ABSTRACT

Chemical evolution models predict a gradual build-up of 13 C in the universe, based on empirical nuclear reaction rates and assumptions on the properties of stellar populations. However, old metal-poor stars within the Galaxy contain more 13 C than is predicted, suggesting that further refinements to the models are necessary. Gas at high redshift provides important supplementary information at metallicities $-2 \leq$ [Fe/H] \leq -1, for which there are only a few measurements in the Galaxy. We obtained new, high-quality, VLT/ESPRESSO observations of the QSO B1331+170 and used them to measure ${}^{12}C/{}^{13}C$ in the damped Lyman- α system (DLA) at $z_{abs} = 1.776$, with [Fe/H]=-1.27. AI-VPFIT, an Artificial Intelligence tool based on genetic algorithms and guided by a spectroscopic information criterion, was used to explore different possible kinematic structures of the carbon gas. Three hundred independent AI-VPFIT models of the absorption system were produced using pre-set ${}^{12}C/{}^{13}C$ values, ranging from 4 to 500. Our results show that ¹²C/¹³C = 28.5^{+51.5}, suggesting a possibility of ¹³C production at low metallicity.

1 INTRODUCTION

Galaxy formation and chemical evolution models are guided by the observed chemical element abundances in stars of different metallicities and in diffuse gas. Isotopic ratio measurements provide additional constraints, since different isotopes are produced by different nuclear reactions within stellar interiors. Given the similar atomic structure of isotopes, measuring their relative abundances is relatively

free from some systematics affecting absolute abundances measurements, such as effects associated with non-local thermal equilibrium, 3-dimensional effects in stellar atmospheres, dust depletion and ionisation in diffuse gas. However, the main problem is that one isotope is often much more abundant than the other(s) and their transitions are usually blended, making isotopic abundance ratios difficult to measure.

Due to the large abundance of carbon and the relatively large energy splitting between certain atomic transitions of ${}^{12}C$ and ${}^{13}C$, $12\text{C}/13\text{C}$ is one of the easier isotopic abundance ratios to measure.

[★] E-mail: dinko@milakovic.net

 $12C$ is produced by helium burning inside massive and short-lived stars as a primary element, whilst 13 C is produced within intermediate and low-mass stars by the CNO cycle as a secondary element. As a result, ¹²C/¹³C is expected to be large (\geq 1000) in the early stages of chemical evolution and then decrease with time [\(Prantzos](#page-11-0) [et al.](#page-11-0) [1996;](#page-11-0) [Wiescher et al.](#page-11-1) [2010;](#page-11-1) [Kobayashi et al.](#page-10-0) [2011\)](#page-10-0). Chemical evolution models for the Galaxy predict a slower build up of secondary elements with time (compared to primary elements), and hence a fast decrease in ${}^{12}C/{}^{13}C$ with increasing metallicity [\(Ro](#page-11-2)[mano & Matteucci](#page-11-2) [2003;](#page-11-2) [Kobayashi et al.](#page-10-1) [2020\)](#page-10-1). However, very recent measurements made in stars with $[Fe/H] \approx -4$ showed a much lower ${}^{12}C/{}^{13}C$ than predicted [\(Molaro et al.](#page-10-2) [2023\)](#page-10-2). All such stars have measured ${}^{12}C/{}^{13}C$ < 100, implying a primary production of 13 C at low metallicities that conflicts with the predictions [\(Kobayashi et al.](#page-10-1) [2020\)](#page-10-1). In particular, several dwarf stars inexplicably have ${}^{12}C/{}^{13}C \le 5$ [\(Molaro et al.](#page-10-2) [2023\)](#page-10-2). Such low values are close to the theoretical lower limit of ${}^{12}C/{}^{13}C = 4$ imposed by the equilibrium value in the CNO bi-cycle [\(Caughlan](#page-10-3) [1965\)](#page-10-3). These new observations suggest that further refinements to chemical evolution models are necessary. In particular, the evolution from very low ${}^{12}C/{}^{13}C$ values at low metallicities to measured solar values $(^{12}C/^{13}C = 91 \pm 1.3$, [Goto et al.](#page-10-4) [2003;](#page-10-4) [Ayres et al.](#page-10-5) [2013\)](#page-10-5) remains unexplained.

Unfortunately, there are only a few ${}^{12}C/{}^{13}C$ measurements in the range −3 < [Fe/H] < −0.2 [\(Kobayashi et al.](#page-10-1) [2020\)](#page-10-1). Gas at high redshift can provide important supplementary information in a metallicity regime for which there is no information in the Galaxy. Few measurements or limits exist at cosmological distances (7 measure-ments are tabulated in [Romano](#page-11-3) [2022](#page-11-3) with $z_{abs} \ge 0.7$, with one further more recent measurement from [Welsh et al.](#page-11-4) [2020\)](#page-11-4). Rotational transitions of molecular gas were used to measure isotopic ratios of several elements, including C, (e.g. [Muller et al.](#page-11-5) [2006;](#page-11-5) [Henkel et al.](#page-10-6) [2010,](#page-10-6) [2014;](#page-10-7) [Wallström et al.](#page-11-6) [2016;](#page-11-6) [Noterdaeme et al.](#page-11-7) [2017\)](#page-11-7). Atomic transitions associated with damped Lyman- α (DLA) absorption systems have also been used to constrain ${}^{12}C/{}^{13}C$ (e.g. [Levshakov et al.](#page-10-8) [2006;](#page-10-8) [Carswell et al.](#page-10-9) [2011;](#page-10-9) [Welsh et al.](#page-11-4) [2020\)](#page-11-4).

Here, we report on ¹²C/¹³C in the DLA at $z_{\text{abs}} = 1.776$ towards the quasar QSO B1331+170, also known as QSO J1333+1649 (R.A. 13h 33m 35.78s, Dec +16◦49′4.014′′, J2000). This quasar $(V = 16.6$ mag, $z_{em} = 2.08895$) was first spectroscopically observed by [Baldwin et al.](#page-10-10) [\(1973\)](#page-10-10) and the DLA was first characterised by [Strittmatter et al.](#page-11-8) [\(1973\)](#page-11-8) and [Carswell et al.](#page-10-11) [\(1975\)](#page-10-11). [Meyer et al.](#page-10-12) [\(1986\)](#page-10-12) used the neutral carbon transitions in this DLA to make the first measurements of the cosmic microwave background radiation temperature, T_{CMB} , at high redshift, with later refinements by [Songaila et al.](#page-11-9) [\(1994\)](#page-11-9), [Cui et al.](#page-10-13) [\(2005\)](#page-10-13), and [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9). Carswell et al. (2011) was the first to constrain ${}^{12}C/{}^{13}C$ in this system, finding it must be >5 (at 2σ confidence limit, CL). Here we present a new $12\text{C}/13\text{C}$ constraint derived from new high spectral resolution, high signal-to-noise ratio (S/N), observations with the Echelle SPectrograph for Rocky Exoplanets and Stable Spectroscopic Observations (ESPRESSO, [Pepe et al.](#page-11-10) [2021\)](#page-11-10) on the ESO Very Large Telescope (VLT). A T_{CMB} measurement from the same observations as are used in this paper will be reported in a separate paper.

