or Prolog interpreters. Other parts of the application – like the Web interface – are however built with "standard" software development technology like Java which means that not only the corresponding interfaces and data exchange mechanisms between the components have to be developed, but also that the software developers have to work with different technologies or even programming paradigms.
In this paper we show how recent "scripting" extensions in a programming language like Java can be exploited to develop highly flexible and extensible knowledge-intensive applications. The different advantages of such an approach are discussed based on the experiences gained from developing a scripting-based software library for building knowledge-based recommender applications.

1. Introduction

The possible advantages of a knowledge-based software development approach are well known. The domain knowledge can be separated from the reasoning knowledge while at the same time optimized off-the-shelf reasoning engines can be used to automate the inferencing or problem solving process.

In many real-world or commercial applications, however, only a part of the "intelligent" system will be developed with the help of special programming environments such as LISP or Prolog or by use of a rule-engine like Jess[1]. The web interface or the database layer will most probably be developed with the help of "standard" technology such as Java, Servlets, or Java Server Pages. This mix of technologies brings additional complexity to the software development process since programmers not only have to implement the different interfaces and data exchange channels but – more importantly – are faced with different programming paradigms.

In the field of programming languages, we can observe signs of a revival of "scripting" languages in recent years. Despite their disadvantages with respect to type-safety, compile-time problem detection and run-time performance, languages like PHP, Python and recently Ruby became popular in particular for web application development as they – according for instance to [13] – promise to be advantageous with respect to flexibility and developer productivity. From our point of view, the aspects of flexibility and in particular extensibility that these interpreted languages provide also make them interesting for the development of knowledge-intensive systems.

In this paper, we report and discuss our experiences gained from developing the light-weight JPFINDER library for building knowledge-based recommender systems . The library is fully written in the Java programming language and exploits the language's recent "scripting" support to achieve the required levels of extensibility and compactness of the knowledge bases. Overall, the work shall thus exemplify one of the options of embedding knowledge-based system development into industrial software development processes and environments.

2. Application domain & system architecture

In the field of recommender systems, the following main approaches can be distinguished: Classical *community-based recommender* systems base their proposals on item ratings, user similarities, and collaborative filtering techniques, see [1] for a recent overview. *Content-* or *knowledge-based* systems on the other hand operate on the basis of further pieces of information, which can for in-

[1] http://www.jessrules.com/jess/index.shtml

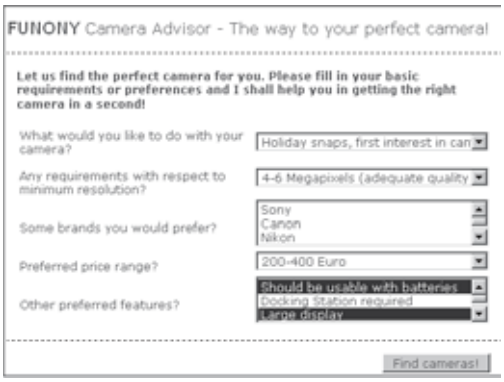

Figure 1. Preference elicitation

Figure 2. Recommendation & explanation

stance be knowledge about the items to be recommended and/or knowledge about directly or indirectly acquired preferences of the users. Typical techniques used in the latter type of systems are for instance filter-based matching, similarity-based retrieval or utility-based ranking [4].

Screenshots of a typical interactive recommender application in the sense of [5] are shown in Figure 1 and Figure 2. The user is first guided through a series of possibly personalized questions in order to determine her specific needs (Figure 1). At the end of this dialog, the system comes up with a recommendation and – due to its knowledge-based nature — is also capable of explaining the reasons for this particular proposal, retrieve other similar catalog items, or let the user revise or specify additional requirements.

It can be easily observed that such applications are *knowledge-intensive*, meaning that various pieces of domain-specific information have to be encoded in the background. Examples for such knowledge chunks are for instance the *matching rules* that determine which items suit some given requirements, utility functions for ranking the items, or personalization rules to adapt the user interface and navigation path according to the current user profile.

In [5], CWADVISOR, an integrated environment for the development of such knowledge-based and highly interactive recommender systems is presented. The CWADVISOR system is designed as a classical and to some extent heavy-weight expert system. It relies on the explicit representation of domain knowledge, provides a fully-fledged graphical knowledge acquisition component, a relational database for persisting the knowledge as well as proprietary languages for modeling filtering or personalization rules.

The JPFINDER library discussed in this paper implements many of the features of CWADVISOR and was designed to be a light-weight alternative to the comprehensive CWADVISOR expert system. In particular it should also take advantage of recent scripting features of the Java programming language as to reduce the development efforts that are required for rule processing while at the same time extensibility and flexibility should be retained.

