***Abstract*—Clustering is a widely-used and well-studied AI branch, but defining clustering correctness, as well as verifying and validating clustering implementations, remains a challenge. To address this, we propose a statistically rigorous approach that couples differential clustering with statistical hypothesis testing, namely we conduct statistical hypothesis testing on the outcome (distribution) of differential clustering to reveal problematic outcomes.**

We employed this approach on widely-used clustering algorithms implemented in popular ML toolkits; the toolkits were tasked with clustering datasets from the Penn Machine Learning Benchmark. The results indicate that there are statistically significant differences in clustering outcomes in a variety of scenarios where users might not expect clustering outcome variation.

***Index Terms*—Clustering, Machine Learning, Testing, Statistics**

I. Introduction

Clustering – an AI branch concerned with partitioning sets into subsets whose elements are related – is a well-established area with research going back to the 1950s. However, there is a stringent and urgent need for approaches to testing Clustering implementations due to several converging factors.

First, supervised and unsupervised learning have started to permeate software products, from "smart" home devices [1] to self-driving platforms [2] and predictive analytics [3]. These implementations make critical decisions themselves or are used to aid decision-making (e.g., autonomous driving or financial fraud detection).

Second, there has been a proliferation of clustering implementations, mostly in the form of software toolkits (e.g., MATLAB and R each offer more than 100 clustering packages [4], [5]). These implementations are run by millions of users [6], [7] including non ML-experts (from life scientists to medical professionals) who should be able to assume that the implementations are correct.

Third, software engineers are under pressure to incorporate/adopt Machine Learning into software products and processes [8]–[10]; engineers should be able to (reasonably) assume that clustering implementations are reliable and interchangeable, i.e., for a given algorithm, its implementation is correct and has no negative impact on the clustering outcome.

However, ensuring clustering correctness, or even specifying clustering correctness, remain distant goals. Therefore, we propose an approach that can expose substantial and systematic issues with clustering algorithms' actual implementations, e.g., wide variations across runs for theoretically-stable, deterministic algorithms, widely different outcomes for different implementations of the same algorithm, or consistently poor performance in specific implementations.

Our approach leverages the wide availability of clustering implementations and datasets with ground truth, coupled with a statistics-driven approach to help developers (or toolkit testers) find statistically significant clustering accuracy differences.

To evaluate our approach and conduct our study, we chose 7 popular clustering algorithms, 4 nondeterministic (K-means, K-means++, Spectral Clustering, Expectation Maximization-GaussianMixture); and 3 deterministic (Hierarchical clustering-Agglomerative, Affinity Propagation, DBSCAN).[1] For uniformity and brevity, we use the following shorthands for the algorithms: *kmeans*, *kmeans++*, *gaussian*, *spectral*, *hierarchical*, *dbscan*, *apcluster*. We chose 7 widely-used clustering toolkits: MATLAB, mlpack, R, Scikit-learn, Shogun, TensorFlow, and WEKA. For uniformity and brevity, we use the following shorthands for the algorithms: *matlab*, *mlpack*, *R*, *sklearn*, *shogun*, *tensorflow*, *weka*. Our clustering inputs are 162 datasets from the Penn Machine Learning Benchmark; the datasets are described in Section II-B. 60% of the datasets come from sciences (medicine, biology, physics) with clusters crafted by domain experts.

Our basic metric of clustering similarity and accuracy is the versatile *adjusted Rand index* (ARI) [11], described in detail in Section II-A. The ARI measures the similarity between two partitions U and V of the same underlying set S. The ARI varies between -1 and $+1$, where $ARI = +1$ indicates that U and V are identical; $ARI = 0$ is tantamount to random assignment; $ARI = -1$ corresponds to strong disagreement. We use the term *accuracy* to refer to the ARI in the case when U is a clustering produced by an algorithm and V is the Ground Truth (as labeled in PMLB) for that dataset.

Examples: clustering accuracy in promoters. The clustering accuracy is measured by ARI between clustering results and ground truth. The promoters [12] dataset essentially contains

[1]Deterministic clustering algorithms should, in theory, produce the same clustering when run repeatedly on the same input. For nondeterministic (aka randomized) algorithms, the clustering might vary.