2 DATA

2.1 ESPRESSO observations

ESPRESSO is an optical (380 nm to 790 nm) echelle spectrograph mounted on the VLT, that can be fed by the light of any

one of VLT's four Unit Telescopes. Its high spectral resolution, $(R = \lambda/\Delta\lambda = 140\,000$, where $\Delta\lambda$ is the full-width at half-maximum of the resolution element), ensures that contributions to the absorption profile shapes from 12 C and 13 C can be sufficiently resolved, and its wavelength calibration allows individual exposures to be combined with precision of several m s^{-1} [\(Schmidt et al.](#page-11-11) [2021\)](#page-11-11). ESPRESSO's optomechanical design is intended to ensure that the recorded spectrum does not depend on seeing conditions and that small guiding errors do not cause spectral shapes to vary, thus potentially emulating the presence of 13 C. However, ESPRESSO's wavelength coverage provides access only to two C_I transitions (λ 1560 and λ 1657, where the wavelengths are in units \hat{A}) of the five known in this DLA (others being λ 1277, λ 1280, and λ 1328).

We used ESPRESSO in its 'singleHR' mode, with one of its two fibres (A) positioned on the object and the second fibre (B) on an empty position 7" away for better sky subtraction. Observations were spread across four years, with 12 observations taken in 2019, 11 observations in 2021, and 9 observations in 2023, for a total exposure time of 41.1 h. The observing log is given in Table [1,](#page-2-0) where we have grouped the observations into three epochs (I-III) for easier referencing later in the text. Note that the pixel binning used during detector read-out was 2×1 (X×Y, spatial × spectral direction) in epoch I and 4×2 in epochs II and III.

2.2 Data reduction, wavelength calibration, and sky subtraction

Observations were processed using ESPRESSO Data Reduction Software (DRS) version 3.0.0 [\(Modigliani et al.](#page-10-14) [2023\)](#page-10-14), adopting default parameters for all recipes except for the sky subtraction, which was smoothed instead of pixel-by-pixel. The DRS removes detector effects and cosmic rays, and extracts the scientific and the sky spectra from the raw frames using a modified version of the optimal extraction algorithm [\(Horne](#page-10-15) [1986;](#page-10-15) [Robertson](#page-11-12) [1986\)](#page-11-12), as de-scribed in [Zechmeister et al.](#page-11-13) [\(2014\)](#page-11-13). The extracted spectra are then corrected for the instrument pixel-to-pixel variations before being wavelength calibrated. ESPRESSO provides two wavelength calibration sources: a Laser Frequency Comb (LFC) and ThAr arc lamp imaged simultaneously with a Fabry-Pérot etalon. For the majority of our observations, the LFC was unavailable or did not cover the two Ci transitions targeted for this analysis so ThAr + Fabry-Pérot etalon frames were used to calibrate the spectra presented here. In the final step, a 100-pixel wide sliding average of the sky spectrum is subtracted from the science spectrum.

2.3 Spectral combination and continuum estimation

UVES_popler version 1.05 [\(Murphy](#page-11-14) [2018;](#page-11-14) [Murphy et al.](#page-11-15) [2019\)](#page-11-15) was used to produce the combined spectrum from reduced observations. UVES_popler defines a new (log-linear) wavelength grid onto which it redisperses the individual spectra and calculates the inverse-variance weighted average of the values falling within each pixel of the new wavelength grid. Observations taken within a single epoch were combined into a single spectrum, with a wavelength increment of 0.4 km s^{-1} (0.8 km s⁻¹) for observations taken with 2×1 (4 \times 2) detector binning. In producing the combined spectrum, UVES_popler leverages the availability of the large number of independent flux estimates in each pixel to remove outlying flux values and clip any remaining cosmic rays. UVES_popler also produces a continuum estimate by fitting a sixth order Čebyšëv polynomial over 2500 km s−¹ wide chunks of the combined spectrum.

Table 1. A summary of observations used in this work. The columns provide information on the observing time, detector pixel binning mode (spatial \times spectral direction), exposure time in seconds, airmass at the end of the observations, and VLT Unit Telescope (UT) used, in that order.

Observing time	Binning	$T_{\rm exp}$	Airmass	Telescope

Table 2. S/N per pixel in the continuum for co-added observations. The first column identifies the observation epoch (or their combination), whilst the second column gives the pixel size (in $km s^{-1}$). The last two columns give the S/N values for the two C_I transitions studied here. Note that the values listed for epochs I-III do not simply add in quadrature to produce the combined epoch I+II+III value since spectral dispersions differ.

2.4 Removing contaminants

2.4.1 Blends with sky lines and systems at other redshifts

No sky lines were found to blend with C_I transitions at $z_{\text{abs}} = 1.776$. [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) reported several transitions at other redshifts in their proximity. Al III λ 1854 at $z_{\text{abs}} = 1.329$ coincides with the expected positions of C₁^{*} transitions in the proximity of λ 1560, and Fe I λ 2484 at $z_{\text{abs}} = 0.7444$ is nearby. To eliminate any impact from these blends, we set the spectral error array in the wavelength ranges 4331.4575 Å $\le \lambda \le 4331.8086$ Å (Al III) and 4333.5781 Å $\le \lambda \le$ 4333.7446 Å (Fe i) to 1000, effectively removing these wavelength ranges from consideration. Our ESPRESSO data does not provide evidence for the existence of the previously reported [\(Carswell et al.](#page-10-9) [2011\)](#page-10-9) blend between C_I λ 1657 at $z_{\text{abs}} = 1.776$ and C_{IV} λ 1550 at $z_{\rm abs} = 1.9662$.

2.4.2 Flux artefacts

Upon combining epoch I spectra, we discovered the unexplained presence of numerous weak but statistically significant flux artefacts in the spectrum. Their presence was first reported in the ESPRESSO spectrum of the quasar HE0515−4414 [\(Murphy et al.](#page-11-16) [2022\)](#page-11-16). The artefacts appear as weak (a few per cent), positive or negative departures from the average of the surrounding flux values. A typical artefact spans several km s^{-1} , appearing at the same (or very similar) positions in the spectrum in each exposure such that traditional outlier rejection methods and spectral combination procedures (as implemented in UVES_popler) resulted in the increased statistical significance of the artefacts instead of their removal.

Comparing the three epoch spectra with each other (and other quasar spectra we obtained), we saw that the positions of the artefacts in each epoch spectrum correlated with Earth's motion with respect to the solar system barycentre, indicating an origin that is fixed in the laboratory rest-frame (see figure 2 of [Pasquini & Milaković](#page-11-17) [2024\)](#page-11-17). The artefacts' origin were tracked to clusters of 'warm' detector pixels, that is pixels which erroneously trap an excess of electrons, but which evade detection in hour-long dark exposures in the default DRS settings. We identified two warm pixel patches in the proximity of transitions of interest: one in between 4330.93 Å and 4331.14 Å, and another in between 4600.94 Å and 4601.08 Å (wavelengths in the Earth laboratory rest-frame). These wavelength ranges were appropriately shifted to the solar system barycentre and masked in all 32 individual spectra, which were then combined as previously described. The final S/N is reported in Table [2.](#page-2-1)

3 AI-VPFIT MODELS

This work leverages the recently developed spectral analysis tool AI-VPFIT to perform a more comprehensive exploration of the uncertainties [\(Lee et al.](#page-10-16) [2021a](#page-10-16)[,b;](#page-10-17) [Webb et al.](#page-11-18) [2021,](#page-11-18) [2022;](#page-11-19) [Lee et al.](#page-10-18) [2023\)](#page-10-18), which expands upon ideas first introduced in GVPFIT [\(Bain](#page-10-19)[bridge & Webb](#page-10-19) [2017a](#page-10-19)[,b\)](#page-10-20). Previous to this work, limits on ¹³C abundances were set by examining how χ^2 changes after a specific quantity of ¹³C has been added into a model of the absorption system containing 12 C only [\(Levshakov et al.](#page-10-8) [2006\)](#page-10-8), or by checking how much 13^C can be accommodated by the data through simulations of spectra with the same characteristics as the observations [\(Carswell](#page-10-9) [et al.](#page-10-9) [2011;](#page-10-9) [Welsh et al.](#page-11-4) [2020\)](#page-11-4).