In the work presented herein, we will particularly focus on how the *rule knowledge* is represented and processed, as the development of software systems that are governed by *business rules* are in wide-spread industrial use also in other application domains. In the CWADVISOR system, a proprietary rule language is used. The statements are either parsed, translated and compiled to Java code [8] or directly executed with the help of a proprietary rule interpreter [5]. In either case, a comparably complex parser and compiler component as well as a graphical tool for modeling the rules (including for instance auto-completion and correction features) are required, whereas JPFINDER relies on scripting technology for that purpose.

The overall architecture of the JPFINDER system is outlined in Figure 3. At the core, the *Recommender Engine* interacts with the different users of the system and correspondingly maintains *Recommender Session* objects that contain the current user's profile. The *Engine* has a defined Application Programming Interface to manipulate the domain knowledge which can also be used for loading the definitions from a persistent data store at system startup. Several pluggable *reasoning modules* are also part of the library and implement specific functionalities such as filter-based matching, utility calculation or techniques for user interface personalization.

3. Recommendation technique implementation

In the following, we will discuss the logic of JPFINDER and some of its modules in more detail and in particular focus on the scripting-based implementation of the functionalities.

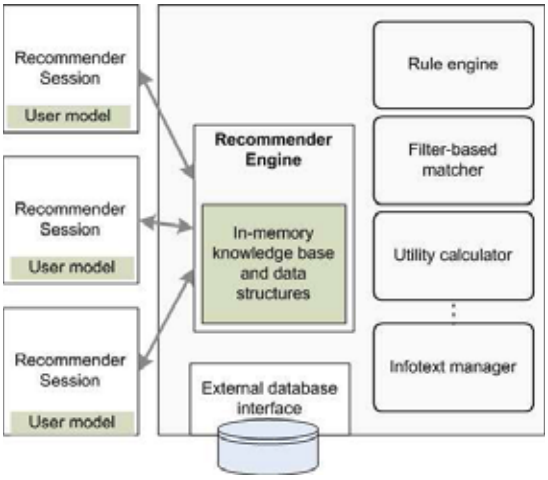

Figure 3. Architecture overview.

3.1. The user & product model

In JPFINDER, every piece of information about the user and the preferences used for generating recommendations are contained in the *user model*. In order not to limit the generality of the approach, the user model is thus generally defined to be a finite set of variables *UV* (user variables), each of them with a defined data type. Variables can be either string-valued or numeric; of both types, multi-value instantiations are possible, see for instance the choice of preferred features in Figure 1. Note again that the values for variables in *UV* do not necessarily have to be directly acquired through questioning but can also be derived "internally", e.g., based on scoring schemes or other value derivation rules. The set of specific (input) values for one individual user shall be denoted as *IV*. In fact, also complex user modelling techniques – that for instance maintain a history of user interactions – can be employed. The implementation of such profiling or learning techniques is however beyond the scope of JPFINDER.

Similarly, the *product model* defines the characteristics of the items to be recommended. The product characteristics are described by a set of variables *PV* (product variables) with defined data types. Beside regular product features, the product model can also be used to describe "external" product characteristics such as vendor reliability or current stock availability in a given shop.

Each individual recommendable item is thus described by a set of key-value pairs; the set of all items forms the product is denoted as product catalog *PC*.

In the example, *UV*, *PV*, *PC* and some user inputs IV_1 could be as follows, using Java notation for data types.

$$UV = \{pref\_price : Double, \\ pref\_features : String[], ..\}$$

$$PV = \{price : Double, resolution : Double, ..\}$$
$$PC = \{\{price : 400.00, resolution : 3, ...\}, \\ \{price : 300.00, resolution : 2, ...\}\}$$
$$IV_1 = \{pref\_price = 100, pref\_features = ..\}$$

3.2. Filter-based matching

Model. With *filter-based matching* we mean a technique in which customer preferences are directly or indirectly mapped to constraints on product properties. Such filter-based approaches are also commonly used in similarity-based systems to pre-filter the set of products to be compared [11].

In JPFINDER, the mapping from user preferences to desired product characteristics can be expressed in the form of "if-then-style" rules, i.e., a filter rule $FR < AC, FC >$ consists of an *activation condition AC* and a *filter constraint FC*. We use $FR.AC(IV)$ to refer to the evaluation of the activation condition given input values IV and $FR.FC$ to refer to the filter constraint definition.

A typical filter rule in the domain could be: *"**If** the user prefers the lower price range **then** recommend items with a price lower than 200 Euro."* Formally, filter rules are interpreted as follows. Let AC be an expression over variables in UV, FC an expression over the variable set $UV \cup PV$. IV are the customer input values and PC is the product catalog given in the form described above.

Given these inputs, the "catalog query" Q is thus the conjunction of FC-expressions of those filter rules for which AC evaluates to *true*, i.e.

$$Q \equiv \bigwedge(f.FC) | f \in FR \wedge f.AC(IV) = true$$

If we interpret the product catalog PC as a relational database table, filtering the set of recommended products RP corresponds to performing the database query σ_Q on PC.