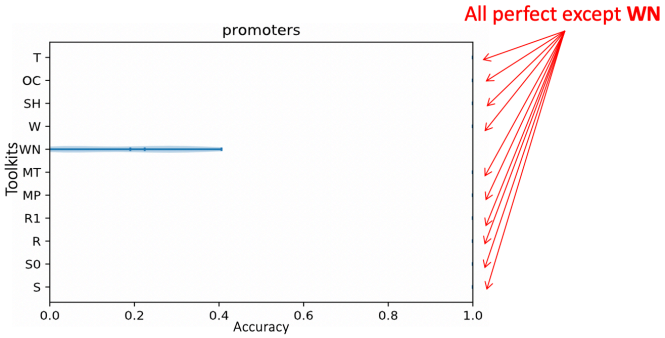

Fig. 1. Kmeans++: Accuracy distributions for 11 toolkits on dataset promoters (WN = WEKA with default normalization).

two clusters that partition the underlying E.coli DNA (gene) sequences into "promoters" [2] and "non-promoters". We ran our statistical approach on clustering outcomes of algorithm K-means++ in 11 toolkit configurations (sample size = 30, corresponding to the 30 repeated runs of that configuration on the same dataset). The resulting accuracy range is shown in Figure 1. Note that 10 toolkits achieve identical, perfect clusterings in each of the 30 runs, i.e.,

$$minAccuracy = maxAccuracy = 1$$

However, the toolkit WEKA's accuracy across 30 runs varied:

$$minAccuracy = -0.01; maxAccuracy = 0.4$$

This allows us to make two observations: (1) WEKA's accuracy varies substantially across re-runs on the same input dataset; and (2) all toolkits achieve perfect clusterings in every run, whereas's WEKA's best run has accuracy 0.4. This clearly indicates a clustering implementation issue.[3]

Our approach exposes such issues (and more) in a statistically rigorous way. *This is the first statistically rigorous approach to testing clustering implementations.*

Our approach has 4 components; we present each component in the context of using that component to test a null hypothesis:

1) How different runs of the same algorithm in the same implementation lead to different clusterings (Section III).
2) How different implementations of the same algorithm in different toolkits lead to different clusterings (Section IV).
3) The toolkit's impact when comparing algorithms (Section V).
4) How different toolkits "disagree" (Section VI).

[2]A *promoter* sequence marks the DNA region where the transcription of that gene into RNA should begin.

[3]WEKA developers were able to attribute this low accuracy to WEKA's default normalization setting.

II. BACKGROUND

A. Definitions

Clustering. Given a set S of n points (d-dimensional vectors in the $\mathcal{R}^d$ space), a clustering is a partitioning of S into K non-overlapping subsets (clusters) $S_1, \ldots, S_i, \ldots, S_K$ such that intra-cluster distance between points (that is, within individual S_i's) is minimized, while inter-cluster distance (e.g., between centroids of S_i and S_j where $i \neq j$) is maximized.

Accuracy. The *adjusted Rand index* (ARI) is a versatile, widely used [13] clustering comparison metric. Let us assume a set D and two partitionings A and B on it: P_A, Q_A (where $P_A \cup Q_A = D$ and $P_A \cap Q_A = \emptyset$) and respectively P_B, Q_B (where $P_B \cup Q_B = D$ and $P_B \cap Q_B = \emptyset$). We can measure these two clustering's similarity using the ARI. When $ARI = +1$, we have $P_A = P_B$ and $P_B = Q_B$. When $ARI \neq +1$, the two partitioning schemes differ. The case $ARI = 0$ corresponds to D elements being assigned randomly across P_A/P_B and Q_A/Q_B, respectively. The case $-1 < ARI < 0$ is defined as "worse-than-random", because it in worse than randomness clustering. Technically, the ARI of A and B is defined:[4]

$$ARI(A,B) = \frac{2(N_{00}N_{11} - N_{01}N_{10})}{(N_{00}+N_{01})(N_{01}+N_{11}) + (N_{00}+N_{10})(N_{10}+N_{11})}$$

B. Datasets

We chose 162 datasets from the 166-dataset PMLB (Penn Machine Learning Benchmark) [15], a benchmark suite that includes "real-world, simulated, and toy benchmark datasets" [15].[5] PMLB was designed to benchmark ML implementations and avoid imbalance across meta-features (which often plagues handpicked datasets). The geometric means across the dataset collection – roughly, the chracteristics of the typical dataset – were 809 instances, 15.41 features, and 3.18 clusters.

[4]Where "N_{11} is the number of pairs that are in the same cluster in both A and B; N_{00} is the number of pairs that are in different clusters in both A and B; N_{01} is the number of pairs that are in the same cluster in A but in different clusters in B; and N_{10} is the number of pairs that are in different clusters in A but in the same cluster in B" [14].