Given an observed spectrum, AI-VPFIT uses artificial intelligence methods to produce a model for the data, relying on genetic algorithms in combination with a spectroscopic information criterion (SpIC, [Webb et al.](#page-11-18) [2021\)](#page-11-18) to guide the modelling process. SpIC penalises the retention of model parameters fitting weak features more heavily than it penalises parameters fitting strong features. The validity of this modelling system, in terms of obtaining unbiased parameter estimates, has been examined in some detail using simulated spectra by [Lee et al.](#page-10-16) [\(2021a\)](#page-10-16); [Webb et al.](#page-11-19) [\(2022\)](#page-11-19). The simulated spectra were fitted using AI-VPFIT to compare input and estimated parameter values, finding that AI-VPFIT provides robust and unbiased estimates.

Figure 1. ESPRESSO spectrum of QSO B1331+170 in the wavelength region of the two C₁ transitions studied here (indicated in the bottom left corner of each panel). The black histogram is the summed spectrum from all three epochs with 0.8 km s−¹ wide pixels (Figure [A1](#page-12-0) shows the individual epoch spectra). The solid red line going through the spectrum shows a 12-component AI-VPFIT model with an assumed ${}^{12}C/{}^{13}C = 28.14$, close to the final value derived in Section [4.](#page-6-0) The model has $\chi^2_{\nu} = 0.6362$. Tick marks above the data show the positions of individual components in the model, with blue and orange ticks showing 12 C and 13 C, respectively. Continuous solid tick marks show ground state transitions (which are the only ones labelled), whereas dashed and dotted ticks show the fine-structure transitions (Ci* and C i**, respectively). The thin black histogram above the spectrum shows the normalised residuals (data − model)/error. Missing residuals seen in λ 1560 transition indicate spectral regions contaminated by transitions at other redshifts (Al μ λ 1854 at $z_{abs} = 1.329$ is at −60 km s^{−1} and Fe i λ 2484 at $z_{\text{abs}} = 0.7444$ is at +80 km s⁻¹), which were not modelled. Thin horizontal black lines indicate $\pm 1\sigma$ ranges. Labels for all transitions are provided in another figure included as supplementary material.

This is as expected, since VPFIT [\(Carswell & Webb](#page-10-21) [2014\)](#page-10-21) is embedded within AI-VPFIT, the former being an extensively tested system. Further, spectral models constructed using SpIC retrieved parameter values more accurately than those guided by the corrected Akaike Information Criterion [\(Akaike](#page-10-22) [1974;](#page-10-22) [Hurvich & Tsai](#page-10-23) [1989\)](#page-10-23) or the Bayesian Information Criterion [\(Bozdogan](#page-10-24) [1987\)](#page-10-24).

Starting from a single-component model in the first generation, AI-VPFIT increases the number of absorbing components in each generation by trying out a user-specified number of trials for additional components (8 in our case) and choosing the one that minimises SpIC. Positions at which the new components are tried is fully determined by a (user specified) seed for the random number generator, making the whole process fully reproducible. This process ends when a set number of attempts fail to further minimise SpIC (30 in our case). AI-VPFIT then performs small adjustments to the model by including modifications to the continuum estimate and tests whether all of the components are necessary (on the basis of SpIC). AI-VPFIT is also capable of identifying blends with unidentified species (interlopers). Having removed known contaminants in Section [2.4,](#page-2-2) the option of using interlopers was turned off to remove the possibility of fitting real $1\overline{3}$ C absorption in this way. Further details on AI-VPFIT procedures are given in [Lee et al.](#page-10-16) [\(2021a\)](#page-10-16).

AI-VPFIT was used to produce three hundred independent spectral models to determine χ^2 as a function of assumed ¹³C abundance in the spectrum and to take into account uncertainties associated with slightly different kinematic structures caused by model non-

MNRAS **000**, [1](#page-0-0)[–18](#page-18-0) (2015)

uniqueness. This was not done before since interactive analysis by a human modeller is time-consuming. AI-VPFIT also allows for examining any biases that may be present by first constructing a model containing 12 C only and to explore the impact of model nonuniqueness on the final result [\(Lee et al.](#page-10-17) [2021b;](#page-10-17) [Webb et al.](#page-11-19) [2022\)](#page-11-19).

3.1 Resolution and instrumental profile

Theoretical absorption system models are convolved with the assumed shape of ESPRESSO's instrumental profile (IP) before calculating the descent direction in model parameter space. Empirical ESPRESSO IP models were not available at the time, so the IP was approximated to be Gaussian in shape. The resolution for the Gaussian profiles was determined from LFC calibration frames, again available in epoch III, with an extended wavelength range that covers also the two Ci transitions of interest. The full-width at halfmaximum (FWHM) was determined in all locations at which the two Ci transitions appear. The final FWHM values used inside AI-VPFIT were their average values: $v_{\text{FWHM}}(\lambda 1560) = 2.362 \text{ km s}^{-1}$ and $v_{\text{FWHM}}(\lambda 1657) = 2.341 \text{ km s}^{-1}$. Our results are insensitive to small uncertainties on the FWHM values used. For one of the models produced, we explored how best fit parameters change when the FWHM is changed by $\pm 1\%$ (based on typical variations seen in LFC calibration frames). We found that model parameter values changed by $\ll 1\sigma$, where σ here denotes their uncertainties derived from the covariance matrix at best fit.

3.2 Setting up the calculations

The calculations were set up to step through $\mathcal{R} \equiv {}^{13}C/{}^{12}C$ to avoid mathematical infinities associated with low ¹³C abundances. All AI-VPFIT calculations were set up in exactly the same way, except for the assumed R , which varied from 0.002 to 0.25 in 100 logarithmic steps (sampling was denser at low \mathcal{R}). The upper limit on \mathcal{R} is set by the CNO bi-cycle [\(Caughlan](#page-10-3) [1965\)](#page-10-3). Three different seeds for the random number generator were used for each R value, for a total of 300 models.

Information on the ratio was provided to AI-VPFIT through the 'atom.dat' file, containing laboratory wavelengths, oscillator strengths, and natural damping constants (Γ) for the transitions (see Table [3\)](#page-5-0). This file was modified in two ways. First, all ground state atomic transitions originating either in 12 C or in 13 C were labelled simply as C, such that inserting a C component would automatically result in absorption from both isotopes. The same was also done for C_1 ^{*} and C_1 ^{**}, the fine-structure states. Secondly, all oscillator strengths f for the relevant transitions were modified according to the equations:

$$
f^{\text{modified}}(^{12}\text{C}) = x f^{\text{lab}},\tag{1}
$$

$$
fmodified(13C) = (1 - x)flab,
$$
\n(2)

where $x = {}^{12}C/C = 1/(1 + R)$ and the superscript *lab* refers to the measured laboratory value (see Table [3\)](#page-5-0).

Provided with the modified 'atom.dat', AI-VPFIT is able to produce a model for the observations with a pre-determined \mathcal{R} . In producing the models, the three epoch spectra were kept separate, and all C species were required to be present in all components with their redshifts tied together. Column densities of the tied C_I, C_I^{*}, and C_1 ^{**} were independent free parameters. A trivial constraint (for numerical convenience) was imposed such that the minimum column density N allowed for any species was $\log(N/\text{cm}^{-2}) = 7.99$. This value is well below any detection threshold in our data and hence has no impact on the results obtained. 12 C and 13 C were assumed to have the same line widths, i.e. fully turbulent broadening was imposed. We return to this approximation in Section [6.](#page-9-0) For similar reasons of numerical convenience, the smallest allowed Doppler b -parameter was 0.03 km s^{-1} , $\leq 10\%$ of the pixel size. None of our AI-VPFIT models contain components with b -parameters near this limit (the smallest was three times larger).