Scripting-based implementation The implementation of filter-based matching in JPFINDER relies on a recent algorithm [9] which also supports fast query relaxation for failing queries and which is based on compact in-memory data structures and partial in-advance query evaluation.

Note that although there have been several efforts to defining a common knowledge interchange format (see, e.g., KIF[2]), no common representation mechanism for rules or constraints is yet broadly established. In more recent efforts, the general constraint language ESSENCE [7] has been proposed and SWRL[3] has been submitted to the W3C as a rule language in the Semantic Web. Still, besides problems of syntactic complexity (SWRL) or limited expressiveness (ESSENCE), special purpose parsers, compilers, or interpreters have to be employed to support these languages.

[2] http://logic.stanford.edu/kif/kif.html
[3] http://www.w3.org/Submission/SWRL/

```
<xml>
  <FilterRule>
    <if condition="c_pref_price_range = 'medium'"/>
    <then constraint="p_price > 200 && p_price < 400"/>
    <explanation text="I could obey your price preferences
                       (medium price range)"/>
    <excuse      text="Note that due to your other requirements I could
                       not obey your price preferences"/>
    <priority="3"/>
  </FilterRule>
  <FilterRule>
     <if condition="..."/>
                ...
</xml>
```

Figure 4. XML representation of filter rules.

As a knowledge representation mechanism for the filter constraints, JPFINDER therefore relies on JavaScript, which is the default scripting language supported by the recent Java 6 SE release. As described above, the filter rules are written in a simple "if-then"-style, which in our experience (see, e.g., [5]) is easy to comprehend also for domain experts who are not experienced in programming or specific knowledge representation techniques. The activation condition and the filter constraint are formulated as JavaScript expressions over the variables of the user model.

In Figure 4, an example of a filter rule including relaxation priorities and explanation texts in the sense of [9] is shown. At run time, the variables of the user model – which may have been acquired via an ordinary Java Server page or from a more elaborate user modelling component – are forwarded to the scripting engine which then evaluates the activation conditions of the rules. Those expressions that evaluate to true are then used to filter the suitable catalogue items. Note that The XML representation in Figure 4 is optional as the library provides an appropriate Java-based application programming interface for registering the filter rules.

Within the expressions statements, all JavaScript language constructs can be used and arbitrarily complex calculations are thus possible. The actual values of the variables of the user- and product model are automatically put into the scope of the scripting engine. With respect to extensibility aspects, the chosen scripting approach also allows us to define custom JavaScript functions that can be seamlessly used within expressions. Consider, for instance, that a filter constraint should be written that is activated whenever the user has chosen a particular value from a *set of options* like *"**if** the customer preferences (among others) contain 'usb' **then** ..."*.

To that purpose, the knowledge engineer can write a standard JavaScript program that tests for set membership:

```
function isContainedIn(value,um_var) {..}
```

Custom functions like this can then be registered to the recommender engine at runtime and used within the filter constraint. Internally, the script code are automatically compiled into Java code for performance reasons, which is a standard feature of Java SE. The only task of the recommender engine is to put the current values of the session into the execution scope when the function is called.

3.3. Utility- and similarity-based retrieval

Retrieving items based on their expected utility to the user or based on the similarity with (individual features of) another item are two other techniques used in knowledge-based recommendation, see [2] or [3].

At the core of *utility-based approaches*, a *utility function* is used whose value either depends on specific product features alone or which also takes the user's preferences into account. A typical evaluation scheme for determining such personalized utility values can for instance be based on Multi Attribute Utility Theory (MAUT) [8, 14].

Within JPFINDER, such arbitrarily complex utility functions can be defined in a similar way like the custom extensions mentioned above, i.e., with the help of JavaScript functions.

```
<UtilityFunction type="dynamic">
      function myUtility() {
            var utility_total = 0;
            // Utility dimension mobility
            var utiltiy_mobility = 0;
            if (p_weight < 300)
                  utiltiy_mobility += 3;
            if (p_batteries = 'yes')
                  utiltiy_mobility += 2;
            ...
            // Weighting based on user prefrences
            if (pref_mobility == 'high')
                  ...
            return utility_total;
      }
</UtilityFunction>
```

Figure 5. Fragment of utility function.

A fragment of a possible utility function that both evaluates product features and user preferences is sketched in Figure 5. At run time, JPFINDER applies the function on

each catalog item separately. The resulting utility values can then be used to sort the items in the recommendation list accordingly. JPFINDER supports two variants of utility functions, *static* and *dynamic* ones. If a utility function is marked to be static then no user model variables must be used in the function. This differentiation is mainly introduced for performance purposes. If no user model variables are used, the values of the utility function will be the same for all customers, which in turn means that the corresponding values can be pre-computed when the library is initialized. "Dynamic" evaluation functions have to be evaluated in the context of the requirements of a specific user like in the MAUT approach.