[5]For efficiency, we set aside four large datasets: connect-4, poker, mnist, kddcup.

C. Clustering Algorithms

We now present a brief overview of each algorithm.

K-means. The algorithm aims to cluster the observations (points in S) into K distinct clusters, where observations belong to the clusters with the nearest mean. The goal is to minimize the sum of all intra-cluster distances. The algorithm starts from K selected initial points as "centroids" (cluster centers). These centroids play a crucial role in the algorithm's effectiveness: the algorithm is not guaranteed to converge to a global minimum, so with "bad" centroids the algorithm can "fall" into local minima.

Variation due to starting points: the algorithm requires "starting points", that is, initial centroids. To ensure consistency across toolkits, we fed all toolkits the same starting points. We explored the variation in outcome by randomly picking different starting points from the datasets. That is, if a dataset has $K = 2$, for each run we pick two different points in S, s_1 and s_2 as centroids, and run the algorithm from there, with all toolkits starting with s_1 and s_2.

K-means++ was designed to improve K-means by choosing the starting points more carefully so they are farther apart. Theoretically, this improved version ensures that the algorithm is less likely to converge to local minima.

EM/Gaussian. Gaussian mixture clustering is a model-based approach: clustering is first done using a model (i.e., a parametric distribution such as a Gaussian). Each cluster is defined by an initial random model and the dataset is composed of the mixture of these models. Then, the model/data fitness is optimized – a common optimization is Expectation-Maximization.

Spectral clustering computes eigenvalues of the similarity matrix between the data points to reduce the dimensionality of the original data. After the reduction, a clustering algorithm, e.g., K-means, is applied on the reduced-dimensionality data.

The aforementioned 4 algorithms were nondeterministic; we now discuss the 3 deterministic algorithms.

Hierarchical clustering is a deterministic algorithm, based on building a hierarchy of clusters using one of two approaches: (i) a bottom-up approach named "agglomerative": each observation is initially put in its own cluster and then they are merged, (ii) a top-down approach named "divisive": all observations are initially placed in the same cluster and then they are split. We use the first variant.

DBSCAN is a deterministic algorithm based on density, that is, high density regions of data are grouped together in a neighbor graph and form a data cluster.

Affinity Propagation (AP) is based on propagation on a graph in which each data point is a node. The algorithm builds clusters by iteratively passing messages from a node to another until determining which one is part of a specific cluster.

Some toolkits do not support all 7 algorithms; Table II shows the supported algorithm/toolkit combinations; in all, there were 27 algorithm-toolkit configurations.

D. Runs

Our analysis is based on clustering results achieved by each algorithm-toolkit configuration on each of the 162 datasets 30 different times (i.e., more than 160,000 clustering tasks; for all toolkits default settings were used).

Specifically we analyzed the distribution of accuracy (i.e., ARI when comparing the resulting clustering with ground truth) achieved in these 30 different clustering runs. Hence for our subsequent statistical analyses we have sample size $n = 30$ for one-sample tests (and $n_1 = n_2 = 30$ for two-sample tests). Note that K-means requires "starting points" – initial centroids. Hence in configuration *kmeans* each of the 30 runs used a different, randomly-picked, different starting points from the dataset.

III. VARIATION ACROSS RUNS

This testing procedure is shown in Figure 2: a single toolkit is run on a single dataset multiple times (30 in our case), and a statistical analysis is performed on the resulting accuracy distribution.

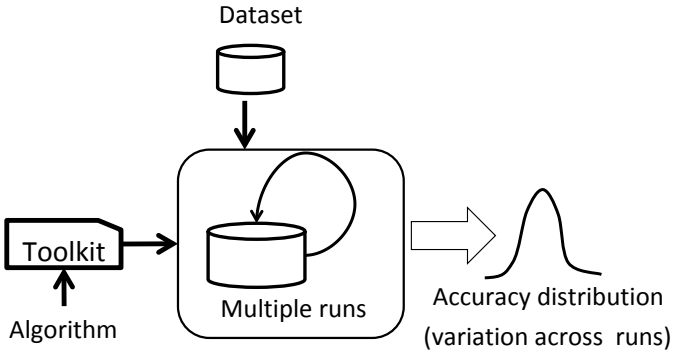

Fig. 2. Testing for variation across runs.