3.3 Quality check of the models

Figure [1](#page-3-0) shows one of the AI-VPFIT models with 12 velocity compo-nents. Figure [2](#page-4-0) shows the number of components (N_C) for all models as a function of R , with a corresponding histogram. No models have been produced with fewer than 9 or more than 16 components, with the median number of components being 12. Interestingly, while models with $N_C = 9$ to 14 were produced over a wide range of R values, the two models with $N_C = 15$ and the one model with $N_C = 16$ are associated only with high R. Examining the latter three models revealed them not to fit well the strong feature at -17 km s^{-1} in C₁ λ 1657 (the residuals systematically deviate from zero), so they were discarded^{[1](#page-4-1)}. Similarly, all three models with $N_C = 9$ were found to erroneously fit the "double" absorption feature (located between -30 km s^{-1} and -36 km s^{-1} in Figure [1\)](#page-3-0) using a single component,

Figure 2. Number of C components, N_C , for the 300 AI-VPFIT models with a histogram. Three models are produced at each R , so multiple models with the same N_C are vertically offset from each other for clarity and visual effect. The total number of models in each group is indicated to the right, where the red numbers in brackets state how many models were removed from the analysis (see text). Removed models are shown as short vertical red lines in the main panel. Ticks in the bottom with black labels show the ${}^{13}C/{}^{12}C$, and ticks on the top with red labels show ${}^{12}C/{}^{13}C$.

and were also discarded. Visual examination of the remaining models did not show obvious problems with fitting the observations. We show several other models in Appendix [A.](#page-11-20) Plots of all models are available as online supplementary material.

Also interesting is the apparent preference towards models with a specific N_C for a given R . For example, fewer components are generally required when R is assumed to be at either extreme of the examined range. Models requiring the largest number of components (14) prefer R between 0.01 and 0.02, and do not spread in R like all the others (ignoring the 2 points at high \mathcal{R}). $N_C = 13$ models seem to preferentially appear between $\mathcal{R} \approx 0.02$ and 0.08 and models with $N_C = 12$ do not appear to cluster significantly at any R value. $N_C =$ 11 models are preferred for two R ranges: between 0.07 and 0.2, and below 0.005. This split is suggestive of different velocity structures and hence model non-uniqueness. On the other hand, $N_C = 10$ appear at all R values but are not very common.

The top panel of Figure [3](#page-5-1) shows the y^2 for all 300 models, calculated as:

$$
\chi^2 = \sum_{i=1}^N \left(\frac{F_i - \mathcal{F}_i}{\sigma_i} \right)^2.
$$
\n(3)

Above, F_i is the observed flux in the *i*th pixel, \mathcal{F}_i is its model predicted value, and σ_i is the observed flux error estimate (in our case, the rootmean-square array produced by UVES_popler was used in place of the spectral variance array produced by the pipeline, for details see [Murphy et al.](#page-11-15) [2019\)](#page-11-15). The bottom panel of the same Figure shows $SpIC = \chi^2$ + a penalty term that is a function of model parameters [\(Webb et al.](#page-11-18) [2021\)](#page-11-18), with the penalty term being different for each model. We note the smaller scatter in SpIC compared to x^2 , a general trend seen before in [Lee et al.](#page-10-17) [\(2021b\)](#page-10-17). See further comments in

¹ The (R, χ^2) values of these models are (0.215973,2093.7281), (0.226768,2100.352), and (0.250001,2114.7071), i.e. they are marked by the three crosses sitting below the black points in the top panel of Figure [3.](#page-5-1)

Table 3. Atomic data for transitions used in this work. The columns give the atomic species, the atomic mass, the laboratory measured wavelength, the laboratory oscillator strength, and the natural damping constant Γ , in that order. AMU stands for atomic mass unit. Empty fields should be interpreted as repeated entries from one line above. All oscillator strengths are from [Gold](#page-10-25)[bach & Nollez](#page-10-25) [\(1987\)](#page-10-25) and all Γ values are from [Li et al.](#page-10-26) [\(2000\)](#page-10-26). Wavelengths for C_I λ 1560 are from [Haridass & Huber](#page-10-27) [\(1994\)](#page-10-27) and for λ 1657 are from [Lai](#page-10-28) [et al.](#page-10-28) [\(2020\)](#page-10-28).

Section [4.3.](#page-7-0) The smallest χ^2 and SpIC values appear between $\mathcal{R} =$ 0.01 and 0.04, corresponding to ${}^{12}C/{}^{13}C$ between 25 and 100.

Twelve models show anomalously large χ^2 values (3, 3, 2, 4 models with $N_C = 9, 10, 11, 12$, respectively, some of which were previously identified as problematic). These models were also rejected. The reduced $\chi^2 = \chi^2/v$ (*v* being the number of degrees of freedom) of the 285 models ranges between 0.621 and 0.678, with 0.638 being the median value. These values are clearly slightly below the expectation of around unity. The reason is well understood: re-dispersion of spectra and their subsequent combination create adjacent pixel correlations in the combined spectrum. Parameter error estimates take this into account, as described in [Carswell](#page-10-29) [\(2023\)](#page-10-29). Since the spectra from three epochs were kept as separate entities during the modelling, we spot-checked for consistency (goodness of fit) for each epoch. In cases examined, the χ^2 values for corresponding regions were fully consistent, i.e. the overall model fitted each epoch equally well.

3.4 Inter-model variation and non-uniqueness

As described above, a large number of models were computed. We used 100 different settings for ${}^{12}C/{}^{13}C$, and at each ${}^{12}C/{}^{13}C$ compute 3 independent AI-VPFIT models. At fixed ${}^{12}C/{}^{13}C$, each of the 3 models is constructed independently, in the sense that trial absorption component placement is random within the fitting range. Model development therefore proceeds differently each time. This emulates, in a rather natural way, the notion of using a large number of independent interactive modellers, and hence avoids bias. The

Figure 3. χ^2 (top panel) and SpIC (bottom panel) for the 300 AI-VPFIT models, as a function of ${}^{13}C/{}^{12}C$ (bottom ticks and black labels) or ${}^{12}C/{}^{13}C$ (top ticks and red labels) on a logarithmic scale. Black dots are the 285 points used in the analysis and 15 models plotted as red crosses have been discarded (see text).

consequence of this is that slight variations from one model to the next are seen in the ensemble of AI-VPFIT models. We illustrate this in Figure [4](#page-6-1) by showing both the astronomical data and the 285 surviving models (see Section [3.3\)](#page-4-2) superimposed. Tick marks show the positions of velocity components for all 285 models, for the dom-inant section of the absorption system (compare Figures [1](#page-3-0) and [4\)](#page-6-1). The colour coding provides further information, since it shows the $12C/13C$ for each model. In Figure [4,](#page-6-1) one must appreciate that not all components illustrated are present in all models. For example, one AI-VPFIT model might opt to use a single velocity component whilst another might prefer to use two weaker ones. The summed optical depths over all models shown therefore is not intended to represent a good fit to the astronomical data, but is instead intended to illustrate model variation.