In the same way, custom functions can be developed to implement *similarity-based retrieval* recommendation techniques. In contrast to utility functions, the return value of a similarity function is not an individual utility value but rather a normalized numerical value that describes the relative similarity between two items. Based on this mechanism, JPFINDER thus supports the implementation of recommender systems like the Wasabi personal shopper [3] or of critiquing approaches [10], in which the user can ask the system to retrieve items that are similar to a given one with respect to some features.

3.4. Rule-based inferencing

In some application domains, additional forms of inferencing (on user model variables) are required. This could be for instance the "internal" derivation of further variable values based on business rules or the determination and personalization of dialog pages in an interactive preference elicitation process [5].

JPFINDER supports the implementation of business rules or additional personalization logic through generic extension patterns that allow the developer to write code fragments, which are executed when certain conditions are fulfilled.

```
<BusinessRule>
  <If>
     c_pref_investment_duration > '10 years'
  </If>
  <Then>
     if (c_pref_question_1 == 'yes')
        c_derived_score += 3;
     if (...)
        …
  </Then>
</BusinessRule>
```

Figure 6. Fragment of business rule.

Figure 6 shows a fragment of a possible business rule in JPFINDER: Depending on some user input the value of *c_derived_score*, which corresponds to an internal variable of the user model, is determined. Note that the consequent of the rule can contain arbitrary code, which means it can also be used to perform mathematical calculations for, e.g., repayment rates commonly used in the financial services domain [6].

Personalized Text Fragments represent another extension pattern of JPFINDER. With the help of rules of this type, the recommender system can select personalized variants of predefined text fragments, which can for instance be used to adapt the graphical user interface according to the knowledge level of the current user. Finally, the pattern of *User Model Expressions* allows the engineer to define arbitrary expressions over user model variables. Based on the evaluation of these expressions for the current user, the dialog flow of the Web interface or other personalization features of the application can be designed in a flexible way.

The implementation of the rule execution engine in the current version of JPFINDER is a rather simple one. For the case of business rules, the engine for instance simply evaluates the rules until no more changes in the user variables can be observed. More elaborate techniques like rule-chaining or more expressive types of rules are planned for future versions.

4. Implementation aspects

Run-time performance is in general one of the key issues for interpreted scripting languages. Thus, particular attention has been paid to these aspects both in the design as well as in the implementation of JPFINDER's algorithms. What became obvious quite soon is that the "immediate" execution of text-based scripts in Mozilla's Rhino engine[4], which is the standard implementation in Java 6 SE, is not applicable for realistic problem sizes.

With respect to algorithms, let us exemplarily discuss the filter-based matching and relaxation problem from section 3.2. In particular the search for optimal "relaxations" of a failing query can be a costly operation as theoretically all combinations of subqueries have to be evaluated. In contrast to previous algorithms used for this task [11, 12], JPFINDER thus implements a novel technique [9] which is based on the in-advance evaluation of the filters and the usage of compact in-memory data structures. It was shown in [9] that this way the number of required "database queries" for determining the optimal relaxation can be limited to the number of given subqueries at the cost of slightly increased memory requirements.

Beside the usage of such recent algorithms, JPFINDER also relies on run-time "compilation" of all scripting code. When the library is initialized with the external knowledge base or additional knowledge pieces

[4] http://www.mozilla.org/rhino/

are added via the API, all JavaScript expressions and functions are automatically translated into Java byte-code. This functionality is implemented based on the built-in Java's `ClassCompiler` and dynamic class loading. Consequently, when scripting code has to be evaluated in a recommendation session, the script interpreter is actually not needed anymore as everything is already available in the form of Java byte code. Still, no manual recompilation is required when the knowledge base changes, as the needed byte code can be generated at run time.

As an example for performance numbers, consider the following rough running time numbers measured on a standard desktop computer (Intel P4, 3.2 GHz, 1 GB RAM). A recommender knowledge base for digital cameras may comprise around 400 products and 30 filtering rules, which in our experience is a realistic size. Let us assume that 15 of the filter rules are "active" in a current session and the best relaxation comprises 12 rules, i.e., three filters have to be relaxed. The running time for such a problem setting (without dynamic filter evaluation as described in [9]) is around only 100ms. Even if we double the problem size (800 products and 60 rules), the response time is still less than half a second, which is appropriate for interactive recommender sessions. Another number can be given for the dynamic construction of new filter conditions, see the "a bit cheaper models" - functionality in Figure 2. Evaluating for instance a single five-atom query with a smaller price for a catalog of 800 cameras requires less than 20ms. The overall memory requirement for both examples is below 15 megabytes, including all the product data which is kept in memory.

5. Conclusions

Based on an example from the domain of knowledge-based recommender systems, the paper has demonstrated how scripting technology can be used to simplify the development of knowledge-intensive software applications.

Compared with complex and heavy-weight expert systems that incorporate specialized programming environments or rule-processing engines, the advantage of the presented approach in particular lies in the fact that the software and knowledge engineer is not confronted with different programming paradigms and languages. In addition, the use of a consistent set of technologies simplifies the integration of such intelligent reasoning modules into standard Web development toolkits and industrial software development processes.