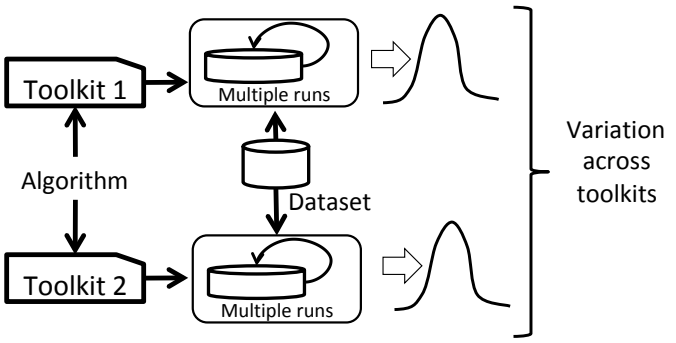

Fig. 3. Testing for variation across toolkits.

Null hypothesis: *accuracy does not vary across runs.*

In other words, for a certain algorithm and dataset, we set out to measure *non-determinism*. To test this hypothesis, we use Levene's test as follows: one sample contains the actual accuracy values for the 30 runs, the other sample has the same mean, size, and no variance, that is, all 30 elements are equal to the mean of the first set. We ran this on all datasets. Rejecting the null hypothesis means that accuracy varies in a statistically significant way across runs. We report results at $p < 0.05$.

In Table III we show the number of datasets where variance is statistically significant at $p < 0.05$; recall that we have a total of 162 datasets. We observe that Spectral is the most stable nondeterministic algorithm; for Spectral, only 93–113 datasets show significant variance. Hierarchical, which should be deterministic, still has 63–71 datasets with significant variance. In contrast, *K-means, K-means++, and Gaussian Mixture, have significant variance from run to run.*

In Table IV we show how broad the accuracy range (difference between minimum accuracy and maximum accuracy) can be. The first three columns show the algorithm, toolkit and dataset. The last two columns show the minimum and maximum accuracy attained over the 30 runs. For example, Gaussian has quite a large range on some datasets: accuracy on the dataset prnn_crabs has a min-max range of *more than 1*, with one run's accuracy below 0 and another run having perfect or (close to perfect) accuracy.

In Table V we show how high the standard deviation of the accuracy can be across runs. For example, accuracy on the dataset twonorm can have a *standard deviation of 0.4*. More than a dozen other toolkit/algorithm setups have *standard deviation higher than 0.2.*

IV. VARIATION ACROSS TOOLKITS

This testing procedure is shown in Figure 3: two toolkits implementing the same algorithms are run on the same dataset multiple times (30 in our case), and a statistical analysis is performed to compare the two accuracy distributions.

Null hypothesis: *For a given algorithm, accuracy does not vary across toolkits.*

To test this hypothesis, we use the Mann-Whitney U test as follows. We fix the algorithm, e.g., K-means++, and the dataset. Next, we compare the distributions of accuracy values pairwise, for all possible toolkits pairs, that is, if we have N toolkits for a given algorithm, for a given dataset there will be $\binom{N}{2}$ Mann-Whitney U tests; hence for each algorithm there will be $162 \times \binom{N}{2}$ tests. Rejecting the null hypothesis means that accuracy varies significantly between toolkits. We report results at $p < 0.05$.

In Table VI we show the number of datasets where accuracy distributions between two toolkits are statistically significant at $p < 0.05$. We observe that Gaussian Mixture and K-means++ induce most differences in toolkit outcomes' distributions (generally over 100 out of 162). Even for apcluster (deterministic), on 40 out of 162 datasets we found statistically significant differences between Sklearn and R.

A. Non-overlaps

In Table VII we show the largest gaps between accuracy intervals, computed as follows: we find all dataset/algorithm combinations where the accuracy intervals for two toolkits, say $[ARI_{1min}, ARI_{1max}]$ and $[ARI_{2min}, ARI_{2max}]$ are non-overlapping, that is, $ARI_{1min} > ARI_{2max}$. In other words, *for any run of toolkit 1, its accuracy floor (min.) is higher than the accuracy ceiling (max.) of any run of toolkit 2*. We call that difference "gap", i.e., $gap = ARI_{1min} - ARI_{2max}$. We show the top-10 gaps in Table VII. Notice that this gap can be as large as 0.966.