There are at least three important features for constraining ¹²C/¹³C: at −38 km s⁻¹, −20 km s⁻¹, and +4 km s⁻¹. ¹²C/¹³C is not allowed to be too high, otherwise there will be excess absorption in the blue wing of C i λ 1560 at −38 km s⁻¹. A low ¹²C/¹³C would result in insufficient absorption at -20 km s^{-1} in C_I λ 1560, but a high $12C/13C$ would cause the model to fall below the data. In the $+4$ km s^{-1 12}C feature, some ¹³C is needed in λ 1560 to fit weak absorption at +1 km s⁻¹ and similarly at +5 km s⁻¹ in λ 1657. Interestingly, the feature at $+4 \text{ km s}^{-1}$ is the only one that is consistently fitted by a single component in all 285 models. Determining which of these three features provides the most stringent constraint is not easy. Isolating any particular component to investigate that component's relative importance in constraining the overall ${}^{12}C/{}^{13}C$ is difficult; artificially freezing some parameters whilst allowing others to vary is likely to make error estimates for parameters of interest unreliable. Irrespective, as Figure [4](#page-6-1) shows, several velocity components contribute to the overall constraint.

The "AI-Monte Carlo" approach used in this work allows us to examine, in detail, model non-uniqueness, which can be seen visually in Figure [4.](#page-6-1) It is interesting that the AI-VPFIT models of ESPRESSO

Figure 4. Illustration of model variation and non-uniqueness. The astronomical data are shown as a black histogram (combined epochs I+II+III, 0.8 km s−¹ wide bins). Individual models are shown as coloured lines, with their colour corresponding to a specific ${}^{12}C/{}^{13}C$ value, as per the colour bar to the right. Coloured tick marks show the positions of ¹²C absorption in those models (also as per the colour bar). There are 2542 C₁ components shown from all 285 models (more components fall outside the plotted velocity range, but they fit weaker absorption features). Thin blue lines show ¹²C absorption and thin orange lines show ¹³C absorption after convolution with the assumed IP. Not all components seen in the Figure are present in all models (see Section [3.4\)](#page-5-2). Note the different ordinate scales for the two panels.

data are in broad agreement with previous measurements for the physical characteristics of the gas by [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9), although the improvement in spectral resolution offered by ESPRESSO means far more components are resolved. Further details can be found in Appendix [B.](#page-16-0) In the following Section, we develop methods to simultaneously use the set of model calculations in order to place simple constraints on the ${}^{12}C/{}^{13}C$ averaged over the absorption complex. We also show how, in this particular case, non-uniqueness turns out to create "groupings" in ${}^{12}C/{}^{13}C$ space.

4 ANALYSIS

The likelihood of R is:

$$
\mathcal{L}(\mathcal{R}) = \exp\left[-\frac{1}{2}\chi^2(\mathcal{R})\right].
$$
 (4)

 χ^2 minimises ($\mathcal L$ maximises) for the physically correct $\mathcal R$, and can be approximated by a parabola around that value:

$$
\chi^2(\mathcal{R}) \approx a(\mathcal{R} - \mathcal{R}_{min})^2 + \chi^2_{min},\tag{5}
$$

where *a* defines the parabola's openness, and \mathcal{R}_{min} and χ^2_{min} are the vertex coordinates. The x^2 values of the 285 models are assumed to scatter normally around Equation [\(5\)](#page-6-2) prediction with variance ζ^2 . Equation [\(4\)](#page-6-3) must be regarded as an approximation because the terms in the x^2 summation are not independent.

4.1 Dividing the models into five subsets

Figure [5](#page-7-1) shows there is a clear stratification in x^2 , most of which can be attributed to the number of free model parameters, that is to the number of carbon components in the model (N_C) . There is also a possible bifurcation for models with the same N_C : models at similar R appear systematically offset in χ^2 by approximately the same amounts, apparently grouping together. Models with $N_C =$

11, 12 and 13 (red squares, blue triangles, and green diamonds, respectively) show this effect most clearly. Comparison of models and their parameters did not reveal any clues on the origin of this effect.

 χ^2 values were divided into subsets according to their N_C , and were henceforth treated independently. The five groups are shown by symbols of different colours in Figure [5.](#page-7-1) Parabola parameters (and their uncertainties) for each subset were determined using MCMC calculations (implemented in numpyro, [Phan et al.](#page-11-21) [2019\)](#page-11-21) such that the uncertainties can be propagated into constraints on R . Parameters a, χ^2_{min} , and \mathcal{R}_{min} were all sampled from uniform prior distributions having the following ranges: (2000,5000), (1900,2200), (0, 0.25), in the same order. ς was independently determined for all five subsets, having an exponential distribution prior with a scale of unity. Ten MCMC chains were ran with 7000 warm-up steps and 2500 sample steps. Convergence was assessed using two diagnostics: the split Gelman-Rubin \hat{R} [\(Vehtari et al.](#page-11-22) [2021\)](#page-11-22) and effective sample size N_{eff} [\(Geyer](#page-10-30) [2011\)](#page-10-30). For all parameters of the five parabolas, $\hat{R} = 1.00$ and $N_{\text{eff}} \gg 1000$, meaning that convergence was achieved. Marginalised posterior distributions of the fitting parameters and their covariances are provided in Appendix [C,](#page-17-0) together with their median values and uncertainties.

Coloured lines in the top panel of Figure [5](#page-7-1) show the median MCMC predictions for the data. Grouping by N_C explains much of the observed scatter between the points. Residuals (bottom panel of the same Figure) show that some substructure remains. Because absorption system models were all derived from the same spectral data, their χ^2 values are not expected to scatter completely randomly. and the remaining substructure may be irrelevant. Alternatively, there may be an additional contribution to the scatter, beyond the one attributable to N_C , for example model non-uniqueness.

Figure 5. Results of MCMC fitting of Equation [\(5\)](#page-6-2) to observed χ^2 values, subdivided according to N_C . Top panel: Coloured symbols are 285 models and the coloured lines are the best fitting parabolas going through them. Parabola parameters are independent from each other. Bottom panel: Residuals (data−model) of the fits shown in the top panel. Some apparently correlated structures remain (see text). The inset shows a stacked histogram of the residuals. In both panels, ticks in the bottom with black labels show the ¹³C/¹²C, and ticks on the top with red labels show ¹²C/¹³C.

4.2 Constraining $\mathcal R$ using χ^2

Substituting Equation [\(5\)](#page-6-2) into [\(4\)](#page-6-3) and normalising, the probability density function (PDF) and the cumulative probability density function (CDF) can be calculated analytically from:

PDF
$$
(\mathcal{R}, \mathcal{R}_{min}, a) = \sqrt{\frac{a}{2\pi}} \exp\left(-\frac{a}{2} (\mathcal{R} - \mathcal{R}_{min})^2\right),
$$
 (6)

$$
\text{CDF}(\mathcal{R}, \mathcal{R}_{min}, a) = \frac{1}{2} \left[1 + \text{erf}\left(\sqrt{\frac{a}{2}} (\mathcal{R} - \mathcal{R}_{min}) \right) \right]. \tag{7}
$$

Figure [6](#page-8-0) shows the results for the PDF (left column) and the CDF (right column) derived from 25 000 different parameter combinations obtained from the MCMC calculations in Section [4.1.](#page-6-4) The first five rows relate to the five data subsets. The last row shows the average of the first five weighted by the number of values in each subset, N_m .

 $N_C = 10$ case provides the most stringent constraints on R, followed by $N_C = 11$, 13, 14 and 12 (in that order). For three subsets $(N_C = 10, 11$ and 13), PDFs are well localised and indicate a statistically significant measurement. Modes of the five curves fall within ${}^{12}C/{}^{13}C = 17.4$ to 41.9, in good agreement with each other (when compared to the width of their PDFs). PDFs of $N_C = 12$ and 14 permit the broadest range of solutions, including ${}^{12}C/{}^{13}C > 1000$. Plotting a subset of $N_C = 12$ and 14 curves (not shown) we identified some which yielded results consistent with the remaining three subsets. Future, improved, data may reveal which ones are correct.