The preliminary evaluation of the presented library, which is based on real-world scenarios and experiences gained from previous projects [5], indicates that (1) many of the functionalities of more complex frameworks can be implemented with less code (as no special parsers, compilers, or interpreters are required), and that (2) performance issues that commonly arise in scripted languages can be successfully addressed with the help of runtime compilation.

Abstract

Sharing files via Internet gains more and more attention now. Recent P2P protocols use a decentralized model of distributing large multimedia files that greatly alleviate the bandwidth demand on the multimedia source. Such open delivery of multimedia files demands an adaptive and robust reputation management system to facilitate file sharing, moreover, security issues such as digital rights and access control need to be resolved. Our approach handles reputation and security issues in P2P file sharing when the attributes and behaviors of the principal are uncertain and mutable. Reputation management is integrated into access control model to support decision making in P2P file sharing in which the environment is ever changing. We solve uncertainty and mutability by an adaptive and decentralized reputation system. The peer with low reputation will be separated from file sharing, and its granted on-going access will also be revoked if access control rules are no longer met. We have applied our reputation-based usage control framework to an application of P2P file sharing.
Keywords*: trust, access control, P2P*

1 Introduction

Making multimedia content available online becomes the next Killer-Application for the Internet. Services such as iTunes, YouTube, Joost. are popularizing delivery of audios and video content to anybody with a broadband internet connection. With new virtual communities emerging, users communicate directly with one another to exchange information or execute transaction in a peer-to-peer fashion. Kazaa is an example of P2P networks and bittorrent is an example of P2P protocols. These services are currently struggling with the challenges of securing large-scale distribution. The dynamism of the P2P communities means that the principal that offer services will meet requests from unrelated or unknown principals. Peers need to collaborate and obtain services within environment that are unfamiliar or even hostile. Therefore, peers have to manage the risks involved in the collaboration when prior experience and knowledge about each other are incomplete. One way to address this uncertainty is to develop and establish trust among peers. Trust can be built by either a trusted third party [1] or by community-based feedback from past experiences [15] in a self-regulating system. Trust leads naturally to a decentralized approach to security management that can tolerate partial information.

In such a complex and collaborative world, a peer can protect and benefit itself only if it can respond to new peers and enforce access control by assigning proper privileges to new peers. Access control models [4, 11] determine authorization based on principals' permission on target objects. Usage of a digital object is temporal and transient in virtual community such as on-line reading, which is beyond an instantaneous access. UCON [14] is proposed to handle continuity of access decisions and mutability of subject and object attributes. Authorization decisions are made before an access, and repeatedly checked during the access. The on-going access may be revoked if the security policies are not satisfied due to changes of the subject, object or system attributes.

The general goal of our work is therefore to investigate the design of a novel approach to addressing both uncertain information and mutable attributes. If successful, this approach will offer significant benefits in emerging applications such as P2P. It will also benefit collaboration over the existing Internet when the identities and intentions of parties are uncertain. We integrate trust evaluation with usage control to handle uncertainty of entities and mutability of attributes. Underlying our framework is a formal computational model of trust and access control that will provide a formal basis to interface authentication with authorization.

2 P2P Delivery of Multimedia

P2P delivery of multimedia aims to deliver multi-media content from a source to a client. We assume that the content comes into existence at the source, i.e. we don't want to consider storing and securing the media at the origin. Example of creating such multi media might be a video camera with microphone. Likewise the client consumes the content, e.g. by displaying it on a TV monitor. We further assume that there is just one original source, but that there are many clients that want to receive the data. Our approach is specifically geared towards being able to scale effortlessly to support millions of clients without prior notice, i.e. be able to handle a "mob-like" behavior of the clients. Some lag time between creation of source data and its consumption by clients is acceptable, but excessive wait will defeat the attractiveness of our approach.

We use a P2P approach. The source data is made available at a preset quality using a variable-rate video encoder. The source data stream is divided into fixed length sequential frames: each frame is identified by its frame number and encrypted (see next section). Clients request frames in sequence, decrypt the frame and reassemble the video stream which is then displayed using a suitable video decoder and display utility. The video stream is encoded in such a fashion that missing frames don't prevent a resulting video to be shown, but rather a video of lesser bit-rate encoding, i.e. quality, will result [18].

Multi-media sources are advertised and made available via a central tracking service: at first, this tracker only knows the network location of the server. Clients that want to access the source do so via the tracker: they contact the tracker, which will respond with the location of the source. The tracker will also remember (or track) the clients as potential new sources of the data. Subsequent client requests to the tracker are answered with all known locations of sources: the original and the known client. Clients that receive locations of sources from the tracker issue frame requests immediately to all sources. Clients will also answer requests for frames that they have received already, which will enable a cascading effect, which establishes a p2p network where each client is a peer.