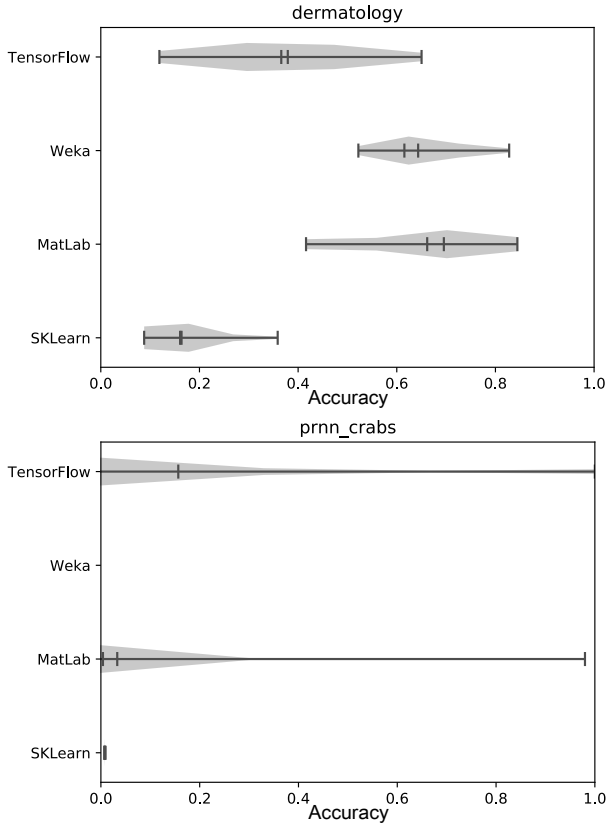

Fig. 4. EM (Gaussian Mixture): differences between toolkits on two datasets, dermatology and prnn-crabs.

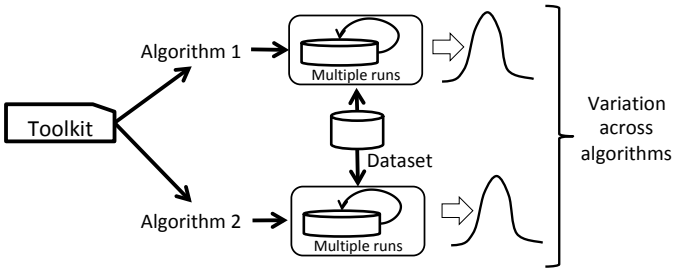

Fig. 5. Testing for variation across algorithms.

We found that 1,776 such gaps exist (out of 34,987 runs of the same algorithm/dataset combinations). This is very problematic, as it shows how toolkits are not "created equal" – even after multiple runs, in 1,776 scenarios, a toolkit's *best* accuracy cannot even reach another toolkit's *worst* accuracy.

In Figure 4 we show violin plots of toolkits' accuracy distributions in the EM algorithm on two datasets. On set dermatology (top) note the wide ranges of TensorFlow and the gap between WEKA and Sklearn. On set prnn-crabs (bottom) note the high-end accuracy of 1 (TensorFlow, MATLAB) and the consistently low accuracy in WEKA and Sklearn.

V. VARIATION ACROSS ALGORITHMS

This testing procedure is shown in Figure 5: implementations of two different algorithms but in the same toolkit are

TABLE VII

run on the same dataset multiple times (30 in our case), and a statistical analysis is performed to compare the two accuracy distributions.

Null hypothesis: *For a given toolkit, accuracy does not vary across algorithms.*

To test this hypothesis, we again use the Mann-Whitney U test. We fix the toolkit, e.g., MATLAB, and the dataset. Next, we compare the distributions of accuracy values pairwise, for all possible algorithm pairs. Rejecting the null hypothesis implies that, for a given toolkit, algorithms' accuracy varies significantly.

In Table VIII we show the number of datasets where accuracy distributions between two algorithms are significantly different. Typically, algorithms' accuracies differ on more than 110 datasets; we expected to see such differences between algorithms. However, we did not expect wide differences when looking at the *same algorithm pairs in different toolkits*. For example, K-means and K-means++ differ on 105/101/115/120 datasets in Sklearn/R/MATLAB/WEKA but only on 27 datasets in MLpack and only 31 datasets in Shogun. This again shows that toolkits are not interchangeable (though users might expect them to be).

VI. TOOLKIT DISAGREEMENT

We next set out to study whether toolkits "agree" or "disagree" on those points that are misclassified w.r.t. ground truth. Specifically, we are interested in those cases where two toolkits have relatively high accuracy w.r.t. ground truth, but there are large disagreements between the toolkits on the remaining, or misclassified points (i.e., where toolkits' clustering differs from ground truth).