Table 4. ${}^{12}C/{}^{13}C$ measurement summary. The first column indicates data subset (N_C or combined). The second column gives the most probable value for $^{12}C/^{13}C$ for each case, i.e. the mode of the PDF. The following three columns provide percentile values for ${}^{12}C/{}^{13}C$. The ultimate two columns give lower 1σ (68.27% probability) and 2σ (95.45% probability) confidence limits on ¹²C/¹³C, derived from the CDFs. Note, although we use the σ terminology here, it is clear from Figure [6](#page-8-0) that the uncertainties are not Gaussian.

Subset	Mode		Percentiles			CL	
		16th	50th	84th	1σ	2σ	
10	17.4	14.1	17.9	24.7	15.8	12.2	
11	21.8	16.4	22.3	34.9	19.1	13.9	
12	41.9	24.8	47.8	693.5	33.1	18.5	
13	27.3	19.1	28.5	56.5	23.0	15.5	
14	36.0	22.8	39.0	133.5	29.1	17.7	
Combined	27.3	18.1	28.5	80.0	22.2	14.6	

Our results here indicate that the probability of ${}^{12}C/{}^{13}C < 100$ is 99.86 %, 98.43 %, 71.17 %, 92.44 % and 80.44 % (from $N_C = 10$ to 14, respectively). The combined PDF (last row, left column) is well localised with a mode at ${}^{12}C/{}^{13}C = 27.3$ and the combined probability that ${}^{12}C/{}^{13}C$ < 100 is 86.48%. Some other statistical properties, including percentiles and lower limits, are summarised in Table [4.](#page-7-2)

4.3 Constraining R **using SpIC**

In the preceding Section, we used χ^2 as the basis for computing likelihood values. An alternative statistical approach is to instead use an information criterion (Burnham $\&$ Anderson [2002\)](#page-10-31), in this case SpIC. We carried out tests, replicating the procedure used for the χ^2 results shown in Table [4.](#page-7-2) The preliminary indication was that, provided sample subdivision is used, the results do not change significantly. If sample subdivision is not used, the tighter grouping for the SpIC measurements (see Figure [3\)](#page-5-1) suggests that the SpIC values yield better constraints on ${}^{12}C/{}^{13}C$. We also note that Bayesian Model Averaging could also be applied using an information criterion likelihood approach. This would offer the simplification of deriving one numerical result from the entire suite of AI-VPFIT models. However, preliminary calculations suggested a strong weighting towards lowest SpIC models, giving an overly stringent result, which we preferred to avoid in this context.

5 DISCUSSION

5.1 Comparison with previous measurements

The result reported here is ¹²C/¹³C = 28.5^{+51.5}. [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) reported a conservative lower limit of ${}^{12}C/{}^{13}C > 5$ (2 σ CL) in this DLA. Looking at their figure 2, 13 C was found only in their component N2 (at -17 km s^{-1} in Figure [1\)](#page-3-0), even though N2 appears (in their spectrum) significantly weaker than component N1 (at −33 km s−¹ in Figure [1\)](#page-3-0). However, our higher resolution ESPRESSO data revealed that their component N1 is actually a blend of several absorption features. No significant substructure is seen for their component N2 in the ESPRESSO spectrum, which also appears as the strongest feature in the absorption complex. The new ESPRESSO data therefore explains why $1\overline{3}$ C seemed to arise in the weaker absorption component in the [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) analysis. Interestingly, their reported ratio between column densities of ${}^{12}C$ and ${}^{13}C$ in N2 equates to ¹²C/¹³C = 19⁺²⁰₋₁₀, in agreement with our findings.

Figure 6. PDF(R), left, and CDF(R), right, for the five data subsets and the full data set. Each row shows one subset of the data, with the inset specifying N_C and the number of models contained in the subset, N_m . The combined PDF and CDF (final row) are averages of the five above weighted by N_m . In all panels, the thick coloured line is the median over parabola parameters derived by MCMC, and the shaded bands enclose the central 68% of the possible curves. In the panels showing the PDF, the red arrow with a number on top indicates the most probable ${}^{12}C/{}^{13}C$ (the mode of the distribution). In the panels showing the CDF, the horizontal dashed black lines show the probabilities corresponding to 1σ and 2σ confidence limits. Red squares show where those lines intersect the CDF, and the vertical dashed black lines show the corresponding ${}^{13}C/{}^{12}C$, printed in black. The red numbers adjacent to the red squares are their inverse, i.e. the ¹²C/¹³C. Ticks in the bottom with black labels show the ¹³C/¹²C, and ticks on the top with red labels show ¹²C/¹³C.

Considering that the inferred column densities are close to the linear part of the curve of growth, this agreement is not surprising.

Only three other ${}^{13}C$ quasar absorption measurements currently exist. Two recent values are: [Noterdaeme et al.](#page-11-7) [\(2017\)](#page-11-7) constrained $^{12}C/^{13}C$ > 40 at z_{abs} = 2.525; [Welsh et al.](#page-11-4) [\(2020\)](#page-11-4) constrained $12 \text{C}/13 \text{C} > 2.3$ at $z_{\text{abs}} = 2.34$. Another seemingly more stringent result is quoted in [Levshakov et al.](#page-10-8) [\(2006\)](#page-10-8), who measured $^{12}C/^{13}C$ > 80 (2σ CL) at $z_{\text{abs}} = 1.15$, although an independent re-analysis of the same data did not support such a high value and instead found $12C^{13}C > 22$ [\(Carswell et al.](#page-10-9) [2011\)](#page-10-9). Table [4](#page-7-2) provides our analogous 2σ lower limit, 14.6, i.e. all quasar results to date appear consistent.

5.2 Chemical evolution models

¹²C is formed in the triple- α process during hydrostatic helium burning and is a primary product of stellar nucleosynthesis. The stable ${}^{13}C$ isotope is produced in the hydrogen-burning shell when the CN cycle converts pre-existing ¹²C into ¹³C via proton capture followed by β decay. As a star evolves off the main sequence, the outer convective envelope expands inwards into the CN-cycle-processed regions producing a mixing episode which is called the 'first dredge-up', which lowers the ¹²C/¹³C [\(Iben & Renzini](#page-10-32) [1984\)](#page-10-32). Mixing also occurs in the thermal pulses of intermediate-mass stars that become AGB stars. This could lead to a CN-cycle equilibrium ratio of about $12C^{13}C \sim 4$. These low values ratios are indeed observed in some red supergiants [\(Lambert & Sneden](#page-10-33) [1977\)](#page-10-33).