Figure 1 shows an example with one source, one tracker and three clients. The source is where the video data is produced, encoded, encrypted and made available. The tracker knows the network location of the source. Tracker and source maintain a secure connection. Clients connect to the tracker first and then maintain sessions for the duration of the download: all 3 clients maintain an active connection to the tracker. The tracker informs the client which source to download from: Client 1 is fed directly from the source; client 2 joined somewhat later and is now being served from the source and client 1; client 3 joined last and is being served from client 1 and client 2. In this example, two of the clients are also serving as intermediaries on the delivery path from original source to ultimate client.

3 Integrating Trust into Usage Control

Integrating trust evaluation into usage control allows collaboration when attributes of a principal are mutual or information of a principal's behavior is incomplete. During collaboration, owner of resources evaluates the trust of requesting principal first and then make authorization decision of resources sharing. The trust evaluation and authorization decision are temporal since they are made before, during and after the resource sharing.

3.1 Trust Evaluation

For every request, the owner of resources assigns a trust value between 0 and 1 to the requesting principal. The trust is evaluated based on both observation and recommendations from referees. Observations are the previous interactions the owner had with the requesting principal. Recommendations may include signed trust-assertions from other principals, or a list of referees whom the owner can contact for recommendations. The owner first computes trust given a sequence of observations from interaction history, then combines the trust with recommendations. The trust value, calculated from observations and recommendations, is a value within [0, 1] interval evaluated from a principal for a request.

The trust is assumed to follow a beta distribution, and represented by the two parameters of the beta distribution. The beta distribution, a conjugate prior, is chosen because of its reproducibility property under the Bayesian framework. When a conjugate prior is multiplied with the likelihood function, it gives a posterior probability having the same functional form as the prior, thus allowing the posterior to be used as a prior in further computations. For

a given requester, we define a sequence of variables T_1, T_2,. . ., T_k characterize the trust at the sampling time k. For instance, at *kth* sampling time, N_k observations are collected by the owner. Let G_k be the number of normal requests or behaviors. If the owner did not detect attacks (i.e., spyware, Trojan horse, SQL injection) associated with a request, he/she deems the request as normal behaviors. Suppose a prior probability density function (*pdf*) of trust T_{k-1}, denoted by $f_{k-1}(t)$ is known. Then the posterior *pdf* of (given $N_k = n$ and $G_k = g$) can be obtained from Bayes theorem [13] as follows:

$$f_k(t) = \frac{f_k(G_k = g|t, N_k = n)f_{k-1}(t)}{\int_0^1 f(G_k = g|t, N_k = N)f_{k-1}(t)dt} \quad (1)$$

where $f_k(G_k = g|t, N_k = n)$ is called the likelihood function and has the form of a binomial distribution:

$$f_k(G_k = g|t, N_k = n) = \binom{n}{g} t^g (1-t)^{n-g} \quad (2)$$

The prior *pdf* $f_{k-1}(t)$ summarizes what is known about the distribution of T_{k-1}. Under the assumption that prior *pdf* $f_{k-1}(t)$ follows a beta distribution, it can be shown that the posterior pdf also follows a beta distribution.

In particular, if $f_{k-1}(t) \sim beta(\alpha_{k-1}, \beta_{k-1})$, we have $f_k(t) \sim beta(\alpha_{k-1} + g_k, \beta_{k-1} + n_k - g_k)$ given that $N_k = n_k$ and $G_k = g_k$. Therefore, $f_k(t)$ is characterized by the parameters α_k and β_k defined recursively as follows: $\alpha_k = \alpha_{k-1} + g_k$ and $\beta_k = \beta_{k-1} + n_k + g_k$. Initially, the owner has no knowledge about the requester. We assume that trust value has uniform distribution over the interval $[0, 1]$, i.e., $f_0(t) \sim U[0, 1] = beta(1, 1)$ which indicates our ignorance about the requester's behavior at time 0. At time k, trust value $\bar{t}$ of the principal is:

$$\bar{t} = \frac{\alpha_k}{\alpha_k + \beta_k} \quad (3)$$

There are two alternative ways to update trust values. One is to update trust values based on all the observations and recommendations. The other ways is to update trust values based on recent information only. The advantage of the latter one is two folds: reduce the computation complexity and detect the changing of behaviors early. For instance, a requestor is misbehaving in a short time range, then recent observation together with reports is more reflective to the behavior changing than the overall observation.

Meanwhile, recommendations from referees bring in new information T_{rq} on requester's behaviors. The owner combines the new data T_{rq} with its own observation T_{oq} on the condition that the referee is one of owner's friends or the recommendation passes the deviation test. Deviation test is to decide recommendation is trustworthy or not. Recommendation R is learned from the past interaction the referee had with the requestor. Trustworthiness of a recommendation also follows a beta distribution. $f_k(t)$ is adjusted by recommendations: $T_{oq} := T_{oq} + \mu T_{rq}$ where T_{oq} is trust that owner has to requester, T_{rq} is trust that referee has to requester, and μ is the owner's belief of referee's recommendations.