We illustrate this in Figure 6. Assuming two toolkits $T1$ and $T2$, their clustering of x_1, x_2, x_3, x_4 (on the bottom) is in agreement, and let us assume this clustering agrees with ground truth as well. We want to measure the disagreement on the remaining points x_5, x_6, x_7, x_8 (on top).

Intuitively, datasets that induce this disagreement between $T1$ and $T2$ on the top points manage to expose differences in toolkit implementations "at the margin"; since agreement with ground truth is high, users might expect the toolkits will be in agreement on the reminaing points, too.

Let ARI_{T1G} and ARI_{T2G} be the accuracy of two different toolkits on the same algorithm and same dataset. Let ARI_{T1T2} be the ARI when comparing the two clusterings (rather than with ground truth). There were 14,831 ARI_{T1T2} comparisons. Out of these, we found 928 cases where:

$$ARI_{T1G} > ARI_{T1T2} \wedge ARI_{T2G} > ARI_{T1T2}$$

That is, there were *928 cases where toolkits' clusterings disagree with each other more than they disagree with ground truth* – in other words, toolkits disagree strongly on those points that are not clustered perfectly.

In Table IX we show the top-10 such disagreements, excluding the trivial cases where one toolkit's accuracy is 1. These datasets are particularly important as they manage to "drive wedges" between toolkits; this has many applications, from differential toolkit testing to constructing adversarial datasets.

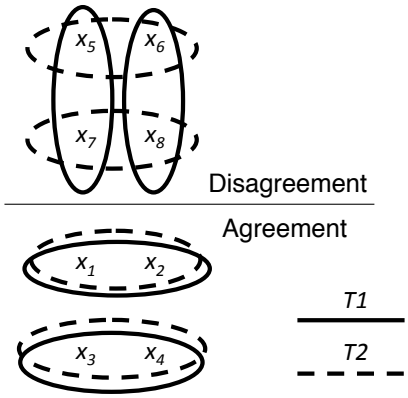

Fig. 6. Toolkit disagreement.

VII. RELATED WORK

There is a surprising scarcity of studies measuring clustering accuracy/outcome across toolkits and across same-toolkit runs.

Fränti [16] has compared performance on clustering basic benchmark, and measure performance on four factors: overlap of clusters, number of clusters, dimensionality and unbalance of cluster sizes. However, they only consider synthesis data and their datasets have simple structures. Our work is based on PMLB which includes mainly real-world datasets allowed for comparing ML methods comprehensively.

Hamerly [17] has proposed a new algorithm for accelerating K-means, and performed an evaluation on efficiency similar to

Kriegel et al.'s (time and memory). Our focus is on accuracy rather than efficiency.

Chen et al. [18] have compared four clustering algorithms – hierarchical clustering, K-means, Self-organizing Map (SOM) and Partitioning around Medoids (PAM) on a single dataset, mouse genomic data. Unlike us, they varied the K, whereas we used the ground truth's K. Our focus is different: varying runs of the same algorithm, and a breadth of datasets. Abu [19] has compared four clustering algorithms – K-means, hierarchical, SOM, and Expectation Maximization (EM), each implemented in two toolkits LNKnet and Cluster/TreeView; they used a single 600-instance dataset, and compared performance/accuracy on this dataset, and a 200-instance subset thereof. Our setup is substantially larger and our focus is substantially broader.

Clustering stability has been defined by Tilman et al. [20] as "solutions [that] are similar for two different data sets that have been generated by the same (probabilistic) source". Our definition of stability is different: similarity of solutions on the same dataset, but produced by two different runs.

Our own work on SmokeOut [21] also explored the space of different clustering outcomes across toolkits and runs, but the goal was to expose outliers and characterize distributions shapes. Descriptive statistics (min/max) were used for the comparison, which is concise but lacks statistical rigor. In contrast, in this paper we introduce and use a statically rigorous approach for comparing runs, toolkits and algorithms. SmokeOut was also run on PMLB. Another goal of SmokeOut was to expose outliers or bimodal distributions in clustering outcomes across repeated runs – information which is useful for debugging.

VIII. CONCLUSIONS

We present the first approach for testing clustering implementations via rigorous statistical analysis. We demonstrate our approach via statistical analysis of clustering outcomes across multiple runs, toolkits and algorithms. We found statistically significant variations across all these dimensions, which might violate users' determinism and invariance assumptions. Our results point out the need for improving the correctness and determinism of clustering implementations.