Due to the secondary nature of 13 C, chemical evolution models predict a monotonic decrease in the isotopic ratio ${}^{12}C/{}^{13}C$ with time [\(Romano & Matteucci](#page-11-2) [2003;](#page-11-2) [Kobayashi et al.](#page-10-1) [2020\)](#page-10-1). This is supported by observations in young molecular clouds for which $12C/13C \sim 60 - 70$, lower than the solar ratio of $12C/13C = 91 \pm 1.3$ [\(Goto et al.](#page-10-4) [2003;](#page-10-4) [Ayres et al.](#page-10-5) [2013\)](#page-10-5). ¹²C/¹³C is also below solar value in the Galactic centre [\(Halfen et al.](#page-10-34) [2017\)](#page-10-34) and measurements in the Galaxy support a gradient with galactocentric distance [\(Yan](#page-11-23) [et al.](#page-11-23) [2023\)](#page-11-23). All of the above is consistent with the secondary nature of ¹³C. For the reasons above, ¹²C/¹³C is predicted to be higher than solar at low metallicities [\(Romano & Matteucci](#page-11-2) [2003;](#page-11-2) [Fenner et al.](#page-10-35) [2005;](#page-10-35) [Kobayashi et al.](#page-10-1) [2020;](#page-10-1) [Romano](#page-11-3) [2022\)](#page-11-3). Unfortunately, only a few observations are available in this regime and the results are controversial. [Botelho et al.](#page-10-36) [\(2020\)](#page-10-36) found a mild increase in the range $-0.2 <$ [Fe/H] $<$ 0 in a sample of solar twins, opposite to what is expected if ${}^{13}C$ is a secondary element. On the other hand, [Crossfield](#page-10-37) [et al.](#page-10-37) [\(2019\)](#page-10-37) measured ¹²C/¹³C = 296 ± 45 and 224 ± 26 in the two components of the brown dwarf system GJ 745 at $[Fe/H] = -0.48$. In some unmixed giants ${}^{12}C/{}^{13}C$ is lower than the solar value [\(Spite](#page-11-24) [et al.](#page-11-24) [2005\)](#page-11-24) and in the metal-poor star HD 140283, ¹²C/¹³C = 33^{+12}_{-6} [\(Spite et al.](#page-11-25) [2021\)](#page-11-25). Moreover, very low values of ${}^{12}C/{}^{13}C$ have been derived for several CEMP-no stars (carbon enhanced metal poor stars with $[Ba/F] < 0$) with metallicities lower than $[Fe/H] \leq -4$ [\(Mo](#page-10-2)[laro et al.](#page-10-2) [2023\)](#page-10-2). At very low metallicities the disagreement with the theoretical expectations is striking since values of several thousands are foreseen due to an initial 13 C close to zero. Internal production and chemical transfer from a possible massive companion have been ruled out, so the 13 C enhancement must originate from their progenitors.

At very low metallicities, mixing between the H- and He-burning zones could be driven by rapid rotation leading to a production of ¹³C [\(Meynet et al.](#page-10-38) [2006;](#page-10-38) [Chiappini et al.](#page-10-39) [2008;](#page-10-39) [Limongi & Chi](#page-10-40)[effi](#page-10-40) [2018\)](#page-10-40). Significant quantities of 13 C are expected from massive, low-metallicity, fast-rotating stars with ${}^{12}C/{}^{13}C$ between 30 and 300 [\(Chiappini et al.](#page-10-39) [2008\)](#page-10-39). Processes necessary to produce 13 C are similar to those invoked to explain the primary N behaviour at very low metallicities in other DLAs [\(Molaro](#page-10-41) [2003;](#page-10-41) [Zafar et al.](#page-11-26) [2014\)](#page-11-26).

No stellar ${}^{12}C/{}^{13}C$ measurements are available at the metallicity of DLA studied here ($[Fe/H] = -1.27$, [Berg et al.](#page-10-42) [2015\)](#page-10-42) so no direct comparison is possible. Our robust lower limit $({}^{12}C/{}^{13}C > 14.6, 2\sigma$ CL) is consistent with both theoretical predictions and low metallicity measurements. On the other hand, the weighted value we obtained $($ ¹²C $/$ ¹³C = 28.5, see Table [4\)](#page-7-2) is consistent with the measurement in the star HD 140283 at [Fe/H] \approx -2.6, but much lower than that of GJ 745 at $[Fe/H] = -0.48$. If our measured value in the DLA studied here is typical of gas with metallicity of $[Fe/H] \approx -1.2$, it would imply there is a significant and early production of 13 C that must necessarily cease to allow ${}^{12}C/{}^{13}C$ to reach the measured values at $[Fe/H] \approx -0.5$.

6 SUMMARY

In this work, we have carried out a detailed AI-VPFIT study of the $z_{\text{abs}} = 1.776$ DLA towards QSO B1331+170 for a $^{12}C/^{13}C$ measurement. The spectral data are very high quality and hence expected to substantially tighten previous error bars for this system. However, perhaps unsurprisingly, the higher ESPRESSO spectral resolution detected structure that had previously been unresolved, such that the new measurement constraints were not as anticipated.

The use of AI-VPFIT permitted us to generate multiple independent models. This means that, for the first time in this context, we have been able to take into account measurement errors associated with model non-uniqueness (Section [3.4\)](#page-5-2). Our weighted final result (Section [4.2\)](#page-7-3) is ¹²C/¹³C = 28.5^{+51.5} (see Table [4](#page-7-2) and Figure [6\)](#page-8-0), a marginal ¹³C detection. Additional ESPRESSO or new ANDES [\(Marconi et al.](#page-10-43) [2022,](#page-10-43) [2024\)](#page-10-44) or G-CLEF [\(Szentgyorgyi et al.](#page-11-27) [2018\)](#page-11-27) observations may lead to more stringent constraints in the future. A further caveat is that our AI-VPFIT analysis required the ${}^{12}C/{}^{13}C$ to be the same in all components. Spatial ${}^{12}C/{}^{13}C$ variations could be present within the absorption complex, so our result represents the mean value over the system.

Finally, as mentioned in Section [3.2,](#page-4-3) we have assumed constant b-parameters for both ¹²C and ¹³C. Since the atomic masses are so similar, modelling the system using thermal broadening is impractical, as numerical instabilities would be introduced into the modelling process. If the overall line broadening contains a thermal contribution, the slightly different atomic masses means our assumption is not quite correct. The maximum impact of this approximation equates to a systematic 4% of the overall b-parameter. The best fractional uncertainty of any b in the absorption complex we measured is slightly below this value, which means the constant- b approximation may impose a slight systematic if there is a significant contribution to thermal broadening. However, the direction of this potential small systematic is such that our lower limit on ${}^{12}C/{}^{13}C$ would increase, that is, our quoted final result is perhaps slightly conservative.

ACKNOWLEDGEMENTS

The authors acknowledge the ESPRESSO project team for its effort and dedication in building the ESPRESSO instrument as well as the teams who developed software used for the analysis – numpy [\(Har](#page-10-45)[ris et al.](#page-10-45) [2020\)](#page-10-45), scipy [\(Virtanen et al.](#page-11-28) [2020\)](#page-11-28), matplotlib [\(Hunter](#page-10-46) [2007\)](#page-10-46), numpyro [\(Phan et al.](#page-11-21) [2019\)](#page-11-21), jax [\(Bradbury et al.](#page-10-47) [2018\)](#page-10-47), and jaxopt [\(Blondel et al.](#page-10-48) [2021\)](#page-10-48). This work was performed on the OzSTAR national facility at Swinburne University of Technology.

The OzSTAR program receives funding in part from the Astronomy National Collaborative Research Infrastructure Strategy (NCRIS) allocation provided by the Australian Government, and from the Victorian Higher Education State Investment Fund (VHESIF) provided by the Victorian Government. APPENDIX A: EXAMPLE MODELS

The figures in this Appendix show four example AI-VPFIT models, each with a different ${}^{12}C/{}^{13}C$, derived as a part of the analysis presented in the main text. Figure [A1](#page-12-0) shows the same model as is shown in Figure [1](#page-3-0) (${}^{12}C/{}^{13}C = 28.14$), but with spectra separated by epoch. The remaining Figures show models with ${}^{12}C/{}^{13}C = 20$ (Figure [A2\)](#page-13-0), solar ¹²C/¹³C (=91, Figure [A3\)](#page-14-0), and ¹²C/¹³C = 500 (Figure [A4\)](#page-15-0).

Figure A[1](#page-3-0). The same as Figure 1 but spectra of the three epochs are shown separately. First two rows are epoch I, second two rows are epoch II, and the final two rows are epoch III. $\chi^2_{\nu} = 0.6362$.