3.2 Overview of UCON

Usage control model UCON proposed by J. Park [14] is a generalization of access control to cover authorization, obligation, conditions, continuity (ongoing controls), and mutability. Authorization handles decision on user accesses to target resources. Obligations are the mandatory requirements for a subject before or during a usage exercise. Conditions are subject, object, environmental or system requirements that have to be satisfied before granting of accesses. Subject and object attributes can be mutable. Mutable attributes can be changed because of accesses, whereas immutable attributes can be changed only by administrative action.

3.3 Trust-based UCON

A state is an assignment of values to variables which consist of principal attributes, object attributes and system attributes. The state transition system can be represented by (Σ, S, s_0, δ, F) where Σ is input alphabet, S is a set of system states, s_0 is the initial state, δ is the state transition function $\delta : S \times \Sigma \rightarrow S$, and F is the final state. We define a special system state to specify the status of a single request and access process. The system state S includes $initialState$, $preTrust$,$deniedEnroll$, $trusting$, $disEnrolled$, $preAccess$, $deniedAcces$, $accessing$, $revoked$, and end. The $initialState$ means the principal has not sent request; $preTrust$ means principal is waiting for the authentication decision; $deniedEnroll$ means the system denies the enrollment of the principal based on history or recommendations; $trusting$ means the principal is allowed to collaborate and will send access requests; $disenrolled$ means the system revokes the enrollment of a principal based on runtime information. The $preAccess$ means the principal is waiting for the authorization decision; $deniedAccess$ means they system denies the authorization request based on access control rules; $accessing$ means the principal is executing granted privilege; $revokedAccess$ means the system denied the privileges of a principal based on runtime mutable attributes; and end means a principal terminates the access. Actions change the state of the system, which is the input alphabet. If the action is performed successfully the action is true, attributes of the principal, object and system are

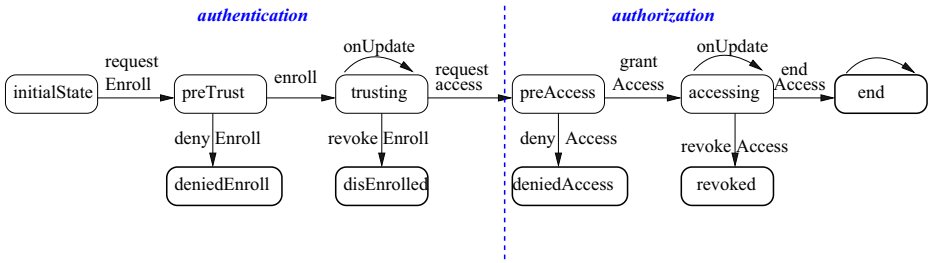

Figure 2. Trust-based UCON Model

assigned a new value. A series of actions are defined to change the status of a request. The transition from one state to another is triggered by an action, shown in Figure 2. $requestEnroll$ generates a new request when a principal tries to join the community. $denyEnroll$ rejects a request to enroll the community because the requester can not meet the minimum authentication or trust requirement. $enroll$ enrolls a principal to the community. $revokeEnroll$ revokes the allowed enrollment. $requestAccess$ generates a new access request. $denyAccess$ rejects an access request. $grantAccess$: grants an access request. $revokeAccess$ revokes an on-going and granted access request. $endAccess$: terminates an access request. $onUpdate$: updates the access request when mutable attributes or uncertain behaviors of a principal change.

4 Architecture of Trust-based Usage Control in P2P Delivery of Multimedia

When a principal p requests to execute a right r on an object o, attribute of the principal, permission (right r and object o, and an optional list credentials are submitted to *Secure Context Handler (SCH)* Module. The credentials may include signed trust-assertions (recommendations) from other users or a certificate signed by certificate authority. The *SCH* looks up the relevant contexts for the requested action, and queries the *Trust Calculator (TC)* component for a trust-value about principal p. Trust calculator calculates the trust value for requester based on both observed history and records in recommendation databases. A trust value is passed to *Access Control Manager (ACM)* Module for decision. The *ACM* looks up Access Control policies that entail several access control constraints. The *Constraint Service (CS)* Module and *Dynamic Manager (DAM)* Module evaluates access control constraints, e.g. time, location, memberships. Two categories of trigger events are possible to result in recalculation of trust value and reevaluation of access control policies. Recalculation and reevaluation may cause the revocation of current enrollment or on-going access. The *Evidence Handler (EH)* Module is listening to the peer reports about the misbehaviors of a requester. The negative report can include ignorance of obligation, dishonest behaviors, or the revocation of a requester's certificate. When the trust value of the request drops below a minimum threshold the on-going granted request will be revoked. The result of trigger event is notified to *SCH* and execution of request is cancelled. The *DAM* Module is listening to the attribute mutability of the principal, objects or a context after the permission is granted. For example, *DAM* Module can be triggered by certain events, for example, the subject left the group that entails the right. Once the *DAM* Module receives an event, the corresponding access control polices are re-checked by *ACM* if necessary (e.g., to allow an ongoing usage to continue or revoke it).

The update in *Trust Calculator (TC)* or *Dynamic Attribute Manager (DAM)* may revoke the granted permission. The mobile peers may report the dishonest behavior of requester or revocation of requester's certificate, so the trust value of request is dropped below a scalar. This update will be notified to Mobile Secure Handler and cancel the execution of request. After the permission is granted, Dynamic attribute manager will be trigger by certain events, the mobile node is moving out of range and not allowed for certain permission (reportAccident). Once the DAM receives an event, the attribute values of the object and subject are retrieved and evaluated and corresponding policies are rechecked by ACM if necessary (e.g., to allow an ongoing usage to continue or revoke it.)

5 Prototype Simulation

The architecture outlined in Section 4 provides the framework for the simulation program of usage-based access control model. This simulation works under the premise of several users who may request access to files owned by other users. Each of these users maintain modules included in trust-based usage control architecture, shown in Fig. 3. For every request, a trust value is calculated given past history and current recommendations for the requesting principal. Another factor in consideration is a risk assessment of the requested action assigned to each available file. Each owner assesses the risks based on sensitivity of his/her

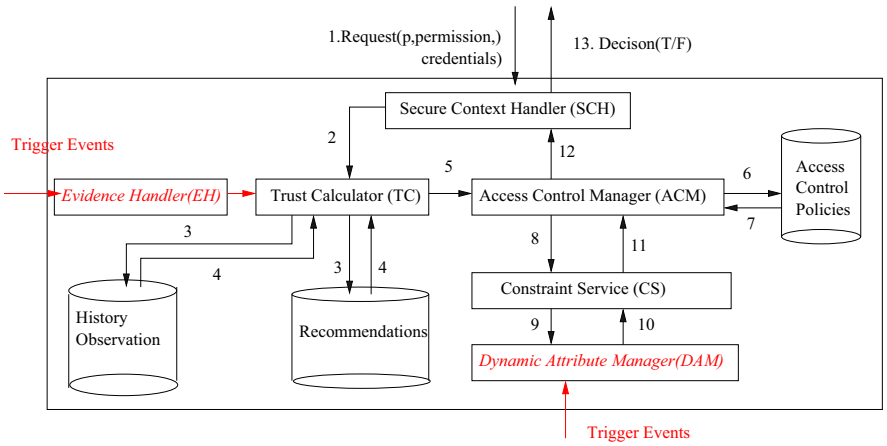

Figure 3. Trust-based Usage Control Architecture in P2P Delivery of Multimedia

file. Access to the file may be granted or denied based on trust evaluation, risk assessment and access control rules. If granted, the continuing usage of this access is contingent on maintaining the trust and risk values within the specified range. The on-going access may be revoked if the trust value is decreased below minimum threshold or access control rules are violated.

Besides successful request, several test scenarios are designed to test ability of our simulation program including how to evaluate trust, evaluate requests against access control rule, and react to evidence alerts and change of mutable attributes. First, a request fails the authentication when trust value of the request is lower than the minimum trust requirements. Second, a request passes the authentication but fails the authorization when a request does not meet the access control rules although its trust value is higher than the minimum trust requirements. Third, a request passes both the authentication and authorization; however, the on-going authorized request is revoked by negative evidence reports. Forth, a request passes both authentication and authorization; however, the on-going authorized request is revoked by mutable attributes such as change of domain or membership, which is triggered by events received from Dynamic Attribute Manager (DAM).

6 Discussion

Most recent research on access control include task-based authorization controls [17], team-based access control [9], role-based access control [8], temporal role-based access control [3], X-GTRBAC [5]. Recently, UCON [14] handles the mutability attributes of a principal or an object when the system makes decision for a request. All of them assume that a principal or an object is defined and represented by its attributes. This means that the identity, role or group of the subject can be identified through certain authentication mechanisms and that information about behaviors of a principal is certain. However, in a pervasive and collaborative environment, identity may not be identified. Moreover, identity itself can not convey priori information about the likely behavior of a principal. Behaviors of a principal may change between friendly and malicious when privileges are executed. A principal can not make access control decision only based on identity information because identity itself can not ensure friendly behaviors.

Reasoning and building trust for each peer allow peers to make decision when they are interacting with others in a peer-to-peer fashion. N. Li et al. [12] and W. Yao [21] use explicit incremental negotiation to establish mutual trust. An overview of trust management is discussed in [10]. Trust management has many applications in e-commerce areas such as works from Y. Atif [1] and P. Resnick et al. [15]. L. Xiong et al. [19] handles trust evaluation, especially the community-related context factors and transaction context factor of e-commerce. C. Zouridaki et al. [22] and L. Yang et al. [20] apply trust evaluation into routing protocols of mobile wireless ad hoc networks (MANETs).