Figure A2. The same as Figure [A1](#page-12-0) but for ${}^{12}C/{}^{13}C = 20$. $\chi^2_{\gamma} = 0.6269$.

Figure A3. The same as Figure [A1](#page-12-0) but for ${}^{12}C/{}^{13}C = 90.71$. $\chi^2_v = 0.6216$.

Figure A4. The same as Figure [A1](#page-12-0) but for ${}^{12}C/{}^{13}C = 500$. $\chi^2_{\gamma} = 0.6448$.

APPENDIX B: COMPARING ESPRESSO CI **VELOCITY STRUCTURE WITH INDEPENDENT MODELS FROM H**2

[Cui et al.](#page-10-13) [\(2005\)](#page-10-13) analysed H² rotational levels seen in the *Hubble Space Telescope*/STIS [\(Kimble et al.](#page-10-49) [1998\)](#page-10-49) data associated with the DLA studied here. Assuming a single velocity component for H_2 , a population analysis of its rotational levels yielded a $H₂$ gas temperature of $T = 152 \pm 10$ K. Subsequently, [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) examined the physical properties of the gas in more detail by combining the same STIS observations of $H₂$ with VLT/UVES [\(Dekker](#page-10-50) [et al.](#page-10-50) [2000\)](#page-10-50) and Keck/HIRES [\(Vogt et al.](#page-11-29) [1994\)](#page-11-29) observations covering the wavelength ranges containing heavy element absorption. In the [Carswell et al.](#page-10-9) (2011) analysis, 52 H₂ rotational levels seen in the STIS data were modelled together with five C i transitions from UVES and HIRES, assuming three velocity components for both H_2 and C i. Only two components had reliably measured temperatures, $T(H_2) = 86^{+14}_{-10}$ K, and 177^{+30}_{-22} K (at $z_{\text{abs}} = 1.7763702$ and 1.7765246, i.e. their components N1 and N2, respectively). A lower limit of $T(H_2) \ge 200 \text{ K}$ was obtained for a component at $z_{abs} = 1.7767176$ (their N3'). [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) suggested N3' to be a blend of several more narrow features that are unresolved in their data. They also suggested that N2 is mostly thermally broadened whereas N1 and N3['] are dominated by turbulent motions. The best estimate for the kinetic temperature of component N2 provided by [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) is $T = 218$ K, from C_I line broadening.

Out of the 285 surviving AI-VPFIT models produced in this work, 281 contain C_I components with b-parameters consistent with temperatures $T \le 218$ K. 26 models have one, 129 models have two, 112 models have three, 11 models have four, and three models have five such components. Figure [B1](#page-17-1) shows where those components tend to fall within the absorption complex. The three most prominent narrow components are found at $z_{\text{abs}} = 1.7763856$ (C1, at -31.2 km s^{-1} in Figure [B1\)](#page-17-1), $z_{\text{abs}} = 1.7765156$ (C2, at -17.2 km s^{-1}), and $z_{\text{abs}} = 1.7767093 \text{ (C3, at +3.7 km s}^{-1})$. The redshifts of the C1 and C2 are 1.7 km s^{-1} and 1.0 km s^{-1} away from the redshifts of N1 and N2 reported by [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9). Such shifts are not surprising, considering that ESPRESSO data allowed for resolving more structure compared to previous UVES and HIRES observations ($R = 42000$ and 48000, respectively, compared to ESPRESSO's $R = 140000$. Component C3 was not known before.

We next derived the temperatures of C1, C2, and C3 assuming that their broadening is only due to thermal gas motions. In doing that, we considered components that are $\leq \pm 0.5$ km s⁻¹ away from their redshifts (see above), and have b -parameters corresponding to a maximum ¹²C gas temperature of 1000 K ($b = 1.18$ km s⁻¹). Median temperatures obtained this way are $T(C1) = 51^{+124}_{-27}K$, $T(C2) =$ 60^{+12}_{-48} K, and $T(C3) = 180^{+159}_{-50}$ K. The quoted errors correspond to the $16th$ and the $84th$ percentiles.

Identifying our C1 with N1 from [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9), we found the temperature derived from the ESPRESSO C_I line widths $(T = 51^{+124}_{-27}$ K) to be in agreement with the temperature derived from H₂ by [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) ($T = 86^{+14}_{-10}$ K). While it may appear that temperature obtained by us for C2 $(T = 60^{+12}_{-48} \text{K})$ is in disagreement with the temperature [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9) reported for N2 ($T = 177^{+30}_{-22}$ K), this is not the case, as ESPRESSO data revealed the presence of several components not resolved in the lower resolution UVES and HIRES data used by [Carswell et al.](#page-10-9) [\(2011\)](#page-10-9). Additional ESPRESSO observations may be used to confirm the presence of cold components at -42 km s^{-1} , -36 km s^{-1} , -34 km s^{-1} , and -15 km s^{-1} (with respect to $z = 1.7766750$) contained in some AI-VPFIT models. Observations using even higher spectral resolution spectrographs (such as G-CLEF, with a planned $R = 300000$, [Szentgyorgyi et al.](#page-11-27) [2018\)](#page-11-27), would also be useful.

Parameter constraints in our calculations required $b < 10 \text{ km s}^{-1}$. an empirically-guided value. We note that some models reveal the presence of broad components i.e. with b -parameters near or at the upper limit. It is unavoidably the case that there may be clumps of blended lines that cannot be resolved (given the intrinsic line properties and spectral resolution). The number of free parameters in our models are decided on by an information criterion, giving the benefit of reproducibility. Given the constraints imposed, statistically the data do not justify additional parameters. Examining where components with $b \ge 8 \text{ km s}^{-1}$ fall within the absorption complex, we found them to be concentrated at the following locations: at -175 km s^{-1} (14% of all broad components), -87 km s^{-1} (1%), -72 km s^{-1} (2%), -64 km s^{-1} (44%), -34 km s^{-1} (1%) , -16 km s^{-1} ($\leq 1\%$), $+9 \text{ km s}^{-1}$ (8%), $+13 \text{ km s}^{-1}$ (15%), and +194 km s−¹ (15%). Two of the strong C i components from which $12C/13C$ constraint is derived are C1 and C2 (see Figure [B1\)](#page-17-1), i.e. the overwhelming majority $(> 98\%)$ of the broad components are located far from regions providing constraints on ${}^{12}C/{}^{13}C$.

Figure B1. Theoretical absorption system models before convolution with the assumed IPs. The models and the colour coding are the same as in Figure [4.](#page-6-1) A single AI-VPFIT model may contain between zero and five narrow ($b < 0.55 \text{ km s}^{-1}$) velocity components, with most models containing two of them. The three most prominent narrow components are at -31.2 km s^{-1} (C1), -17.2 km s^{-1} (C2), and $+3.7 \text{ km s}^{-1}$ (C3). The redshifts and temperatures of C1 and C2 are in agreement with literature reported redshifts of H₂ absorption and their temperatures [\(Carswell et al.](#page-10-9) [2011\)](#page-10-9), but AI-VPFIT derived them completely independently and without instructions. The presence of C3 was previously unknown.

APPENDIX C: MCMC POSTERIORS

Figure [C1](#page-18-0) shows the marginalised posterior distributions for parameters included in MCMC calculations presented in Section [4,](#page-6-0) and their mutual covariances.

This paper has been typeset from a T_EX/LAT_EX file prepared by the author.

Figure C1. Posterior distributions and covariances of Equation [\(5\)](#page-6-2) parameters after MCMC optimisation for the five data subsets (panels a–e). N_C for each subset is indicated in the top right corner of each panel. Numbers are the median and the central 68% limits, indicated by the dashed lines.
